Contents

Dedication / ix
Contributors / xi
Preface / xix
About the Editors / xxi

SECTION I
THE GRAM-POSITIVE CELL WALL / 1
SECTION EDITOR: Vincent A. Fischetti

1 The Gram-Positive Cell Wall / 3
MANFRED ROHDE

2 Surface Proteins on Gram-Positive Bacteria / 19
VINCENT A. FISCHETTI

SECTION 2
THE STREPTOCOCCUS / 33
SECTION EDITORS: Vincent A. Fischetti and Joseph J. Ferretti

A. GROUP A STREPTOCOCCI

3 Intracellular Invasion by *Streptococcus pyogenes*: Invasins, Host Receptors, and Relevance to Human Disease / 35
BEINAN WANG AND P. PATRICK CLEARY

4 Capsular Polysaccharide of Group A Streptococci / 45
MICHAEL R. WESSELS

5 Toxins and Superantigens of Group A Streptococci / 55
BLAKE A. SHANNON, JOHN K. McCORMICK, AND PATRICK M. SCHLIEVERT

6 Genetics of Group A Streptococci / 67
KYU HONG CHO, GARY PORT, AND MICHAEL CAPARON

7 Molecular Mimicry, Autoimmunity, and Infection: The Cross-Reactive Antigens of Group A Streptococci and Their Sequelae / 86
MADELEINE W. CUNNINGHAM

8 Extracellular Matrix Interactions with Gram-Positive Pathogens / 108
SVEN HAMMERSCHMIDT, MANFRED ROHDE, AND KLAUS T. PREISSNER

9 Group A *Streptococcus*-Mediated Host Cell Signaling / 125
VIJAY PANCHOLI

10 Vaccine Approaches To Protect against Group A Streptococcal Pharyngitis / 148
VINCENT A. FISCHETTI

11 The Bacteriophages of *Streptococcus pyogenes* / 158
W. MICHAEL McSHAN, KIMBERLY A. McCULLOR, AND SCOTT V. NGUYEN

12 Molecular Epidemiology, Ecology, and Evolution of Group A Streptococci / 177
DEBRA E. BESSEN, PIERRE R. SMEESTERS, AND BERNARD W. BEALL

Downloaded From Vet-eBooks.com

B. GROUP B STREPTOCOCCI

13 Surface Structures of Group B *Streptococcus* Important to Human Immunity / 204
LAWRENCE C. PAOLETTI AND DENNIS KASPER

14 Group B *Streptococcus* (*Streptococcus agalactiae*) / 228
VANESSA N. RAABE AND ANDI L. SHANE

C. GROUP C AND G STREPTOCOCCI

15 Genetics and Pathogenicity Factors of Group C and G Streptococci / 239
HORST MALKE

16 Pathogenicity Factors in Group C and G Streptococci / 264
CLAIRE E. TURNER, LAURA BUBBA, AND ANDROULLA EFSTRATIOU

17 Infections Caused by Group C and G *Streptococcus* (*Streptococcus dysgalactiae* subsp. *equisimilis* and Others): Epidemiological and Clinical Aspects / 275
GIO J. BARACCO

D. *STREPTOCOCCUS PNEUMONIAE*

18 The Cell Wall of *Streptococcus pneumoniae* / 284
WALDEMAR VOLLMER, ORIETTA MASSIDDA, AND ALEXANDER TOMASZ

19 *Streptococcus pneumoniae* Capsular Polysaccharide / 304
JAMES C. PATON AND CLAUDIA TRAPPETTI

20 *Streptococcus pneumoniae*: Invasion and Inflammation / 316
ALLISTER J. LOUGHRAN, CARLOS J. ORIHUELA, AND ELAINE I. TUOMANEN

21 Phase Variation of *Streptococcus pneumoniae* / 331
JING LI AND JING-REN ZHANG

22 Genomics and Genetics of *Streptococcus pneumoniae* / 344
FRANCESCO SANTORO, FRANCESCO IANNELLI, AND GIANNI POZZI

23 Pneumococcal Vaccines / 362
DAVID E. BRILES, JAMES C. PATON, RESHMI MUKERJI, EDWARD SWIATLO, AND MARILYN J. CRAIN

E. ENTEROCOCCI

24 Pathogenicity of Enterococci / 378
ELIZABETH FIORE, DARIA VAN TYNE, AND MICHAEL S. GILMORE

25 Enterococcal Genetics / 398
KEITH E. WEAVER

F. ORAL STREPTOCOCCI

26 Biology of Oral Streptococci / 426
JJACQUELINE ABRANCHES, LIN ZENG, JESSICA K. KAJFASZ, SARA PALMER, BRINTA CHAKRABORTY, ZEZHANG WEN, VINCENT P. RICHARDS, L. JEANNINE BRADY, AND JOSE A. LEMOS

27 The Biology of *Streptococcus mutans* / 435
J.A. LEMOS, S.R. PALMER, L. ZENG, Z.T. WEN, J.K. KAJFASZ, I.A. FREIRES, J. ABRANCHES, AND L.J. BRADY

28 Genetics of *sanguinis*-Group Streptococci in Health and Disease 449
ANGELA NOBBS AND JENS KRETH

G. LACTOCOCCI

29 Genetics of Lactococci 461
PHILIPPE GAUDU, YUJI YAMAMOTO, PETER RUHDAL JENSEN, KARIN HAMMER, DELPHINE LECHARDEUR, AND ALEXANDRA GRUSS

SECTION 3
THE STAPHYLOCOCCUS / 483
SECTION EDITOR: Richard P. Novick

30 Staphylococci: Evolving Genome / 485
JODIE A. LINDSAY

31 Staphylococcal Plasmids, Transposable and Integrative Elements / 499
NEVILLE FIRTH, SLADE O. JENSEN, STEPHEN M. KWONG, RONALD A. SKURRAY, AND JOSHUA P. RAMSAY

Downloaded From Vet-eBooks.com

32 Temperate Phages of *Staphylococcus aureus* / 521
HANNE INGMER, DAVID GERLACH, AND CHRISTINE WOLZ

33 Pathogenicity Islands and Their Role in Staphylococcal Biology / 536
RICHARD P. NOVICK

34 Respiration and Small Colony Variants of *Staphylococcus aureus* / 549
RICHARD PROCTOR

35 Noncoding RNA / 562
EMMA DESGRANGES, STEFANO MARZI, KAREN MOREAU, PASCALE ROMBY, AND ISABELLE CALDELARI

36 The Staphylococcal Cell Wall / 574
RITA SOBRAL AND ALEXANDER TOMASZ

37 Staphylococcal Protein Secretion and Envelope Assembly / 592
OLAF SCHNEEWIND AND DOMINIQUE M. MISSIAKAS

38 Surface Proteins of *Staphylococcus aureus* / 599
TIMOTHY J. FOSTER

39 Immune Evasion by *Staphylococcus aureus* / 618
NIENKE W. M. de JONG, KOK P. M. van KESSEL, AND JOS A. G. van STRIJP

40 *Staphylococcus aureus* Secreted Toxins and Extracellular Enzymes / 640
KAYAN TAM AND VICTOR J. TORRES

41 Regulation of *Staphylococcus aureus* Virulence / 669
CHRISTIAN JENUL AND ALEXANDER R. HORSWILL

42 Virulence and Metabolism / 687
ANTHONY R. RICHARDSON

43 Staphylococcal Biofilms / 699
MICHAEL OTTO

44 Fulminant Staphylococcal Infections / 712
YVES GILLET, THOMAS HENRY, AND FRANÇIOS VANDENESCH

45 *Staphylococcus aureus* Colonization of the Human Nose and Interaction with Other Microbiome Members / 723
CLAUDIA LAUX, ANDREAS PESCHEL, AND BERNHARD KRISMER

46 *Staphylococcus aureus* in Animals / 731
ANDREAS F. HAAG, J. ROSS FITZGERALD, AND JOSÉ R. PENADÉS

47 Antibiotic Resistance and the MRSA Problem / 747
MARTIN VESTERGAARD, DORTE FREES, AND HANNE INGMER

48 Immunity to *Staphylococcus aureus*: Implications for Vaccine Development / 766
RICHARD A. PROCTOR

49 Nonconventional Therapeutics Against *Staphylococcus aureus* / 776
CAROLINE M. GRUNENWALD, MONIQUE R. BENNETT, AND ERIC SKAAR

SECTION 4
THE LISTERIAE / 791
SECTION EDITOR: Daniel A. Portnoy

50 Epidemiology and Clinical Manifestations of *Listeria monocytogenes* Infection / 793
WALTER F. SCHLECH III

51 Innate and Adaptive Immune Responses during *Listeria monocytogenes* Infection / 803
SARAH E. F. D'ORAZIO

52 Regulation of *Listeria monocytogenes* Virulence / 836
JÖRGEN JOHANSSON AND NANCY E. FREITAG

53 *Listeria monocytogenes*: Cell Biology of Invasion and Intracellular Growth / 851
JAVIER PIZARRO-CERDÁ AND PASCALE COSSART

54 Metabolism of the Gram-Positive Bacterial Pathogen *Listeria monocytogenes* / 864
JOHN-DEMIAN SAUER, ANAT A. HERSKOVITS, AND MARY X. D. O'RIORDAN

Downloaded From Vet-eBooks.com

SECTION 5
SPORE-FORMING PATHOGENS / 873
SECTION EDITOR: Julian I. Rood

55 The *Bacillus cereus* Group: *Bacillus* Species with Pathogenic Potential / 875
MONIKA EHLING-SCHULZ, DIDIER LERECLUS, AND THERESA M. KOEHLER

56 Sporulation and Germination in Clostridial Pathogens / 903
AIMEE SHEN, ADRIANNE N. EDWARDS, MAHFUZUR R. SARKER, AND DANIEL PAREDES-SABJA

57 Clostridial Genetics: Genetic Manipulation of the Pathogenic Clostridia / 927
SARAH A. KUEHNE, JULIAN I. ROOD, AND DENA LYRAS

58 Genomics of the Pathogenic Clostridia / 940
ROBERT J. MOORE AND JAKE A. LACEY

59 Virulence Plasmids of the Pathogenic Clostridia / 954
SARAH A. REVITT-MILLS, CALLUM J. VIDOR, THOMAS D. WATTS, DENA LYRAS, JULIAN I. ROOD, AND VICKI ADAMS

60 Enterotoxic Clostridia: *Clostridium perfringens* Enteric Diseases/ 977
ARCHANA SHRESTHA, FRANCISCO A. UZAL, AND BRUCE A. McCLANE

61 Enterotoxic Clostridia: *Clostridioides difficil*e Infections / 991
S. MILETO, A. DAS, AND DENA LYRAS

62 Histotoxic Clostridial Infections / 1012
MASAHIRO NAGAHAMA, MASAYA TAKEHARA, AND JULIAN I. ROOD

SECTION 6
MYCOBACTERIA AND CORYNEBACTERIA / 1027
SECTION EDITOR: Miriam Braunstein

63 Mycobacteriophages / 1029
GRAHAM F. HATFULL

64 Immunology of *Mycobacterium tuberculosis* Infections / 1056
JONATHAN KEVIN SIA AND JYOTHI RENGARAJAN

65 Unraveling the Structure of the Mycobacterial Envelope / 1087
MAMADOU DAFFÉ AND HEDIA MARRAKCHI

66 The Dream of a Mycobacterium / 1096
CATHERINE BARANOWSKI, E. HESPER REGO, AND ERIC J. RUBIN

67 *Mycobacterium tuberculosis* Metabolism / 1107
GABRIEL T. MASHABELA, TIMOTHY J. de WET, AND DIGBY F. WARNER

68 Protein Export into and across the Atypical Diderm Cell Envelope of Mycobacteria / 1129
VINCENT J. C. van WINDEN, EDITH N. G. HOUBEN, AND MIRIAM BRAUNSTEIN

69 *Corynebacterium diphtheriae*: Diphtheria Toxin, the *tox* Operon, and Its Regulation by $Fe2^+$ Activation of apo-DtxR / 1154
SADIYA PARVEEN, WILLIAM R. BISHAI, AND JOHN R. MURPHY

Index / 1165

Dedication

The editors dedicate this third edition of *Gram-Positive Pathogens* to Olaf Schneewind (1961–2019) in commemoration of his outstanding contributions to the molecular genetics and pathobiology of the staphylococci and other Gram-positive pathogens.

At the time of his death, Olaf was the Louis Block Professor and chair of the Department of Microbiology at the University of Chicago and one of the world's leading authorities on the human pathogens *Staphylococcus aureus*, *Bacillus anthracis*, and *Yersinia pestis*; his extensive contributions to the world of microbiology are represented by over 250 published papers.

Olaf received his MD/PhD degree in 1988 at the University of Cologne in Germany. He then moved to the United States to work as a postdoctoral associate in Vincent Fischetti's laboratory at the Rockefeller University in New York from 1988 to 1992. During this time, Olaf built on the finding that surface proteins on Gram-positive bacteria contained a common LPXTG sequence at their C-terminus. He found that this sequence was essential for anchoring surface proteins to the wall peptidoglycan, setting the stage for his future discoveries. He moved to UCLA in 1992, where he showed that surface proteins are cleaved between the threonine and the glycine of the LPXTG motif by a molecule he termed sortase, a unique enzyme with transpeptidase activity. He subsequently identified four classes of sortases (A to D) that catalyze unique chemical reactions such as the promotion heme-iron scavenging, the formation of infectious spores, and the assembly of pili. These major discoveries, which solved the long-standing mystery of how surface proteins are attached to the bacterial envelop, propelled him to professor by 2001, when he moved to the University of Chicago.

As a faculty member at the University of Chicago and subsequent chair of the Department of Microbiology, Olaf established that surface proteins of *S. aureus* are essential for the pathogenesis of staphylococcal infectious diseases, owing to their role in nutrient acquisition, bacterial agglutination, or downregulation of host immune responses. This work led to the exploration of immune responses and a collaborative research effort with Novartis AG to develop a vaccine against *S. aureus*. In 2003, Olaf established the Great Lakes RCE for Biodefense & Emerging Infectious Diseases and, with the help of an NIH construction grant, built the Howard Taylor Ricketts Laboratory at Argonne National Laboratory, a state-of-the-art biosafety level 4 facility. As director of the Biodefense Center, Olaf expanded his research to study multiple bacterial pathogens, including *Corynebacterium diphtheriae*, pathogenic *Bacillus* species (*B. anthracis*) and *Yersinia* species (*Y. pestis*). He examined the contributions of *Yersinia* type III secretion in pathogen-mediated depletion of host immune cells and developed a subunit vaccine that protects animals against pneumonic plague. Olaf and colleagues discovered the genes and biosynthetic pathway for bacterial lipoteichoic acid as a target for the development of new antibiotics. His research program on *B. anthracis* also focuses on characterizing the assembly of the S-layer, a two-dimensional array of proteins that associates noncovalently with bacterial secondary cell wall polysaccharides, and the development of conjugative anthrax vaccines involving the capsules of these microbes. In his studies of staphylococcal pathogenesis, he developed and analyzed an elegant and highly informative model of how the classic staph abscess forms and evolves within mammalian tissues—a major contribution to the understanding of staphylococcal disease.

Olaf earned multiple honors and awards. Among these are fellowships of the American Association for the Advancement of Science and the American Academy of Microbiology plus recent election to the National Academy of Sciences. Olaf was an inspiring teacher and mentor, and many of his former students and post-docs have established distinguished careers in microbiology and infectious diseases. He had a warm personality, many friends, and a wide international circle of collaborators. He loved to talk science and loved doing it in a group with some good German beer. He will be sorely missed.

VINCENT A. FISCHETTI

Preface

Gram-positive bacteria are structurally unique from their gram-negative counterparts by lacking an outer membrane and related secretory systems and have a thick peptidoglycan. Because of this and other distinctions, they have developed novel approaches to pathogenesis by acquiring (among others) a unique family of surface proteins, toxins, enzymes, and prophages. In this new edition, the editors have enhanced this compendium of gram-positive bacterial pathogens by including new data generated from genomic sequencing as well as the latest knowledge on gram-positive structure and mechanisms of antibiotic resistance and theories on the mechanisms of gram-positive bacterial pathogenicity. This edition emphasizes streptococci, staphylococci, listeria, and spore-forming pathogens, with chapters written by leading researchers in these areas. The chapters systematically dissect these organisms biologically, genetically, and immunologically, in an attempt to understand the strategies used by these bacteria to cause human disease. It is hoped that the insights gained from understanding these strategies will lead to the rational design of novel therapeutics and vaccines to control infections caused by gram-positive bacteria.

About the Editors

Vincent A. Fischetti is Professor and Head of the Laboratory of Bacterial Pathogenesis and Immunology at the Rockefeller University in New York. He received his Ph.D. in Microbiology with honors from New York University School of Medicine and has over 45 years of experience in the anti-infectives field, nearly all of which have been spent at Rockefeller. His laboratory was the first to identify phage lytic enzymes as novel therapeutics to treat infections caused by the major antibiotic-resistant bacterial pathogens. Several of these lysins are now in the clinical development pipeline. His group has also engineered lysins and IgG immunoglobulins to create chimeric high affinity antibodies directed to bacterial wall carbohydrates for passive immune protection from infection. Dr. Fischetti is a fellow of the American Academy of Microbiology and the National Academy of Inventors and has received two NIH MERIT awards. He has been editor-in-chief of *Infection and Immunity* for 10 years and serves as advisory editor for the *Journal of Experimental Medicine* and *Trends in Microbiology*, among others.

Richard P. Novick received his M.D. with honors in microbiology from New York University. Following postdoctoral studies at the National Institute for Medical Research in London and at Rockefeller University, he joined the Public Health Research Institute in New York. There he developed the fields of staphylococcal molecular genetics and plasmid biology, founding the plasmid biology department at PHRI and the journal *Plasmid*. After 10 years as Director of the PHRI, he returned to full-time lab work at the NYU School of Medicine where, among other important contributions to the plasmid field, he discovered the *agr* quorum-sensing system that regulates staphylococcal virulence and the phage-inducible staphylococcal pathogenicity islands (SaPIs). He is a Fellow of the AAAS and of ASM and was elected to the National Academy of Sciences in 2006. He is currently the Recanati Family Professor of Science, Emeritus, at NYU and is engaged in developing the SaPIs as a nonantibiotic antibacterial platform.

Joseph J. Ferretti is an Emeritus Professor in the Department of Microbiology and Immunology at the University of Oklahoma Health Sciences Center in Oklahoma City. He has worked in the area of *Streptococcus pyogenes* research for over 50 years since his early days at the University of Minnesota, where he trained under the tutelage of Lewis Wannamaker, Elia Ayoub, and Ernest Gray. Following a postdoctoral fellowship at The Johns Hopkins University, where he worked with Philip E. Hartman in the study of microbial genetics, he joined the University of Oklahoma College of Medicine in 1969. His main research contributions, supported by years of support from the National Institutes of Health and other agencies, have been in the areas of streptococcal genetics, regulation of virulence factors, bacteriophages, and genomics. Dr. Ferretti is the author or coeditor of six books, including both previous editions of *Gram-Positive Pathogens.*

Daniel A. Portnoy received his Ph.D. in 1983 under the tutelage of Stanley Falkow at the University of Washington and at Stanford University. After postdoctoral training at the Rockefeller University, he moved first to Washington University, where he began working with *Listeria monocytogenes*, and then to the University of Pennsylvania. In 1997, Dr. Portnoy moved to the University of California–Berkeley, where he currently holds joint appointments in Molecular and Cell Biology and Plant and Microbial Biology and teaches a course in bacterial pathogenesis to approximately 200 undergraduates. His lab works on a wide range of topics, including the cell biology of infection and innate immunity, and has collaborated with the private sector on the development of recombinant *L. monocytogenes*-based vectors for cancer immunotherapy. Dr. Portnoy's contributions were recognized by his election to the National Academy of Sciences in 2013 and the National Academy of Inventors in 2017.

Miriam Braunstein is a Professor of Microbiology and Immunology at the University of North Carolina School of Medicine. She received her Ph.D. from Princeton University, where she carried out graduate research on histone acetylation with James Broach. After completing her degree, she became a Life Sciences Research Foundation Fellow working at the Albert Einstein College of Medicine with William Jacobs, Jr. It was during her postdoctoral training that she began studying *Mycobacterium tuberculosis*. Dr. Braunstein's laboratory studies the mechanisms of protein secretion pathways and secreted virulence effectors of *M. tuberculosis*. Her laboratory also works on developing inhaled therapies to treat tuberculosis. Dr. Bruanstein is the recipient of a Burroughs Welcome Fund Investigators in the Pathogenesis of Infectious Disease Award.

Julian Rood is Professor of Microbiology at Monash University in Melbourne, Australia. He graduated with a Ph.D. from the University of Melbourne and did postdoctoral work at the University of Wisconsin and the Australian National University. After starting his own laboratory in 1980 at Murdoch University in Western Australia, he moved to Monash University in 1985, where he was awarded a Personal Chair in Microbiology in 1998. His current research interests are centered upon *Clostridium perfringens*, focusing on the role of toxins in disease pathogenesis, the regulation of toxin and virulence gene expression, and the mechanism by which conjugative antibiotic resistance and toxin plasmids can move between *C. perfringens* strains. He is a Fellow of the American Academy of Microbiology, a Fellow and Life Member of the Australian Society for Microbiology, and a past president of the Australian Society for Microbiology. He is the Editor-in-Chief of Plasmid.

SECTION 1

The Gram-Positive Cell Wall

Section Editor: **Vincent A. Fischetti**

The Gram-Positive cell wall structure differs in many respects from its gram-negative counterpart. While much has been reported regarding the complexity of the gram-negative envelope,until recently similar information has not been available for the gram-positive wall. The following chapters provide the reader with new insight into the gram-positive cell wall structure and the increasing complexity of its surface protein coat, as well as our increasing knowledge of its polymeric nature and the location of its periplasmic constituents, offering the most comprehensive understanding to date of the gram-positive envelope.

The Gram-Positive Bacterial Cell Wall

MANFRED ROHDE

1

HISTORICAL BACKGROUND

In 1884, the Danish bacteriologist Hans Christian Gram developed a staining procedure to view stained bacteriaunder the light microscope (1). His staining method, nowadays simply called Gram staining, discriminated between a Gram-positive and Gram-negative bacterial cell wall. He introduced a dye, gentian violet, which penetrates the cell wall and cytoplasmic membrane, thus staining the cytoplasm of the heat-fixed bacteria. After addition of iodine, an insoluble complex is formed which is retained by the Gram-positive bacterial cell wall upon addition of a decolorizer such as ethanol. Therefore, Gram-positive bacteria appear almost purple, while Gram-negative bacteria retain the dye to a lesser extent or not at all and have to be counterstained with a second dye, safranin or fuchsine, appearing pink or reddish. It is noteworthy that some mycobacteria showed an indifferent staining behavior when Gram stained, suggesting that the cell wall of mycobacteria might be somehow different from the other two types. In the following decades, it became obvious that cell walls/cell envelopes are more diverse and that Gram staining alone often could lead to misinterpretations of the cell wall composition.

Before the early 1950s, when the chemical composition of bacterial cell walls was not known, it was speculated that chitin or cellulose, polymers recognized as providing rigid structures to other organisms, might also represent the building material of the bacterial cell wall. In 1951, experiments with a phenol-insoluble material from *Corynebacterium diphtheria* (2) revealed glucosamine and diaminopimelic acid as components of the bacterial cell wall which are associated with polysaccharides. Chemical examination of streptococcal cell wall layers highlighted the presence of amino acids and hexosamines in the cell wall extract, as well as rhamnose as a main component in Gram-positive bacteria (3, 4). Systematic analyses of a number of Gram-positive bacteria identified the hexosamines glucosamine and muramic acid as major components together with three prevalent amino acids, namely, d-alanine, lysine or diaminopimelic acid, and glutamic acid. By then, a typical basic basal unit in Gram-positive cell walls was also recognized in which glucosamine and muramic acid are linked with three amino acids via a peptide bond (5, 6). Gram-negative bacteria express the identical basal unit. Numerous analyses of other bacteria revealed that each bacterial genus or even species is often characterized by a distinctive pattern of amino acids, amino sugars, and sugars connected to the basic basal unit. It was believed that these differences should provide a valuable pattern to discriminate between bacterial genera/species (7, 8). Over the following years other compounds of the Gram-positive cell wall were recognized, such as teichoic acids (TAs), which are polyribitol phosphates (9), and lipoteichoic acid (LTA). Furthermore, numerous proteins were found to be linked to the cell wall.

Methods of staining bacteria for light microscopic examinations have limitations since the resolution is not high enough to reveal structural details. With the advent of transmission electron microscopes (TEMs) in the 1930s and the parallel development of preparation methods for biological samples, electron microscopic imaging of ultrathin sections of embedded bacteria became the method of choice to study bacterial cell walls in detail at high resolutions (10–13). With this methodology, it was possible for the first time to discriminate between the structures of Gram-positive and Gram-negative bacteria based on morphological differences in an image. First, electron microscopic preparation protocols developed for eukaryotic cells or tissues were also applied for bacteria. The most fruitful era started when embedding protocols were customized for bacteria and new kinds of embedding resins became available, for example, the Lowicryl resins for low-temperature embedding, which allowed the introduction of the progressive lowering of temperature method (14–16). This development was paralleled by technical inventions, especially cryo-methods in which bacteria are physically instead of chemically fixed, and it opened up a new horizon in understanding bacterial cell walls. It should be mentioned that even today new methodologies are arising and pushing morphological studies toward vitrified and unstained bacteria in a fully hydrated status and therefore in a close-to-nature condition. It is noteworthy that major developments in electron microscopic methodology required a long period of invention and testing before the technique was introduced to the market. For example, three-dimensional (3D) electron microscopy was developed about 30 years after the invention of the TEM. Invention and precommercial development of cryo-electron tomography (CET) occurred another 30 years later. Due to the rapid development of computer performance and the progress in specialized software nowadays, one can estimate that new imaging techniques are introduced faster. For example, the introduction of cryo-focused ion beam (cryo-FIB) combined with a scanning electron microscope (cryo-FIB-SEM) as a new close-to-nature approach was sold a few years after the

doi:10.1128/microbiolspec.GPP3-0044-2018

Downloaded From Vet-eBooks.com

first advent of FIB-SEMs for conventional resin-embedded biological samples.

THE BACTERIAL CELL WALL

Bacteria are mostly unicellular organisms which can be found in a wide variety of environments. Therefore, bacterial cell walls deserve special attention because they (i) provide the essential structure for bacterial viability by protecting against the often hostile environment, (ii) are composed of unique components found nowhere else in nature, (iii) are responsible for the shape of the bacteria, (iv) provide a halt for ligands and proteins for adherence to host cells, (v) expose receptor sites for drugs or viruses, (vi) represent the most important sites for attack of antibiotics, (vii) provide structures for immunological distinction and variation, and (viii) can cause symptoms of disease in animals and humans.

Chemistry of the Bacterial Cell Wall Backbone

The major backbone of the bacterial cell wall is the peptidoglycan, also called murein, which consists of repeating linear units of the disaccharide *N*-acetylglucosamine (NAG) linked to *N*-acetylmuramic acid (NAM). The disaccharides are cross-linked via often flexible pentapeptide amino acid chains forming a mesh-like framework (17). Chemically, the peptidoglycan consists of alternating β-1,4-linked *N*-acetylglucosamine (GlcNAc; NAG) and *N*-acetylmuramic acid (MurNAc, NAM, a variant of GlcNAc with a D-lactate attached to the C-3 by an ether bond). Termination of a peptidoglycan strand is achieved at the reducing end by a 1,6-anhydroMurNAc residue, in which the C-1 and C-6 of the sugar backbone are bound through an ether linkage. The appearance of the unusual 1,6-anhydroMurNac is used to determine the end of the strands. The peptide stems are covalently linked to the glycan strands with an amide bond to the carboxyl carbon of the D-lactyl group of MurNAc. One hallmark of the peptidoglycan is that the glycans are conserved across bacterial species, whereas the peptide stem is often modified and diverse, containing D-amino acids. An L-alanine is usually found in the first position of the pentapeptide stem from the lactyl group of MurNAc, which can be replaced by glycine or L-serine in some rare exceptions. The second amino acid is mostly occupied by a D-isoglutamic acid (D-iGlu). In *Streptococcus pneumoniae* this D-iGlu is amidated to yield a D-isoglutamine (18). The γ-carbon of D-iGlu is bound to the third amino acid. This amino acid in the third position of the peptide stem has the highest diversity among bacteria. Generally, one can summarize that in most Gram-negative bacteria and some Gram-positive bacteria, like in the bacilli and mycobacteria, this third position is occupied by the unusual amino acid *meso*-diaminopimelic acid. In contrast, in most other Gram-positive bacteria it is usually an L-lysine (see Fig. 1). The peptide stem is finally terminated by two D-alanines, although different D-amino acids can be found in this place, too (17).

In summary, one hallmark of Gram-positive bacteria is the observed differences in the types of cross-links in which the peptides are connected to the peptidoglycan. Today more than 100 chemotypes can be distinguished, and their differences are based on different linking units and substituents in the peptide chain (19).

Due to its unique chemical structure, the peptidoglycan sacculus forms a large polymer that can be isolated and viewed even with a light microscope (see Fig. 2). The difference between Gram-negative and Gram-positive bacteria is the thickness of the peptidoglycan layer surrounding the cytoplasmic membrane. Gram-positive bacteria exhibit a layer of peptidoglycan strands which can reach a size of between 30 and 100 nm or even thicker, whereas Gram-negative bacteria have a layer of only a few nanometers (see Fig. 3). While the chemical composition of peptidoglycan and the family of proteins for assembling is known for a number of different bacteria, the overall arrangement of these components in Gram-positive cell walls is not fully solved. For Gram-negative bacteria it has been shown with CET that individual very thin densities, probably representing glycan strands, run circumferentially around the long axis of the bacterial cell (20). In contrast, the 3D arrangement of peptidoglycan in Gram-positive bacteria is still under discussion (21). Three models have been proposed over the years. The first model suggests that glycan strands run circumferentially around the long axis as in Gram-negative bacteria. This model is called the "circumferential" or "layered" model (22). In the second model the glycan strands are supposed to run perpendicular to the bacterial cell wall in a hexagonal lattice, so this is called the "perpendicular" or "scaffold" model (23, 24). This model was proposed on the basis of nuclear magnetic resonance studies applying a synthetic 2-kDa fragment of the peptidoglycan formed from NAG-NAM (pentapeptide)-NAG-NAM (pentapeptide). Nuclear magnetic resonance revealed that this fragment forms a right-handed helix with a periodicity of three NAG-NAMs per helix turn. The first two amino acids can adopt a limited number of conformations (24). Atomic force microscopy (AFM) studies with gently disrupted sacculi of *Bacillus subtilis* established the so-called coiled cable model, in which bundles of glycan strands form thicker moieties of around 50 nm that run around the cell (25). It should be noted that a model with glycan strands running parallel to the long axis has never been considered, because it was unclear how such a sacculus could elongate. In addition, the coiled cable model is not considered nowadays since CET did not show any cable-like structures in the thick peptidoglycan layer. These earlier observations might have been based on the fact that isolated peptidoglycan was harvested by boiling bacteria, opened up by a French press cell, diluted in water, and air dried on mica before AFM imaging was performed.

Biochemical Synthesis of the Peptidoglycan Layer

Synthesis of the peptidoglycan is a three-step mechanism, which is localized at three locations within a bacterium. The sequential Mur ligase pathway is involved in biosynthesis of the peptidoglycan. The early steps of synthesis start in the bacterial cytoplasm, where precursors linked to undecaprenyl pyrophosphate (UDP), such as UDP-NAM-pentapeptide (UDP-NAM) and UDP-NAG, are formed. In the second step UDP-NAM is bound to another cytoplasmic membrane-bound UDP functioning as a transport lipid. This complex is called lipid I and is located at the inner cytoplasmic face of the membrane. Covalent attachment of the second precursor UDP-NAG forms the transport lipid complex lipid II. Then, for example, in the case of *Staphylococcus aureus*, a peptide cross-bridge is attached to the third amino acid in the pentapeptide, consisting of five glycine residues. Next, the entire lipid II complex is flipped over the cytoplasmic membrane to the extracellular side by a flippase. The precise biochemical process of the flipping mechanism is not yet fully understood. Lipid II is incorporated into nascent growing peptidoglycan by penicillin binding proteins (PBPs) on the extracellular side of the membrane. This third step involves, first, a transglycosylation and, second, a transpeptidation reaction performed by PBPs for incorporating new glycans with flexible

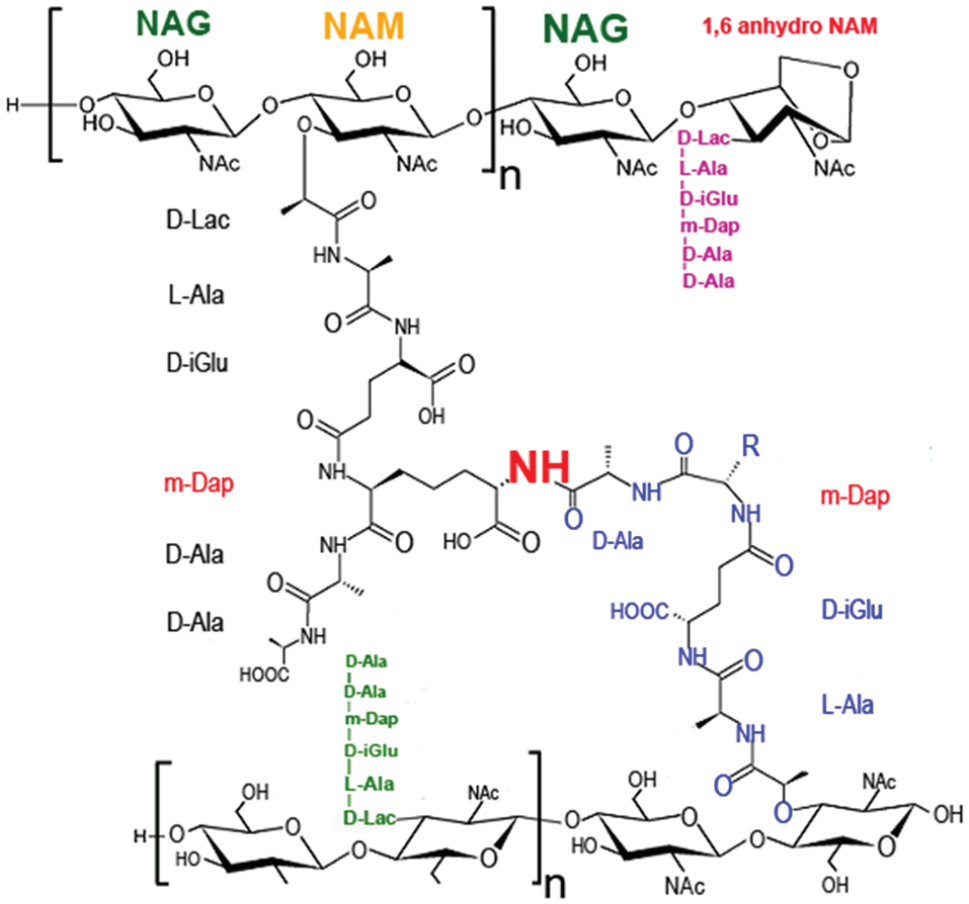

FIGURE 1 The bacterial cell wall backbone, peptidoglycan; shown are the two glycan strands (in black). Peptide stems are depicted in black (left side), and the second peptide stem, in blue. Note the cross-linking NH (in red) via the two unusual amino acids m-diaminopimelic acid (m-Dap, in red) and the presence of D-alanine in the peptide stems. Two more peptide stems (green and pink) are depicted which can interact to build the next cross-linking between glycan strands.

peptides into the existing peptidoglycan layer (18, 26–31). For detailed reading about chemical reactions and enzymes involved in this process, please refer to the review by Teo and Roper (18).

Turnover of Peptidoglycan

The first report describing the bacterial cell wall turnover concerned the Gram-positive bacterium *Bacillus megaterium* and was published more than 50 years ago (32). Later, pulse-chased experiments demonstrated with radioactively labeled cell wall precursors that all studied Gram-positive bacteria as well as Gram-negative bacteria carry out a cell wall turnover (33–36). The model for peptidoglycan growth in Gram-positive bacteria implies an inside-to-outside growth in which newly synthesized peptidoglycan is delivered to the cytoplasmic membrane face of the peptidoglycan layer in a relaxed form. With polymerization and cross-linking, peptidoglycan moves to the outside of the cell wall and is stretched due to the high turgor pressure within the bacterial cell (37). Once the maximally stretched peptidoglycans in the outer layers start to age, they are subsequently hydrolyzed by autolysins (38). It was estimated that around 50% of the total cell wall mass is turned over within one generation. This would have been a massive loss of resources for the bacteria, and it was speculated that hydrolyzed constituents of the cell wall might be recycled by bacteria. Indeed, this was found to be the case in Gram-negative bacteria such as *Escherichia coli*, and the biochemical pathways are well understood (39, 40). It remained unclear if Gram-positive bacteria would also recycle cell wall material. It was found that large amounts of cell wall fragments could be detected in growth medium of exponentially grown Gram-positive bacteria such as *Bacillus*,

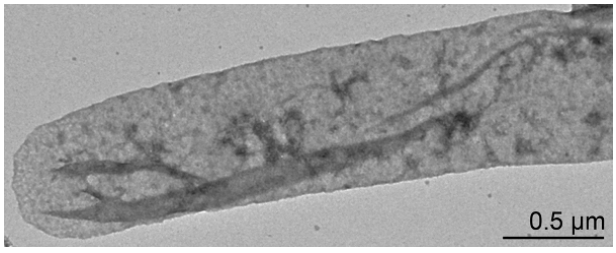

FIGURE 2 TEM image taken at an acceleration voltage of 80 kV of a peptidoglycan sacculus of *E. coli* after boiling for 3 h in 10% SDS. The mesh-like sacculus was negatively stained with 1% aqueous uranyl acetate, air-dried, and observed in a normal TEM.

Downloaded From Vet-eBooks.com

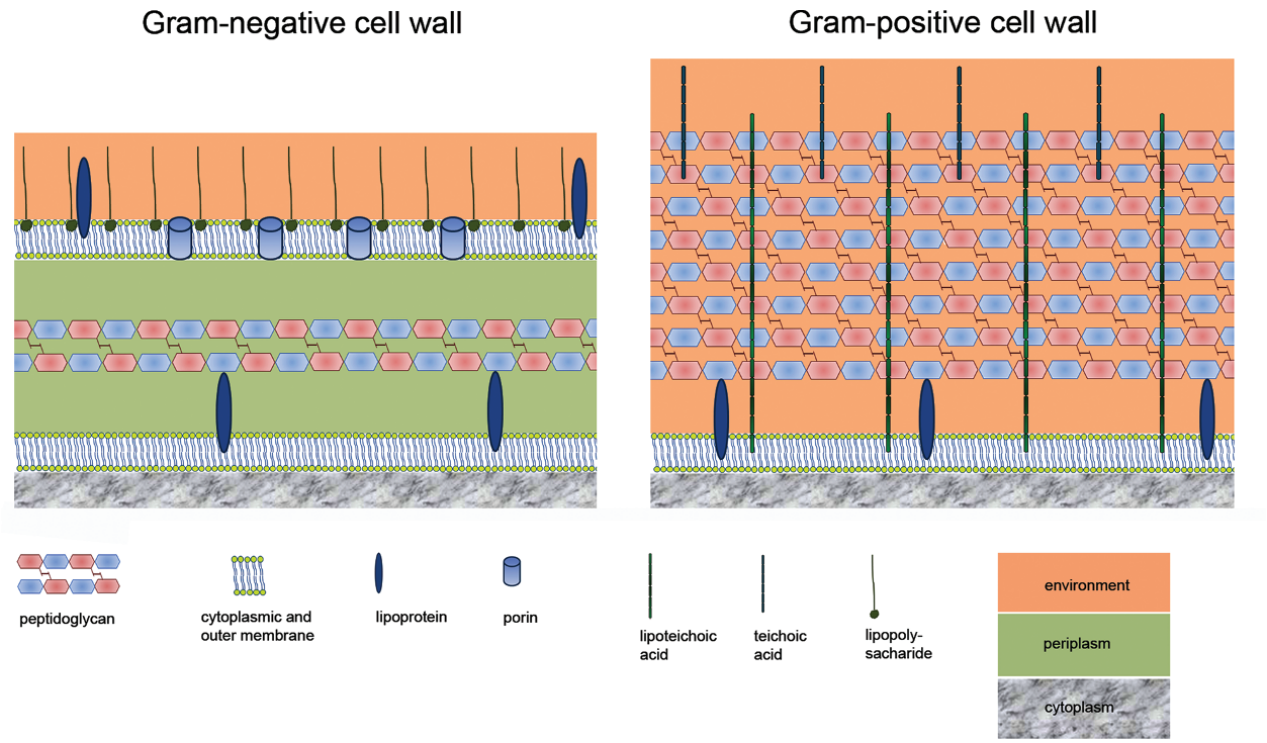

FIGURE 3 Schematic drawing of Gram-negative and Gram-positive cell walls. A characteristic of Gram-negative cell walls is the presence of two membranes, the cytoplasmic membrane and the outer membrane. Between these membranes is the periplasmic space, in which a very thin layer of peptidoglycan is found; lipopolysaccharides are attached to the outer membrane, and porins are inserted in the outer membrane. A thick layer of peptidoglycan and the lack of an outer membrane are the main characteristics of Gram-positive cell walls; instead of lipopolysaccharides, Gram-positive bacteria have lipoteichoic acid and teichoic acid localized in the cell wall. The periplasmic space is not shown since the existence of such a periplasm in Gram-positive bacteria is still being studied.

Lactobacillus, *Listeria*, and *Staphylococcus* strains (39). Thus, a robust turnover of cell wall components was established, but it was only shown recently that this correlates with high recycling rates of such compounds. In the early 2010s it was demonstrated that Gram-positive bacteria recycle hydrolyzed cell wall material, as does *E. coli*, although key steps and particular aspects of the involved pathways are less well understood. Meanwhile, orthologs of *E. coli* enzymes involved in the biochemical process of cell wall recycling were found in several Gram-positive bacteria (41). Interestingly, new observations suggest that cell wall recycling is turned on when Gram-positive bacteria reach the transition to the stationary phase of growth, not in the exponential growth phase, explaining why massive hydrolyzed cell wall constituents were detected in the exponential phase. Furthermore, it has been reported that in Gram-positive bacteria cell wall recycling is a crucial step for survival in the stationary phase and/or in a resting or persistence phase for pathogenic bacteria (39, 42). In addition, it should be noted here that the process of delivering newly synthesized peptidoglycan to the inner side of the cell wall and hydrolyzing "older" peptidoglycan at the outside of the wall has to be in an extremely strongly regulated dynamic equilibrium to ensure bacterial cell growth and division. If this equilibrium is somehow altered and more older peptidoglycan is shed from the outside of the cell wall than newly synthesized peptidoglycan can be delivered to the inner side of the peptidoglycan layer, the layer gets thinner, with the consequence that the entire bacterial cell can be lysed by intracellular turgor pressure. In addition, antibiotics such as penicillin and cephalosporins might bind better to PBPs and further inhibit the delivery of newly synthesized peptidoglycan, resulting in an even thinner peptidoglycan layer (43).

LIPOTEICHOIC ACID AND WALL TEICHOIC ACID AS MAJOR CONSTITUENTS OF THE CELL WALL

TA, which represents an important cell wall polymer and is found in many Gram-positive bacteria, was first described in 1958 (44, 45). Today TAs enclose two abundant bacterial cell wall polymers: (i) LTAs, which are anchored via lipid domains in the cytoplasmic membrane, and (ii) wall TAs (WTAs), which are covalently bound in the peptidoglycan layers. TAs consist of a diverse family of bacterial cell surface glycopolymers chemically defined as phosphodiester-linked polyol repeat units, or glycerol phosphate or ribitol phosphate residues. Structurally, WTA and LTA expose highly negatively charged properties due to the multiple phosphate groups in the structure and less positively charged groups due to inserted d-alanine residues. LTA shows relatively low differences in the structures of different bacteria, whereas WTA is extremely versatile in its structural groups. Why Gram-positive bacteria produce so much LTA and WTA at the same time is not well understood. For example, LTA can be deleted, but only if bacteria are grown below 30°C, whereas WTA is dispensable in *B. subtilis* and *S. aureus* under laboratory conditions (46). Deletion of LTA and WTA together is lethal because both cannot compensate for one another anymore (47, 48). Therefore, WTA and LTA have to fulfil vital functions, and indeed, for *S. aureus* it was shown that loss of WTA results in less colonization and infection in

Downloaded From Vet-eBooks.com

in vivo experiments in the rabbit endocarditis model (49). Based on the chemical structures, LTAs are grouped into at least five LTA types. Despite their role in infection, other major functions of TA have been established over the past years: (i) WTA and LTA can protect against environmental stress (50); (ii) LTA protects against harmful molecules such as antimicrobial peptides and cationic antibiotics (interestingly, in the structure of LTA a d-alanine is inserted which is responsible for the protection) (51–53); (iii) WTA and LTA are the main controlling mechanisms for enzyme activities, especially for autolysins and cation concentrations in the peptidoglycan layer (54); (iv) WTA is responsible for receptor binding and binding to surfaces in pathogenicity (49); (v) LTA directs the right placement of cell division machinery (50, 55); (vi) WTA serves as a phage receptor (56); and (vii) WTA and LTA mediate biofilm formation and binding to medical devices (57).

Different pathways, despite the fact that LTA and WTA show similarities in structure, perform biosynthesis of LTA and WTA. It is known that the *S. aureus* system needs at least 12 genes for WTA synthesis of the backbone structure of poly-Rbo-P (polyol ribitol phosphate). In contrast, only three genes are involved in synthesis of the LTA backbone poly-Gro-P (polyol glycerol phosphate) (58). For modification of the backbones, numerous other genes are involved in incorporation, for example, of d-alanine or hexoses. Synthesis of WTA is accomplished in *S. aureus* in five steps. Interestingly, the WTA synthesis pathway shares UDP as a common lipid carrier. As mentioned above, UDP is also involved in the first steps of peptidoglycan synthesis. Most genes involved are arranged in gene clusters (58–61). On the other hand, LTA synthesis starts directly from phosphatidylglycerol, which is located in the cytoplasmic membrane. Synthesis initiates on the glycolipid, which also serves as the membrane anchor for LTA. Therefore, no nucleotide activated precursor like UDP is needed. Again, between different Gram-positive bacteria, extensive differences exist in the amount of genes involved, the lengths of the LTA and WTA molecules, and modification of the synthesized backbones. For further detailed information on WTA and LTA biosynthesis, I strongly recommend the reviews by Brown et al. (58) and Percy and Gründling (62).

In summary, new studies will shed light on the structural and functional relationships of different LTA and WTA types and their impact on cell division, bacterial cell surfaces, and interaction with host receptors and should allow for the identification of new receptors in the bacteria-host interplay. Furthermore, the role of LTA in inducing immune stimulatory effects will be further developed. In particular, the question of cell tropism should be addressed, since the various differences observed in the chemical structures of LTA and WTA between Gram-positive bacteria might reveal evidence that these molecules play an important role in cell tropism recognition reactions.

CAPSULE

The capsule represents the outermost layer of a Gram-positive bacterial cell wall. It consists of a gelatinous polymer composed of polysaccharides or polypeptides, or both, and surrounds the entire bacterium with a thick layer. The capsule of *Bacillus anthracis*, for example, is composed of polymeric D-glutamic acid, whereas the capsule of group A streptococci consists of hyaluronic acid, a repeat polymer of disaccharides composed of D-glucuronic acid, and *N*-acetyl-D-glucosamine. In a proper capsule the polymer is firmly attached to the cell wall, whereas if the polymer is only loosely attached, the structure is often referred to as a slime layer, which has no repeated pattern. Major functions of capsules in pathogenic bacteria are (i) the protection against phagocytosis by neutrophils or macrophages due to the smooth capsular surface and the highly expressed negative charges, (ii) the prevention of complement-mediated bacterial lysis, and (iii) the contribution to virulence determinants. Furthermore, the capsule composition is responsible for different serotypes, which are observed particularly in certain species of streptococci. In the case of pneumococci, the different capsule polysaccharides are used as vaccine antigens. The capsule is synthesized and assembled at the cytoplasmic membrane and then extruded or secreted through the cell wall to the outside (63).

Since the major component of the capsule is water, it is not easy to preserve such polymeric polysaccharides in a natural state for electron microscopic observation. A method of choice is to introduce a kind of a scaffold within the capsule layers to prevent collapsing through chemical fixation and dehydration. As has been explicitly described several times in this chapter, fully hydrated and vitrified samples give the best close-to-nature view of the dimensions of a given bacterial capsule. Nevertheless, the incorporation of lysine as a positively charged component, which reacts by van der Waals forces with the capsule layer negative charges from the polysaccharides, provides a reasonable method to preserve the capsular ultrastructure in ultrathin sections. For a rapid visualization of capsules in a TEM, the capsule can be stained with cationic-coated gold nanoparticles (lysine-coated gold nanoparticles). For *S. pneumoniae* it has been demonstrated that fixation with 1% formaldehyde further supports the capsule structure, whereas fixation with glutaraldehyde results in loss of the capsule structure (64). The bound gold particles around the bacterium show indirectly the presence of the capsule and its dimensions (see Fig. 4). For ultrathin sections, bacteria are incubated with lysine acetate. In the second step the bound lysine reacts with ruthenium red, which subsequently is precipitated by osmium tetroxide. The precipitates formed in the capsular layers give reasonable support for preservation of the capsules in various Gram-positive bacteria, which allow for measurements of capsule dimensions or for imaging of the *in vivo* expressed capsules in blood or organs (52) (see Fig. 5).

EXTRACELLULAR VESICLES OF GRAM-POSITIVE BACTERIA

The extracellular vesicles formed by Gram-negative bacteria have been known of since the 1960s, whereas reports about extracellular vesicles from Gram-positive bacteria first appeared in the early 1990s (65, 66). The entire process of forming extracellular vesicles is nowadays referred to as vesiculogenesis (67). One reason for the lack of studies of extracellular vesicles of Gram-positive bacteria might be that it was believed that such vesicles simply could not be generated, due to the thick peptidoglycan layer in such bacteria. No decent model was able to explain mechanistically the formation and passage through such a thick peptidoglycan mesh at that time. Extracellular vesicles from Gram-negative bacteria are often referred to as outer membrane vesicles (OMVs) since they generate by pinching off as vesicles from outer membranes (68, 69). In contrast, extracellular vesicles of Gram-positive bacteria are often called membrane vesicles (MVs). It was reported that OMVs serve as a cargo vehicle for DNA, RNA, virulence factors, immunomodulators, and adhesions for pathogenic bacteria. Therefore, OMVs are considered to play an important part in the pathogenesis of Gram-negative pathogens (70, 71). Both types of extracellular

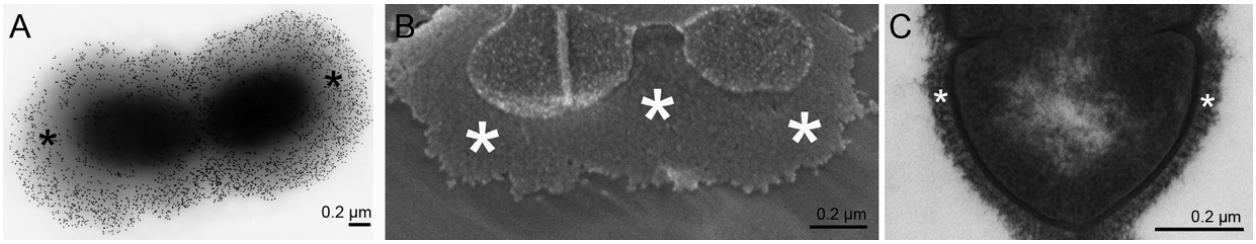

FIGURE 4 Visualization of Gram-positive bacterial capsules. (A) Cationic gold nanoparticles (lysine-coated 15-nm gold nanoparticles) label the thick capsule of *Streptococcus pneumoniae* after fixation with 1% formaldehyde at low pH (stars). (B) Cryo-FESEM at close-to-nature conditions reveals the thick capsule layer of *S. pneumoniae* marked with white stars. The thickness is comparable to the labeled capsule in (A); samples were nitrogen-slush-frozen, freeze-fractured at –105°C, freeze-etched at –105°C for 30 sec, and sputter-coated with gold/palladium. (C) For ultrathin sections, capsules can be preserved with the lysine-ruthenium-red osmium embedding protocol (see reference 52). Following embedding in LRWhite resin, *Streptococcus suis* is surrounded by a dense capsule layer (white stars).

vesicle have in common that they are formed by a lipid bilayer that forms an inner lumen in which the varying cargos are engulfed. Vesicle size ranges from 20 to 500 nm, and vesicles are best viewed using a TEM with negative staining or by field emission SEM (FESEM). In 2009 the first report about MVs from *S. aureus* was published. The study found that MVs were more or less identical to the described OMVs from Gram-negative bacteria, with the exception that MVs exhibit a mostly smaller vesicle size of up to about 200 nm compared to OMVs (72). It is noteworthy that MVs from *S. pneumoniae* and *Listeria monocytogenes* are considerably smaller than those from other Gram-positive bacteria, suggesting that bacteria synthesize and regulate MVs in different ways (72–74).

Generation, translocation, and secretion are the main unresolved issues about MVs, considering that they need to be released through the thick peptidoglycan layer into the environment. Three hypothetical models have been reported or discussed: (i) vesicles generate from the cytoplasmic membrane in a process comparable to the pinching off of OMVs from the outer membrane and are then pushed by the interior turgor pressure through the peptidoglycan layers. This suggests that MVs' size is small since the diameter is regulated by the known particle size exclusion of the given peptidoglycan layer for a specific bacterium. (ii) Cell wall-modifying enzymes are released or transported by the MVs, thus facilitating transmigration through the peptidoglycan layers possibly by losing the mesh at the site of travel. (iii) Transport occurs through channels in the layer, which suggests that MVs are extremely flexible in morphology, i.e., not always spherical vesicles, and can be released through much smaller channels then the actual size of the spherical MVs found in the environment (72). Therefore, further investigations are needed to clarify the enigmatic release of MVs through the Gram-positive peptidoglycan layers. CET could serve as the method of choice to clarify the transmigration through the peptidoglycan layer since bacteria are snap-frozen and even fast events can be fixed. However, the search for such events in tomograms can be very time consuming.

Nevertheless, more and more evidence is emerging that MVs of Gram-positive bacteria play an important role in pathogenesis, since for *S. aureus* it is reported that MVs contain PBPs, which can block the activity of β-lactam antibiotics. Furthermore, the global regulator MsrR, which is involved in methicillin resistance, was also detected in *S. aureus* MVs. MVs can be considered Trojan horses involved in passing on resistance genes among Gram-positive bacteria (75). In addition, several toxins have been found in MVs, such as listerolysin O in *L. monocytogenes* and pneumolysin in *S. pneumoniae*. Both toxins induce pore formation in the host cells and are therefore important virulence factors for colonization and invasion (73, 74). MVs have also been described in group A streptococci and their content characterized in detail (see Fig. 6). In summary, not only were virulence-associated proteins such as M1 protein,

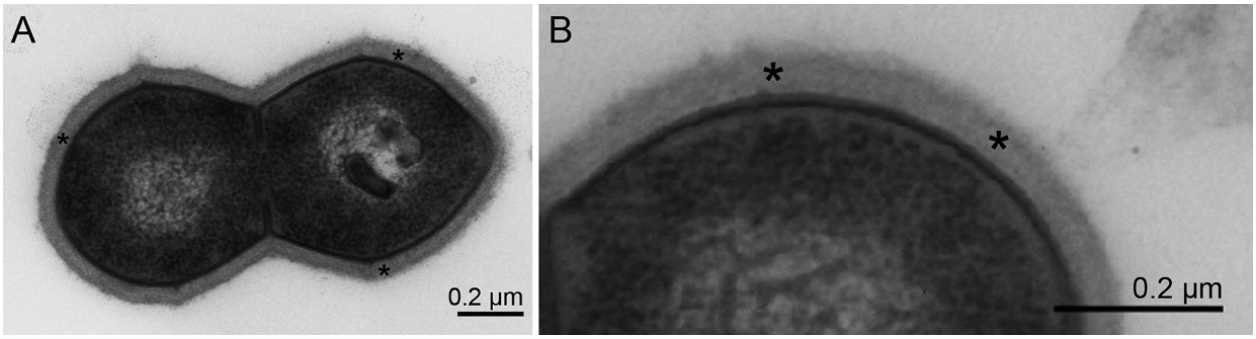

FIGURE 5 Good preservation of streptococcal capsules under *in vivo* conditions. (A) Streptococcal capsules (*Streptococcus pyogenes* administered intravenously) are well preserved (black stars) in spleen under *in vivo* conditions in the mouse model even after fixation with glutaraldehyde and formaldehyde, dehydration with acetone, and embedding in epoxy resin and ultrathin sectioning. (B) Enlargement of another bacterium depicting nicely preserved capsule (black stars). Most likely, proteins in the blood have covered and preserved the capsule and prevented loss of capsule during aldehyde fixation.

streptolysin O, and serine protease HtrA detected, but numerous metabolic proteins residing in the streptococcal cytoplasm were also identified, as well as surface-exposed proteins including anchorless surface proteins, lipids, and RNA. Furthermore, the involvement of the virulence-associated two-component regulator CovRS was demonstrated, and loss of CovRS resulted in increased vesicle formation (76).

A SPECIALIZED CELL WALL IN MYCOBACTERIA

Mycobacteria are classified as Gram-positive bacteria, although they are also referred to as acid-fast bacteria due to the high density of lipids in the cell wall, which prevents accurate Gram staining. Thus, the staining is performed with Ziehl-Neelsen stain. The complexity of mycobacteria cell walls is a distinct feature that is not found in other bacteria. Three major macromolecules—peptidoglycan, arabinogalactan, and mycolic acids—are the building blocks of the mycobacterial cell wall. The structure of the mycobacterial cell wall was described in the 1960s and 1970s, and electron microscopy played an important role in describing the unusual morphological structures of the cell wall. The current accepted model of the cell wall is based on studies which identified the mycolyl-arabinogalactan-peptidoglycan complex as the core structure of mycobacteria (77). This unique arrangement that includes lipids and proteins is responsible for the characteristically important and efficient permeability barrier of the mycobacterial cell wall, particularly against drugs, and provides the basis for the potent pathogenicity of mycobacteria (see Fig. 7). Due to the presence of a large amount of lipids in the cell wall, earlier studies were confronted with the difficulty of extracting the lipids during the dehydration protocol. Therefore, for a long time whether the lipids formed a lipid bilayer in the cell wall, as suggested by Minnikin in 1982 (77), was discussed. He suggested an asymmetrical membrane to which the mycolic acids are covalently attached as an inner leaflet. The presence of such a lipid bilayer was confirmed by freeze-fracture studies, which clearly defined a second fracture plane, which is typical for a lipid bilayer. These findings supported the hypothesis of a second bilayer outside the cytoplasmic membrane, even though these studies were performed with corynebacteria (78, 79).

However, the existence of a bilayer outside of the cytoplasmic membrane was still heavily criticized because the proposed bilayer has never been clearly identified in ultrathin sections due to artefact-producing embedding preparations such as chemical fixation and dehydration with acetone. Instead, a more or less lucent zone, an outer layer, probably representing lipids and mycolic acids, was detected dividing the mycobacterial cell wall into a triple-layer structure composed of the cytoplasmic membrane, cell wall, and outer layer (see Fig. 8). This translucent zone is covered with a very thin stainable layer consisting of capsule and attached proteins. Freeze substitution revealed more or less similar images, even though the cell wall appeared thinner (80–82). A major step forward in elucidating the mycobacterial outer cell wall structure was performed with close-to-nature imaging applying cryo-ultrathin sections and CET of fully hydrated and vitrified samples (83). These studies revealed important changes to the current model. First, a lipid bilayer was detected covering the outside of the cell wall, indicating that mycobacteria express a similar outer membrane resembling Gram-negative bacteria. Second, no evidence was found for an asymmetrical membrane; instead, a symmetric membrane and an additional periplasmic space was postulated (79). In addition, it is clear that extractable lipids play a dominant role in mycobacterial membrane integrity and properties.

The mycobacterial peptidoglycan is synthesized as observed in other bacteria, in the cytoplasm, using UDP and is then flipped over the cytoplasmic membrane and inserted in the growing peptidoglycan network by the action of hydrolases and PBPs. Nevertheless, mycobacteria exhibit a number of differences compared to model bacteria: (i) mycobacterial peptidoglycan is extremely cross-linked, (ii) the cross-links are based on up to 80% of the total peptidoglycan on 3-3 peptide cross-links instead of the 4-3 peptide cross-links found in other bacteria, and (iii) the peptidoglycan backbone shows modifications such as glycolylations of NAM and amidation of D-glutamic acid and *meso*-diaminopimelic acid (84–88). Furthermore, the mycobacterial peptidoglycan is surrounded by a layer of arabinogalactan, a disaccharide, which has long arabinan polymers attached. It is noteworthy that some galactans remain free of arabinan polymers, and most important, the arabinan chain ends are branched. These branched ends are the binding partners for the long carbon chains of mycolic acid. These incorporated fatty acids are responsible for the extremely thick waxy coat of mycobacteria and make the mycobacterial cell wall mostly impermeable, contributing to pathogenicity. For detailed reactions and enzymes involved in the process, please refer to the review by Jankute et al. (84).

ELECTRON MICROSCOPIC TECHNIQUES APPLIED TO STUDY THE MORPHOLOGY OF GRAM-POSITIVE BACTERIA CELL ENVELOPES

Since the early 1950s TEM has been applied for studying the morphology and ultrastructure of Gram-positive bacterial cell walls. Surprisingly, even today a single unique method that would allow study of the ultrastructural details of all the different Gram-positive bacteria under close-to-nature conditions with an electron microscope is still needed. The newly developed CET might be the current method of choice, though CET has some drawbacks and restrictions, especially when bacteria with a width of more than 0.4 to 0.5 µm have to be imaged. The new super-resolution light microscopy methods such as stimulated emission depletion, photoactivated localization microscopy, structured illumination microscopy, and total internal reflection fluorescence were all very promising, but a breakthrough was hindered by the limitations when imaging immune fluorescent-labeled structures. The expression of fluorescence tags or fluorescence proteins, such as green fluorescent proteins, might alter the *in vivo* biological activities to a certain extent, therefore giving rise to inaccurate localizations within the bacterial cell. If the reader is interested in pursuing this topic in detail, I recommend the literature regarding the MreB protein (involved in the bacterial division process) over the past years. Depening

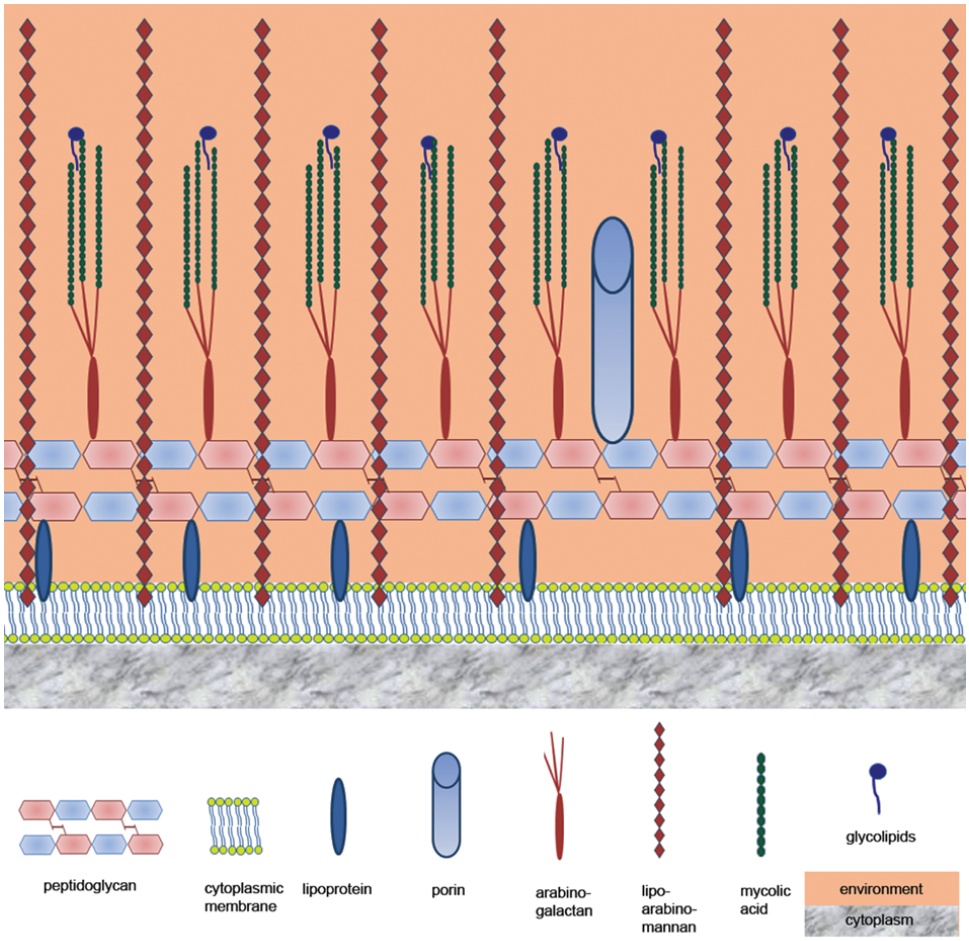

FIGURE 7 Schematic drawing of a mycobacterial cell wall. A thin layer of peptidoglycan and arabinogalactan, to which large amounts of mycolic acids are attached, is characteristic. An unusual compound is lipoarabinomannan, which is attached to the cytoplasmic membrane. On the outermost outside, glycolipids are attached to the mycolic acids; transport is facilitated by inserted porins. The mycobacterial outer membrane is not included in the scheme since the presence of such an outer membrane is still under discussion.

on the high-resolution imaging method applied, different asumptions about its distribution, arrangement, and localization in *B. subtilis* were made, i.e., looking at if MreB forms helices in the bacterial cell (89).

Several attempts have been undertaken to elucidate the ultrastructure of Gram-positive cell walls. In early TEM imaging of embedded and ultrathin cut bacteria, the preparation scheme included chemical fixation with aldehydes, introduction of heavy metals, dehydration with acetone/ethanol, and embedding in suitable resins. All these preparation steps had to be done to cope with the "hostile" environment created by the electron microscope, namely, high vacuum and bombardment with high-energy electrons resulting in heating up the section. Thus, it is obvious that these treatments might not result in proper preservation of the native cell wall. To overcome some of these detrimental effects in the preparation of bacteria, cryo-methods were introduced, such as freeze-substitution or hydrated cryo-ultrathin sections. With the advent of high-pressure-freezing techniques, preservation of bacterial cell wall structures was pushed further in the direction of close-to-nature conditions. Nowadays, CET is the best method to perform imaging in a frozen vitrified hydrated state of the bacteria (90). However, the drawbacks of this technique are that it is only available in certain institutes and it needs a sophisticated infrastructure and time for performing in-depth analysis. The future will show if the newly developing cryo-FIB-SEM micromachining will advance the deciphering of the ultrastructural details of the bacterial cell wall since the examined bacteria are in their fully hydrated condition and physically frozen, overcoming the problem of chemical fixation with aldehydes. This technique allows the observation of lamellae (about 10 to 20 nm thick) cut out of the bacterium, thus gaining access to small ultrastructural details. It should also be mentioned that other techniques, such as X-ray diffraction and X-ray lithography, have been unsuccessful because the bacterial cell wall is not crystalline. AFM has also been implemented, but with AFM only the surface of a sample can be imaged, and therefore, only limited ultrastructural information was obtainable.

The same restriction holds true for SEM. With the advent of FESEM it became possible to study bacterial structures at very high magnification (up to 400,000-fold) and resolution. Nevertheless, FESEMs have never been able to provide the amount of ultrastructural details observed with TEMs on

Downloaded From Vet-eBooks.com

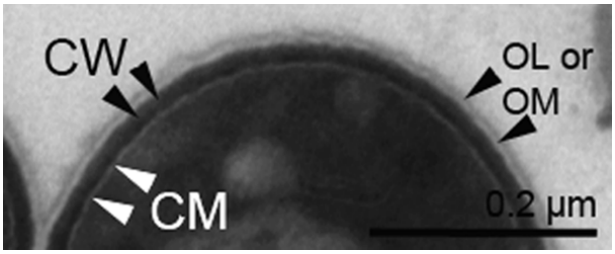

FIGURE 8 Typical appearance of a triple-layer structure of the mycobacterial cell wall of *Mycobacterium avium* ssp. *paratuberculosis* after special embedding applying the osmium-thiocarbohydrazide (TCH)-osmium method; this method especially preserves lipids much better than other methods because after the first osmium tetroxide step TCH binds to the sample bound osmium, and in the second osmium step more osmium is bound to TCH, therefore stabilizing lipids. In addition bacteria were embedded by applying the progressive lowering of temperature method down to –50°C, and bacteria were then embedded in the hydrophobic Lowicryl resin HM20; this protocol makes it possible to clearly define the triple-layer structure of the mycobacterial cell, which is lost in most other embedding methods, despite the cryo-based protocols. CM, cytoplasmic membrane; CW, cell wall; OL, outer layer; OM, outer membrane.

ultrathin sections. This is simply because FESEM reveals only the surface topography of a bacterial cell. It is noteworthy that FESEM does not allow discrimination between Gram-positive and Gram-negative bacteria (see Fig. 9). In addition, FESEM samples need to be coated to be conductive. This so-called sputter-coating is often the last step in an SEM preparation protocol. Samples are usually sputter-coated with a thin 5- to 8-nm film of either gold, gold palladium, or platinum. Even though these layers are very thin, they might cover some fine ultrastructural details of interest when observed at high magnifications. Surprisingly, high-resolution images of the Gram-positive cell wall do not exist. However, FESEM has been very useful in studying the interactions of pathogenic bacteria with host cells.

The following subsections give a general description of most of the electron microscopic methods applied for studying bacterial surface structures. If the reader is interested in detailed protocols, please refer to specialized text books on electron microscopic methods.

Heavy Metal Coating or Shadowing

When biological samples were examined for the first time under a TEM, it became obvious that the contrast of the biological material is fundamental and that methods had to be developed to increase the contrast for TEM images. One of the first approaches applied was coating with heavy metals (91, 92). A shadow line behind the exposed structures appeared when the metal coating was performed at a certain angle. If the coating angle and the measured length of the resulting shadow were known, the height of the structure could be determined. In earlier years, metal coating became the method of choice for the ultrastructural description of regularly patterned cell wall structures, named S-layers, attached to the bacterial cell wall (44, 93–95).

Negative Staining

The metal coating approach has restrictions when macromolecules or protein complexes have to be imaged. For such

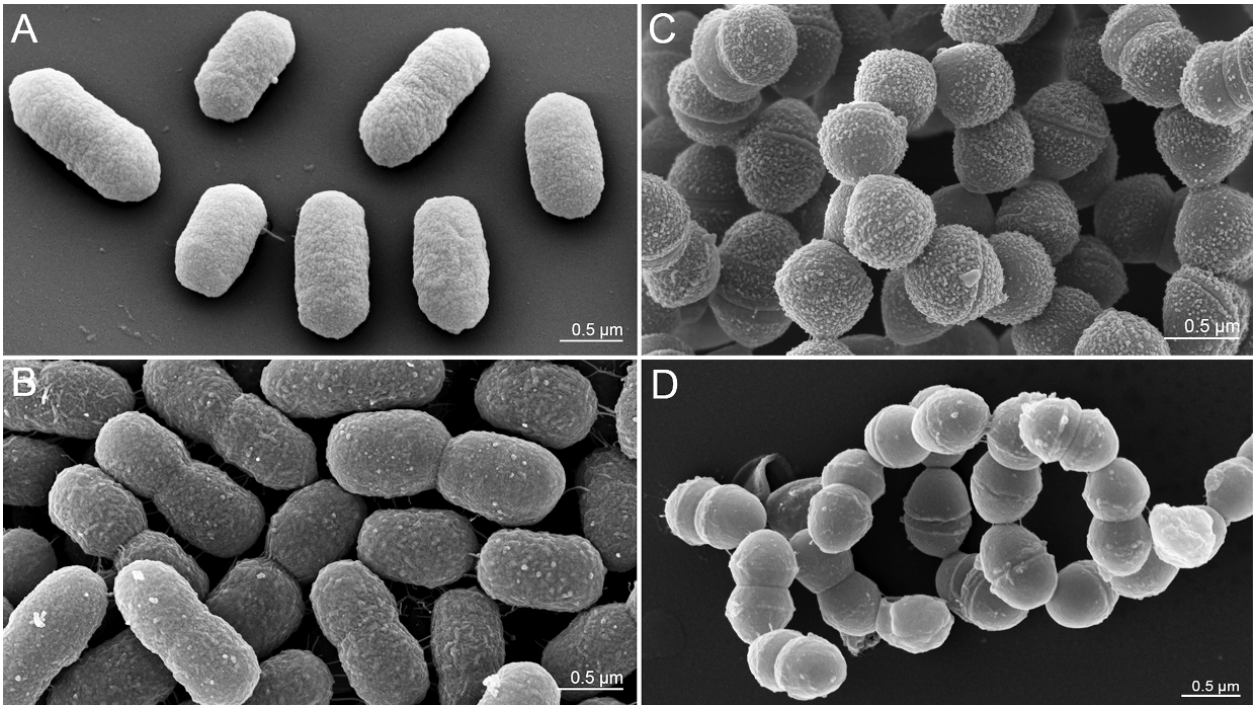

FIGURE 9 FESEM of aldehyde-fixed, acetone-dehydrated, critical-point-dried, and gold/palladium sputter-coated samples. (A) *Escherichia coli* (Gram-negative), (B) *Acinetobacter baumannii* (Gram-negative), (C) *Streptococcus pyogenes* (Gram-positive), and (D) *Enterococcus faecium* (Gram-positive). Since FESEM reveals only the surface structures and no information from inside the bacteria, FESEM does not distinguish between Gram-negative and Gram-positive bacteria.

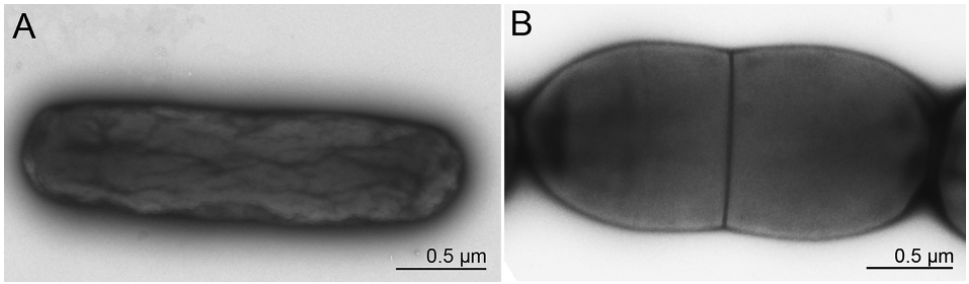

FIGURE 10 TEM images of negatively stained bacteria. (A) *Escherichia coli* (Gram-negative) and (B) *Streptococcus gordonii* (Gram-positive). Negative staining with 1% aqueous uranyl acetate cannot discriminate between Gram-negative and Gram-positive bacteria because the different peptidoglycan thicknesses cannot be resolved.

purposes the idea of embedding macromolecules into heavy metal salts such as Na-K-phosphotungstate, and later, uranyl acetate and others, was considered. The advantages of negative staining are manifold: it is (i) reliable and repeatable, (ii) fast, (iii) avoids flattening of macromolecules on the support film when air-drying, (v) stabilizes the protein in the electron beam, and (vi) allows determination of the shape and quaternary structure of an enzyme complex at around 1.3-nm resolution. In addition, the use of different heavy metal salts results in higher or lower contrasts (96–98). It is noteworthy that negative-stained viruses and larger enzymes opened the door for 3D microscopy and image processing beginning in the 1970s (99, 100). Negative staining was the method of choice when isolated peptidoglycan sacculi or pole caps were analyzed (68). Nevertheless, negative staining is not suitable to differentiate between Gram-negative and Gram-positive bacteria (see Fig. 10).

Conventional Embedding

In the 1950s, the embedding technique was introduced to analyze the ultrastructural details of bacteria (10) because intact bacteria were unsuitable for these studies. Therefore, ultrathin sectioning of bacteria was needed to gain access to internal morphological structures. With the invention of ultramicrotomes, it was possible to obtain ultrathin sections of biological samples, thus facilitating detailed studies of bacterial cell walls (see Fig. 11).

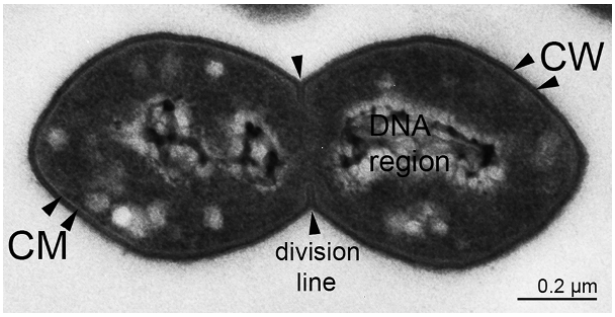

FIGURE 11 Typical image of a conventional embedded Gram-positive bacterium, *Streptococcus pneumoniae*, after aldehyde fixation, contrasting with osmium tetroxide and uranyl acetate, dehydration, and embedding in epoxy resin. In ultrathin sections the DNA region is typically aggregated and forms a translucent area within the bacterial cell. The thick peptidoglycan layers are dark featureless structures. CM, cytoplasmic membrane; CW, cell wall.

After that, morphological studies of bacterial cell walls started to blossom. Ultrathin sections have a thickness of around 50 to 80 nm, meaning that a single bacterium measuring 1 µm in length can be cut into nearly 15 sections. Again, one was directly confronted with the problem of the low contrast of biological samples. Thus, the early embedding protocols usually included fixation with aldehydes; contrasting with heavy metals such as osmium tetroxide, ruthenium red, and uranyl acetate; and dehydration with acetone/ethanol depending on the resin used for embedding. At that time epoxy or methacrylate resins were used the most, and polymerization was carried out at 60 to 70°C. Nowadays, many different resins are available, and every class of resin offers a slightly different image of the embedded bacterial ultrastructure, depending on the embedding protocol (see Fig. 12). In addition, the counterstaining of ultrathin sections before TEM examination influences the appearance of ultrastructural details in the sections. These protocols revealed unequivocally the visible differences between Gram-positive

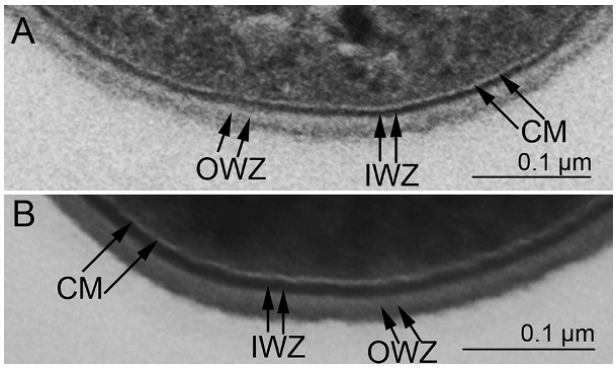

FIGURE 12 Comparison of embedding in different embedding resins. (A) *Staphylococcus aureus* embedded in low-viscosity (LV) resin. (B) *S. aureus* embedded in LRWhite resin. *S. aureus* was fixed, stained with osmium and uranyl acetate during dehydration with ethanol, and embedded in the epoxy LV resin, a replacement for the widely used Spurr resin, and the aromatic acrylic resin LRWhite. Both protocols show similar features, namely, a clearly defined cyoplasmic membrane (CM) and a peptidoglycan with two distinct zones, the dark inner wall zone (IWZ) and the outer wall zone (OWZ), which is more translucent in appearance. LRWhite resin preserves the OWZ much better compared to LV resin. In addition, the cytoplasm of both identically treated bacterial cells looks quite different. LRWhite has proven to be a reliable resin for studying bacterial ultrastructures.

Downloaded From Vet-eBooks.com

and Gram-negative bacterial cell walls. In most of the ultrathin sections, the Gram-positive cell wall appears as an amorphous structure and, depending on the resin and applied embedding protocol, some structural details can be detected, such as the periplasmic space in Gram-positive cell walls (101, 102). It should be clearly stated here that these embedding protocols are prone to inducing artifacts in the samples and therefore influence the interpretation of the observed ultrastructural details (103). Nevertheless, these methods served as a basis for most of the descriptions of bacterial ultrastructure, and they are widely available in nearly all life science electron microscopy units.

Cryo-Methods

Conventional embedding approaches lack the accuracy required to investigate tiny ultrastructural details because of the potential adverse effects of chemical fixatives, the introduction of heavy metals, and dehydration during preparation. The development of cryo-methods began in the early 1980s, when vitrification of water in biological samples for electron microscopic studies was applied for the first time by Mayer and Brüggeller (104) and Dubochet et al. (105–107). Earlier, freeze-fracturing was introduced in the 1960s (108).

Freeze-fracturing and freeze-etching

One of the earliest cryo-methods applied was freeze-fracturing and freeze-etching. Samples are frozen in nitrogen slush, and thereby, water in the samples is brought into its vitrified state. Then the samples are fractured, sometimes etched, and subsequently coated with metal or carbon or both. From this sample a replica is produced which exhibits the surface topography. The depth of the topographical structures depends on the etching time (109, 110). Usually, during freeze-fracturing, the fracture line is in the hydrophobic region of a membrane, i.e., in the bacterial cytoplasmic membrane, thus exposing transmembrane or membrane-bound proteins. Only rarely does a fracture line run across the cell wall or inside a cell wall. Areas which are exposed give a more or less featureless matrix or, such as in cross-fractures, show a polymeric network which cannot be further resolved. These findings did not succeed in producing considerable new understandings of the Gram-positive cell wall (111).

High-pressure freezing and freeze-substitution

The development of freeze-substitution of quickly frozen samples, which was paralleled by the invention of low-temperature embedding of resins such as the Lowicryl series of methacrylate resins, began in the 1980s (14, 16). Bacteria are snap-frozen in liquid propane or ethane and then rapidly transferred into a substitution medium containing osmium and/or uranyl acetate in acetone. Remarkably, it was demonstrated that a certain water content in acetone (up to 4%) resulted in much better visibility of membranes (112). Samples are then kept for 2 days at –80°C, warmed up to –50°C and then –20°C and left for 1 day at each step. The following embedding can be performed with low-temperature resins, such as Lowicryl resins, or samples are brought to ambient temperature and embedded with conventional resins (81, 103, 113). During substitution, bacteria are stained and dehydrated, resulting in visibly better preservation of ultrastructural details. Most freeze-substituted bacteria in ultrathin sections are recognizable by the fact that no distinct DNA region can be observed, whereas in conventional embedding, DNA mostly aggregates and forms the typical lucent DNA region in the middle of the bacterial cell (see Fig. 13).

Currently, hundreds of substitution protocols exist which are customized to fulfill the needs of the examined biological samples and to address the study purpose, e.g., for ultrastructural studies or immune cytochemical localization studies. Freeze-substitution was pushed forward even more by the high-pressure freezing of bacteria. This method was developed in the 1960s (108). At ambient temperatures adequate freezing of bacteria is reached with cooling rates of more than 10,000 Kelvin/second to vitrify the water content in the sample. High pressure is a potent physical cryo-protectant because it lowers the freezing point of water considerably, and thicker samples can be vitrified. The currently available equipment freezes samples at about 200,000 kPa. At this pressure, samples of up to 200 µm can be frozen without formation of ice crystals (108, 114–116). The combination of these two methods is now considered to be the best approach for ultrastructural studies of bacteria when no access to CET is possible. One result of such studies is the above-mentioned appearance of a periplasmic space in Gram-positive bacteria (79, 117, 118). Nevertheless, CET observations have raised questions about these assumptions.

Cryo-sections of hydrated vitrified bacteria and Cryo-FIB-SEM

Even though high-pressure freezing and freeze-substitution have been steps toward close-to-nature conditions, it is without doubt that ultrastructural details and the organization of macromolecules are still changing to a certain degree. This occurs because replacement of vitrified water and introduction of heavy metals during the substitution process for staining bacterial components—even when performed in cold conditions—are expected to change native structures. For real close-to-nature observations, the water content of samples has to be vitrified to guarantee a fully hydrated status, and samples should be observed in the vitrified frozen status below –80°C. Hydrated cryo-ultrathin sections fulfill these two criteria (see Fig. 14).

The expression CEMOVIS (cryo-electron microscopy of vitreous sections) was introduced for this cryo-method (119). The technique of cutting cryo-ultrathin sections at –110°C or below is very demanding and has been realized only by some laboratories for studying bacterial cell walls (117, 118, 120). As with nearly every method, cryo-ultrathin sectioning of bacteria has its drawbacks, such as knife marks and compressions. For example, forces working during the cutting process, i.e., compression in the cutting direction, can be harmful to the preservation of cell walls or lipid membranes (121–123). A method which overcomes the thinning of bacteria without introducing any compression on the sample is highly desirable. Dual-beam imaging with an SEM (FIB-SEM) with an attached ion gun (focused gallium gun) was introduced in the 1990s, particularly for material sciences. The ion gun is used to mill away material from a sample, which then is imaged by the electron beam with suitable detectors, often called back-scattered electron detectors. This is followed by the next cutting step, imaging step, and so on. This process is also known as serial block face sectioning. Thus, a series of sections is generated which can be aligned and further processed with suitable software to reveal 3D structures of the imaged regions. The use of ion beam milling was later extended to plastic-embedded biological samples such as bacteria, eukaryotic cells, and tissues (124, 125). As early as 2006 a cryo-version of FIB-SEM was invented and was tested for cutting frozen vitrified bacteria with ion milling (126, 127). Soon after, cryo-FIB-SEM was introduced to the life sciences and is now optimized for 2D and 3D imaging. Studies highlighted the fact that ion beam milling is an

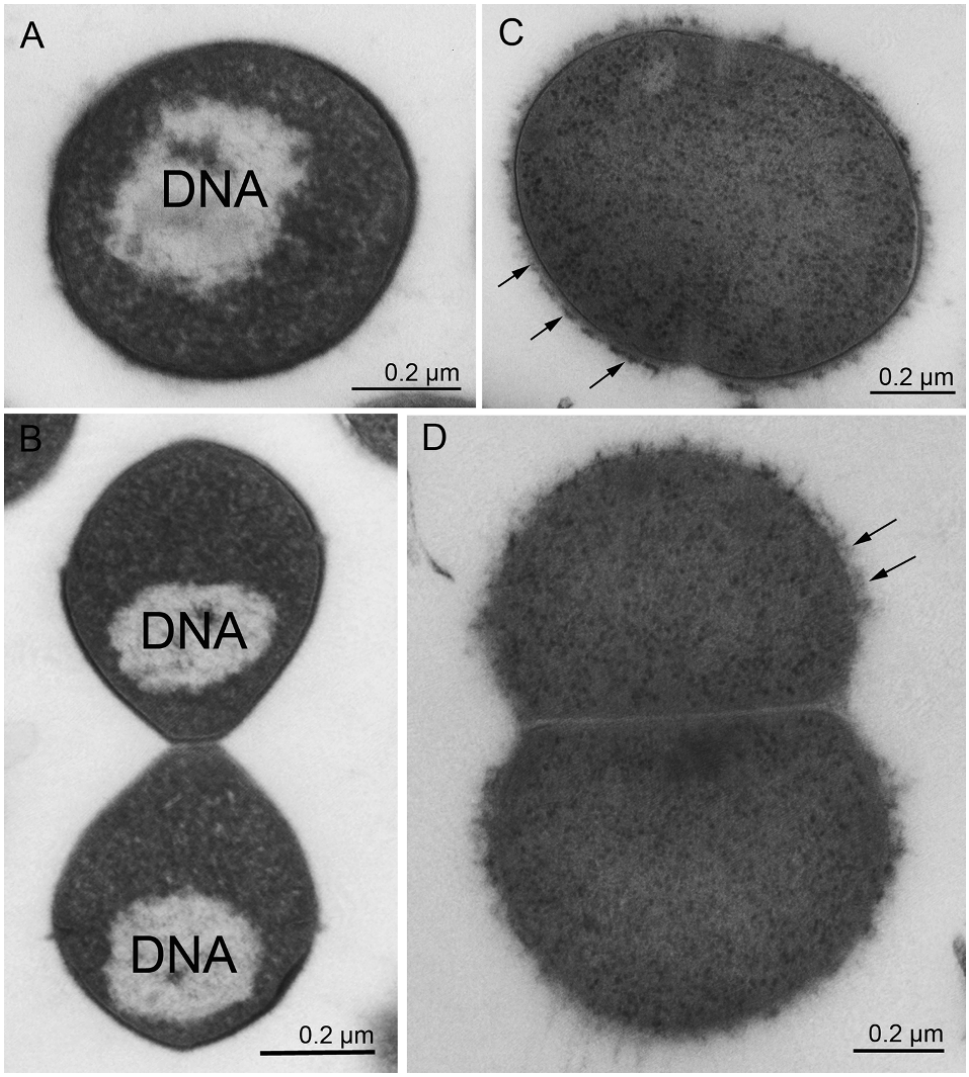

FIGURE 13 Comparison of conventional embedded and high-pressure frozen and freeze-substituted group G streptococci. (A and B) Cross-section and longitudinal section of dividing conventional embedded bacteria. Note the prominent translucent DNA region and the absence of any material attached to the outside of the bacterial cell wall. (C and D) Cross-section and longitudinal section of high-pressure frozen and freeze-substituted bacteria. No translucent DNA region is detectable, and the bacterial cytoplasm appears as a uniform structure throughout. Some material attached on the outer side of the bacterial cell wall is also preserved.

artifact-free method without any compression to cut vitreous frozen fully hydrated biological samples (128, 129). Today, the technique is so advanced that lamellae of a thickness of around 20 to 30 nm can be cut out of the vitrified bacteria, transferred to a cryo-TEM, and imaged under vitrified conditions. This modern invention allows the performance of CET on such lamellae and 3D analysis of the cut-out lamellae. For this, the next modern electron microscopic imaging technique, namely CET, is applied.

Cryo-electron tomography

CET, also called electron cyrotomography, reveals structures within a bacterial cell in essentially close-to-nature conditions. 3D reconstruction with a TEM can be achieved with a tomographic approach. For this, the sample is tilted usually between –70° to +70° around an axis. Every 1- or 2-degree tilting step is recorded to collect a 3D data set. The data set is aligned and the tomogram, a density map, is calculated. Since a 3D view is available, one can scan through every slice in the tomogram and can view structures in that specific slice. The basis for CET has been known since the early 1960s, but technical progress for cryo-TEMs had to be invented, such as automatization of electron microscopes, electron energy filtering, introduction of highly sensitive slow charged-couple-device cameras for recording images, 300-kV cryo-TEMs, imaging plates, and phase-plates for recording very low signals (130–135). One of the major drawbacks is the "bad" signal-to-noise ratio in CET imaging; thus, again, missing contrast in the images is a problem which had to be circumvented.

CET is perfectly suitable for bacteria that are not thicker than about 300 to 400 nm and for studying bacterial ultrastructures under close-to-nature conditions. If thicker bacteria need to be imaged, cutting lamellae from the sample

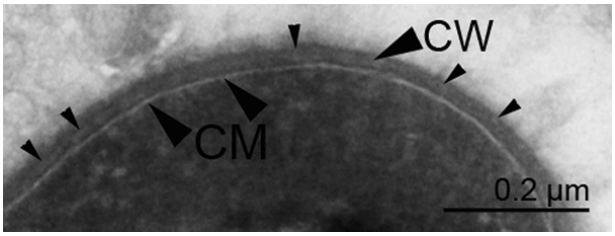

FIGURE 14 Cryo-electron microscopy of a vitreous ultrathin section (CEMOVIS) of *Streptococcus pyogenes*. Note that the very well-preserved cytoplasmic membrane (CM) and some structural details can be detected in the peptidoglycan layers of the cell wall (CW, arrow heads) when compared to the dark appearance of cell walls in conventional embedded bacteria (compare to Fig. 11).

by cryo-FIB-SEM is the most promising approach. Since the image in CET is generated solely by the density of the biological material by itself, most imaging is performed at reasonable underfocused settings to obtain contrast in the images. Therefore, the peptidoglycan layer is in most cases seen as a solid structure without any more details. For example, the membrane bilayer is not represented as conventional embedding images have shown. Nevertheless, by changing and adjusting imaging conditions, the outer membrane and cytoplasmic membrane of *E. coli* were clearly visible in reconstructions, and new insights were gained into the architecture of mycobacterial cell walls (20, 83).

OUTLOOK

The advent of the new cryo-approaches described in this article should allow researchers to examine Gram-positive cell walls under close-to-nature conditions and will certainly help us to achieve a better understanding of the micromorphology of the peptidoglycan together with its attached components. In particular, the discussion of a periplasmic space in Gram-positive bacteria comparable to the one in Gram-negative bacteria should be resolved by cryo-methods. It is expected that new and unanticipated structures, which have not been seen before, will be made visible. This should occur despite the fact that most cryo-studies performed to date used model Gram-positive bacteria laboratory strains of *S. aureus*, *S. pneumoniae*, and *B. subtilis*. Once imaging of newly isolated Gram-positive bacteria from nature is performed, it should reveal new scenarios of the Gram-positive cell wall. This occurred very recently when Dobro et al. (136) conducted studies of uncharacterized Gram-negative bacterial structures. These structures will certainly open up a new avenue for research. The downside of the implementation and further development of these cryo-techniques is that the equipment required for these studies is very expensive and therefore such electron microscopic platforms might be available in only a few institutions. In addition, the new technology requires experienced personnel, special software, and a certain computing environment. Plus, researchers have to be convinced that studying the Gram-positive bacterial cell wall is a fascinating research goal, and more cryo-approaches are needed to decipher the secrets of the peptidoglycan layers. Nowadays, electron microscopy and fluorescence light microscopy are joining forces in a correlative light and electron microscopy approach in which fluorescent-labeled structures can be made visible and then studies with CET at high resolution under vitrified conditions. Therefore, correlative light and electron microscopy opens up another new field of imaging in which fluorescence-labeled structures of interest, even mobile structures in the bacterial cell, can be followed by live imaging, be snap-frozen at a certain time point, and then be imaged at high resolution by CET in close-to nature conditions.

Surface Proteins on Gram-Positive Bacteria

VINCENT A. FISCHETTI

2

In the same way arms, legs, hair, and fur are used in higher species for their survival in the environment, bacteria use surface appendages for similar purposes. Surface molecules in bacteria range from complex structures, such as flagella that propel the organism in aqueous environments, to less sophisticated polysaccharides and proteins. All of these molecules benefit the organism for survival in a hostile environment, such as the waters of a rushing stream, the blood of an infected animal, the surface of an object, or the surface of a mucosal epithelium. Although it was previously believed that bacteria were simple single-cell organisms with little complexity, it is now apparent that they are highly evolved, advanced particles that possess a wide array of surface molecules that manipulate the organism in its environment. For human pathogens, surface molecules have been finely tuned to allow adherence and colonization of host surfaces, invasion of cells, evasion of the host's immune response, and persistence in infected tissues.

In an effort to emphasize the complexity of bacterial surface molecules and their use in the everyday life of the bacterium, this article focuses on the surface proteins found on Gram-positive bacteria. For an extensive review of the subject, see references 1 and 2.

THE GRAM-POSITIVE CELL WALL

From electron microscopic analysis of the Gram-positive cell envelope and from a number of elegant chemical, structural and immunological analyses (also, see Chapter 1 of this volume), a picture of the Gram-positive cell wall has emerged (Fig. 1). The structure differs significantly from the Gram-negative cell wall in two ways: (i) the presence of a thicker and more cross-linked peptidoglycan and (ii) the lack of an outer membrane. Because of these differences, surface molecules on Gram-positive organisms vary from those on Gram-negative organisms, which requires specialized systems to transport and anchor molecules through the outer membrane (3, 4). In general, surface proteins in Gram-positive bacteria can be separated into three categories: (i) those that anchor at their C-terminal ends (through an LPxTG motif), (ii) those that bind by way of charge or hydrophobic interactions, and (iii) those that bind via their N-terminal region (lipoproteins) (Fig. 1).

C-TERMINAL-ANCHORED PROTEINS

Decades ago, relatively harsh treatments of extraction were used to remove surface proteins from Gram-positive bacteria, resulting in the isolation and characterization of molecular fragments rather than complete molecules. It was not until the early 1980s that the genes for surface proteins on Gram-positive bacteria were first published (protein A from *Staphylococcus aureus* [5] and M protein from *Streptococcus pyogenes* [6]). Although at first glance these molecules had little in common, it was soon realized that the C-terminal end of the protein A sequence contained a sequence error. Upon correction (5), it became apparent that this region of protein A exhibited very close sequence homologies with the M protein molecule. As other protein sequences from Gram-positive bacteria were published in the ensuing years, it was obvious that a common theme existed within the structure of these C-terminal-anchored molecules. Since then, hundreds of proteins from Gram-positive bacteria that anchor through their C-terminal region, based on the presence of an LPxTG motif (7), have been reported (see Table 1 for a short representative list). Because of the number of molecules reported and their varied functions, the M protein molecule will be used here as a model for surface proteins anchored via an LPxTG motif.

M Protein Structure

Of the C-terminal-anchored proteins, the M6 protein may be considered an archetypical molecule since it was the first Gram-positive surface protein to be completely sequenced (6). A unique characteristic of this molecule is the presence of regions with sequence repeats and a conserved anchor region. As shown in Fig. 2, the M6 protein is composed of four repeat blocks, each differing in size and sequence (6). The A-repeats are each composed of 14 amino acids in which the central blocks are identical and the end blocks diverge slightly from the central consensus repeats. The B-repeats, composed of 25 amino acids each, are arranged in the same way. The C-repeats, composed of 2.5 blocks of 42 amino acids each, are not as similar to each other as are the A- and B-repeats. There are also four short D-repeats that show some homology. These repeat segments make up the central helical rod region of the M molecule because of the high helical potential ascribed to the amino acids found within this segment, as determined by conformational analysis (8, 9).

A close examination of the sequence within the M molecule revealed a repeating seven-residue periodicity of nonpolar amino acids, a basic characteristic of α-helical coiled-coil proteins such as mammalian tropomyosin. In

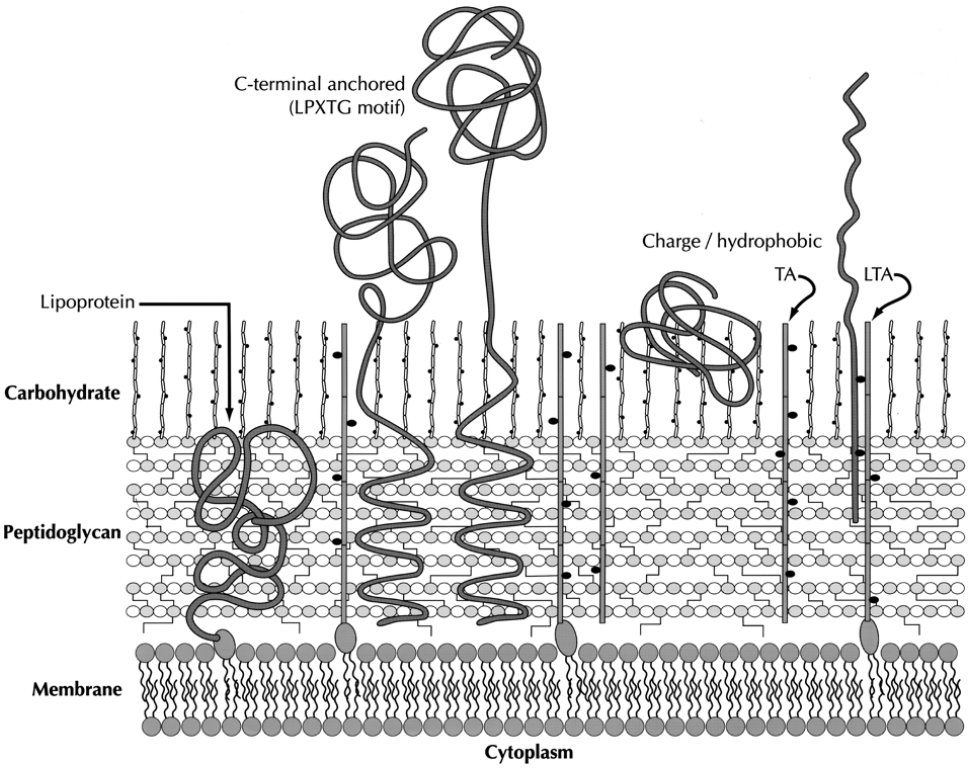

FIGURE 1 Major surface structures of the cell wall of Gram-positive bacteria. Linked to the surface of the peptidoglycan, many Gram-positive organisms have polysaccharide structures that in some cases are used for their immunological classification. Surface proteins are linked by three mechanisms. (i) Lipoproteins have a lipid linked through a cysteine at the N terminus. (ii) C-terminal-anchored proteins are attached and stabilized in the peptidoglycan through a C-terminal complex containing an LPxTG motif. (Most surface proteins are anchored this way.) (iii) Certain surface proteins are attached through hydrophobic and/or charge interactions to the cell surface. (Some proteins are bound ionically to the lipoteichoic acid.) The teichoic acids (TA) are a common feature of the Gram-positive cell wall. TA is usually composed of a repeating carbohydrate-phosphate polymer linked through a phosphodiester linkage to the peptidoglycan. Lipoteichoic acid (LTA) is composed of a similar polymer linked to the cytoplasmic membrane through a fatty acid.

general, α-helical coiled-coil proteins are constructed from a reiterating seven-residue amino acid pattern (a-b-c-d-e-f-g)*n* in which residues in positions a and d are hydrophobic and form the core residues in the coiled coil, and the intervening residues are primarily helix-promoting. The arrangement of amino acids of the M6 protein within the seven-residue pattern is shown in Fig. 3. The seven-residue periodicity from amino acids 12 through 362 strongly suggests that this region is in a coiled-coil conformation and forms the helical central rod region of the molecule. Discontinuities in the heptad pattern (seen especially in the B-repeat region), which have been found in the sequence of other M proteins and other coiled-coil molecules, probably account for the flexibility of the M molecules observed in electron micrographs (9). Based on these irregularities in the heptad pattern, the central rod region is divided into three subregions that correlate with the A-, B-, and C-repeat blocks (8).

Subsequent sequence data on a variety of M protein molecules revealed that while all M proteins retain a common structural organization, they vary in the N-terminal and central domains while keeping the conserved C-terminal region (10–25) (Fig. 4). One of the striking features observed in these various M molecules is their size variation (see below), which is affected by the presence, number, and size of the sequence repeat regions (particularly the A and B repeats) and the length of the N-terminal nonhelical region. Based on the nine M proteins in Fig. 4, the A repeats are more the exception than the rule. The biological meaning of this is unclear, since all the M types depicted are found on clinical isolates of *S. pyogenes*. Though they may vary somewhat in number, the C-repeats are present in all M proteins and are surface exposed. This conserved sequence among different M molecules has vaccine implications (refer to Chapter 10 in this volume). For a different perspective on the M molecule please refer to reference 26.

Electron and Fluorescence Microscopy

Although early electron micrographs of the surface of Gram-positive bacteria revealed certain structures, it was not known whether they were proteinaceous or polysaccharides. It was not until Swanson et al. (27) published the first electron micrographs of the M protein on the surface of group A streptococci that it was realized that the molecule was an elongated structure. Although other proteins were also reported to be on the streptococcal surface, they were not apparent in these electron micrographs. Thus, direct visualization of surface molecules is limited to molecules with

[c]Surface protein: proteins that have been identified to have a C-terminal anchor motif, but function is unknown.

certain physicochemical characteristics. In the case of the M protein, it is the α-helical coiled-coil structure that allowed its visualization by electron microscopy (8).

In experiments designed to answer questions about the synthesis and placement of M protein on the cell wall, Swanson et al. (27) found that after trypsinization to remove existing M protein on living streptococci, newly synthesized M protein was first seen by electron microscopy on the cell in the position of the newly forming septum. In similar experiments designed after the classical experiments of Cole and Hahn (28) using fluorescein-labeled anti-M antibodies, trypsinized streptococci placed in fresh medium for 10 min revealed M protein first at the newly forming septum (Fig. 5). On organisms examined after 40 min of incubation or longer, M protein was not observed in the position of the old wall, suggesting that the M molecule is produced only where the new cell wall is synthesized. This confirmed the observation of Swanson et al. (27).

In their pioneering work in 2006, Carlsson et al. showed that the sequence of the signal peptide which contains a YSIRK-G/S motif (SP_{+YSIRK}), found in M protein, directs the molecule to the division septum, while proteins lacking this motif (SP_{-YSIRK}), such as that found in streptococcal protein F (also called SfbI), are directed to the poles (29). Modern microscopic techniques were used to better visualize this sorting phenomenon on the bacterial surface (30). The data show that M protein rapidly appears and accumulates at the septum during bacterial growth, while SfbI slowly gathers at the poles, where the peptidoglycan is older and more heavily cross-linked (Fig. 6). Data showing decreased M protein (but not SfbI) expression using methicillin or the division regulator DivIVA strongly suggest a close connection between the regulation of cell division and protein anchoring.

C-Terminal Anchor Region

An examination of the C-terminal end of surface molecules that anchor at that end revealed, without exception, that all have a similar arrangement of amino acids. Up to seven charged amino acids are found at the C terminus which are composed of a mixture of both negatively and positively charged residues. Immediately N-terminal to this short charged region is a segment of 15 to 22 predominantly hydrophobic amino acids sufficient to span the cytoplasmic membrane of the bacterium, placing the charged end in the cytoplasm (Fig. 2). In all these proteins, the sequences found in the hydrophobic and charged regions are not necessarily the same, but the chemical characteristics of the amino acids used to compose them are conserved. Beginning about eight amino acids N-terminal from the hydrophobic domain is a heptapeptide with the consensus sequence LPxTG, which is extraordinarily conserved among the C-terminal-anchored proteins examined (31). Although several amino acid substitutions are seen in position 3 of the heptapeptide (predominantly A, Q, E, T, N, D, K, and L), positions 1, 2, 4, and 5 are nearly completely conserved (~100% in the L and P positions and >85% in the T and G positions). This conservation is also maintained at the DNA level. The preservation of this heptapeptide and the high homology within the hydrophobic and charged regions suggest that the

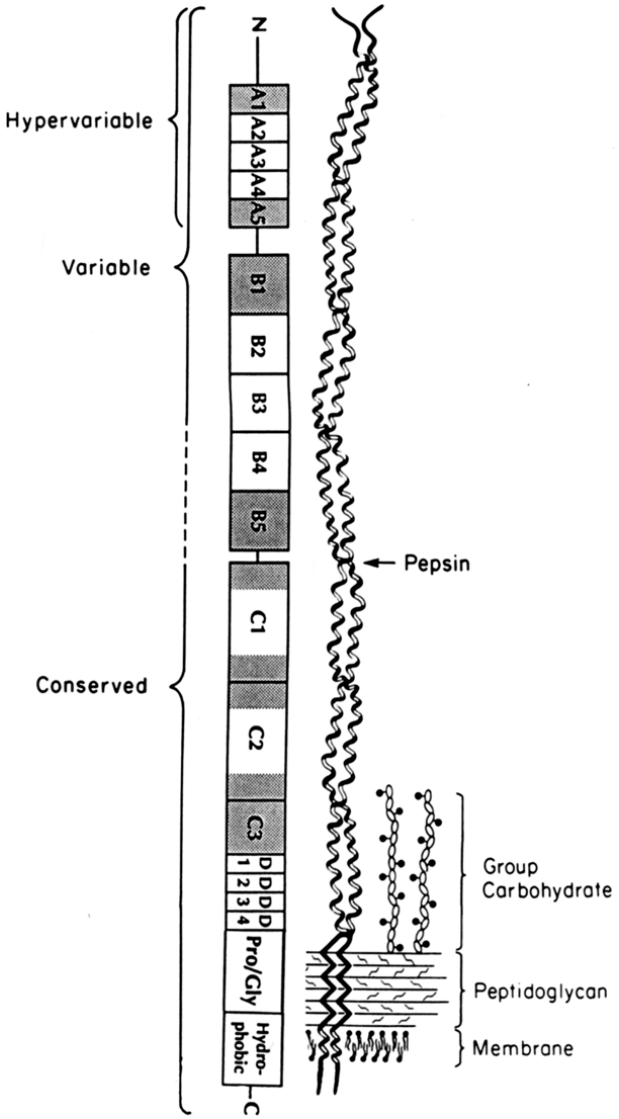

FIGURE 2 Characteristics of the complete M6 protein sequence. Blocks A, B, C, and D designate the location of the sequence repeat blocks. Block C3 is half the size of blocks C1 and C2. Shadowed blocks are those in which the sequence diverges from the central consensus sequence. Pro/Gly denotes the proline- and glycine-rich region likely located in the peptidoglycan. The membrane anchor is a 19-hydrophobic-amino-acid region adjacent to a 6-amino-acid charged tail. Pepsin identifies the position of the pepsin-sensitive site after amino acid 228. The C-terminal end is located within the cell wall and membrane.

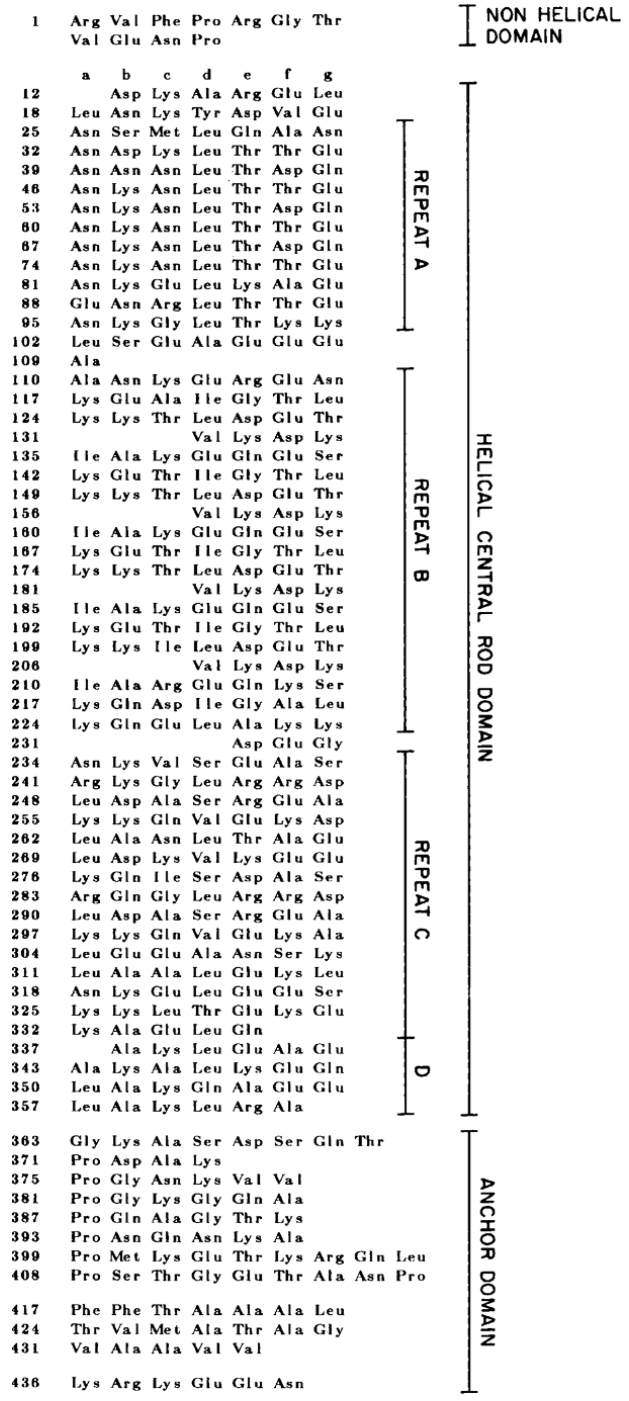

FIGURE 3 Complete M6 protein sequence arranged to highlight the seven-residue periodicity found in the helical central rod region. Region assignments are based on sequence and conformational analyses. Arrangement of the sequence is based on the position of amino acids in a seven-residue periodicity designated by letters a through g beginning at residue 12 and continuing through residue 362, with interruptions at residues 109, 131, 156, 181, 206, 231, and 337. Alignment from residues 363 to 416 is used essentially to highlight the regularity of the position of prolines in the sequence. No periodicity is found from residue 417 to the end. Three major regions are indicated (nonhelical, helical, and anchor). The pepsin-sensitive site is between Ala-228 and Lys-229.

method of anchoring these molecules within the bacterial cell is also highly conserved, and the LPxTG motif may serve as an enzyme recognition sequence.

Thus, C-terminal-anchored surface proteins in Gram-positive bacteria (which could number >25 different molecules in a single organism) that contain an SP_{+YSIRK} leader sequence, are synthesized and exported at the septum, where new cell wall is also being produced and translocated to the surface (8, 28). Therefore, to coordinate the export and anchoring of all these proteins, the C-terminal hydrophobic domain and charged tail function as a temporary stop,

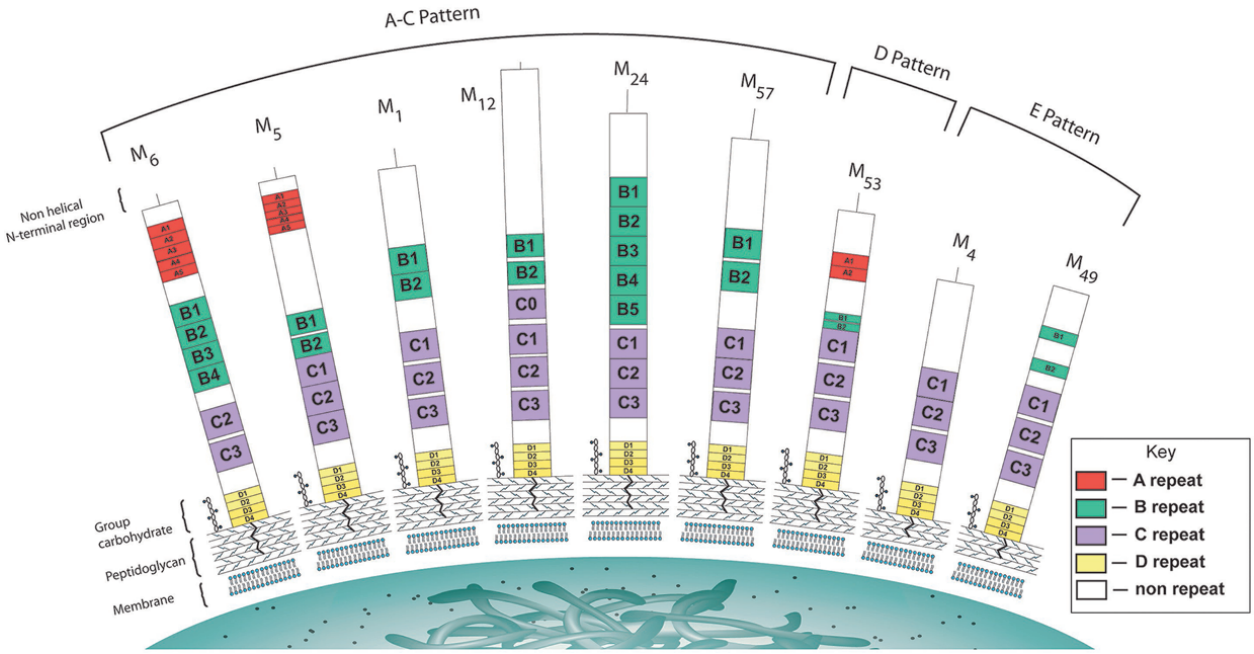

FIGURE 4 Schematic representation of the organization of nine well-described M proteins showing the presence and location of the sequence repeat regions and pattern arrangement. Figure reused from reference 26 with permission.

precisely positioning the LPxTG motif at the outer surface of the cytoplasmic membrane (Fig. 7). This motif is then cleaved by the transpeptidase sortase, ultimately resulting in the attachment of the surface-exposed segment of the protein to the peptidoglycan (32). For an extensive review see reference 33. This idea is supported by studies indicating that the C-terminal hydrophobic domain and charged tail are missing from the streptococcal M protein extracted from the streptococcal cell wall (32, 34). Studies indicate that the substrate in the peptidoglycan to which the protein is linked is the cross bridge (e.g., glycine in *S. aureus*, alanine in *S. pyogenes*) of the pentapeptide (35).

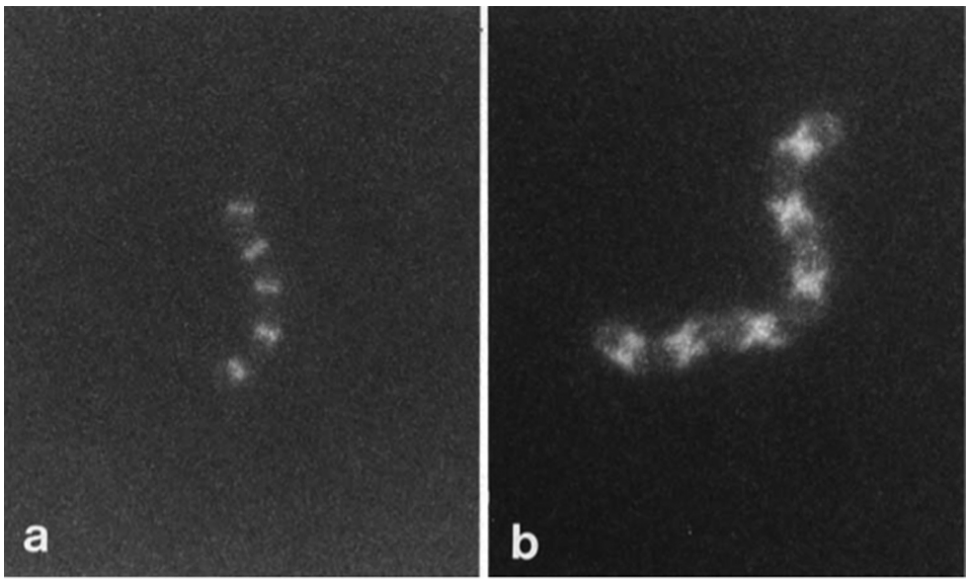

FIGURE 5 Fluorescein-labeled anti-M6 antibody analysis of the appearance of M6 protein on streptococcal cell walls. M6 streptococci were treated with trypsin to remove surface M protein. Cells, reincubated at 37°C, were removed at intervals, fixed, and stained with fluorescein-labeled anti-M6 antibody. (a) After 10 min of incubation the M protein is located within a thin band at the position of the newly forming septum. Magnification, ×5,000. (b) Location of the M protein after 40 min of incubation. Note that no fluorescein label is seen in the position of the old wall. Magnification, ×6,000.

Downloaded From Vet-eBooks.com

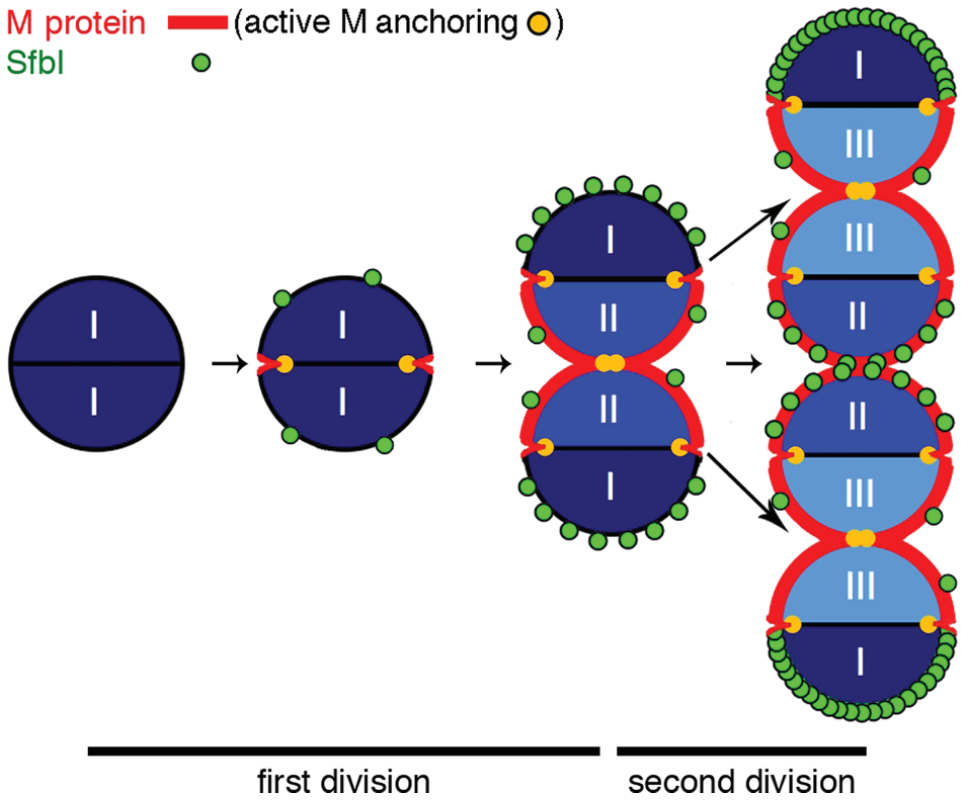

FIGURE 6 A model representation of the anchoring of M protein and SfbI. The regeneration of surface proteins during two division cycles is presented. M protein (red) is anchored exclusively to newly synthesized peptidoglycan at the septum (sites of active anchoring are labeled yellow). Anchoring of M protein at daughter septa begins before the mother septum is completely closed, resulting in simultaneous anchoring at both locations. Following two generations, M protein is anchored to all newly synthesized, but not pre-existing, peptidoglycan. SfbI (green) is anchored over time in patches to peripheral peptidoglycan, with some preference to the poles. Following two generations, the oldest poles (I) display the most intense SfbI labeling, while one-generation-old poles show less labeling (II), and newly formed poles (III) show little SfbI labeling with permission reference 30.

Enzymes That Cleave the LPxTG Motif

Sortase

Sortase is a membrane-bound transpeptidase found in Gram-positive bacteria (2, 36–42), with the capacity to both cleave the LPxTG motif and anchor the newly formed C terminus to the nascent cross bridge in the peptidoglycan (39, 43) (for a detailed review see reference 44). Mutants in the sortase gene (*SrtA*) have been shown to be defective in their ability to surface display proteins (36–38, 45). Because surface proteins are essential for the infectivity and survival of Gram-positive bacteria in the host, SrtA mutants have been shown to be attenuated in colonization experiments (46) and animal infection models (45). A genome-wide analysis of sortases revealed that sortase-like proteins were present in almost all Gram-positive bacterial species and that in every Gram-positive bacterium in which one sortase-like protein was identified, at least one other was also found, and in most cases several others (36, 47). Further analysis indicates that genes encoding sortase-like proteins are usually found to be clustered along with genes encoding their probable substrates. Because of their importance in surface protein display, sortase molecules could be a target for antibiotic development. However, unlike current antibiotics, which affect bacterial viability, antibiotics that block the action of sortases would compromise the pathogenicity of a pathogen, yielding a new class of anti-infectives.

LPxTGase

Recently, a new enzyme was identified from *S. pyogenes* that differs significantly from sortase but also cleaves within the LPxTG motif of surface proteins (48, 49). This unique enzyme, termed LPxTGase, has no aromatic amino acids, is rich in alanine (particularly D-Ala [50]), is heavily glycosylated, and is 30% composed of uncommon amino acids, suggesting that it may be constructed independently of ribosomes. The enzyme, which is also found in *S. aureus*, is also important in cell surface protein display, as well as in cell wall assembly. Because the cleavage activity of LPxTGase is at least two orders of magnitude greater than that of sortase (43), LPxTGase may play an essential role in the rapid display of thousands of surface protein molecules during a short (20- to 30-min) bacterial division cycle.

Wall-Associated Region

Immediately N-terminal from the LPxTG motif is the wall-associated region, which spans about 50 to 125 amino acid

Downloaded From Vet-eBooks.com

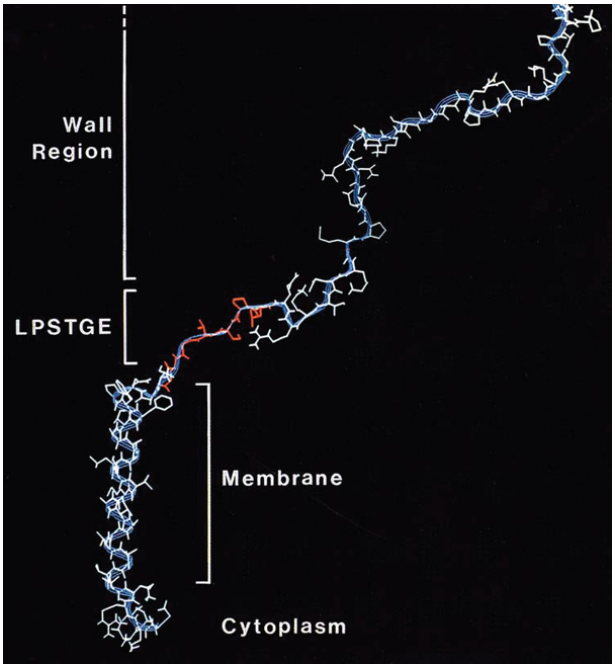

FIGURE 7 Computer-generated model of the C-terminal end of the M protein sequence (residues 371 to 441). A comparable region is found in all C-terminal-anchored surface proteins from Gram-positive bacteria (see Table 1). The predicted location of this segment of the molecule is shown in the cytoplasm, membrane, and peptidoglycan. The space between the membrane and peptidoglycan (wall region) may be considered the "periplasm" of the Gram-positive bacterium. The figure was generated on a Steller computer using the Quanta 2.1A program for energy minimization.

residues and is found in nearly all the proteins analyzed. Although this region does not exhibit a high degree of sequence identity among the known surface proteins, it is characterized by a high percentage of proline/glycine and threonine/serine residues. For some proteins (such as the M protein) the concentration of proline/glycine is significantly higher than that of threonine/serine, while in others this relationship is either reversed or nearly equal. Because of its proximity to the hydrophobic domain (which is located in the cell membrane), this region would be positioned within the peptidoglycan layer of the cell wall (34) (Fig. 1). The reason for the presence of these particular amino acids at this location is unknown. One hypothesis suggests that the prolines and glycines, with their ability to initiate turns and loops within proteins, allow the peptidoglycan to become more easily cross-linked around these folds, thus stabilizing the molecule within the cell wall (34). The function of the threonines and serines within this region is not immediately apparent, despite the fact that these amino acids are substrates for glycosylation.

Surface-Exposed Region

As the C-terminal region (buried within the cell wall/membrane) is characteristically conserved among the C-terminal-anchored surface proteins, the surface-exposed region is characteristically unique. Despite their differences, this region falls into three distinct groups: (i) those with several sequence repeat blocks, (ii) those with repeat blocks located close to and within the cell wall region, and (iii) those without any repeat sequences (Fig. 8). Streptococcal M protein and protein G may be considered molecules representative of those containing several sequence repeats. However, the most commonly found structures are those with repeats located close to the cell wall and an extended nonrepetitive region N-terminal to this segment.

Conformational analysis of 12 representative surface molecules by the algorithm of Garnier et al. (51) revealed that, in general, proteins containing repeat sequences were predominantly helical within the region containing repeat segments (Fig. 9). Conversely, regions and molecules without repeat blocks were predominantly composed of amino acids exhibiting high β-sheet, β-turn, and/or random coil potential. Thus, within most of these molecules, the presence of repeat segments usually predicts the location of a helical domain. Perhaps the pressure to maintain repeat blocks is to preserve the helix potential within specific regions of these molecules, the presence of which may determine an extended protein structure, as has been shown for the M protein (9).

Seven-Residue Periodicity

As shown above, most of the surface molecules containing repeat sequences were found to be α-helical in regions composed of repeats, while molecules without repeat blocks exhibited a high degree of β-sheet, β-turn, and random coil. However, little information is available to indicate that, except for M6 protein, any of these surface proteins are also in a coiled-coil conformation. To attempt to answer this question, an algorithm (Matcher) was developed (31) and used to determine if a seven-residue periodicity also exists in molecules containing α-helical regions. When this algorithm was applied to representative sequences, extended regions of seven-residue periodicity were found in Arp4, FcRA, protein H, PAc, and spaP proteins (Fig. 9). This strongly suggested that these molecules may attain a coiled-coil conformation within these α-helical segments. It is apparent that only proteins that contain sequence repeats and exhibit high α-helical potential show the presence of a seven-residue pattern of hydrophobic amino acids. On the other hand, even though protein G exhibits extensive helix potential, only a limited portion was found to contain the heptad pattern. Interestingly, however, the PAc protein from *Streptococcus mutans* has only one small segment between residues 120 and 520 that displays repeat blocks, and this segment exhibits strong helix potential. This is precisely the region that was also found to contain a regular seven-residue heptad

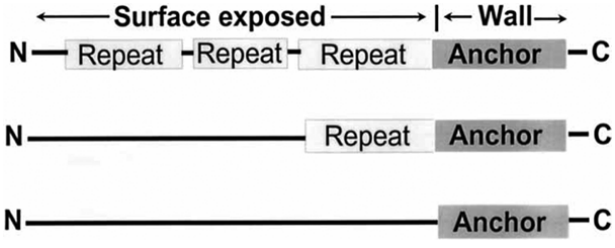

FIGURE 8 Characteristics of C-terminal-anchored surface proteins. These proteins fall into three basic categories: those with multiple repeats, single repeats, or no repeats. Proteins with a single repeat located close to the cell wall are the most common. The anchor is the region of the molecule located within the cell wall carbohydrate and peptidoglycan.

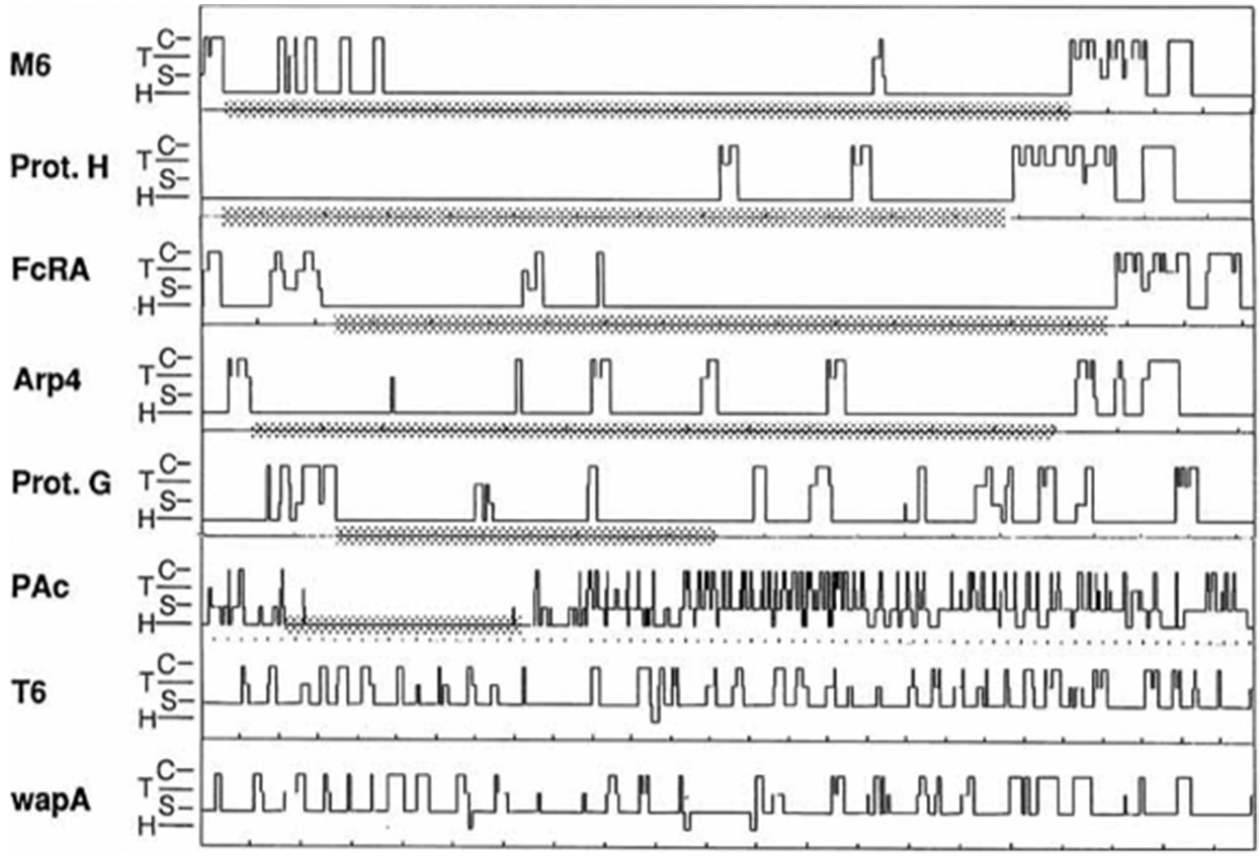

FIGURE 9 Conformational characteristics of the surface molecules from Gram-positive bacteria. The sequences were analyzed by the Garnier-Robson algorithm supplied with the EuGene protein analysis package. The location within these molecules of regions exhibiting random coil (C), β-turn (T), β-sheet (S), and α-helix (H) are designated. Sequences were derived from the references listed in Table 1. Shaded areas are those containing a seven-residue periodicity based on the Matcher program. Proteins T6 and wapA exhibit no extended helical regions or seven-residue periodicity.

pattern. Taken together, these data strongly suggest that the coiled-coil conformation may also be a common characteristic of surface proteins found on Gram-positive organisms.

Size Variation

To fully appreciate the diversity among certain surface proteins on Gram-positive organisms, it is important to understand a property of the M protein molecule, namely, size variation. Using an M protein-specific but broadly cross-reactive monoclonal antibody as a probe, the size of the M protein, extracted by solubilizing the cell wall with phage lysin from a number of streptococcal strains, was examined by Western blotting. M protein derived from 20 different serotypes exhibited variations in size ranging from 41 to 80 kDa in molecular mass, depending on the strain (8). Subsequent sequencing of the M protein genes (*emm*) from other serotypes revealed that though the overall arrangement of the M molecules was the same, differences in the overall size of the repeats and the presence or absence of certain repeat blocks resulted in the observed size variation (see Fig. 4). This variation may be explained by the long reiterated DNA sequence repeats likely to serve as substrates for recombinational events or replicative slippage, generating deletions and duplications within the *emm* gene leading to different sizes of M proteins (52). Based on these specific characteristics, M proteins were grouped into four distinct constructions, called *emm*-patterns A, B, C, and D (53). Interestingly, it was discovered that *emm*-patterns A, B, and C were predominantly associated with pharyngeal infections, and D-pattern strains were associated with skin infections (26, 53).

Sequence analysis of the *emm6* gene from small streptococcal outbreaks (i.e., classroom or school) revealed that they are clonally related and not the result of separate acquisitions of unrelated M6 strains during the course of the infection (data not shown). The observation that size variants occur among separate clinical isolates within the same outbreak suggests that the size mutant constituted the major organism in the streptococcal population at the time of isolation and that a given size mutant has a selective advantage under those clinical conditions (54). Perhaps serological pressure as a result of a local immune response forces the appearance of the size variant.

Although sequence repeats have been reported in several surface proteins on Gram-positive bacteria, size variation has not been reported or tested for all these proteins. However, in addition to M protein, size variation has been observed in PspA from *Streptococcus pneumoniae* (55), HagA from *Porphyromonas gingivalis* (56), protein A from *S. aureus* (44), and Sfb1 from *S. pyogenes* (57).

Multifunctional Proteins

Of the >200 proteins identified on the Gram-positive bacterial surface, the great majority contain domains that bind

Downloaded From Vet-eBooks.com

molecules found in body secretions (Table 1), including immunoglobulins (IgA and IgG), albumin, fibronectin, and fibrinogen. Other surface proteins have been identified because of the presence of enzymatic domains. Based on current data, it is clear that the majority of these proteins are multifunctional, and the identified function is limited to only one segment of the molecule. In most cases, the function of the other domains have not been identified. For example, as described above, it appears that many surface proteins contain a repeat region located close to the cell wall and a nonrepetitive segment N-terminal to it (Fig. 8). In most cases the binding domain (e.g., fibronectin, immunoglobulin) has been localized to the repeat segment, while the N-terminal region exhibits no known function. In the case of streptococcal opacity factor, both domains have been defined (58); the repeat region binds fibronectin, while the N-terminal domain has the catalytic function that cleaves ApoA1 of high-density lipoprotein, resulting in the opacity of serum. In the case of highly repetitive proteins such as M protein and protein G, each repeat domain has a specific function. In M protein, the A-repeats bind albumin, mucin, and C4 binding protein, while the B-repeats bind fibrinogen (59–63), and the C-repeats as well as the hypervariable region bind factor H of complement (64, 65). The C repeats also bind keratinocytes (66). In protein G, one repeat domain binds IgG and the second binds albumin. The multifunctional characteristic of surface proteins is not limited to molecules anchored via their C-terminal region. Proteins bound through hydrophobic/charge interactions and N-terminally anchored proteins also exhibit this characteristic (see below).

Thus, in general, surface proteins on most Gram-positive organisms are multifunctional molecules with at least two and in some cases three or more independent functions. Given that up to 25 or more of these surface proteins may ultimately be found on a single cell surface, the potential complexity associated with the bacterial surface becomes enormous.

PROTEINS ANCHORED BY CHARGE AND/OR HYDROPHOBIC INTERACTIONS

Although the great majority of proteins identified on the surface of Gram-positive bacteria anchor through their C termini, a few have been identified to bind through less-defined charge and/or hydrophobic interactions (Table 1).

Surface Glycolytic Enzymes

Through an analysis of the individual proteins identified in a cell wall extract of group A streptococci, it was discovered that some proteins were enzymes normally found in the glycolytic pathway located in the cytosol (67). In all, five enzymes have been identified (triosephosphate isomerase, glyceraldehyde-3-phosphate dehydrogenase [GAPDH], phosphoglycerate kinase, phosphoglycerate mutase, and α-enolase) that form a short contiguous segment of the glycolytic pathway. Interestingly, they are a complex of enzymes involved in the production of ATP as well as other functions (67–70). Thus, given the right substrate, streptococci have the capacity to produce ATP on the cell's surface, which further increases surface complexity. These glycolytic enzymes have been identified on the surface of nearly all streptococcal groups, and certain enzymes have been found on some other pathogens such as *Candida albicans*, trypanosomes, and schistosomes (Table 2). Support for the specific translocation of these enzymes to the cell surface instead of nonspecific release and cell surface attachment through cell lysis comes from the inability to identify cytoplasmic markers or other glycolytic enzymes in the growth medium or on the cell surface.

TABLE 2 Glycolytic enzymes found on the surface of microorganisms

Enyzme[a]	Bacteria	Fungus	Parasite
GAPDH	Streptococci *S. pneumoniae* *S. aureus* *Mycobacterium avium*	*Candida albicans*	Schistosome Trypanosome
PGK	Streptococci	*C. albicans*	Trypanosome
TPI	Streptococci		Trypanosome
PGM	Streptococci		
α-Enolase	Streptococci	*C. albicans*	

[a]GAPDH, glyceraldehyde-3-phosphate dehydrogenase; PGK, phosphoglycerate kinase; TPI, triosphosphate isomerase; PGM, phosphoglycerate mutase.

Two of the best-characterized surface glycolytic enzymes on streptococci are GAPDH and α-enolase (66, 68). Like other surface proteins on Gram-positive bacteria, GAPDH is a multifunctional protein with binding affinities for fibronectin and lysozyme as well as for cytoskeletal proteins such as actin and myosin. GAPDH has also been shown to have ADP-ribosylating activity in addition to its GAPDH activity. α-Enolase is also multifunctional in its ability to specifically bind plasmin(ogen) (71). It is the major plasmin-binding protein for streptococci. Evidence has shown that there is one gene for each of these enzymes, which are produced in the cytosol. A proportion (roughly 30% to 40%) is then translocated to the surface. Because these molecules are not synthesized with an N-terminal signal sequence, it is unclear how they are transported to the cell surface. Also, because they do not contain an apparent anchor motif, it is not known how they are attached to the cell surface. Because they can be removed with chaotropic agents, it is reasonable to assume that they are bound through charge and/or hydrophobic interactions (72). Pancholi and coworkers (97) produced a GAPDH mutant that could not be secreted to determine the importance of this molecule's export to the cell surface. Results revealed downregulation of most genes involved in *S. pyogenes* virulence and genes belonging to carbohydrate and amino acid metabolism and upregulation of those related to lipid metabolism. This mutant also affected virulence in a mouse model, indicating that the GAPDH export process is also involved in regulating *S. pyogenes* virulence.

Other Proteins

PspA, a surface protein and a virulence determinant for *S. pneumoniae* (73), has many of the structural characteristics found in M protein, such as sequence repeats and α-helical coiled-coil conformation, but it does not contain a C-terminal-anchor motif. It has been shown that after surface translocation, PspA anchoring requires charge interactions between the membrane-associated choline-containing lipoteichoic acid and the C-terminal repeat region of the PspA molecule (74) (Fig. 1).

N-TERMINAL-ANCHORED LIPOPROTEINS

Although lipoproteins (proteins containing a lipid covalently linked to an N-terminal cysteine) have been described

Downloaded From Vet-eBooks.com

in Gram-negative bacteria, they have also been identified in Gram-positive bacteria (for reviews, see references 75 and 76). While most are predicted to be lipoproteins by genetic analysis based on the consensus sequence for lipoproteins (77), they usually comprise molecules that are not surface-exposed but are located between the cytoplasmic membrane and the peptidoglycan, equivalent to the periplasm of Gram-negative bacteria. These proteins are involved in transport systems such as the *mal* and *ami* operons of *S. pneumoniae* and the Msm system of *S. mutans*. A few of these lipoproteins have been identified by their ability to act as adhesins, allowing these organisms to adhere to a variety of substrates. SsaB, a lipoprotein from *Streptococcus sanguis* that shares sequence homology with other streptococcal adhesins, has been implicated in interaction with a salivary receptor and the coaggregation with *Actinomyces naeslundii*. Many of these so-called adhesins have also been found to participate in various transport systems for the streptococcus. Lipoproteins have also been implicated in the spore cell cycle of *Bacillus subtilis* (78), conjugation in *Enterococcus faecalis* (79), and enzymatic functions (80, 81).

Thus, it is expected that these proteins are located predominantly on the surface of the cell membrane, with the majority of the molecule located within the peptidoglycan (Fig. 1). In some cases certain domains would be surface exposed, allowing them to function as adhesins or even surface enzymes. The *Mycobacterium tuberculosis* cell wall consists predominantly of mycolic acids, which is atypical, but its hydrophobicity could serve as an anchoring point for lipoproteins (82).

CONCLUSION

Based on current information, the surface of the Gram-positive bacterial cell wall is highly complex (Fig. 10) and could even be considered to be a distinct organelle because it is composed of proteins with specific binding functions and enzymatic activity combined with the ability to generate energy. Considering the fact that there could be more than 25 different proteins on a given bacterial cell surface (83), each with the potential of up to three functional domains, more than 75 independent activities could potentially be present on the cell surface, much more than had ever been previously anticipated.

Because extensive cytoplasmic domains are not present within the C-terminal region of surface proteins thus far identified in Gram-positive bacteria, it is unlikely that the binding of these molecules to specific ligands induces a cytoplasmic signal to activate a gene product. It is more likely that binding initiates a conformational signal on the bacterial cell surface to perform a specific function. For example, streptococci usually infect the pharynx, particularly the tonsils, through contact with contaminated saliva. Upon entering the oral cavity, the organism first encounters the mucus that coats the mucosal epithelium. Not being a motile organism, it must navigate the mucus to reach the tonsilar epithelial surface to initiate infection. Soluble components found in the mucus, such as IgA, IgG, albumin, fibronectin, etc., are able to interact with their respective binding proteins on the streptococcal surface. This binding may initiate a set of conformational events within these proteins to drive the organism through the mucus to the epithelial surface. Perhaps the energy required for this is derived from the surface glycolytic enzymes necessary to generate ATP, or perhaps an enzyme is activated to solubilize the mucin. This must all occur quickly, or the organism will be swept into the gut and eliminated by ciliary action. Thus, the molecules necessary to initiate infection are poised and ready on the bacterial surface. Therefore, before arriving on the mucosal epithelium, the organism may be considered an inert particle with a wide array of surface proteins capable of driving the organism to the mucosal surface. When stable contact is made with the epithelial surface, the organism has time to initiate the infection process. Attempting to sort out when and how these proteins function during the infection process will be the challenge for future studies. With this understanding, however, new strategies could be developed in controlling diseases caused by this class of bacteria.

SECTION 2

The Streptococcus

Section Editors: **Vincent A. Fischetti and Joseph J. Ferretti**

As a species, the streptococci are a diverse group, ranging from commensal organisms which occupy various niches of the body to pathogens having the capacity to infect a wide range of tissue sites. They are also diverse in their resistance to current antibiotic therapy, from the multi resistant enterococci to the barely resistant *S. pyogenes*. It is thus not surprising to find, when looking back over the past century of research on pathogenic organisms, that the streptococcus appears as one of the best studied of the gram-positive pathogens.

Although published results have steadily increased during the first three quarters of this period, the introduction of molecular techniques in the latter quarter of the century has seen a nearly logarithmic increase in new information. Despite this wealth of knowledge, however, numerous questions still remain unanswered. The first part of the century relied on the biology of the organism to answer questions of pathogenesis; in the latter part, however, molecular techniques overshadowed the biology in a

Downloaded From Vet-eBooks.com

mad scramble to understand the genetic complexity of these bacteria. Since the last edition, the complete genome sequences of eleven different species of streptococci have been completed. Analyses of multiple genome strains in the same species have shown that significant differences may occur, even in the same species. A common feature of all the streptococci is the presence of horizontal gene transfer and recombination systems, allowing for enhanced survival of an organism in its ecological niche, often by the emergence of new strains with increased virulence properties.

The chapters to follow are the best of a mixture of genetics, biology, and immunology designed to both ask and answer questions pertaining to the pathogenicity of the streptococci. The information gained from these studies and the ideas they stimulate for future experiments will allow the development of new tools not only to prevent infection by these organisms specifically but perhaps by gram-positive bacteria in general.

Intracellular Invasion by *Streptococcus pyogenes*: Invasins, Host Receptors, and Relevance to Human Disease

BEINAN WANG AND P. PATRICK CLEARY

3

Streptococcus pyogenes has evolved a variety of both surface-bound and extracellular factors that alter the inflammatory response and impair phagocytic clearance of the bacteria. The more than 150 genotypes use both similar and different strategies at the biochemical level to colonize their host and avoid protective defenses. These are reviewed elsewhere (5). Intracellular invasion is dependent on at least two classes of surface proteins, the M proteins (6, 7) and fibronectin (Fn)-binding proteins (3, 8). The M proteins serve many functions in the pathogenesis of *S. pyogenes*, including resistance to phagocytosis, adherence, and intracellular invasion (5, 9). The Fn-binding protein F (PrtF) and the allelic variant SfbI are also adhesins and invasins, produced by 50 to 60% of the M genotypes. The function of these proteins in the context of intracellular invasion is described below.

IMPACT OF INTRACELLULAR INVASION ON *S. PYOGENES* INFECTION

Many geographic and temporal clusters of sepsis and toxic shock, caused by a few serotypes of *S. pyogenes*, have been reported (10, 11). An M1 subclone was associated with many such clusters (10, 12). Surprisingly, devastating soft tissue infections were often reported in patients who had not experienced previous trauma or wounds that might initiate systemic spread of the organism (11). Cleary and coworkers (2, 13) considered the possibility that intracellular invasion of mucosal surfaces provides a window for streptococci to reach deeper tissue, even the bloodstream. Indeed, a globally disseminated M1 subclone invaded A549 epithelial cells at significantly higher frequency than did other subclones of M1 streptococci. The source of M1 subclones, i.e., uncomplicated disease or more invasive disease (blood isolated), did not correlate with efficiency of ingestion by epithelial cells (13). Only the M1 subclone that had acquired 70 kb of DNA sequence from two distinct prophages (13) was associated with high-frequency invasion of cultured cells. To date, no relationship to prophages and intracellular invasion has been discovered.

Although an association between high-frequency intracellular invasion and systemic streptococcal disease is still uncertain, the intracellular state may significantly increase the capacity of this bacterium to disseminate in human populations. When strains from carriers and patients with uncomplicated pharyngitis and sepsis were compared, those from carriers were observed to be internalized by HEp2 cells at the highest frequency (14). A highly variable M1 culture could be enriched for more invasive streptococci by *in vitro* serial passage through human epithelial cells (15); therefore, *in vivo* cycling of streptococci between the interior and exterior of the mucosal epithelium may select for variants that are more efficiently internalized. From 10 to 40% of children continue to shed streptococci after treatment with penicillin (16). Brandt et al. reported 80% relapse, by the same initial strain following vigorous penicillin therapy, when 40 consecutive isolates from 18 patients were characterized (17). Treatment failures and subsequent carriage of streptococci were reported to be more common when the infecting strain produced PrtF (also termed SfbI), an invasin that promotes high-frequency ingestion of streptococci by epithelial cells (18). This correlation was not, however, confirmed by a smaller study (17). *In vitro*, intracellular *S. pyogenes* can resist at least 100 μg/ml of penicillin (Cleary, P. unpublished data); therefore, penicillin treatment may further select for strains that can be efficiently internalized by epithelial cells. High-frequency intracellular invasion may increase the rate of antibiotic therapy failure and therefore increase the size of the human reservoir that can disseminate the organism to others in the population. As the reservoir enlarges, the probability of serious, systemic infection also increases. Thus, strains or serotypes that are less able to acquire an antibiotic-free niche may be less often associated with severe disease. Facinelli and colleagues observed an association between genetic resistance to erythromycin and more efficient uptake of *S. pyogenes* by epithelial cells (19). They suggested the frightening possibility that erythromycin resistance had become genetically linked to efficient invasion of human cells and thus coselected by antibiotic therapy. A genetic link was not established, however, nor did the authors exclude the possibility that a single subclone had disseminated in the study population. A thorough analysis of a cluster of toxic shock in southern Minnesota showed that nearly 40% of the school children in nearby communities

doi:10.1128/microbiolspec.GPP3-0049-2018

Downloaded From Vet-eBooks.com

were carriers of a serotype M3 clone that was responsible for systemic disease in adults (20). These investigators suggested that school children served as the reservoir for *S. pyogenes* that produced toxic shock in adults with underlying physical disabilities.

ARE TONSILS A RESERVOIR FOR *S. PYOGENES*?

The best and most direct evidence that intracellular bacteria are an important source for dissemination of streptococci and the cause of recurrent tonsillitis is based on microscopic studies of surgically excised tonsils (16). This study found that 13 of 14 tonsils from children plagued by recurrent tonsillitis harbored streptococci within epithelial cells in the tonsillar crypts. *S. pyogenes* was also observed in macrophage-like cells at high frequency in these specimens. Tonsils from control subjects who had tonsils removed for other reasons did not contain streptococci. Intracellular streptococci were also observed in cultured tonsils infected with *S. pyogenes* (21). The invasive M1 subclone was confirmed *in vitro* to efficiently invade primary keratinized tonsillar epithelial cells (22). In a murine intranasal infection model this M1 subclone and an M49 strain were shown to specifically invade nasal-associated lymphoid tissue, tissue known to be functionally homologous to human tonsils (23). Initially, streptococci were associated with M-like cells, sporadically located along the base of the nasal epithelium, and by 24 h postinoculation had formed microcolonies throughout the lymphoid tissue. From 1 to 10% of the streptococci, depending on the mouse, were intracellular. This study suggests that M-like cells are the primary portals for transport of *S. pyogenes* across the nasal mucosa into lymphoid tissue. Subsequent studies also demonstrated that nasal-associated lymphoid tissue is the initial, primary location for antigen-specific T cell priming and activation following intranasal infection by *S. pyogenes* (24, 25).

S. PYOGENES INVASINS AND HOST RECEPTORS

The intracellular state has many advantages for a bacterium's survival in a host, such as evading phagocytic killing, escaping neutralization by antibodies, and avoiding antibiotics. In many respects *S. pyogenes*' invasion of human cells is analogous to that of *Yersinia pseudotuberculosis*, which involves a bacterial outer membrane protein, InvA, binding to integrins (26). Integrins are a mammalian family of heterodimeric, transmembrane glycoproteins that bind to cell-secreted extracellular matrix (ECM) proteins, a collection of extracellular molecules, such as collagen, Fn and laminin (Ln), secreted by mammalian cells (27). Engagement of integrins by ECM proteins results in activation of host signal transduction pathways that lead to rearrangements of host cell cytoskeleton, cell membrane movement, and other cellular activities (28). Bacterial invasins are a subclass of bacterial adhesin molecule required for ingestion by host cells. Typically, invasins are proteins expressed on the surfaces of bacterial cells that directly or indirectly recognize specific host cell receptors (26). In general, invasins are capable of inducing reorganization of the host cell's cytoskeleton by generating specific signals from receptors with which they interact. Integrins are often exploited for microbial entry into mammalian cells. This may be due to their ubiquitous expression and their ability to affect cytoskeletal arrangement (27).

S. pyogenes has evolved multiple surface molecules that bind to various ECM proteins, which tether them to and activate integrin signaling pathways required for invasion. In addition, this bacterium has also evolved multiple mechanisms for invasion of a wide variety of mammalian cells. The host cell receptors, bacterial ligands, and biochemical pathways vary, depending on the strain of streptococcus and host cell type, adding another layer of complexity (6).

Streptococcal adhesins are a variety of surface molecules which can be grouped into four families, depending on their association with their surfaces: (i) those that are covalently linked by their C-terminus to the cell wall peptidoglycan through an LPxTz motif, (ii) those that are tethered to the bacterial cell membrane through N-terminal modifications of lipids to form lipoproteins, (iii) those that are bound to the bacterial surface by noncovalent interactions, and (iv) those that are expressed and retained on the surface by an as yet unknown mechanism. The most prominent adhesins belong to the family of cell wall-anchored proteins that are covalently linked to the peptidoglycan by a membrane-associated transpeptidase called sortase A (29).

ZIPPER AND OTHER MECHANISMS OF STREPTOCOCCAL INGESTION

Cytoskeletal events accompanying the uptake of a variety of pathogenic bacteria have been studied. Ruffling of the membrane precedes the entry of *Shigella* and *Salmonella* spp. (26). In contrast, internalization by a zipper mechanism is mediated by interactions between surface invasins, ligands, and host cell receptors. These interactions lead to pseudopod formation, which requires the extension of actin filaments beneath the host cell membrane (7).

Scanning electron microscopy revealed that adherent $M1^+$ bacteria are often in close contact with host cell microvilli, suggesting that this association may be an initial step in internalization (Fig. 1A). Microvilli frequently extend across bacterial surfaces and appear to entrap streptococci. Microvilli increase in number near adherent streptococci and appear to morphologically expand into pseudopodia-like structures, although these structures may arise independently (Fig. 1B). Membrane engulfment of streptococci suggests a zipper mechanism of uptake, as shown in Fig. 1C. The M1 strain of streptococcus, like *Listeria* and *Yersinia* spp., can be internalized by this zipper-like mechanism (7, 26). In contrast to $M1^+$ streptococci, $M1^-$ bacteria are rarely observed to interact with microvilli, and no pseudopodia-like structures were seen (7). *De novo* actin polymerization is essential for uptake of these streptococci, whether M^+ or M^- strains, because invasion is blocked by cytochalasin D, an inhibitor of actin polymerization (2). Confocal immunofluorescent microscopy confirmed that vacuoles containing internalized streptococci are surrounded by polymerized actin. Actin is occasionally associated with membrane-spanning chains and seems to disappear soon after entry.

Other microscopic studies demonstrated that physical events leading to ingestion of *S. pyogenes* vary dramatically between strains and serotypes (30, 31). Strain A40 induces the accumulation of small-membrane omega-shaped cavities in the host cell membrane near adherent streptococci. Shortly thereafter, membrane invaginations are formed into which streptococci enter. The integrity of the membrane is not disrupted, and streptococci end up in a cytoplasmic vacuole. These cell membrane changes are dependent on Fn and $\alpha_5\beta_1$ integrins, but focal adhesion complexes were not observed to contain polymerized actin (30). Further studies showed that these membrane structures are caveolae, structures previously found to mediate entry of both viruses and parasites into cells. In contrast, invasion of HEp2 cells by

Downloaded From Vet-eBooks.com

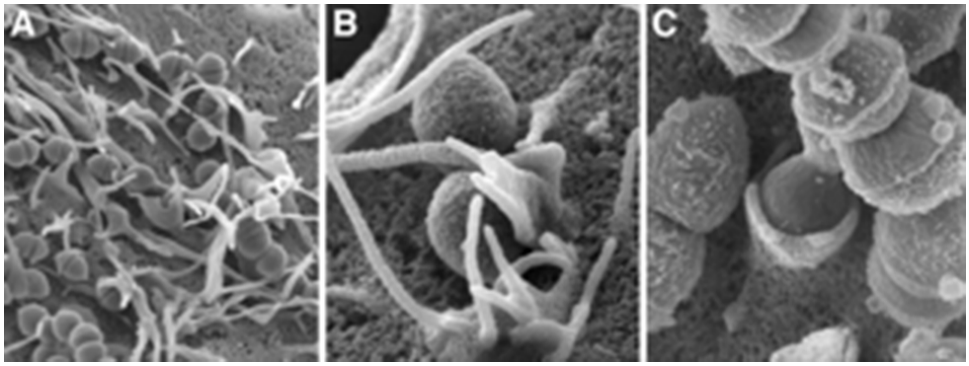

FIGURE 1 Scanning electron micrographs showing different stages of streptococci-HeLa cell interactions. (A) A high density of microvilli surrounding and in contact with adherent streptococci. (B) A common morphological change that microvilli undergo. The cup-like structure appears to gradually engulf the bacteria and ultimately pull them into a vacuole. (C) A streptococcal chain has been partially ingested by a mechanism that morphologically resembles a receptor-ligand interaction. It is not known whether microvilli are involved in the latter or whether streptococci are ingested by two physically different cytoskeletal rearrangements.

strain A8 (M40 Sfb1$^-$) was not inhibited by an Fn peptide analogue, nor by anti-$\alpha_5\beta_1$ antibody. This strain induced dramatic aggregation of microvilli near and around attached streptococci, and ingestion of this strain was independent of caveolae and lipid rafts. However, invasion of HEp2 and A549 epithelial cells by the M1 strain is dependent on Fn and $\alpha_5\beta_1$ integrins (22, 32). Comparison of strains A40 (M12 Sfb1$^+$) with A8 (M40 Sfb1$^-$) revealed striking differences. It is unclear whether these differences reflect yet another mechanism of streptococcal uptake or merely depend on different experimental conditions. Irrespective of differences, this study further implicated participation of microvilli in the uptake of streptococci by epithelial cells.

M PROTEINS AND OTHER Fn-BINDING PROTEINS ARE INVASINS

S. pyogenes expresses an array of cell surface proteins that facilitate bacterial colonization of a variety of human tissues (33). Some are adhesins that also function as invasins. The proteins SfbI and F1 (PrtFI) are closely related streptococcal adhesins that bind Fn with high affinity. Approximately 50% of *S. pyogenes* isolates carry the gene encoding SfbI/PrtFI, although many do not express the gene under laboratory conditions (3, 14, 18). Prebinding of soluble Fn to PrtFI-bearing streptococci can promote bacterial adherence to cultured cells and dermal tissue. This and experimental evidence from several laboratories are consistent with SfbI/PrtFI promoting intracellular invasion via a similar mechanism.

Molinari et al. (3) demonstrated that SfbI can mediate invasion of HEp2 cells. Streptococcal invasion can be ablated by antiserum raised against SfbI or by preincubation of host cells with recombinant SfbI. Latex beads coated with recombinant SfbI readily adhere to and are efficiently ingested by epithelial cells, demonstrating that the interaction of SfbI with host cells is sufficient for internalization. Fn binding by SfbI is required for invasion, because beads coated with a recombinant SfbI peptide lacking the Fn-binding domains do not efficiently adhere to HEp2 cells. Ozeri et al. (8) reported that invasion of HeLa cells by PrtFI$^+$ bacteria is dependent on addition of serum or purified Fn. In both studies, antibodies against Fn inhibited invasion. Also, PrtFI peptides, containing at least one Fn-binding domain, were found to inhibit PrtFI-mediated invasion. PrtFI binds to a 70-kDa N-terminal fragment of Fn. This region of Fn differs from the region bound by epithelial cells. The 70-kDa fragment can inhibit Fn-mediated invasion by competing with intact Fn for PrtFI binding; however, only intact Fn molecules are capable of supporting bacterial invasion (8). Antibody directed against the integrin $\beta1$ subunit specifically blocks Fn-PrtF1-mediated invasion of HeLa cells (8). This result suggests that one or more $\beta1$-containing integrins are involved in bacterial internalization. In contrast, invasion of GD25 (embryonic mouse stem) cells appears to be mediated by integrin $\alpha v\beta3$ (the major Fn-binding integrin of this cell line), since invasion is inhibited by a peptide that specifically blocks Fn binding to this integrin (8). Collectively, these results demonstrate that Fn functions as a molecular bridge between SfbI/PrtFI and host cell Fn receptors. At least 11 Fb-binding proteins of *S. pyogenes* have been identified (34), indicating that *S. pyogenes* has evolved multiple invasins to utilize the Fn-integrin mechanism for internalization of host cells.

Expression of Sfb1/PrtF1 is not a prerequisite for high-frequency intracellular invasion. For example, serotype M1 strains typically lack the gene encoding SfbI/PrtFI, but some can invade human epithelial cells with high efficiency (13, 18). Invasion of cultured cells by the globally disseminated M1 strain 90-226 is primarily dependent on expression of M1 protein. Inactivation of the M1 protein gene, *emm1*, decreased invasion of HeLa, A549, and HEp2 cells by 50-fold (7, 32), and latex beads coated with M1 are readily ingested by HeLa cells (7). These results indicate that invasion of epithelial cells by strain 90-226 is mediated in large part by M1 protein.

Expression of M1 protein is not sufficient for invasion, however, because bacterial internalization is dependent on exogenous serum, the ECM proteins, Fn or Ln (32). M1protein appears to be the major Fn-binding protein expressed by strain 90-226, because inactivation of *emm1* reduces binding by 88%. Also, purified M1 protein can bind Fn *in vitro* (32). This protein is also able to bind collagen VI, an ECM molecule that is distributed underneath the respiratory epithelium in the upper and lower airways (35). However, this is not a general property of all M proteins; only three, M1, M6, and M3 proteins are known to bind Fn (32, 36; Cleary P. unpublished data). Interestingly, M3 protein was also found to promote serum-dependent invasion of HEp2 cells (6).

Downloaded From Vet-eBooks.com

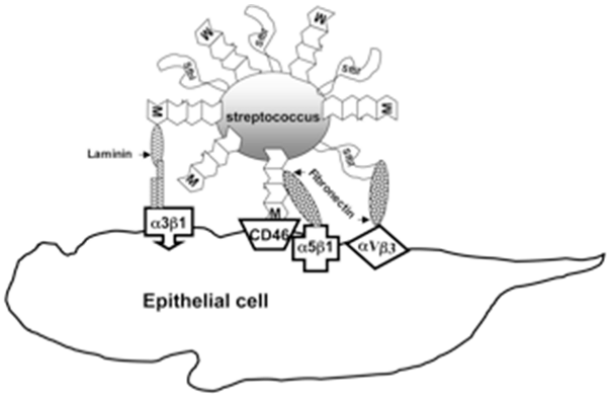

FIGURE 2 The various agonist and cellular receptors which streptococci commandeer to promote their own phagocytosis by epithelial cells. Both the M protein and high-affinity fibronectin proteins SfbI/PrtF1 are known invasins which depend on formation of a fibronectin bridge between the bacterial surface and integrin receptors α5β1 or αVβ3. Although less well studied, laminin can also serve as an agonist for ingestion of streptococci by linking them to α3β1 integrins. For some strains fibronectin-mediated invasion of epithelial cells also requires interaction between M protein and the complement regulatory protein CD46.

In the presence of Fn, internalization of M1 streptococci is dependent on the interaction of M1, Fn, and the epithelial cell Fn receptor α5β1 (Fig. 2). A monoclonal antibody that specifically blocks Fn binding to this integrin can ablate invasion of A549, HeLa, and human tonsillar epithelial cells (22, 32). Low-molecular-weight nonpeptidyl α5β1 antagonists are also effective inhibitors of invasion of A549 and human tonsillar epithelial cells (22). The inhibitory effects of α5β1 antagonists are not due to generalized effects on either bacterial or host cells, because the inhibitors do not abrogate Ln-mediated invasion. Rather, the inhibitory effects of α5β1 antagonists are observed only when bacteria are exposed to either serum or purified Fn. Thus, as in the case of Sfb1/PrtF1$^+$ strains, Fn appears to function as a bridging molecule in promoting invasion by M1$^+$ bacteria. Ln can replace Fn as the agonist in invasion assays (Fig. 2). Failure of Ln to promote invasion of A549 cells by M$^-$ mutants suggests that this ECM protein binds sufficiently to M1 protein to serve as a bridge between streptococci and α3β1 integrins.

The invasion efficiencies of M1 strains are not dictated solely by the presence of invasion agonists. LaPenta et al. (2) and Cleary et al. (15) reported that M1 isolates exhibit widely varying invasion efficiencies, even when experiments are performed in the presence of serum. These variations are likely due, at least in part, to varying levels of M1 protein expression. Transcription of *emm1* can vary considerably between isolates and even between different cultures of the same isolate (15). While this possibility has yet to be thoroughly investigated, it is consistent with the finding of Ozeri et al. (8) that the number of integrin-binding sites on bacteria can greatly affect invasion efficiency. Expression of different M proteins, M6, M3, or M18, in a common streptococcal background demonstrated that M proteins can differ widely in their capacity to promote ingestion of streptococci. Serum and the cellular receptor CD46 (Fig. 2) were required for uptake of streptococci that expressed M3 protein, whereas neither were required when the recombinant expressed M6 protein (6). Efficient invasion of A549 cells by strain 90-226 also requires that the M1 protein engage both CD46 and, indirectly, α5β1 integrins (37). Thus, it appears that M proteins of different serotypes often recognize different receptors on surfaces of mammalian cells. Berkower's results suggest that the invasion potential is actually determined by the primary amino acid sequence of the respective M protein (6). While it is clear that several types of M protein can facilitate invasion by *S. pyogenes*, there is no single mechanism underlying M protein-mediated ingestion of streptococci.

STREPTOCOCCAL FOCAL ADHESION AND SIGNAL TRANSDUCTION

The complex networks of intracellular events that lead to ingestion of several microbial pathogens have begun to be unraveled. Studies have not only identified potential targets for therapeutics but in some cases revealed insight into basic cell biology questions. Uptake by host cells requires streptococci to manipulate normal outside-inside signals spawned from cellular receptors. Interactions of Fn-binding-proteins and integrins trigger a cascade of signals that cause cytoskeleton rearrangement leading to ingestion of streptococci by nonphagocytic epithelial cells. Analyses of streptococci-induced signaling pathways have focused on two major invasins and Fn-binding proteins, SfbI/PrtF1 and M1 protein. Ozeri et al. reported that infection of epithelial cells with an M6 SfbI/PrtF1$^+$ strain caused integrins to be recruited to sites of bacterial adhesion and colocalization of phosphorylated focal adhesion kinase (FAK) and paxillin, common signaling and structural components of focal adhesion complexes (38). Invasion of epithelial cells by the M6 strain was significantly reduced when host cells were pretreated with genistein, a general inhibitor of protein tyrosine kinases, such as Src kinases and FAK. Invasion was also reduced by inhibitors of the small GTPases Rac and Cdc42. Moreover, internalization of this strain by FAK$^{-/-}$ and Src$^{-/-}$ cells and cells expressing dominant negative forms of Rac1 or Cdc42 was less efficient. From these findings, Ozeri et al. proposed a model for SfbI/PrtF1-mediated *S. pyogenes* invasion which is incorporated into Fig. 3: Fn bound to surface SfbI/PrtF1 protein associates with integrins to cause integrin clustering, followed by recruitment of paxillin, FAK, and other focal adhesion proteins at the site of entry. This initiates autophosphorylation of FAK, which creates a docking site for Src kinases. Paxillin present in this complex and additional sites on FAK is then phosphorylated by Src. Ozeri et al. proposed that Rac and Cdc42 are required to orchestrate signaling events initiated by Fn bound to SfbI/PrtF1 protein. Then the focal adhesion complex provides an anchor for actin polymerization and cytoskeleton rearrangements required for internalization of streptococci. To date, however, the relationship between integrin-generated signals, formation of focal adhesion complex, and Rac and Cdc42 is poorly understood and is unsupported experimentally. It is also possible that streptococci interact with additional receptors which in turn activate other mechanisms of signaling and pathways of ingestion.

M1$^+$ strains of *S. pyogenes* invade epithelial cells efficiently without expression of SfbI/PrtF1 protein. M1-mediated invasion of epithelial cells was shown to require phosphatidylinositol 3-kinase (PI3K) (39), a heterodimer consisting of the regulatory subunit p85 and the catalytic subunit p110. Activation of PI3K catalyzes phosphorylation of membrane-associated phosphatidylinositol, which binds to downstream targets, including integrin-linked kinase (ILK) (40). Experiments that disrupted activity found that ILK is also required for *S. pyogenes* invasion of HEp2 cells (41). ILK is known to be a crucial link between integrins and the cytoskeleton, is capable of phosphorylating the β_1 integrin cytoplasmic domain, and can be coimmunoprecipitated with β_1 integrin

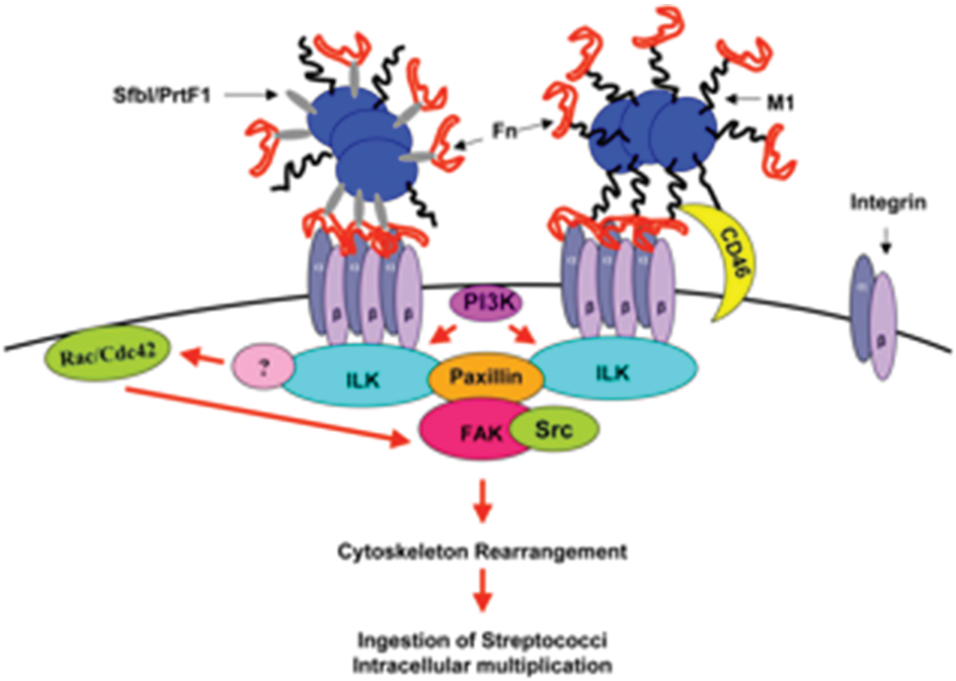

FIGURE 3 Postulated and confirmed components of streptococci-induced focal adhesion complexes and signaling molecules required for formation of those complexes and subsequent cytoskeletal changes that lead to ingestion of streptococci by epithelial cells. Fibronectin (Fn) bound to surface M1 or SfbI/PrtF1 proteins associates with integrins to cause integrin clustering leading to ILK activation in a PI3K-dependent manner. For some strains contact between M protein and CD46 is also required for high-frequency invasion. The function of CD46 in this process, however, is unknown. Following recruitment of paxillin, FAK, and other focal adhesion proteins, autophosphorylation of FAK creates a docking site for Src kinases to phosphorylate recruited paxillin and additional sites on FAK. Alternatively, Rac and Cdc42 are activated by ILK through an intermediate to participate in formation of focal adhesion complexes, which provide an anchor for actin polymerization and cytoskeleton rearrangement that ultimately results in uptake of *S. pyogenes*.

in lysates of mammalian cells (42). Invasion of epithelial cells by $M1^+$ group A streptococci was impaired up to 80% by a specific ILK inhibitor. Inhibition of ILK expression with small interfering RNA or inhibition of activity by transfection with a kinase-inactive ILK gene also significantly reduced GAS invasion. Controls, assays of the non-integrin-dependent invasion of epithelial cells by *Salmonella*, confirmed that inhibitors of either PI3K or ILK did not have a general negative impact on the host cell's ability to ingest bacteria but were specific for Fn-mediated uptake of *S. pyogenes*. ILK is known to be activated upon integrin engagement in a PI3K-dependent manner and to require that its pleckstrin homology-like domain be bound to phosphatidylinositol 3,4,5-triphosphate, a product of PI3K. Therefore, it is possible that PI3K indirectly provides the cytoplasmic membrane anchor for ILK.

Invasion of epithelial cells by M6 $SfbI/PrtF1^+$ streptococcus was also reduced 70 to ~80% by inhibitors of PI3K and ILK. In addition, interaction of M49 streptococci with plasminogen facilitates integrin-mediated and ILK-dependent internalization of bacteria into keratinocytes (43), also suggesting that ILK is a critical signal component involved in integrin-mediated invasion. This is consistent with the possibility that ILK indirectly activates Rac and Cdc42 (44, 45), which can regulate actin cytoskeleton rearrangement (46, 47), leading to various forms of cell adhesion complexes and stress fibers (41). Therefore, ILK may be an intermediate between integrins and Rac and/or Cdc42. Although M1-Fn and SfbI/PrtF1-Fn complexes may induce cellular changes by shared mechanisms, M1-mediated invasion is significantly less sensitive to genistein (41), again indicating that different mechanisms of signaling likely exist.

Paxillin, a cellular signaling molecule involved in cytoskeleton rearrangement downstream of ILK, is phosphorylated in response to Fn-bound streptococci that express either M1 or PrtF1/SfbI protein but is not phosphorylated in response to a mutant streptococcus deficient in both proteins. Inhibition of paxillin phosphorylation significantly reduced invasion by $M1^+$ but did not affect ingestion of $PrtF1/SfbI^+$ strains, indicating that paxillin phosphorylation is induced by both invasins but only required for M1-mediated invasion (48). M3 streptococci lack the major epithelial invasins SfbI/PrtF1 and M1 protein but have the potential to cause invasive disease. Experiments demonstrate that Src kinase and Rac1 but not PI3Ks are essential for internalization of these streptococci (49). There appears to be a bifurcation point downstream of ILK leading to PI3K or Src/Rac1, and it appears that *S. pyogenes* has evolved different invasins, which utilize various cellular signaling pathways to promote ingestion, pathways that lead to the distinct morphological changes observed in electron microscopic studies.

M1 protein can interact with multiple cellular receptors, either directly or indirectly (Fig. 2). For example, CD46, a cofactor in factor I-mediated inactivation of complement

Downloaded From Vet-eBooks.com

proteins C3b and C4b (50) and expressed on the surface of all nucleated human cells, enhances invasion of epithelial cells by $M3^+$ and $M1^+$ streptococci (6, 37). Overexpression of a mutant form of CD46 with a deletion in the cytoplasmic domain results in partial reduction of invasion. Feito et al. analyzed CD46 binding to clinical isolates of *S. pyogenes* using a soluble construct encompassing the extracellular domain and showed strong binding to M types 1, 3, 8, 18, 24, 28, 29, 31, and 78, weak binding to M6 and M29 strains, and no binding to M types 11, 12, 27, or 30. Although only a limited number of strains have been studied for the interactions between CD46 and streptococci, it is likely that the well-conserved C repeats of M proteins expressed by these different clinical isolates also contain the CD46-binding sites (51). CD46's role in intracellular signaling and identification of its docking partners are poorly defined; however, these preliminary studies suggest that M1 protein-mediated ingestion of *S. pyogenes* requires costimulation from two cellular receptors (37).

Diverse invasins, agonists, and cellular receptors predict that the signaling networks which lead to ingestion of streptococci by epithelial cells may also be varied and multiple. Although our knowledge of the signaling mechanisms responsible for ingestion of *S. pyogenes* is rudimentary, Fig. 3 attempts to interpret what is known. Association of multimeric Fn-binding protein-Fn complexes with $\alpha5\beta1$ integrins on the bacterial surface cause integrin clustering that leads to activation of ILK in a PI3K-dependent manner and recruitment of paxillin and FAK. Autophosphorylation of FAK creates a docking site for Src kinase resulting in phosphorylation of paxillin and additional sites of FAK. Rac and Cdc42 proteins are likely activated by ILK signaling, building focal adhesion complexes which ultimately regulate localized actin depolymerization and polymerization and the cytoskeletal changes that engulf the bacteria. Many gaps in the pathway exist, but the tools are now available to further dissect the mechanisms.

OTHER INVASINS

A few serotypes, including M1 strain 90-226, produce the Fn-binding protein Fba. Like M protein, the C5a peptidase (SCPA) and Fba expression are positively controlled by Mga, a multigene transcriptional activator. Mutation and complementation experiments demonstrated that Fba promotes adherence and uptake of streptococci by epithelial cells in the presence of Fn (52). More recent studies found that Fba binds the complement regulatory factor FHL-1 and that this agonist also promotes uptake of streptococci in $M1^-$ mutants of strain 90-226 (53). Elsner et al. reported that mutants which lack the lipoprotein Lbp/Lsp showed reduced adherence and invasion of epithelial cells (54). However, others found that Lbp/Lsp functions as an adhesin but reported that mutations which eliminate expression of Lpb/Lsp had no impact on invasion of HEp2 cells (55). Our laboratory also found that mutation of Lpb/Lsp protein had no effect on invasion of A549 cells by strain 90-226. Expression of that protein on the surface of lactococcus imparted the organism with the potential to adhere to A549 cells but did not promote bacterial uptake. It is possible that this lipoprotein varies between strains or that differences in experimental conditions account for the different conclusions. Thus, binding Fn to the streptococcal surface is not in itself sufficient to promote invasion of epithelial cells. Fn density and/or conformation in the context of the streptococcal surface more than likely influences its potential to promote integrin aggregation or the signals generated by the occupied integrin.

The surface-bound protease SCPA was demonstrated to be the primary, Fn-independent invasin for *Streptococcus agalactiae* (56). Although M1 protein is the primary invasin for strain 90-226, SCPA accounts for 15 to 20% of bacteria internalized by A549 cells (57). Complete deletion or amino acid substitutions that block protease activity also reduced the capacity of SCPA to promote ingestion of *S. pyogenes*. Cheng et al. postulated that autocatalytic removal of the propeptide during protease maturation might uncover the protein's cell-binding site (56).

Serum opacity factor is known to mediate invasion through binding of Fn to its C-terminal domain (58). Experiments revealed that the N-terminal, opacification domain of serum opacity factor also contributes to epithelial cell invasion independently of the C-terminal Fn-binding domain (59). Although the host invasion agonist and cellular mechanisms have not been identified, it appears that like M1 protein, serum opacity factor can use different pathways for cellular internalization.

Invasins that are independent of Fn have also been identified. Human plasminogen that is present in plasma and extracellular fluids has been linked to streptococcal invasion of human cells. Several plasminogen-binding proteins have been identified; however, the plasminogen-binding M-like protein (PAM) and PAM-related protein (Prp), which have high affinity for human plasminogen, are the most studied and are associated with an *S. pyogenes* strain isolated from a severe invasive infection (60, 61). Plasminogen-mediated invasion is significantly reduced after preincubation of bacteria with either $\alpha_1\beta_1$ or $\alpha_5\beta_1$ integrins but not after preincubation with $\alpha_v\beta_5$ integrin. Uptake of streptococci via plasminogen was also shown to be dependent on ILK signaling (43), indicating that *S. pyogenes* can use a variety of agonists to instigate integrin-mediated internalization by human cells.

M-like proteins bind C4BP, an inhibitor of the classical pathway of complement activation that blocks opsonization by C3b and phagocytosis of *S. pyogenes* by polymorphonuclear leukocytes (PMNs). Recent work demonstrated that a highly virulent M1 strain expresses protein H, a member of the M protein family that binds C4BP and enhances invasion of endothelial cells, independent of M1 protein (62). In addition, the proline-rich protein in human saliva associates with GrpE, a chaperone protein primarily expressed at cell division sites on the surface of *S. pyogenes* and significantly promotes internalization of streptococci, independent of M1 and PrtF1/SfbI proteins (63). Whether ingestion of streptococci, mediated by C4BP or proline-rich protein requires integrin signaling, is dependent on cytoskeleton rearrangement should be investigated.

FATE OF INTRACELLULAR STREPTOCOCCI

Listeria spp. can escape from vacuoles, and subsequent formation of actin tails allows the bacteria to spread to neighboring cells (26). Immunofluorescent microscopy did not reveal actin tails associated with streptococci at 5 or 7 h postinfection (7). Transmission electron microscopy showed streptococci enclosed in vacuoles within host cells (1, 2). Both *Mycobacterium tuberculosis* and *Listeria* are able to block the killing mechanisms of macrophages, providing a safe cellular compartment for persistent infection. The ultimate fate of internalized streptococci has, however, been controversial. Several studies failed to observe growth of intracellular streptococci, and infected cell lines eventually clear most of the bacteria (1, 64). Consistent with these findings are transmission electron micrographs taken 8 h postinfection showing degraded streptococci inside phagolysosomes

Downloaded From Vet-eBooks.com

(1). An early study described a unique strain of *S. pyogenes*, strain A8, that survived and multiplied within HEp2 cells (14), but to date this observation has not been confirmed or expanded. Thulin et al. found live *S. pyogenes* within macrophages at the noninflamed edge of soft tissue infections sampled by biopsy (65) and suggested that phagocytes containing intracellular streptococci contribute to the expansion of these rapid and sometimes lethal wound infections. Microscopic analysis of PMNs from intravenously infected mice contained intracellular streptococci in vacuoles, and mice inoculated with these purified infected PMNs died within 5 days, suggesting that the intracellular bacteria were not only viable but more virulent than those grown in culture medium (66). Staali et al. showed that M protein and M-like protein H are required for *S. pyogenes* to survive ingestion by PMNs. They discovered an undefined mechanism that prevents fusion of azurophilic granules with the phagosome (67). Although Cywes et al. originally suggested that uptake of *S. pyogenes* by epithelial cells was a host defense mechanism (4), their more recent experiments seem to show the opposite, i.e., intracellular invasion provides a safe haven for *S. pyogenes* (68). They demonstrated that two extracellular toxins, NADase and streptolysin O, produced by the highly invasive M1 clone of streptococcus, work together to prevent trafficking of intracellular streptococci to lysosomes, allowing 15% of bacteria to survive within immortalized keratinocyte lines. We reported many years ago that M1T1 streptococci isolated before 1980 did not efficiently invade epithelial cells (2), whereas the highly invasive M1T1 clone isolated in the 1990s invaded A549 cells at high frequency. The highly invasive M1T1 strain that Sharma et al. (68) used harbored a 36-Kb genetic element that encoded the *nga* and *slo* genes, providing a mechanism for coexpression of NADase and SLO, which in turn promoted intracellular survival. One wonders whether this genetic element is related to the prophage which we reported to distinguish the invasive M1 clone from less invasive M1 strains (13).

Historically, a primary focus of *S. pyogenes* pathogenesis has been the M protein and its capacity to block phagocytic uptake by PMNs. Now the field faces the dichotomy that this pathogen can not only resist engulfment by professional phagocytes but also survive ingestion by PMNs, which may then become a Trojan horse for dissemination of bacteria through human tissues. Finally, the outcome of streptococcal uptake by epithelial cells or phagocytes depends on the strain and the spectrum of proteins expressed on their surface.

OTHER MECHANISMS

The levels and distribution of cellular agonists are important determinants of the frequency of ingestion of *S. pyogenes* by human cells. The growth factor TGF-β1 is known to regulate the expression of Fn and other ECM proteins and positively control the integrin signaling pathway. Wang et al. (25)

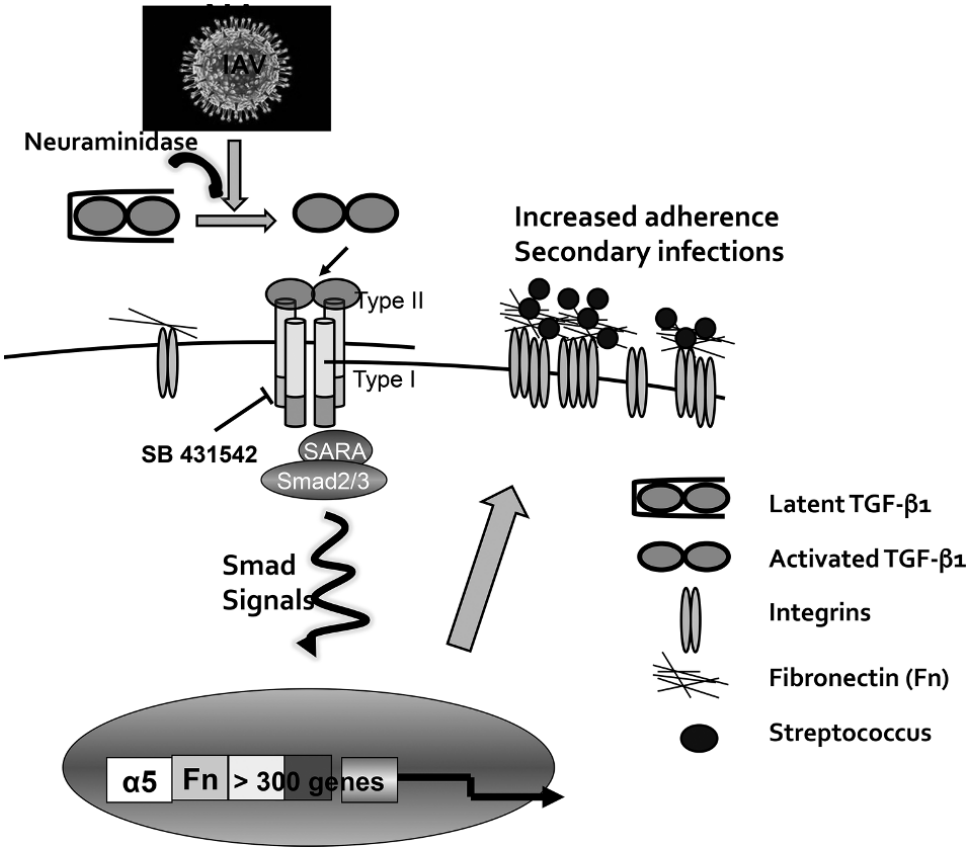

FIGURE 4 IAV facilitates bacterial adherence through the activation of the TGF-β signaling pathway. IAV neuraminidase activates latent TGF-β, which launches Smad signals that locally upregulate integrin and Fn expression by infected cells, providing increased numbers of receptors for adherence of streptococci. This in turn could lead to increased susceptibility to more frequent and more serious streptococcal infections.

Downloaded From Vet-eBooks.com

reported that infection of HEp2 cells or mice with *S. pyogenes* induces TGF-β1 expression by host cells. Moreover, pretreatment of HEp-2 cells with TGF-β1 increases expression of α5 integrin and Fn by HEp2 cells and therefore increases the frequency of ingestion of streptococci by these cells. The increased ingestion is blocked by inhibition of TGF-β1 signaling or by antibodies directed against α5 integrin or Fn. More recently, Li et al. reported that the neuraminidase of influenza A virus (IAV) enhances expression of α5 integrin and Fn on the surface of lung epithelial cells through activation of TGF-β1 (Fig. 4). This promotes FnBP-dependent adherence to these cells *in vitro* and secondary infections of lungs following inoculation with *S. pyogenes* (69). They found that inhibition of TGF-β1 or the activity of viral neuraminidase impeded upregulation of these cellular adhesins and IAV-enhanced bacterial adherence. Further study with $Smad^{-/-}$ mice, which are TGF-β1 signaling deficient, revealed that significantly larger numbers of streptococci were recovered from the lungs of IAV-infected $Smad3^{-/-}$ mice than from $Smad3^{+/+}$ littermates. Flow cytometry demonstrated that IAV infection of $Smad3^{+/+}$ mice increased the number of lung cells with high levels α5 integrin/Fn expression, whereas the number of these cells in lungs from $Smad3^{-/-}$ mice did not change after IAV infection. These results indicate that loss of TGF-β1 signaling prevents the upregulation of α5 integrin/Fn expression in IAV-infected mice and reduces host susceptibility to *S. pyogenes* coinfection. These finding are consistent with the possibility that neuraminidase in the presence of *S. pyogenes* (70) could enhance TGF-β1 activity, leading to global upregulation of integrins and ECM proteins, and increased invasion of lung epithelium, leading to systemic streptococcal infections subsequent to or during IAV infections.

SUMMARY

S. pyogenes has evolved multiple mechanisms for invading epithelial cells. Strains of this species differ substantially in invasion frequency and their dependence on invasion agonists. High-frequency internalization is mediated by ECM proteins, such as Fn, Ln, and collagen proteins that form bridges between a surface invasin and the appropriate integrin receptor on the target mammalian cell. Because adherence and invasion can be independent events, mediated by distinct surface proteins and distinct integrins, a two-receptor process is proposed for high-efficiency internalization. The spectrum of target host cells, invasion efficiency, and the ECM-binding proteins displayed on the bacterial surface determine the requirement for serum agonists. No single invasin or surface protein accounts for high-efficiency invasion of epithelial cells by all strains of streptococci. These findings suggest that intracellular invasion may be triggered by different agonists in different tissues or at different stages of infection. Intracellular streptococci appear to account for the persistence of streptococci after penicillin therapy and to be one source of streptococci that are responsible for recurrent tonsillitis. Therefore, the capacity to invade epithelial cells may influence the prevalence of a given strain of *S. pyogenes* in human populations. Multiple invasins may be differentially expressed in response to varying environmental cues at a specific tissue site. Invasins can bind the same, different, or multiple host proteins and then trigger different cellular signaling pathways. These variations may permit the bacteria to colonize various sites of a host and help explain the diverse manifestation of streptococcal diseases. A better understanding of streptococcal invasins, host cell receptors, and downstream signals may reveal the underlying mechanisms, which could lead to new and improved treatment strategies.

Capsular Polysaccharide of Group A *Streptococcus*

MICHAEL R. WESSELS

4

INTRODUCTION

In her early studies of group A streptococci (*Streptococcus pyogenes*), Rebecca Lancefield noted an association between virulence and a distinctive appearance of the bacterial colonies on solid media. Isolates that were highly virulent for mice and that grew well in fresh human blood typically formed large colonies with a translucent, liquid appearance (mucoid) or an irregular, collapsed appearance (matte). By contrast, avirulent isolates that grew poorly in human blood formed compact, opaque colonies (glossy). Strains that grew as mucoid or matte colonies usually produced large amounts of M protein, which Lancefield gave the designation "M" because of this association with colony morphology (1, 2). Later work by Armine Wilson demonstrated that the mucoid or matte appearance of such strains was in fact due to elaboration of capsular polysaccharide, not M protein (3). Wilson showed that the mucoid or matte colony type was converted to a nonmucoid or glossy colony by growth on medium containing hyaluronidase which digested the hyaluronic acid capsule, whereas growth on medium containing trypsin, which digested M protein, had no such effect. Furthermore, while many strains that produced abundant capsular polysaccharide also were rich in M protein, expression of the two surface products was not always linked; certain mucoid or highly encapsulated strains produced little or no M protein, and certain strains rich in M protein produced little or no capsule (1, 4).

Both M protein and capsule have since been shown to contribute independently to *S. pyogenes* virulence. The association of mucoid strains of *S. pyogenes* with both invasive infection and acute rheumatic fever suggested a role for the capsular polysaccharide in virulence. Anecdotal observations that linked the capsule to pathogenesis of streptococcal disease were supported by a study that characterized the colony morphology of more than 1,000 *S. pyogenes* clinical isolates received by a streptococcal reference lab in the 1980s. In that study, only 3% of *S. pyogenes* isolates from patients with pharyngitis had a mucoid colony morphology, whereas 21% of isolates from patients with invasive disease syndromes such as bacteremia, necrotizing fasciitis, or streptococcal toxic shock syndrome and 42% of isolates associated with acute rheumatic fever were mucoid (5). The overrepresentation of mucoid strains among isolates associated with invasive infection and rheumatic fever suggested that the capsule contributes to enhanced virulence. The occurrence of outbreaks of acute rheumatic fever associated with mucoid strains of *S. pyogenes* at several locations in the United States in the 1980s supported the same inference (6–8). These clinical and epidemiologic observations implicating the capsule in pathogenesis have been corroborated by extensive experimental studies that have demonstrated a definite role of the hyaluronic acid capsule as a virulence factor in *S. pyogenes* infection.

BIOCHEMISTRY AND GENETICS OF CAPSULE PRODUCTION

Hyaluronic Acid Biosynthesis

The *S. pyogenes* capsular polysaccharide is composed of hyaluronic acid, a high-M_r (>10^6 kDa) linear polymer made up of β(1→4)-linked disaccharide repeat units of D-glucuronic acid(1→3)-β-D-*N*-acetylglucosamine. The polysaccharide is synthesized from the nucleotide sugar precursors UDP-glucuronic acid and UDP-*N*-acetylglucosamine by a membrane-associated enzyme, hyaluronan synthase. High-M_r hyaluronic acid (or hyaluronan) can be produced by incubation of cell-free membrane extracts of *S. pyogenes* with the two substrate UDP-sugars in the presence of divalent cations (9–11).

A genetic locus required for hyaluronic acid production in *S. pyogenes* was located independently by three laboratories using transposon mutagenesis to produce acapsular mutants from a mucoid *S. pyogenes* strain. Transposon insertions that produced the acapsular phenotype were mapped to a locus that was highly conserved among *S. pyogenes* strains (12–14). Characterization of this region of the *S. pyogenes* chromosome revealed a cluster of three genes, *hasABC*, whose products are involved in hyaluronic acid biosynthesis. The first gene, *hasA*, encodes hyaluronan synthase, a protein with a predicted M_r of 47.9 kDa that includes at least four predicted membrane-spanning domains, consistent with evidence that the enzyme is membrane associated (15, 16). The *hasA* gene product shares significant similarity with the NodC protein of *Rhizobium meliloti*, which is required for synthesis of an *N*-acetylglucosamine-containing polysaccharide, with chitin synthases, and with hyaluronan synthases from other microbial and higher animal species (17, 18). The *S. pyogenes* hyaluronan synthase has been expressed in *Escherichia coli* as a His_6-fusion protein. Activity of the purified enzyme is strongly stimulated in the presence of certain phospholipids, particularly cardiolipin (diphosphatidylglycerol), which appears to

doi:10.1128/microbiolspec.GPP3-0050-2018

Downloaded From Vet-eBooks.com

be associated with the enzyme in *S. pyogenes* (19). Cardiolipin molecules may contribute to formation of a transmembrane pore for export of the hyaluronic acid polymer, since the hyaluronan synthase itself contains only two relatively small extracellular domains (20).

The second gene, *hasB*, encodes UDP-glucose dehydrogenase, a protein with a predicted M_r of 45.5 kDa that catalyzes the oxidation of UDP-glucose to UDP-glucuronic acid (21). The third gene in the cluster, *has*C, encodes a predicted 33.7-kD protein identified as UDP-glucose pyrophosphorylase (22). The function of this enzyme is to catalyze the condensation of UTP with glucose-1-phosphate to form UDP-glucose. Thus, the reaction catalyzed by the *has*C product yields a substrate for UDP-glucose dehydrogenase encoded by *hasB*, whose reaction product is, in turn, a substrate for hyaluronan synthase encoded by *hasA* (Fig. 1). While the enzyme protein encoded by *has*C is enzymatically active, it is not required for hyaluronic acid synthesis by *S. pyogenes*. Selective inactivation of *has*C resulted in no decrement in hyaluronic acid synthesis by a highly encapsulated strain of *S. pyogenes*; the implication is that another source of UDP-glucose is available within the cell (23). Furthermore, expression of recombinant *hasA* and *hasB* (without *has*C) resulted in synthesis of hyaluronic acid in *E. coli* and *Enterococcus faecalis* (13, 15). Together, these observations have led to the conclusion that *hasA* and *hasB* are the only two genes uniquely required for bacterial synthesis of hyaluronic acid. The three genes *hasABC* are transcribed as a single message of approximately 4.2 kb from a promoter immediately upstream of *hasA* (24). The identification of a potential *rho*-independent terminator at the 3′ terminus of *has*C suggests that no additional genes are included in the operon. A paralog of *hasB*, *hasB2*, is present at a chromosomal location remote from the *has* operon. Its product is able to support a low level of hyaluronic acid production in the absence of *hasB* (25).

The simplicity of the capsule gene cluster in *S. pyogenes* contrasts with the size and complexity of capsule synthesis loci in other encapsulated Gram-positive bacteria, which generally consist of at least 12 genes (26–30). One exception is the type 3 pneumococcus, whose capsule production is strikingly similar to that in *S. pyogenes* with respect to the structure of the polysaccharide and the capsule synthesis genes; in type 3 pneumococci, capsule synthesis involves three genes that are homologs of *hasABC* (31, 32). In both *S. pyogenes* and type 3 pneumococci, it seems likely that the capsule synthesis gene cluster was acquired from another species by horizontal gene transfer. This hypothesis is also suggested by genome comparisons of *S. pyogenes* with group B *Streptococcus*: with the exception of the *hasABC* cluster that

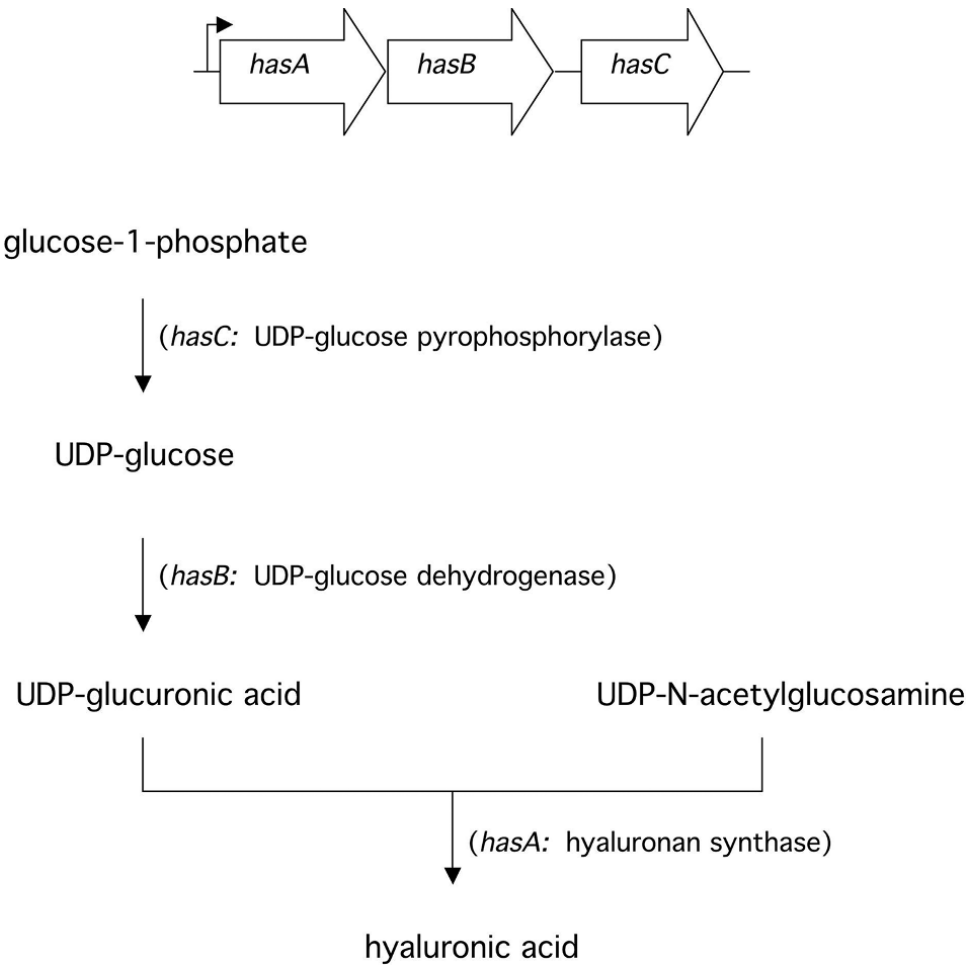

FIGURE 1 Schematic diagram of the *has* operon and the function of each gene product in the biosynthetic pathway for synthesis of hyaluronic acid in *S. pyogenes*.

Downloaded From Vet-eBooks.com

is absent in group B *Streptococcus*, there is a high degree of gene synteny over more than 25 kb of the corresponding chromosomal region in *S. pyogenes* and group B *Streptococcus*.

While the *has* operon is highly conserved, it is not universally present in *S. pyogenes* clinical isolates. In particular, strains of M types 4 and 22 and some isolates of M 89 lack the capsule synthesis operon and do not produce a hyaluronic acid capsule (33–36). Interestingly, the absence of the capsule synthesis genes in M types 4 and 22 is associated with the presence of enzymatically active hyaluronidase, whereas in serotypes that produce capsule, the chromosomal *hylA* gene contains a point mutation that renders it catalytically inactive. These divergent patterns of gene expression suggest that *S. pyogenes* has evolved two mutually exclusive survival strategies: production of an antiphagocytic hyaluronate capsule or production of hyaluronidase, presumably as a spreading factor in host tissues and/or to degrade host hyaluronic acid as a source of nutrition.

Regulation of Hyaluronic Acid Biosynthesis

The *has* operon is highly conserved among *S. pyogenes* strains. A study of nine *S. pyogenes* isolates that came from diverse settings and whose dates of isolation spanned 75 years found only six mutations within a 300-nucleotide central region of the *hasA* gene (17); all were single nucleotide substitutions, and none resulted in a change in the amino acid sequence of the protein. Despite the high degree of conservation of the hyaluronan synthase gene, individual *S. pyogenes* strains vary widely in the amount of capsule they produce. Since the *has* genes are conserved, differences in capsule expression among strains are likely to reflect differences in the regulation of *has* gene transcription. Experimental support for this hypothesis comes from the observation that *has* gene transcripts are detected during exponential growth of well-encapsulated strains of *S. pyogenes* but not in strains that do not produce detectable hyaluronic acid (24). Analysis of the *has* operon promoter using a reporter system in which the promoter was fused to a promoterless chloramphenicol acetyl transferase (CAT) gene showed that full activity of the *has* promoter required no more than 12 nucleotides of chromosomal DNA upstream of the promoter's –35 site (37). This observation is consistent with the finding that many strains of *S. pyogenes* (10 of 23) contain the insertion element IS*1239′* approximately 50 nucleotides upstream of the –35 site without any apparent effect on capsule production (Figure 2) (23).

One factor that influences the amount of capsule produced by a particular strain is the structure of the *has* operon promoter itself. Experiments using CAT reporter gene fusions revealed 3-fold higher activity of the *has* promoter from a highly encapsulated M type 18 strain than that from a poorly encapsulated M type 3 strain (37). Construction of hybrid promoters by site-directed mutagenesis demonstrated that nucleotide substitutions in two regions accounted for the differences in promoter activity between the two serotypes: three nucleotides in the −35, −10 spacer region and four nucleotides in the +2 to +8 positions relative to the start site of *hasA* transcription. The characteristic fine structure of the *has* operon promoter in type 18 strains may account in part for the observation that M18 strains are typically mucoid (i.e., highly encapsulated) since the precise sequence of the *has* promoter appears to be serotype-specific.

Capsule production varies not only among strains but also in an individual strain under different circumstances. For example, during growth in liquid batch culture, *S. pyogenes* organisms produce large capsules during the exponential phase and then shed their capsules into the medium during the stationary phase. Studies using a *has* promoter-CAT fusion integrated into the *S. pyogenes* chromosome demonstrated a rapid increase in promoter activity to a maximal level during the exponential phase of growth, with a sharp fall as the organisms entered the stationary phase. The production of cell-associated capsular polysaccharide followed an identical but slightly delayed pattern, consistent with the expected lag for changes in the translation of enzyme proteins that are subsequently reflected in the rate of polysaccharide synthesis. These results indicate that the changing levels of encapsulation observed during different phases of growth are due to transcriptional regulation of *has* operon expression. Further studies of the effect of growth rate on capsule expression in a chemostat continuous culture system found that levels of CAT activity and capsule production were at least three times higher in cells maintained at a constant rapid growth rate (doubling time of 1.4 hours) than in cells maintained at a slow growth rate (doubling time of 11 hours) (S. Albertí, J.L. Levin, and M.R. Wessels, unpublished observations).

Upregulation of capsule production is likely to occur during infection when the organism moves from the external environment into the pharynx or deep tissues, where both temperature and nutrient availability are optimal for bacterial growth. This hypothesis was supported by experiments using a reporter strain of *S. pyogenes* in which expression of green fluorescent protein was controlled by the *has* operon promoter. Introduction of the strain into the mouse peritoneum or into the baboon pharynx triggered a rapid increase in fluorescence, reflecting transcription from the *has* promoter (38). Thus, the regulation of capsule expression may be a useful adaptation to survival in host environments in which the capsule is required to defend the organism against complement-mediated phagocytic killing.

The dynamic changes in *S. pyogenes* capsule expression with changes in growth rate and the observation that some strains of *S. pyogenes* appear more highly encapsulated after animal passage have suggested that capsule gene transcription is regulated by cellular mechanisms in addition to those attributable to the intrinsic structure of the *has* operon promoter. Mga, the *trans*-acting regulatory protein that influences expression of several *S. pyogenes* proteins, appears not to regulate capsule expression, at least in most strains of

FIGURE 2 Map of the region of the *S. pyogenes* chromosome that includes the *has* operon encoding enzymes required for hyaluronic acid synthesis. The other genes shown appear not to be involved in capsular polysaccharide synthesis or surface expression. In some strains insertion sequence IS*1239′* is present approximately 50 nucleotides upstream of the *has* operon promoter (adapted from the genome sequence of M1 strain SF370, GenBank accession number AE004092 [93]).

Downloaded From Vet-eBooks.com

S. pyogenes. Inactivation of Mga was associated with reduced *has* gene transcription in an M1 strain (39); however, no effect on capsule production and/or *has* transcription was observed upon Mga inactivation in strains of M6, M18, or M49 (40–42). RofA, a regulatory protein involved in control of protein F expression, also is not known to affect capsule production (43).

Transposon mutagenesis of a poorly encapsulated M3 strain of *S. pyogenes* resulted in the identification of a novel regulatory locus whose inactivation dramatically increased capsule production (42). The locus consists of two genes, *csrR* and *csrS* (also called *covR* and *covS*), whose predicted products resemble the regulator and sensor proteins, respectively, of bacterial two-component regulatory systems (Fig. 3). Targeted inactivation of *csrR* by allelic exchange mutagenesis resulted in a 6-fold increase in capsule production. The increase in hyaluronic acid synthesis was accompanied by a parallel increase in *has* gene transcription—evidence that CsrR regulates transcription of the capsule synthesis genes. Mutation of *csrR* appeared not to affect expression of M protein or hemolytic activity, but subsequent work in several laboratories has demonstrated that the system also represses expression of several other virulence factors, including streptokinase (*ska*), streptolysin S (*sag* operon), mitogenic factor/streptodornase (*speMF*), an integrin-like protein/IgG protease (*mac* or *ideS*), and in some strains, cysteine protease (*speB*) (44–47). Microarray transcriptional profiling experiments suggested that CsrRS is involved directly or indirectly in regulation of approximately 10% of *S. pyogenes* genes (44, 48–50). The membrane-associated CsrS protein is a histidine kinase thought to respond to at least two environmental signals: an elevated extracellular Mg^{2+} concentration is associated with increased phosphorylation of the cognate regulator CsrR, presumably as a result of stimulating CsrS autokinase activity and/or inhibiting CsrS phosphatase activity for CsrR (51). The human antimicrobial peptide LL-37, at concentrations below those that inhibit *S. pyogenes* growth, has an effect on CsrR phosphorylation opposite to that of elevated magnesium (52, 53). Phosphorylation of CsrR increases its affinity for binding to the promoter region of the *has* operon and most other regulated genes to repress transcription (46, 54, 55). The likely importance of this regulatory system in virulence is supported by the markedly greater resistance to *in vitro* phagocytosis displayed by a (highly encapsulated) *csrR* mutant than by the wild-type parent strain and a 500-fold increase in the mutant's virulence for mice after intraperitoneal challenge (42). Up to 40% of invasive *S. pyogenes* isolates have inactivating mutations in CsrS or CsrR, whereas such mutations are rare among isolates from pharyngitis patients (56–58).

Capsule production is also controlled by RocA, a protein first identified as a regulator of CsrR expression and later shown to influence phosphorylation of CsrR (59, 60). Mutations in *rocA* are associated with increased expression of the *has* operon and of other genes regulated by the CsrRS system. *S. pyogenes* strains of *emm* types 18 and 3 each harbor a mutation in *rocA* that results in expression of a truncated RocA protein and increased capsule production (61, 62).

THE CAPSULE AND HOST IMMUNE DEFENSES

Immunogenicity of Hyaluronic Acid

In 1937, Kendall et al. reported the purification of capsular polysaccharide from mucoid strains of *S. pyogenes* (63). Their analysis revealed that an apparently identical capsular material was produced by different M types of *S. pyogenes*. The *S. pyogenes* polysaccharide contained equal amounts of *N*-acetylglucosamine and glucuronic acid as exclusive components of monosaccharides; this finding suggested that it might be structurally identical to a polysaccharide isolated from bovine vitreous humor and human umbilical cord. Immunization of rabbits and horses with mucoid *S. pyogenes* cells failed to elicit antibodies detectable by precipitin reactions with the polysaccharide. Later studies have confirmed that the "serologically inactive" polysaccharide produced by *S. pyogenes* is hyaluronic acid, a high M_r polysaccharide with a repeating unit structure identical to that of hyaluronic acid isolated from animal sources. Presumably because it is recognized as a "self" antigen, hyaluronic acid is poorly immunogenic in several animal species. Fillit and colleagues evoked antibodies to hyaluronic acid by immunization of rabbits with encapsulated streptococci of group A or C and by immunization of mice with hyaluronidase-treated hyaluronic acid linked to liposomes (64, 65). Such antibodies, however,

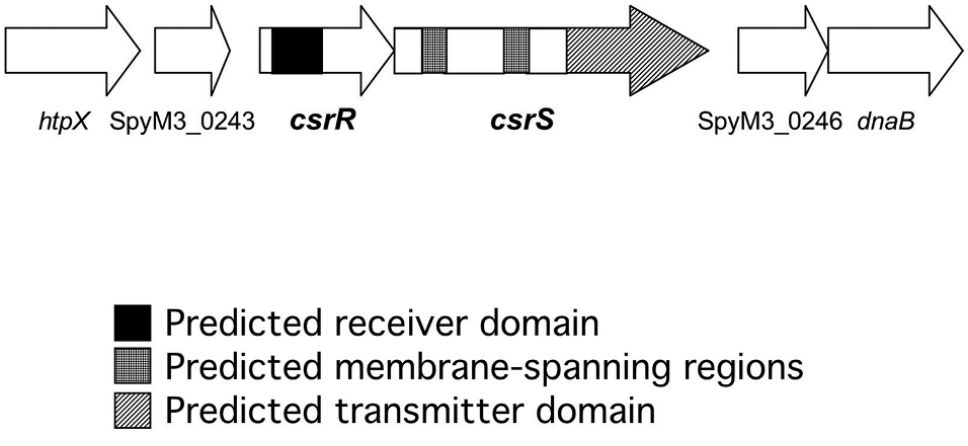

FIGURE 3 Diagram of the *csrRS* chromosomal locus encoding a two-component regulatory system that regulates hyaluronic acid synthesis. Sequences corresponding to regions of the predicted proteins with properties characteristic of the response regulator (CsrR) or sensor (CsrS) components are indicated (adapted from the genome sequence of M3 strain MGAS315, GenBank accession number AE014074 [94]).

Downloaded From Vet-eBooks.com

have not been shown to have any opsonic activity against *S. pyogenes in vitro* or to confer protection against *S. pyogenes* infection *in vivo*.

Capsule and Resistance to Phagocytosis

S. pyogenes, like other Gram-positive pathogens, is resistant to direct bacteriolysis by complement and antibodies. Therefore, clearance of the organisms from the blood or deep tissues depends largely on uptake and killing by phagocytes. This concept was supported by the observations of Todd, Lancefield, and others that virulence of *S. pyogenes* isolates in both clinical settings and in experimental animal infections was closely paralleled by the capacity of the strains to resist killing by human blood leukocytes. *S. pyogenes* strains that produced large amounts of M protein multiplied in fresh human blood, while those that lacked M protein did not (66, 67). In addition, however, early studies demonstrated a relationship between surface expression of the hyaluronic acid capsule and resistance to phagocytosis. Mucoid or highly encapsulated strains tended to be resistant, and hyaluronidase treatment increased their susceptibility to phagocytosis *in vitro*, a result that suggested a protective effect of the capsule (68–70). More recent work with acapsular mutants has provided definitive evidence that the capsule is a major determinant of resistance to phagocytic killing. In several assays measuring complement-dependent phagocytic killing by human blood leukocytes, acapsular mutants of type 18 and type 24 *S. pyogenes* were significantly more susceptible than the corresponding encapsulated wild-type strains (14, 71, 72).

One mechanism through which capsular polysaccharides may confer resistance to phagocytosis is the inhibition of complement activation. The type III capsular polysaccharide of group B *Streptococcus*, for example, prevents deposition of C3b on the bacterial surface through inhibition of alternative complement pathway activation by sialic acid residues present in the polysaccharide (73, 74). In *S. pyogenes*, however, the presence of the capsular polysaccharide appears to have no effect on the amount of C3b deposited on the bacterial surface. Similar amounts of C3 were detected on acapsular mutants and on encapsulated wild-type strains after incubation of the organisms in serum (71). The increased resistance of well-encapsulated *S. pyogenes* strains to complement-dependent phagocytic killing, therefore, must reflect the capacity of the capsule to block access of neutrophils to opsonic complement components bound to the bacterial surface rather than inhibition of C3b deposition (Fig. 4).

Resistance of *S. pyogenes* to phagocytosis has been assessed most often with the bactericidal test of Lancefield, in which a small inoculum of the test strain is rotated for 3 hours in heparinized fresh human blood (67). Strains that exhibit a significant increase in CFU during rotation in blood are considered resistant. An effect of the capsule is evident in this assay (acapsular mutants show less net growth than encapsulated wild-type strains), but the effect of M protein is more striking (14, 72). M protein-deficient strains not only fail to grow but typically are reduced in number after a 3-hour incubation. By contrast, when resistance to phagocytosis is assessed with a different assay, the effect of capsule is more dramatic than that of M protein. In this second assay system, a larger bacterial inoculum is rotated for 1 hour with human peripheral blood leukocytes in the presence of 10% normal human serum as a complement source (75, 76). In the latter assay, acapsular mutant strains and poorly encapsulated wild-type strains are killed (~90% reduction in CFU) despite the presence of M protein, while well-encapsulated strains do not change or increase in number. A mutant that is deficient in M protein but that produces wild-type amounts of capsule is killed less efficiently than a capsule-deficient mutant in the same background (72). In a study of isogenic mutants deficient in capsule, M protein, or both in the background of a mucoid type 18 *S. pyogenes* strain, mouse virulence correlated better with results in the second assay system than with the Lancefield whole-blood assay (72).

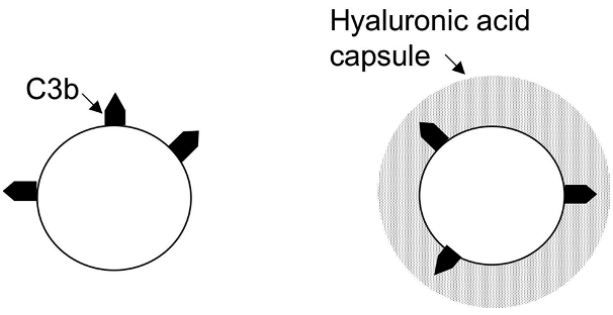

FIGURE 4 The hyaluronic acid capsule and resistance to complement-mediated phagocytosis. The capsule does not prevent deposition of C3b on the bacterial cell wall but, rather, interferes with the interaction of bound C3b with phagocyte receptors.

CAPSULE AS A VIRULENCE FACTOR

Experimental Infection Models

In the 1940s, investigators attempted to determine experimentally whether the hyaluronic acid capsule contributed to the virulence of *S. pyogenes*. Hirst found that decapsulating *S. pyogenes* by treatment with leech extract containing hyaluronidase had no effect on virulence of the bacteria in mice (77). However, Kass and Seastone found reduced virulence of decapsulated *S. pyogenes* in mice, perhaps because the latter authors administered hyaluronidase to the infected mice at frequent intervals to prevent regeneration of the capsule after challenge (78). Subsequently, more direct proof that the capsule contributes to virulence has come from several studies using acapsular mutant strains of *S. pyogenes* derived by transposon mutagenesis or by targeted inactivation of gene(s) required for hyaluronic acid synthesis (Table 1).

Because the capsule is required for *S. pyogenes* resistance to complement-mediated phagocytic killing (see above), it is not surprising that capsule expression enhances virulence in systemic infection models in which the animals succumb to overwhelming bacteremia. In addition, however, the hyaluronic acid capsule contributes in a pivotal fashion to the capacity of the organisms to produce invasive soft tissue infection. A mouse model of invasive *S. pyogenes* soft tissue

TABLE 1 Animal models in which the hyaluronic acid capsule has been shown to enhance virulence of group A streptococci

infection has been developed in which the bacterial inoculum is delivered by superficial injection just below the skin surface in a small volume and with minimal trauma to the tissues (79, 80). Mice challenged with the highly encapsulated M24 strain Vaughn developed dermal necrosis with underlying purulent inflammation and secondary bacteremia, while mice challenged with the acapsular mutant strain 24-4 developed no lesion at all or minor superficial inflammation and no bacteremia (79). Similar results were observed in the same model with a moderately encapsulated M3 strain of *S. pyogenes* (originally isolated from a patient with necrotizing fasciitis) which was compared with two isogenic acapsular mutants derived by allelic exchange mutagenesis of the *has*A (hyaluronan synthase) gene. In the latter experiments, the majority of animals challenged with the encapsulated M3 parent strain developed spreading, necrotic soft tissue infection and died, whereas the acapsular mutants produced only mild local infection and no deaths (80). The dramatic impact of the capsule on virulence in this model is correlated with equally striking histopathologic findings: In animals challenged with an acapsular mutant, a small focus of neutrophilic inflammation and necrosis is confined by a well-formed abscess. By contrast, after challenge with the encapsulated wild-type strain, acute inflammatory cells extend throughout the subcutaneous tissue and are associated with thrombosis of blood vessels, with infarction and necrosis of the overlying dermis—a histopathologic picture very similar to that in patients with *S. pyogenes* necrotizing fasciitis. Examination of the histologic sections by immunofluorescence microscopy with an *S. pyogenes*-specific antibody showed that the acapsular *S. pyogenes* cells were confined to the abscess cavity, while the encapsulated wild-type organisms were widely dispersed throughout the subcutaneous tissues.

Capsule and Mucosal Colonization

Studies by at least two groups have demonstrated a critical role for the hyaluronic acid capsule in pharyngeal colonization in mice. BALB/c mice inoculated intranasally with the stable (transposon insertion plus chromosomal deletion) acapsular mutant strain 24-4 rapidly cleared the organism from the pharynx, and no mice died (81). In contrast, throat cultures of mice challenged with the revertible (simple transposon insertion) acapsular mutant 24-72 yielded encapsulated revertants, and the rate of persistent throat colonization and lethal systemic infection was similar to that in animals challenged with the encapsulated type 24 parent strain. A study of an acapsular mutant derived from the mouse-virulent M50 strain, B514, yielded similar results: intranasal challenge with the wild-type strain resulted in chronic throat colonization in C57BL/10SnJ mice. After intranasal challenge with an acapsular mutant derived by plasmid insertion mutagenesis of the *has*A gene, encapsulated revertants accounted for all *S. pyogenes* recovered from throat cultures 4 days after challenge (82). Intratracheal inoculation of C3HeB/FeJ mice with the wild-type strain produced pneumonia and secondary systemic infection in approximately 50% of the animals within 72 hours, while only 2 animals challenged with the acapsular mutant became ill, 5 and 6 days after challenge, respectively. In both cases only encapsulated revertants were recovered from cultures of the throat, lungs, and blood (82). The findings in both studies of impaired colonization by the acapsular mutant strains and the rapid emergence of encapsulated revertants together provide strong evidence that encapsulation confers a powerful survival advantage for *S. pyogenes* in the upper airway. This conclusion was supported also by experiments in a primate model of *S. pyogenes* pharyngeal colonization: an acapsular mutant derived from an M3 strain was cleared from the pharynx of baboons more quickly than the wild-type parent strain (83). While these results suggest that capsule production enhances initial survival and persistence of *S. pyogenes* in the pharynx, studies of long-term carriage in a primate model and in human carriers have shown that carriage isolates acquire mutations that result in reduced or absent hyaluronic acid production (84, 85). Taken together, the results of these studies suggest that the hyaluronic acid capsule enhances transmission and initial colonization but that prolonged carriage in human beings may be favored by subsequent downregulation or loss of capsule production.

Capsule and *S. pyogenes* Attachment to Epithelial Cells

The influence of the hyaluronic acid capsule on the capacity of *S. pyogenes* to colonize the pharyngeal epithelium may be explained, at least in part, by the protective effect of the capsule in preventing opsonophagocytic killing, although the importance of resistance to opsonophagocytosis at a mucosal site is less well-defined than in blood or deep tissues. In addition, the capsule is an important factor in the process of *S. pyogenes* attachment to epithelial cells, both by modulating interactions of other bacterial surface molecules with the epithelium and by direct interaction of *S. pyogenes* capsular hyaluronic acid with eukaryotic cells. The capsule may influence adherence by interfering with the interaction of any of a variety of *S. pyogenes* surface molecules that have been implicated as adhesins: M and M-like proteins, fibronectin-binding proteins, lipoteichoic acid, and glyceraldehyde-3-phosphate dehydrogenase. In general, acapsular mutant strains of *S. pyogenes* attach in higher numbers to skin or throat keratinocytes than do the corresponding encapsulated wild-type strains. For type 24 *S. pyogenes*, the capsule prevents M protein-mediated adherence to keratinocytes, since inactivation of the *emm24* gene reduced adherence in the background of an acapsular mutant but not in the background of the same strain expressing wild-type amounts of capsule (86). It is likely that the capsule exerts a similar modulating influence on bacterial adherence mediated by other *S. pyogenes* surface molecules.

Not only does the capsule influence the binding interactions of other *S. pyogenes* surface structures, but there is evidence that the capsule itself can serve as a ligand for attachment of *S. pyogenes* to CD44 on epithelial cells. CD44 is a hyaluronic acid-binding glycoprotein found on a variety of human cells, including epithelial and hematopoietic cells. The interaction of CD44 with hyaluronic acid appears to have important functions in cell migration, organization of epithelia, lymphocyte homing, and tumor metastasis. Because CD44 is expressed on the surface of tonsillar epithelial cells, it may serve as a receptor for binding of hyaluronic acid on the surface of *S. pyogenes*. This hypothesis was supported by the finding that a monoclonal antibody to CD44 reduced attachment of wild-type strains of *S. pyogenes* to human pharyngeal keratinocytes by ~90% but had no effect on attachment of acapsular mutant strains (86). Further evidence that CD44 acts as a receptor for *S. pyogenes* came from the observation that transfection of K562 cells with cDNA encoding either of two epithelial isoforms of CD44 conferred on the cells the capacity to bind *S. pyogenes*. Cells expressing CD44 bound a variety of *S. pyogenes* wild-type strains, including several in which the level of capsule expression was below the limit of detection in a dye-binding assay; however, inactivation of the hyaluronan synthase gene in such a poorly

Downloaded From Vet-eBooks.com

encapsulated *S. pyogenes* strain completely abrogated binding (86). A study of transgenic mice with defective expression of epithelial CD44 found reduced pharyngeal colonization compared to that in wild type mice after intranasal challenge with *S. pyogenes*, evidence that CD44 can function as a receptor for *S. pyogenes* binding to the pharyngeal epithelium *in vivo* (87).

Capsule and CD44-Mediated Tissue Invasion

CD44 is a transmembrane protein, and its ligation by hyaluronic acid can result in signal transduction and induction of cellular events involved in cell migration. Binding of *S. pyogenes* to CD44 on human pharyngeal keratinocytes *in vitro* has been shown to trigger a similar pattern of cellular responses, including the formation of lamellipodia or membrane ruffles at the site of *S. pyogenes* attachment and disruption of intercellular junctions (88). These events were associated with enhanced translocation of encapsulated *S. pyogenes* compared to an acapsular mutant across epithelial cell layers *in vitro*. The results suggested that interaction of the *S. pyogenes* capsule with CD44 manipulates a host signaling pathway to disrupt epithelial integrity and enable bacterial penetration into underlying tissues.

Capsule and *S. pyogenes* Entry into Epithelial Cells

Several laboratories have documented the entry of *S. pyogenes* into human epithelial cells, a process that has been proposed to represent a virulence mechanism—either a step in bacterial invasion into deep tissues or a means of escape of the organism into an intracellular sanctuary shielded from antibiotics and host immune defenses (79, 89–91). However, while there is irrefutable evidence that the capsule plays a key role in invasive infection *in vivo*, there is equally clear evidence that the capsule prevents *S. pyogenes* entry into epithelial cells. In studies of *S. pyogenes* entry into cultured human keratinocytes from pharyngeal epithelium or external skin, poorly encapsulated strains entered cells far more efficiently than well-encapsulated strains, regardless of M type or clinical source of the isolates (79). Acapsular mutants entered more than 1,000 times more efficiently than corresponding encapsulated parent strains. The apparently opposite effects of the capsule on invasive infection *in vivo* compared to those on epithelial cell "invasion" *in vitro* suggest that bacterial entry into epithelial cells is not a step in productive infection but rather a host response that limits the spread of poorly encapsulated strains. By contrast, virulent encapsulated strains resist ingestion by eukaryotic cells, both epithelial cells and professional phagocytes, and invade deep tissues by an extracellular route, a process that appears to be facilitated by CD44-mediated disruption of cell-cell junctions. This hypothesis is supported by the finding that clinical isolates from patients with invasive *S. pyogenes* infection "invade" epithelial cells at much lower rates than throat or skin isolates (92). After internalization, the viability of *S. pyogenes* within epithelial cells *in vitro* falls rapidly after bacterial entry (79, 90). It is possible, however, that transient intracellular survival of *S. pyogenes*, perhaps in a cyclic fashion, contributes to persistent carriage.

CONCLUSIONS

Careful observations by microbiologists and clinicians in the 1920s and 1930s pointed to a link between the hyaluronic acid capsule and *S. pyogenes* disease pathogenesis. More recent studies have defined the genetic locus that directs hyaluronic acid biosynthesis and have characterized the molecular mechanisms through which the capsule enhances *S. pyogenes* virulence. It is now appreciated that the *has* capsule synthesis operon is both highly conserved and widely, but not universally, distributed among *S. pyogenes* strains, attesting to the adaptive role played by the hyaluronic acid capsule in the coevolution of *S. pyogenes* with the human host. As a poorly immunogenic "self" antigen, the capsular polysaccharide appears to have persisted in an invariant form in *S. pyogenes*, presumably because it has not been subject to the selective pressure of an effective, polysaccharide-specific, humoral immune response in the infected host that has led to emergence of multiple capsular types in other pathogenic bacteria. Studies of acapsular mutant strains have demonstrated that the capsule protects *S. pyogenes* from complement-mediated phagocytic killing and is essential for full virulence in a variety of experimental infection models. The *S. pyogenes* capsule also influences attachment of the bacteria to human epithelial cells, both by modulating the interaction of M protein and other potential adhesins and by itself serving as a ligand for attachment of *S. pyogenes* to CD44 on epithelial cells. The latter mechanism may be of particular importance in *S. pyogenes* colonization of the pharynx, because it appears to participate in the adherence of diverse *S. pyogenes* strains, including those that produce only small amounts of capsule. Finally, the successful adaptation of *S. pyogenes* to survival in the human host involves regulation of capsule expression that is dependent on the fine structure of the *has* operon promoter, on the CsrRS two-component regulatory system, and likely, on additional mechanisms yet to be uncovered.

Toxins and Superantigens of Group A Streptococci

BLAKE A. SHANNON, JOHN K. McCORMICK AND PATRICK M. SCHLIEVERT

5

Streptococcus pyogenes (i.e., the group A *Streptococcus*) is a human-restricted and versatile bacterial pathogen that produces an impressive arsenal of both surface-expressed and secreted virulence factors. *S. pyogenes* exists primarily as an asymptomatic colonizer of the skin and mucous membranes of the nasopharynx, and despite being universally sensitive to β-lactam antibiotics *in vitro*, this bacterium continues to generate significant morbidity and mortality on a global scale. Human diseases induced by *S. pyogenes* usually occur as relatively uncomplicated manifestations such as pharyngitis and skin infections, but it may also cause more problematic diseases including erysipelas and scarlet fever. In addition, *S. pyogenes* can cause devastating invasive diseases including puerperal sepsis, bacteremia, necrotizing fasciitis, and streptococcal toxic shock syndrome (TSS). This bacterium is further recognized as a very important cause of postinfection sequelae including acute rheumatic fever and rheumatic heart disease, acute glomerulonephritis, and potentially, pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections. Although surface-expressed virulence factors are clearly vital for colonization, establishment of infection, and the development of disease, the secreted virulence factors are likely the major mediators of tissue damage and toxicity seen during active infection. The collective exotoxin arsenal of *S. pyogenes* is rivaled by few bacterial pathogens and includes extracellular enzymes, membrane active proteins, and a variety of toxins that specifically target both the innate and adaptive arms of the immune system, including the superantigens; however, despite their role in *S. pyogenes* disease, each of these virulence factors has likely evolved with humans in the context of asymptomatic colonization and transmission. In this article, we will focus on the biology of the true secreted exotoxins of the group A *Streptococcus*, as well as their roles in the pathogenesis of human disease.

THE CYTOLYTIC TOXINS OF *S. PYOGENES*

β-hemolytic activity on blood agar is a hallmark feature of the group A *Streptococcus*, and this phenotype has been used clinically for over a century. The streptolysin S (SLS) exotoxin is a small, oxygen stable hemolysin that is responsible for the characteristic β-hemolysis of *S. pyogenes* (1). SLS is a cytolytic toxin that has features of the ribosomally synthesized and posttranslationally modified lantibiotic bacteriocins from other Gram-positive bacteria; however, lantibiotic bacteriocins mostly function as antibacterials without cytotoxic activity for eukaryotic cells (2). Production of SLS is encoded by the SLS-associated gene (*sag*) cluster, which contains genes encoding the structural SLS protein (*sagA*) as well as enzymes responsible for the posttranslational modification and transport of the toxin and, potentially, an immunity function (*sagB* through *sagI*) (3). Furthermore, the *sag* locus is conserved among group A *Streptococcus* strains regardless of M protein serotype (3). SLS has been shown to target and disrupt the function of multiple host cells, including erythrocytes, macrophages, neutrophils, and keratinocytes (2, 4–6). The exact mechanism of action of SLS is not completely clear, although it is thought to act by forming a pore in host cell membranes (7). However, a recent study has demonstrated that SLS lyses erythrocytes by disrupting the function of anion transporters to cause an influx of chloride anions (Cl^-). The influx of Cl^- is followed by an influx of water, resulting in colloidal-osmotic rupture of erythrocytes (8). Furthermore, SLS has been shown to work in conjunction with the host protease calpain to facilitate the destruction of intracellular junction proteins, promoting paracellular invasion of the bacteria across the epithelial barrier (9). To examine the role of SLS in invasive models of disease, infection of an *S. pyogenes* strain deleted for SLS function was tested in a murine model of necrotizing soft tissue infection, and SLS was determined to be essential for pathogenesis (3). A similar study using transposon mutagenesis created a mutant deficient in SLS production that remained normal with respect to other exoprotein expression and was also shown to be markedly less virulent in a mouse model of subcutaneous infection than in the isogenic wild-type strain (10). Therefore, SLS likely contributes to *S. pyogenes* pathogenesis through a combination of inhibiting phagocyte function and damaging epithelial barriers.

Streptolysin O (SLO) is a well-characterized exotoxin that functions as a thiol-activated cytolysin and is secreted from nearly all group A *Streptococcus* isolates (11). The *slo* gene encodes SLO monomers that oligomerize on eukaryotic membranes in a cholesterol-dependent manner, resulting in the formation of a large pore. This produces significant damage and ultimately results in host cell apoptosis (12). The SLO toxin is active in a reduced state and is rapidly inactivated in the presence of oxygen; thus, activity is not thought to be visible on routine blood agar plates (13). Previous studies have shown that the host targets of SLO include erythrocytes, macrophages, neutrophils, and keratinocytes (14–17). SLO has also been shown to inhibit neutrophil degranulation at sublytic concentrations (16). In addition to SLO, the *slo* gene

doi:10.1128/microbiolspec.GPP3-0054-2018

Downloaded From Vet-eBooks.com

resides in an operon that additionally encodes *S. pyogenes* NADase (SPN). The NADase functions by hydrolyzing cellular NAD^+ and by depleting cellular ATP to decrease the host energy sources (18). Multiple studies have concluded that the entry of SPN into host cells is dependent on SLO pore formation (19, 20), and SPN and SLO in conjunction increase epithelial cell apoptosis, compared to SLO alone (21). Using immortalized human keratinocytes, strains lacking SLO were attenuated for intracellular survival compared to the wild-type strain (20). Furthermore, in a murine model of necrotizing soft tissue infection, *S. pyogenes* strains lacking SLO were deficient in causing myositis, bacteremia, and soft tissue infection (22). Another study demonstrated lower infectivity of SPN mutant strains in models of necrotizing fasciitis, although the deletion of SLO led to an inability to cause disease (22). Therefore, SLO likely promotes the pathogenesis of *S. pyogenes* in invasive skin and soft tissue infection through the destruction of phagocytes, as well as the cytolysin-mediated translocation of SPN into target cells.

Independent studies investigating the role of both SLO and SLS in murine models of necrotizing fasciitis and systemic infection each demonstrated that both cytolytic toxins significantly contribute to the development of murine necrotizing fasciitis (23, 24). Although SLO and SLS have been extensively studied and shown to be important contributors to the pathogenesis of invasive *S. pyogenes* infections, their roles during colonization and acute nasopharyngeal infection have yet to be defined.

STREPTOCOCCAL SUPERANTIGENS

S. pyogenes is recognized as one of the few bacterial pathogens that produces superantigen exotoxins. Streptococcal superantigens are ribosomally synthesized, relatively low molecular mass (~22 to 28 kDa) proteins that contain classical signal peptides that are cleaved after secretion to release the mature toxin. Superantigens function by activating T cells and are among the most potent known activators of T cells. The term "superantigen" was first used to describe the massive primary T cell response to these bacterial toxins (25). However, the *S. pyogenes* superantigens are also historically known as the erythrogenic toxins or scarlet fever toxins, due to their role in causing a red rash in the context of scarlet fever (26–28). In fact, the characteristic rash seen in scarlet fever is likely due to an amplified hypersensitivity reaction resulting from superantigen activity (28). Since the appearance of a rash was the defining feature of the "erythrogenic" toxins, Watson (27) first proposed the name "streptococcal pyrogenic exotoxin" (Spe) owing to the fever-producing ability, because he initially believed that the Spes belonged to a separate family of toxins. We now know that these represent the same group that belongs to a larger group of structurally conserved exotoxins that are also produced by *Staphylococcus aureus* (29–32) and some Lancefield group C and G β-hemolytic streptococci (33–37). There are now at least 14 characterized and genetically distinct *S. pyogenes* superantigens, and many of them are encoded within lysogenic bacteriophage, or putative bacteriophage, elements. Therefore, different strains often encode different repertoires of typically between 3 and 6 distinct superantigen genes (38–42). Although nomenclatural inconsistencies exist in the literature, a recent comprehensive review of the streptococcal superantigens has clarified many of these issues (43). Using this updated nomenclature, the currently known repertoire includes streptococcal pyrogenic exotoxin (Spe) types A, C, G, H, I, J, K, L, M, N, O, and P, as well as the streptococcal superantigen and streptococcal mitogenic exotoxin Z (SmeZ) (Fig. 1A). The SpeN, SpeO, and SpeP superantigens were first identified in *Staphylococcus equi* subsp. *zooepidemicus* (originally defined as SzeN, SzeF, and SzeP, respectively) (36), but to our knowledge, these particular superantigens have not been identified in *S. pyogenes*. Additionally, *S. equi* subsp. *equi* can encode SeeH, SeeI, SeeL, and SeeM, which are highly orthologous to SpeH, SpeI, SpeL, and SpeM, respectively (37). Although most of the streptococcal superantigens are encoded on bacteriophage elements, SpeG and SmeZ are exceptions in that they appear to be encoded within the core chromosome (35, 38–42). SpeJ is also not found in association with bacteriophage genes (40), yet it is not present in the many sequenced strains. SmeZ, in particular, is known to have many allelic variants, and most of the sequence changes are located on the surface of the toxin and rarely found within the predicted receptor binding domains. This indicates that SmeZ is likely under significant immunological pressure to alter antigenic characteristics as a possible immune evasion strategy (35). Despite the fairly weak primary amino acid sequence homology (Fig. 1B), crystal structures determined for these toxins share the "generic" superantigen fold (Fig. 1C) (44). Each structure includes an N-terminal α-helix which leads into a β-barrel domain, also known as the oligosaccharide/oligonucleotide binding fold (45). A central α-helix then joins this domain to a β-sheet structure known as the β-grasp domain. Despite the clear similarities to the overall fold, there are also important differences in how these toxins engage their host receptors.

Superantigens function by causing excessive T cell activation through simultaneous engagement of both the variable region of the T cell antigen receptor (TCR) β-chain (referred to as "Vβ") on T cells and to different regions of major histocompatibility complex (MHC) class II molecules on antigen-presenting cells (44, 46). Thus, superantigens are remarkable in that they have evolved to target two critical and extremely diverse receptors of adaptive immunity. In superantigen-mediated T cell activation, the toxin binds directly to MHC class II molecules, and this occurs without processing by the antigen-presenting cell. Superantigens do not undergo major modifications after release from the cell or major structural alterations upon binding to their ligands. The interaction with the TCR is dependent on binding to different Vβ regions, and this occurs, generally, away from the regions of the TCR that are critical for peptide-specific recognition. Due to the unconventional contacts created by these interactions, superantigen-mediated T cell activation is also not MHC restricted, and furthermore, both $CD4^+$ and $CD8^+$ T cells are stimulated in a Vβ-specific manner. Thus, superantigens can "force" an excessive primary response that is not seen with conventional peptide antigens. In the most severe case, this excessive activation of T cells results in the massive release of proinflammatory cytokines from both T cells and antigen-presenting cells (47) that can result in a serious and potentially lethal disease defined as TSS (32).

Cocrystallization structures have been determined for SpeA and SpeC in complex with the mouse Vβ8.1 and human Vβ2.1 chains, respectively (48). Earlier cocrystal structures exist for the staphylococcal superantigens staphylococcal enterotoxin B (SEB) and staphylococcal enterotoxin C (SEC) in complex with the mouse Vβ8.1 chain (49, 50). Although highly homologous superantigens, such as SEB, SEC, and SpeA, may have similar architectures for their Vβ chain interactions, the β-chain-SpeC complex involved a significantly larger contact surface, a different orientation, and contacts with the complementarity determining region (CDR) 3 loop, whereas SEB, SEC, and SpeA had no intermolecular

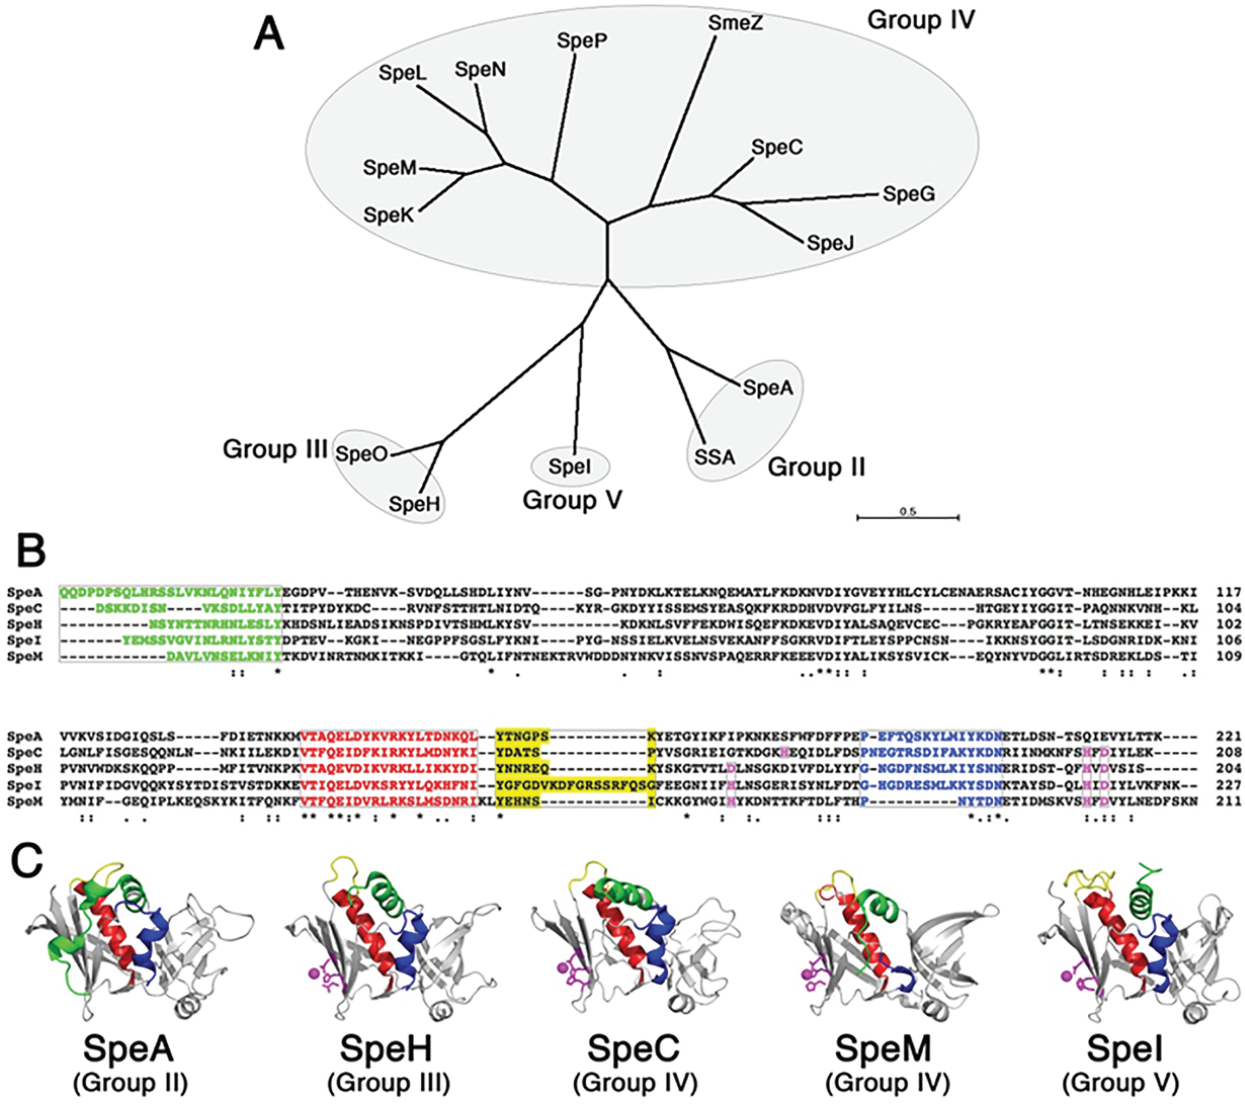

FIGURE 1 Phylogenetic relationships and structural conservation of the streptococcal superantigens. (A) Unrooted neighbor-joining tree showing phylogenetic relationships of known streptococcal superantigens. The unrooted tree was based on the alignment of amino acid sequences using CLUSTAL W (166) and constructed using MEGA7 (167). The groups indicate a prior classification scheme for the superantigen family (32). (B) Amino acid alignment of five representative streptococcal superantigens. The colors designate distinct domains in the superantigen structure, including the N-terminal α-helix (green), the central α-helix (red), the α3-β8 loop that is unique to the group V superantigens (168), and a C-terminal α-helix that is lacking in a subgroup of group IV. Residues involved in the coordination of a zinc atom important for binding to the MHC class II β-chain are colored magenta. (C) Crystal structures of representative streptococcal superantigens are colored as in panel B.

contacts with this loop (48). Nevertheless, it appears that the critical component for functional recognition of the TCR is the CDR 2 loop of the β-chain (51).

The interaction of superantigens with MHC class II can also show considerable diversity, because superantigens have two independent binding domains. One binding face occurs through the N-terminal oligosaccharide/oligonucleotide binding fold domain and is of relatively low affinity ($\sim 10^{-5}$ M). Although somewhat controversial (52–55), it appears likely that most, if not all, streptococcal superantigens contain this low-affinity MHC binding domain. A second, zinc-dependent MHC binding face occurs on the β-grasp domain and is of relatively high affinity ($\sim 10^{-7}$). The zinc ion, shown in magenta in Fig. 1C, is coordinated through three conserved residues, whereas the fourth ligand is from a conserved residue on the MHC β-chain.

Figure 2 presents the complexes for a conventional TCR-MHC class II interaction, as well as how SpeA (which lacks a high-affinity MHC class II binding domain) likely engages TCR Vβ and MHC class II and SpeC, which crosslinks MHC class II (56). The SpeA model is analogous to the standard "wedge" model of superantigen-mediated T cell activation (49), whereas the SpeC model is analogous to the proposed model for staphylococcal enterotoxin A (57, 58). In these models, the mechanism by which superantigens subvert the normal T cell activation process is apparent, whereby the

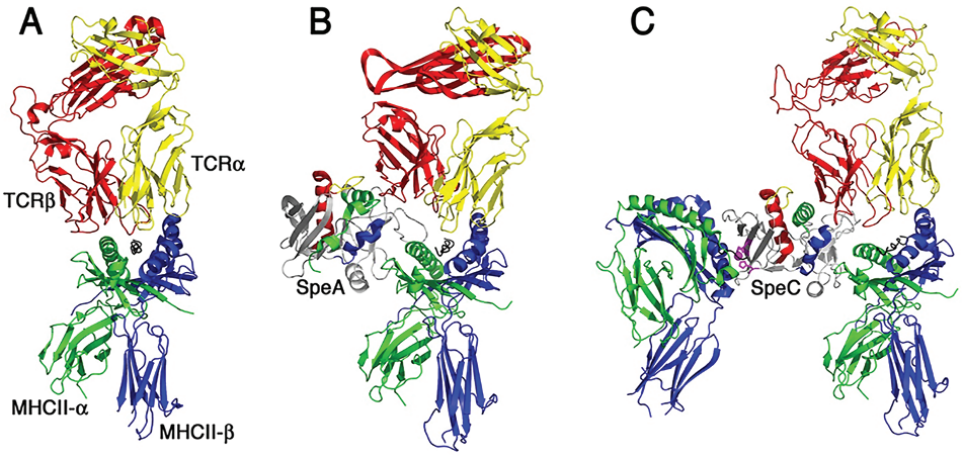

FIGURE 2 Models of T cell activation complexes for streptococcal superantigens. Ribbon diagrams demonstrating typical antigen-mediated T cell activation (A) and modeled T cell activation complexes for SpeA (B) and SpeC (C). The cocrystal structures of SpeA and SpeC in complex with their respective TCR β-chains (48) and of SpeC in complex with the MHC class II through the zinc-dependent high-affinity binding domain have been determined (169). SpeC also activates T cells in a mode similar to the staphylococcal enterotoxin A model (58) where SpeC engages MHC class II α-chain through a generic low-affinity binding domain (170) and engages the MHC class II β-chain through a zinc-dependent, high-affinity binding domain (169). The binding architecture for the generic low-affinity MHC class II binding to SpeA and SpeC is modeled using the staphylococcal enterotoxin B-MHC class II cocrystal structure (171). Note the presence of the zinc ion (magenta) coordinated in the high-affinity binding site for SpeC and that SpeA lacks this zinc site. The TCR α-chain (shown in gray) for both the SpeA and SpeC diagrams is modeled for clarity by superimposition of the α/β TCR shown on the left of the respective TCR β-chains for both superantigens. The figure was generated using Pymol.

antigenic peptide is displaced from the TC, and the specificity of the reaction is governed by superantigen recognition of the Vβ CDR2 loop (51).

Since early in the past century, the incidence of serious streptococcal disease greatly decreased, likely owing to the widespread use of antibiotics (59). However, it was not until the late 1980s that descriptions of well-defined cases led to the recognition of a severely toxic streptococcal superantigen-mediated disease called streptococcal TSS (60, 61). Indeed, since the mid-1980s there has been a sustained resurgence in the frequency and severity of streptococcal TSS and other invasive diseases caused by group A streptococci (62–64). This led to the hypotheses that there was an emergence of an excessively virulent strain or strains or, alternatively, that there had been major changes in host susceptibility to these infections. Indeed, many of the contemporary invasive infections have been attributed to the M1T1 clone (62), which is now recognized to have acquired an $SpeA_2$- and DNAse-encoding bacteriophage, as well as a horizontally acquired region encoding the SLO and SPN, likely from an M12 serotype (65). These acquisitions increase the virulence of this clone (66). Over the past decade, there has also been a dramatic resurgence in scarlet fever in mainland China and Hong Kong, South Korea, the United Kingdom, and Germany (67–70). Although it is not yet entirely clear, these large-scale outbreaks are likely linked to the acquisition of superantigen-producing bacteriophage elements in *S. pyogenes* (71–73).

Multiple lines of experimental evidence indicate that the streptococcal superantigens are significant virulence factors for severe streptococcal disease. The prototypical streptococcal superantigens are SpeA and SpeC, and these two toxins have been recognized as the likely causative agents in most cases of streptococcal TSS (61, 62, 74). Indeed, SpeA and SpeC are produced by many *S. pyogenes* strains isolated from patients with streptococcal TSS (29, 74–78). Due to the association of SpeA and SpeC with streptococcal TSS, two toxoid vaccines have been generated for these toxins that, when used in the rabbit model of TSS, provided complete protection to lethal quantities of the respective superantigen (53, 79). There are at least six naturally occurring alleles of *speA* (80, 81), and serotype M1 and M3 strains expressing the $speA_2$ and $speA_3$ alleles caused the majority of streptococcal TSS in the 1980s (81). Of the streptococcal superantigens that have been tested, the toxins share the properties of inducing fever (pyrogenicity) and lethal shock in the rabbit model. For example, recombinant SpeA, SpeC, and SpeJ can induce symptoms of streptococcal TSS without necrotizing fasciitis/myositis in this model (53, 79, 82), and SpeA administered to rabbits as a vaccine also conferred significant protection from TSS with necrotizing fasciitis/myositis after challenge with viable M1 and M3 streptococci (64). Circulating superantigens have also been found in patients with streptococcal TSS (83), and the lack of humoral immunity to the superantigens is a risk factor for the development of streptococcal TSS (84, 85).

Although significant immunological research with bacterial superantigens has been conducted in mouse models, conventional mice are no longer considered appropriate models to evaluate the biological effects of these toxins. Lethal effects are not seen at very high relative doses without the coadministration of a liver-damaging agent, whereas the rabbit model is susceptible to fairly low doses when administered continuously (86). It has further been demonstrated that HLA-DQ transgenic mice were more susceptible to SpeA-induced lethality whether administered as a pure toxin or during infection with $SpeA^+$ *S. pyogenes*, whereas nontransgenic mice

Downloaded From Vet-eBooks.com

did not show an obvious effect (87, 88). Consistent with this, it has been established that in humans, MHC class II allelic variation contributes to the differences in severity seen for invasive streptococcal infections (89). This is understood to be due to differential cytokine production triggered by streptococcal superantigens, and MHC class II α-chain polymorphisms affect superantigen responses (90, 91). Recently, using infection models with transgenic mice expressing human MHC class II alleles, we demonstrated that the SpeA superantigen is a critical bacterial factor that is necessary to induce an acute nasopharyngeal infection (92). Using this model, SpeA was shown to activate specific Vβ-subsets *in vivo* (93), and strikingly, functional Vβ-specific T cell subsets were required for the infection phenotype (94). Furthermore, humoral immunity to the SpeA superantigen dramatically inhibited infection by *S. pyogenes* (92, 94). We believe that these findings support the further development of toxoid superantigens as vaccines to target the transmission and colonization by *S. pyogenes*.

STREPTOCOCCAL PYROGENIC EXOTOXIN B

SpeB is highly conserved in virtually all *S. pyogenes* isolates (95, 96), although despite its original name as a streptococcal pyrogenic exotoxin, SpeB is known to function as a broad-spectrum protease and is secreted as a 40-kDa zymogen. The pro-domain is auto-catalytically cleaved to generate an active 28-kDa proteinase (97, 98). Additionally, an SpeB inhibitor located downstream of *speB* is cotranscribed with the protease. The inhibitor, termed Spi, has sequence and predicted structural homology with the pro-domain of SpeB (99). The inhibitor is resistant to cleavage by active SpeB, making it an effective inhibitor of protease activity within the bacterial cytoplasm (99). Although SpeB is highly conserved across most *S. pyogenes* strains, its expression may vary depending on the type of infection (100). For example, when analyzing isolates from patients with pharyngitis, impetigo, invasive disease, or acute rheumatic fever, 40% of isolates from patients with acute rheumatic fever produced SpeB, compared to only 5.5% of isolates from impetigo patients (100). Therefore, the variability in SpeB expression suggests that SpeB is more important for certain forms of disease progression.

SpeB is considered an important virulence factor most likely due to the immunomodulating effects of its protease activity (101, 102). SpeB has broad proteolytic activity against a number of human proteins, including interleukin-1β (102), immunoglobulins (101), fibrinogen (103), fibronectin (104), kininogens (105), and a metalloprotease (106). Although SpeB has been shown to cleave certain immunoglobulins, a study investigating the cleavage of IgG under physiologic conditions found that IgG is only cleaved in a reduced form, whereas physiologic IgG is active in an oxidized form (107). Therefore, SpeB likely does not contribute to *S. pyogenes* pathogenesis through the cleavage of IgG. The innate host immune system is also weakened through proteolytic destruction of complement factors such as C3 and the membrane attack complex (108, 109). SpeB also has the capacity to cleave many human chemokines (110), further disrupting the immune response. In addition to the many immune modulating factors degraded by SpeB, the cysteine protease also degrades tight-junction proteins such as E-cadherin and desmogleins, facilitating the paracellular invasion of the bacteria across the epithelial barrier (111, 112). Therefore, the broad spectrum of SpeB targets likely ameliorates the virulence of *S. pyogenes* by perturbing the host immune system and compromising the epithelial barrier.

Given the broad spectrum of SpeB, *S. pyogenes* proteins can also be proteolyzed (113). SpeB can directly degrade multiple superantigens, such as SmeZ, which affects the ability of the superantigen to induce proliferation of human lymphocytes (114, 115). In addition, the cleavage of protein F1, an *S. pyogenes* cell wall-attached fibronectin-binding protein, decreased the fibronectin-dependent internalization of *S. pyogenes* into human cells, suggesting that SpeB also plays a role in the internalization process (116). Likewise, SpeB-deficient mutants were shown to have enhanced *in vitro* internalization into human epithelial and endothelial cells (117). Therefore, an inactive SpeB may be favored later during infection to promote the dissemination of the bacteria (116). Furthermore, earlier work identified a phase shift in an invasive M1T1 strain *in vivo* favoring a nonfunctional cysteine protease to conserve the function of the multiple virulence factors normally degraded by SpeB (118, 119). This phase shift is linked to inactivating mutations within the two-component CovRS sensor kinase, which results in a hypervirulent phenotype in the serotype M1 background (120). An inverse relationship has also been identified between SpeB expression and the severity of invasive group A streptococci infections, further suggesting that *S. pyogenes* may need to differentially regulate SpeB expression, depending on the site of infection and events occurring during infection (121).

In vivo studies supporting the role of SpeB as a virulence factor have not always been congruent. For example, an *S. pyogenes* strain with decreased SpeB expression exhibited a decreased capacity to cause murine necrotizing fasciitis, and complementation of SpeB restored the wild-type phenotype (122). Alternatively, isogenic gene replacement strains and a mouse model of invasive soft tissue infection showed that *speB* mutants had no apparent effect on the ability of group A streptococci to cause local tissue injury and invasive infection (123). Overall, the diversity of SpeB targets may contribute to the protease being both a virulence factor and a form of virulence regulation through the degradation of bacterial proteins.

DNases OF *S. PYOGENES*

The DNases of *S. pyogenes* constitute an additional mechanism that contributes to the pathogenicity of the bacterium. Through the analysis of all known *S. pyogenes* genomes, eight DNases have been identified (124): *spnA*, *spdB*, *sda1*, *sda2*, *spd1*, *spd3*, *spd4*, and *sdn*. Of the known DNases, *spnA* and *spdB* are chromosomally encoded and are found across all *S. pyogenes* isolates (125, 126). The six other DNases are prophage associated, and therefore they are only found in certain *S. pyogenes* strains (124). Furthermore, the DNase *spnA* is the only known cell wall-anchored DNase of *S. pyogenes* (124, 126).

DNases contribute to the pathogenesis of *S. pyogenes* by facilitating innate immune evasion of the pathogen. During infection, neutrophils release antibacterial granule proteins and chromatin to create neutrophil extracellular traps (NETs) (127). NETs bind and trap bacteria and degrade bacterial virulence factors, ultimately resulting in bacterial death (127). The secreted DNase Sda1 and the cell wall-anchored DNase SpnA are both able to degrade the chromatin backbone of NETs, allowing the bacteria to avoid the degradation of their virulence factors and promote bacterial survival (128–130). *S. pyogenes* DNases further contribute to pathogenesis through the degradation of bacterial DNA (131). By degrading CpG-rich bacterial DNA, the TLR9-mediated immune response is weakened due to the

Downloaded From Vet-eBooks.com

degradation of the TLR9 activating signal (131). In a model of mouse necrotizing fasciitis, Sda1 was shown to suppress TLR9-dependent tumor necrosis factor-α and tumor necrosis factor-α induction, promoting evasion of the innate immune system (131). Additionally, a murine model of skin and soft tissue and a cynomolgus macaque model of pharyngitis infection showed that isogenic mutants of *S. pyogenes* lacking DNase production were less virulent than the wild-type strain, highlighting their importance in pathogenesis (129). The ability of DNases to degrade NETs and bacterial DNA, along with the decreased virulence of DNase-deficient mutants *in vivo*, emphasize the importance of *S. pyogenes* DNases as extracellular virulence factors.

STREPTOCOCCAL INHIBITOR OF COMPLEMENT

The streptococcal inhibitor of complement (SIC) is a 31-kDa protein secreted by certain *S. pyogenes* strains, most notably M1 serotypes (132). SIC is highly variable, with large numbers of variants arising *in vivo* during epidemic spread of the organism (133, 134). Such high variation suggests that the phenomenon offers selective advantage to the microbe. Most of the variants are single amino acid changes, insertions, or deletions. Other M types may make related proteins, some of which have minimal effect on the complement system (135). SIC was originally identified as a protein that inhibits the membrane attack complex of the complement system, with its mechanism being the inhibition of C567 insertion into the membrane (136). Furthermore, SIC is rapidly internalized by neutrophils and binds specifically to ezrin and moesin, proteins that link the actin cytoskeleton to the host cell surface, interfering with polymorphonuclear opsonophagocytosis and intracellular killing (136). SIC also directly inhibits other components of the innate immune system, including lysozyme, secretory leukocyte proteinase inhibitor, human defensins, and cathelicidin LL-37, all of which can be toxic to *S. pyogenes* (137–140). Additionally, SIC inhibits the release of bradykinin, a potent vasodilator, which could function to decrease inflammation at the site of infection, allowing the bacteria to persist (141). More recently, SIC also inhibited the bactericidal activity of histones, which are found in NETs (142).

In vivo studies suggest that SIC increases streptococcal virulence. Mice that were inoculated intranasally with M1 SIC-negative streptococci had a lower incidence of throat colonization than mice inoculated with the wild-type M1 strain (143). SIC-negative strains also exhibited a decrease in survival in macrophages (137). Therefore, SIC likely promotes bacterial survival and dissemination by allowing the organisms to avoid innate immune defenses in the extracellular environment.

IgG-TARGETING ENZYMES OF *S. PYOGENES*

S. pyogenes has evolved multiple mechanisms to target IgG antibodies, a major effector molecule of the humoral immune system. The immunoglobulin G-degrading enzyme (IdeS, also known as Mac) is a protease that removes the Fc region of IgG antibodies and can thus inhibit opsonophagocytosis of *S. pyogenes* (144, 145). This virulence factor is specific for IgG and does not target IgM, IgE, or IgD antibodies (144). However, *in vivo* studies using a mouse invasive infection model failed to demonstrate a contribution of IdeS to virulence (146). Endoglycosidase S (EndoS) is an ~108-kDa secreted enzyme that hydrolyzes the β-1,4 linkage between the first two *N*-acetylglucosamine residues on the glycan linked to Asn297 within the C_H2 domain of the IgG Fc region (147). Deglycosylation of IgG through this mechanism impairs antibody effector functions, including binding to the Fc-gamma receptor and complement activation (148). Nevertheless, similar to IdeS, deletion of the gene encoding EndoS in the M1 5448 background had no obvious phenotype in an invasive intraperitoneal mouse infection model (149). In both cases, the lack of an *in vivo* phenotype may reflect a more subtle role for these enzymes that is not apparent through acute, invasive infections. In addition to EndoS and IdeS, which show high levels of specificity for IgG, the broad-spectrum SpeB cysteine protease is also capable of cleaving IgG in the hinge region, similar to protease papain (147); however, the *in vivo* relevance of this has been questioned (107).

STREPTOKINASE

Streptokinase is a single-chain 414-amino acid protein that is able to activate the host protein plasminogen (150). Streptokinase forms a complex with the inactive zymogen plasminogen, or a trimolecular complex with plasminogen and fibrinogen, to generate the active serine protease plasmin (151, 152). These activator complexes bind to the bacterial surface, allowing the bacteria to acquire additional protease activity. Plasmin is responsible for degrading fibrin clots, connective tissue, extracellular matrix components, and adhesion proteins (153). Therefore, the improper activation of plasmin could result in widespread tissue damage and dissemination of the bacteria (154, 155). Transgenic mice expressing human plasminogen had an increased mortality rate compared to mice without the transgene. This susceptibility was directly related to streptokinase expression, highlighting the importance of streptokinase in *S. pyogenes* virulence (154). Furthermore, increased levels of bacteria-bound plasmin correlated with a decrease in C3b deposition and a decrease in C3b-mediated neutrophil killing (156). Additionally, bacteria-associated plasmin has been shown to prevent histone-mediated killing by NETs (157). In addition to activating plasminogen, streptokinase has also been shown to activate the contact system, resulting in the release of bradykinin (158). The release of bradykinin triggers vascular leakage, which could further promote the dissemination of the bacteria (159, 160). The release of streptokinase by *S. pyogenes* ultimately promotes the dissemination of the bacteria by facilitating the conversion of plasminogen to plasmin.

FUTURE PERSPECTIVES

The increased incidence of severe invasive group A streptococcal diseases, and the recent resurgence of scarlet fever, still remain incompletely explained; however, the streptococcal superantigens are clearly implicated in both illnesses and thus are key virulence factors driving the evolution of *S. pyogenes* pathogenesis. Indeed, the majority of genetic diversity in different strains and serotypes of *S. pyogenes* occurs due to the presence or absence of large mobile genetic elements, including lysogenic bacteriophage and integrative conjugative elements (161, 162). In particular, many of the superantigens, as well as DNases, and some other select toxins are encoded within bacteriophage elements, and this provides *S. pyogenes* with an extra level of adaptability. The apparent excessive redundancy of these toxins has yet to be explained, although we believe this allows *S. pyogenes* to avoid neutralizing antisuperantigen antibodies and may also provide additional means to efficiently target polymorphic MHC class II molecules from different populations.

Downloaded From Vet-eBooks.com

Although most research on streptococcal exotoxins has focused on their role in severe streptococcal diseases, the established niche for *S. pyogenes* is a state of colonization in the throat or on the skin of humans. Also, multiple *S. pyogenes* virulence factors do not operate efficiently in mouse models (92, 154, 163–165). To understand the basic biology of this organism, which is not related to severe and invasive disease, better models will be necessary to evaluate specific virulence factors, therapies, and vaccines. Thus, most, if not all, of these remarkable exotoxins that can alter normal immune system function, damage tissue, and promote disease have each likely evolved in the context of streptococcal persistence and transmission. We hope a clearer understanding will lead to further rationales to design vaccines capable of targeting the colonization state of *S. pyogenes*.

Genetics of Group A Streptococci

KYU HONG CHO, GARY C. PORT AND MICHAEL CAPARON

6

INTRODUCTION

Streptococcus pyogenes (the group A streptococcus) is remarkable in terms of the large number of very different diseases it can cause in humans. These range from superficial and self-limiting diseases of the pharynx (e.g., pharyngitis, commonly known as strep throat) and skin (impetigo) to infections that involve increasingly deeper layers of tissue and are associated with increasing degrees of destruction of tissue (e.g., erysipelas, cellulitis, necrotizing fasciitis, and myositis). The organism has the ability to spread rapidly through tissue and to penetrate into the vasculature to cause lethal sepsis. Other diseases result from the production of toxins that spread through tissue or spread systemically from a site of local infection (scarlet fever and toxic shock syndrome). Still other diseases are the result of an immunopathological response on the part of the host that is triggered by a streptococcal infection. These diseases include rheumatic fever, acute glomerulonephritis, certain types of psoriasis, and potentially even some forms of obsessive-compulsive syndrome disorder (pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections).

S. pyogenes is even more remarkable in terms of the large number of factors that have been identified as potential virulence determinants for these various diseases. These include surface proteins (M proteins, fibronectin-binding proteins, surface dehydrogenases, C5a peptidase), the hyaluronic acid capsule, secreted degradative enzymes (several distinct DNases, a cysteine protease, NAD^+-glycohydrolase, hyaluronidases,) and many secreted toxins (streptolysin S, streptolysin O, the pyrogenic exotoxins, streptococcal superantigens, streptokinase). This is only a partial list of the potential virulence factors this bacterium can produce, and many of these are considered in more detail elsewhere.

Until recently, the function that any of these potential virulence factors contributed to the pathogenesis of any specific streptococcal disease was only poorly understood. A major reason for this deficiency was the lack of sophisticated genetic systems that could be applied to the analysis of a specific virulence factor according to modern molecular criteria. These criteria were succinctly outlined by Falkow in his "Molecular Koch's Postulates" (1). These state that (i) the phenotype under investigation should be associated with pathogenic members of a species, (ii) the gene(s) associated with the virulence trait should be identified and isolated by molecular methods, (iii) specific inactivation of identified gene(s) should lead to a measurable loss in pathogenicity, and (iv) reintroduction of the unmodified wild-type gene should lead to a restoration of pathogenicity. An exciting development is that, over the past several decades, the work of many groups has contributed to the development of sophisticated group A streptococcal genetic systems that now allow the many diseases that this organism can cause to be studied at this level of molecular resolution. The modern *S. pyogenes* genetic modification systems are supported by the numerous complete genome sequences now available. Since the first complete genome sequence of an *S. pyogenes* strain in 2001 (2), 61 complete genome sequences and approximately 300 draft sequences have been deposited as of March 2018 (3). The average *S. pyogenes* genome is approximately 1.85 Mb and encodes ~1,800 genes, the function of many of which remains to be elucidated (4). The other major advance has been in the development of a variety of genetic tools aimed at manipulating the *S. pyogenes* genome. The goal of this article is to present an overview of these tools, including the methods of genetic modification and their applications.

GENETIC EXCHANGE

Transduction

A key element of any genetic system involves some system of genetic exchange between bacterial hosts, allowing the construction of an altered genome in the target host which can then be subjected to an analysis of its virulence phenotypes. Unlike several other species of streptococci, the group A streptococci are not naturally competent for the uptake of exogenous DNA, even though their genomes encode many of the genes required for transformation (see below). Conjugative DNA transfer does occur in group A streptococci; however, this is restricted to the transfer of conjugative plasmids and conjugative transposons (see below), and there is no evidence of mobilization of chromosomal markers. There is also no evidence that any important virulence traits are encoded by these types of mobile elements, although they are undoubtedly important in the transmission of resistance to various antibiotics.

Even though there is no evidence to support genetic exchange by transformation or by conjugation, analysis of several polymorphic loci, most notably the genes which encode the M proteins and the fibronectin- and collagen-binding proteins and T antigen (FCT)/pilus region have provided considerable evidence of horizontal transfer of

doi:10.1128/microbiolspec.GPP3-0056-2018

Downloaded From Vet-eBooks.com

genetic material among natural populations of *S. pyogenes* (5). In this regard, considerable attention has been focused on the contribution of phage to genetic transfer (5). *S. pyogenes* strains are rich in phage, and several of these have been demonstrated to encode virulence factors, including the pyrogenic exotoxins SPE-A and SPE-C (6). Thus, it is not surprising that transduction was the first mechanism of genetic exchange that was exploited in the manipulation of the *S. pyogenes* genome (7). The most highly developed of these are derivatives of phage A25. This lytic phage is classified as a Bradley group B phage that recognizes the peptidoglycan of groups A, C, and G streptococci as its cellular receptor. It has a 35-kb double-stranded genome with circular permutation and terminal repetition (8), and it is proficient in transducing markers *in vitro* (for a detailed description of a method of transduction, see reference 9). The most useful derivatives of A25 for use in transduction are those developed by Malke and colleagues, who constructed a derivative with two distinct temperature-sensitive lesions ($A25_{ts1\text{-}2}$) that becomes defective for growth at 37°C (10). This feature is useful for transduction, since it allows the production of a transducing lysate of the donor host at the permissive temperature (30°C) but prevents the killing of transduced hosts when infection is performed at the nonpermissive temperature. The A25 phage was used in some of the first mutagenesis studies in group A streptococci, including the original identification of Mga, the master regulator of M protein (7). In spite of the early use of this method, genetic manipulation via phage transduction is inherently limited in application since it requires preexisting antibiotic resistance markers within or near genes of interest. Additionally, some phage possess narrow host specificities, thereby limiting their utility to only a few strains. Furthermore, phage transduction can be laborious. Fortunately, simpler and more rapid genetic engineering methods, including electroporation of shuttle plasmids and saturating transposon mutagenesis, have largely replaced phage transduction (see below).

Transformation

One of the most significant advances in genetic technology for *S. pyogenes* has been the development of methods for transformation. This has allowed the introduction of heterologous DNA into an *S. pyogenes* host and has opened the door to a large number of techniques for mutagenesis and allelic exchange that are described in greater detail below. The breakthrough technology that began the era of transformation for *S. pyogenes* was the introduction by several companies of reasonably priced instruments for the introduction of DNA by electroporation. As is true for most methods of transformation, success with electroporation-based transformation results from careful attention to growth conditions. Electroporation of streptococci generally requires that the cell walls be weakened. Most successful methods have adapted the techniques originally developed by Dunny and colleagues for electroporation of the enterococci (11). This method uses cells from the early exponential stages of growth in medium supplemented with glycine. The addition of glycine is thought to contribute to a decreased level of cross-linking in the cell wall, and the exact stage of growth and concentration of glycine is determined empirically (for a detailed description of the method, see references 9, 12–14).

It is of interest to note that the genomic sequences of several *S. pyogenes* strains of the M1, M3, and M5 serotypes have revealed that while they have genes required for DNA uptake by natural transformation and that while these genes are expressed in response to a peptide pheromone, they remain nontransformable (15). In addition, a cluster of genes associated with the ability to cause disseminated infection, called the Sil locus, contains genes highly homologous to the *comAB* competence locus (16). To date, the Sil genes have only been found among serotype M14 and M18 strains, and since their G+C content is markedly lower than the rest of the *S. pyogenes* chromosome, they may have been more recently acquired by these lineages from horizontal transmission (17).

Plasmid Technology

The development of efficient transformation systems has allowed for the rapid genetic modification of *S. pyogenes* hosts through the introduction of plasmids into *S. pyogenes*. Applications include (i) construction of chromosomal allelic replacements, gene deletions, and site-specific mutations; (ii) complementation of chromosomal mutations *in trans*; (iii) analysis of reporter gene expression; and (iv) delivery of transposable elements to construct random mutant libraries for forward genetic screens. Common Gram-negative plasmid replicons (including pUC, pBR322, and pSC101) are unable to replicate in Gram-positive species and can therefore serve as "suicide" delivery vectors for transposon delivery or recombination-based chromosomal integrative elements (see below). Also, many of the plasmids which have proven useful for genetic analysis in other Gram-positive species, including pC194, pE194, and pUB110, appear unable to replicate reliably in *S. pyogenes*. Fortunately, a handful of plasmids have been identified that do replicate in *S. pyogenes*, and these plasmids have been engineered over the past 20 years to give rise to a growing set of tools aimed at manipulating the *S. pyogenes* chromosome (Table 1).

The most widely used plasmid for *S. pyogenes* genome engineering is derived from pWV01 (18). This plasmid was isolated from a lactococcal species and is the prototype member of a family of "promiscuous replicons" that have the remarkable property that they can replicate in both Gram-negative (e.g., *Escherichia coli*) and Gram-positive (e.g., *S. pyogenes*) hosts. pWV01 replicates using a rolling-circle type mechanism characteristic of many single-stranded bacteriophages and likely exists in a single-stranded conformation for extended periods of time in replicating cells. This can have consequences for plasmid structural integrity, segregation instability, and expression of open reading frames inserted for complementation or ectopic or orthogonal expression (19). Common derivatives of pWV01 include plasmids such as pABG5 (Fig. 1), which include an *S. pyogenes* promoter for ectopic or orthogonal expression (20), and the high-copy variant pBAV1kT5, which lacks a set of inverted repeats and an open reading frame thought to be responsible for copy number regulation (21). A versatile and widely used derivative of pWV01 known as pG+host4 was developed by Maguin and coworkers to contain a temperature-sensitive (ts) replicon (22). The plasmid contains four amino acid substitutions in the RepA protein, which is responsible for nicking one DNA strand at the plus origin to initiate replication, thus rendering the process temperature sensitive. Subsequent derivatives of this plasmid include pJRS233 (23) and pGCP213 (24), which add low copy (pSC101) or high copy (ColE1/pUC) thermo-stable Gram-negative replication origins, respectively, to facilitate various applications for subcloning and plasmid propagation in *E. coli*. In addition, pGCP213 includes a full-length gene encoding LacZ containing the multiple cloning site from pCR2.1 (Invitrogen), allowing for blue/white screening of insertions via

TABLE 1 Common plasmids utilized for *S. pyogenes* genome engineering

Capability	Name	Ori G+/G–	Ab cassette(s)	Features	Reference(s)
Site-directed mutagenesis	pJRS233	pWV01 ts/pSC101	*erm*C	Low copy (*E. coli*) thermosensitive shuttle vector	23
	pGCP213	pWV01 ts/pUC (pBR322)	*erm*C	High copy (*E. coli*) thermosensitive shuttle vector	24
	pCRK	pWV01 ts/pUC (pBR322)	*aphA3*	High copy (*E. coli*) thermosensitive shuttle vector	25
	pCRS	pWV01 ts/pUC (pBR322)	*aad9*	High copy (*E. coli*) thermosensitive shuttle vector	25
	pHY304	pWV01 ts/NA	*erm*C	Thermosensitive vector, must be grown at 30°C	111
	pSinS/pHlpK	pCRS (ΔrepA) pCRK (ΔpUC)	*aad9*/*aphA3*	Conditional suicide plasmid pSin stabilized by temperature-sensitive helper plasmid	42
Complementation	pABG5	pWV01/NA	*aphA3*/*cat*A	Thermostable shuttle vector, ProfA promoter	20
	p7INT, p7INT[a] (pGCP365)	NA/pUC (pBR322)	*erm*C	Integrates into prophage tmRNA attB site	33
	pEU7742	pAMβ1/NA	*aad9*	Single copy with toxin/antitoxin, contains theophylline-inducible riboswitch and *gusA* reporter	32
	pGCP189	pWV01 ts/pSC101	*erm*C	Insert gene of interest downstream of GuaB in synthetic polycistron	45
Transposon	pMGC57-TnErm	NA/pHSG396 (pBR322)	*cat*A/*erm*C (for Tn)	Tn*4001*	80
	EZ-Tn*5*	NA/NA	*erm*C	Tn*5*	43
	pOSKAR	pWV01 ts/pUC (pBR322)	*aad9*/*aphA3* (for Tn)	Mariner Kan-Tn flanked by T7 For microarrary TraSH	25
	pKRMIT	pWV01 ts/pUC (pBR322)	*aad9*/*aphA3* (for Tn)	Mariner Kan-Tn flanked by MmeI For TnSeq	42
Reporter	pGCP070	pWVO1/NA	*aphA3*/*cat*A	TetR inducible sfGFP	100
	pWAR303	pWV01	*erm*C	Luciferase LuxAB	112

[a]Common antibiotic markers used in group A streptococcus mutagenesis include *aad9* (spectinomycin resistance, Sp^r), *cat*A (chloramphenicol resistance, Cm^r), *aphA3* (kanamycin resistance, Km^r) and *ermC* (erythromycin resistance, Em^r). Because group A streptococcus remains sensitive to penicillin and is a preferred clinical treatment, the use of β-lactamase for selection during group A streptococcus mutagenesis is both unethical and prohibited.

α-complementation in *E. coli*. Plasmids pCRS and pCRK are similar to pGCP213, differing primarily in their antibiotic resistance cassettes (25). The modifications to the standard electro-transformation conditions described by Scott's group greatly increase the transformation efficiency of these ts plasmids (23). The main application of the pG+host-derived ts plasmids has been in the construction of in-frame deletions and allelic replacement to introduce site-specific mutations of chromosomally encoded genes and in the delivery of transposable elements for mutagenesis (see below).

These plasmid-based methodologies can be adapted for functional studies to validate the contribution a given gene confers to a given phenotype via expression in a heterologous host. The heterologous host can be an *S. pyogenes* strain which naturally lacks the phenotype under investigation or can be another streptococcal or enterococcal species. In one of the first examples of this strategy, Scott and Fischetti's group introduced a copy of the gene which encodes the M6.1 protein (*emm6.1*) on a mobilizable plasmid vector, used this to transform a naturally competent streptococcal species, and then mobilized the plasmid by conjugation into an *emm*-deficient *S. pyogenes* host (26). Analysis of the resulting strain demonstrated that the introduction of *emm6.1* converted the host strain from being sensitive to killing in a bactericidal assay to being resistant to killing in the assay. This study was the first formal application of Falkow's molecular Koch's postulates to *S. pyogenes* pathogenesis (26). Additional applications of this approach have included the demonstration that protein F is sufficient to confer a fibronectin-binding phenotype to non-fibronectin-binding *S. pyogenes* and enterococcal hosts (27) and that the *has* operon is sufficient to confer the ability to produce hyaluronate to both acapsular *S. pyogenes* and enterococcal hosts (28).

The second class of commonly used vectors in *S. pyogenes* was based on the low-copy pAMβ1 replicon originally isolated from *Enterococcus faecalis* (29). Unlike pWV01, the pAMβ1 replicon cannot replicate in *E. coli*, so derivatives have been engineered to contain an origin of replication that is proficient in an *E. coli* host (19). The plasmid pAT28 developed by Courvalin's group (30) is typical of the pAMβ1-derived vectors and contains the high-copy pUC replicon derived from ColE1 for replication in *E. coli* and several other useful features including the multiple cloning site and the *lacZα* reporter gene of pUC18,

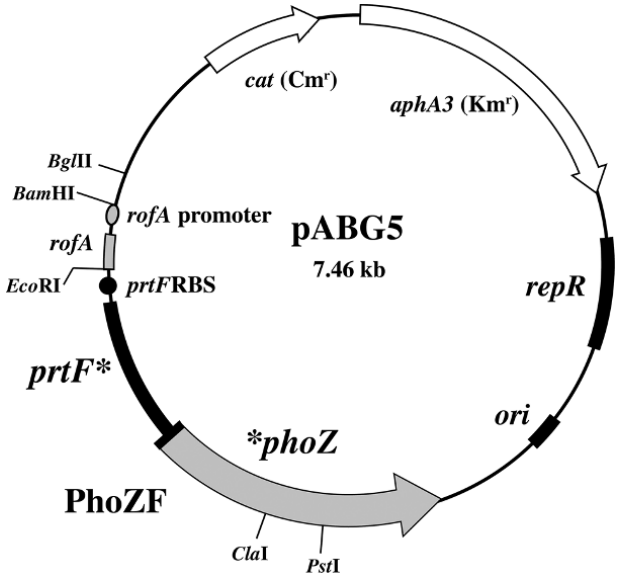

FIGURE 1 A chimeric secreted alkaline phosphatase reporter gene. The plasmid pABG5 is a pWV01-based *E. coli*-streptococcal shuttle vector which encodes resistance to chloramphenicol (*cat*) and kanamycin (*aphA3*). The plasmid contains a promoterless reporter gene formed by the fusion of the N-terminal region of the cell wall-associated protein F (*prtF**) to the enzymatic domain of the enterococcal alkaline phosphatase (**phoZ*). Since the chimeric protein (secreted protein F-PhoZ reporter, or PhoZF) lacks the C-terminal cell wall attachment domain of protein F and the N-terminal lipoprotein tethering domain of PhoZ, it is freely secreted from the cell. The PhoZF chimera retains the enzymatic activity of PhoZ and can be easily quantitated in culture supernatants. Restriction sites for *Bgl*II or *Bam*HI and *Eco*RI can be used to place the promoter of interest in an orientation to direct transcription of *phoZF*, which is then translated using the ribosome-binding site of *prtF* (RBS). Insertion of an open reading frame of interest between the *Eco*RI and either the *Cla*I or *Pst*I site places the open reading frame under the control of the strong *rofA* promoter for ectopic expression and/or complementation analyses.

which allows screening for insertion of cloned DNA by α-complementation in *E. coli* (30). In contrast to the rolling circle replication of pWV01, pAMβ1 replicates via a double-stranded θ-type mechanism which typically leads to greater plasmid stability. Also, as a general rule, pWV01-based vectors transform *S. pyogenes* at a much higher efficiency than do pAMβ1-derived vectors. Because of their different modes of replication, this difference may involve how the restriction system of *S. pyogenes* recognizes the two plasmids. However, it should be noted that very little is currently understood about restriction in *S. pyogenes* and that, in general, it has not posed a significant barrier to the introduction of DNA purified from any number of different *E. coli* K12 hosts. Despite its lower transformation efficiency, the pAMβ1-derived vectors have proven very useful in obtaining expression of cloned genes that were only poorly expressed by pWV01-based vectors (31). A useful derivative of pAMβ1 is pEU7742 (32), which includes a toxin-antitoxin cassette (axe-txe) from an *Enterococcus faecium* plasmid for enhanced plasmid stability.

An alternative to using replicating plasmids for expression of heterologous genes or genes *in trans* is the vector system known as p7INT, which contains an *E. coli* origin of replicon to facilitate manipulation in *E. coli*, along with the integrase gene (*int*) and attachment site (*attP*) from the T12 temperate bacteriophage of *S. pyogenes* (33) (Fig. 2). Following its introduction into *S. pyogenes*, *int* catalyzes the site-specific recombination of the entire circular molecule into the chromosomal phage T12 attachment site (*attB*) located at the 3′ end of the transfer-messenger RNA gene (33) by a mechanism resembling integration of lambda phage (34). Because the plasmid lacks the phage excisionase, integration is highly stable. Derivatives of p7INT have been used to study Rgg-dependent gene regulation through use of a *luxAB* luciferase-based reporter system (35). It should be noted that integration of p7INT is strain specific, because two alleles of transfer-messenger RNA (tmRNA) exist among the published sequences, which are distinguished by a single nucleotide polymorphism in *attB*. Common strains, including NZ131 and HSC5, have an *attB* site compatible for p7INT integration, while others, including JRS4, have an incompatible site. However, p7INT can be modified by a single base change, generating p7INT*, which can integrate into the alternative *attB* site (G.C. Port and M.G. Caparon, unpublished) (Fig. 2).

DIRECTED MUTAGENESIS

The techniques developed for directed mutagenesis (reverse genetics) in *S. pyogenes* have proven invaluable for the analysis of the contributions that specific genes make to pathogenesis. In this approach, a defined mutation is constructed to inactivate, or in some cases modify, a specific gene to construct an isogenic mutant strain for analysis. These techniques have become particularly useful with the availability of the complete or draft genome sequences of *S. pyogenes* (3). In the following, we consider methods to alter or inactivate a targeted gene on the *S. pyogenes* chromosome using (i) allelic replacement using linear DNA, (ii) directed insertional integration, and (iii) construction of in-frame deletion alleles.

Allelic Replacement Using Linear DNA

This method of mutagenesis is straightforward and involves first cloning the gene of interest into any suitable plasmid vector in *E. coli*. With the available genome information, this has become a simple task of analyzing the sequence and designing suitable primers for PCR amplification, followed by insertion of the amplification product into an *E. coli* cloning vector. As a general rule, *S. pyogenes* DNA is most stable when cloned on low-copy vectors in *E. coli*, and several vectors have been used with great success. The standard PCR methodology is then used to insert a selectable marker into the open reading frame to inactivate it. The markers that have been most successful are those derived from Gram-positive organisms that can also be used for selection in *E. coli* and include *erm*C (resistance to erythromycin; GenBank accession no. NG_047805.1), *aphA3* (resistance to kanamycin; GenBank accession no. V01547.1), *tet*M (resistance to tetracycline; GenBank accession no. X92947.2), *aad*9 (resistance to spectinomycin; GenBank accession no. M69221.1), and *cat*A (resistance to chloramphenicol; GenBank accession no. NG_047564.1). It should be noted that because resistance to β-lactam antibiotics does not naturally exist among clinical *S. pyogenes* isolates, for ethical reasons, genes encoding any type of β-lactamase must not be used for this application. Strong polar mutations can be introduced through the use of dedicated insertional mutagenesis cassettes,

Downloaded From Vet-eBooks.com

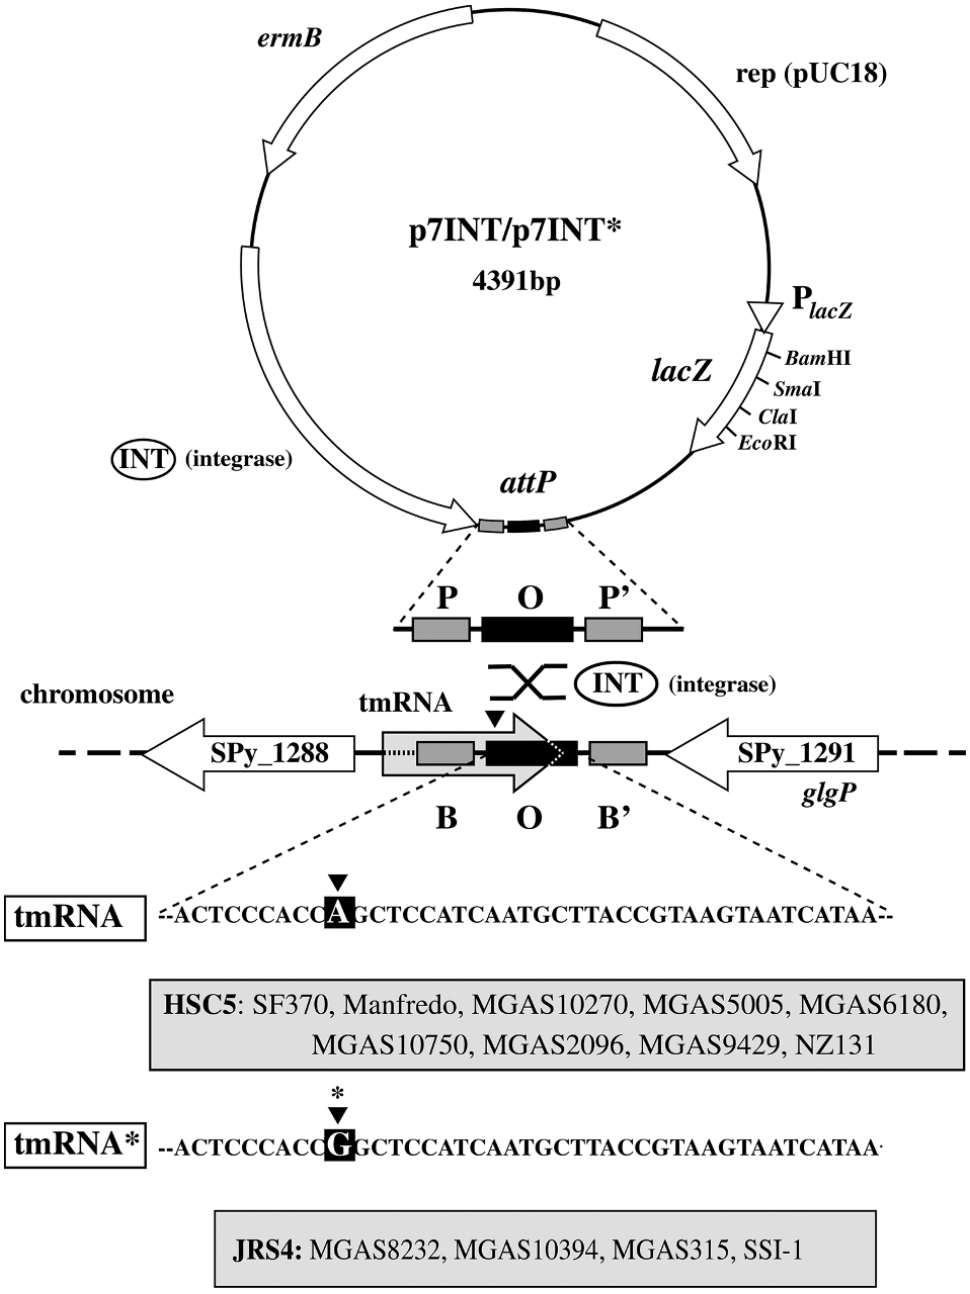

FIGURE 2 p7INT and p7INT*. The plasmids p7INT and p7INT* are pUC18-based *E. coli* vectors that encode resistance to erythromycin (*erm*). Restriction sites for *Bam*HI, *ClaI*, *SmaI*, and *Eco*RI within *lacZ* can be used to insert any promoter and gene of interest for ectopic expression and/or complementation analyses. The plasmids also contain a phage integrase (INT) and an *attP* sequence which targets integration into the *S. pyogenes* chromosome at the 3′ end of the tmRNA locus within the 96-bp "O" site of POP′ and BOB′ of *attP* and *attB*, respectively. With respect to O sites, *S. pyogenes* has been found to contain one of two alleles with either an A or G (see text). Plasmid p7INT contains an A, whereas p7INT* has been mutated to contain a G, and the appropriate plasmid must be used depending on the allele found within the *S. pyogenes* strain of interest. Following introduction of the appropriate plasmid into *S. pyogenes*, selection for the antibiotic-resistant determinant of the plasmid (*erm*) selects for chromosomes in which the plasmid has integrated into the chromosome at the *attB* site. The distribution of tmRNA and tmRNA* between a selection of commonly used strains is shown, with GenBank accession numbers as follows: HSC5, CP006366.1; SF370, AE004092.2; Manfredo, AM295007.1; MGAS10270, CP000260.1; MGAS5005, CP000017.2; MGAS6180, CP000056.1; MGAS10750, CP000262.1; MGAS2096, CP000261.1; MGAS9429, CP000259.1; NZ131, CP000829.1; JRS4, CP011414.1; MGAS8232, AE009949.1; MGAS10394, CP000003.1; MAGS315, AE014074.1; SSI-1, BA000034.2.

Downloaded From Vet-eBooks.com

such as the Omega interposon (ΩKm-2), which contains strong transcription and translation termination signals (36). Following its construction, the insertionally inactivated allele is converted to a linear molecule by PCR amplification or restriction digestion of the backbone plasmid. The resulting linear molecule is then used to transform the target *S. pyogenes* host with selection for the inserted resistance marker. Transformation of linear DNA is best conducted using highly purified salt-free DNA (for example, see 37). Because the introduced molecule is linear, preservation of the circular chromosomal structure requires that all resistant transformants arise by two homologous recombination events flanking each side of the inserted resistance marker. The end result is the exchange of the wild-type allele for the inactivated allele (Fig. 3). While this type of recombination does not occur at high frequency, the method is usually successful because the frequency of nonhomologous recombination is typically extremely low. Insertion into the expected locus is confirmed using PCR-based analyses and/or genome sequencing, and the resulting mutant can be subjected to functional studies. However, in interpreting the resulting functional data, it should be kept in mind that this method of mutagenesis generates strong polar mutations. Thus, expression of distal genes should be examined using quantitative real-time reverse transcriptase PCR (qRT-PCR) or other methods suitable for analysis of gene expression.

A variation of this technique can be used to subject a large cloned region to rapid high-resolution insertional mutagenesis, which can be useful for analyses of complex phenotypes and pathways whose genes are often clustered together on the chromosome. This method uses a version of the *E. coli* transposon mini-γδ (mγδ-200) that has been modified to contain a kanamycin-resistance gene that can be selected for in both *E. coli* and *S. pyogenes*. Called "shuttle mutagenesis," this technique uses the ability of m-γδ to easily and efficiently generate a large number of random transposon insertions into a segment of DNA cloned on a plasmid to obtain a series of mutations along the entire length of the cloned streptococcal DNA. These sets of nested insertions are then crossed into the streptococcal chromosome as described above. This method has been successfully used to identify regulatory genes linked to a target gene of interest (38). For a detailed description of this technique, consult Hanski et al. (39).

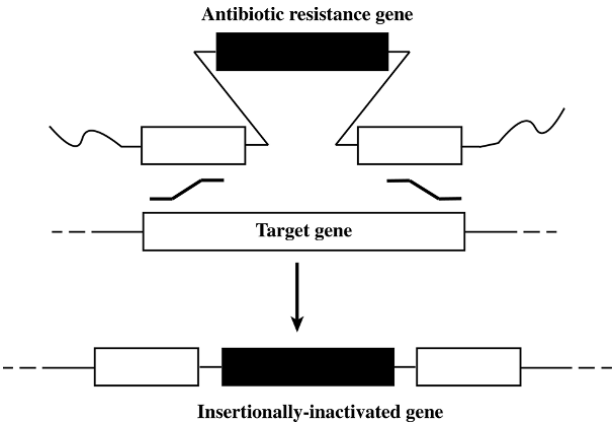

FIGURE 3 Strategy for allelic replacement mutagenesis using linear DNA. Segments of DNA homologous to the 5′ and 3′ ends of the target gene are placed flanking a gene encoding a selectable antibiotic resistance gene, typically on a standard plasmid vector using *E. coli*-based molecular cloning technology. The resulting *E. coli* plasmid vector is converted to a linear molecule by PCR or by digestion using restriction enzymes with sites outside of the cloned streptococcal gene (vector DNA is represented by the curved lines) and introduced into *S. pyogenes* with selection for resistance to the antibiotic encoded by the introduced resistance gene. Recombination between the two homologous sequences (indicated by the lines between the introduced DNA and chromosome) results in the replacement of the insertionally inactivated allele for the native chromosomal allele (shown below the arrow).

Directed Insertional Inactivation

A commonly used technique for directed mutagenesis employs mutations constructed as the result of a single homologous recombination event. For this technique, an internal segment of the target gene lacking the 5′ and 3′ ends is cloned into a Gram-negative restricted plasmid. A selectable marker for *S. pyogenes* is also included on the plasmid located adjacent to the cloned segment, but this marker should not be a β-lactamase (see above). As a general rule, the larger the fragment that is amplified, the greater the frequency at which allelic exchange occurs, although this method has been successful with fragments in the 250- to 500-bp range. The resulting plasmid is purified from *E. coli* and used to transform *S. pyogenes* with selection for resistance to the introduced marker. Because the commonly used *E. coli* replicons do not replicate in *S. pyogenes*, resistant transformants most frequently arise as a result of a single homologous recombination event between the internal segment of the gene introduced on the plasmid and the identical sequence on the streptococcal chromosome. The resulting chromosomal structure is generated by integration of the entire plasmid and consists of a partial duplication of the target gene, which now flanks the integrated plasmid sequences (Fig. 4A). As a consequence of using only an internal fragment of the target gene, one of the duplicated copies lacks its 3′ end and the other lacks its 5′ end such that both partial copies should be inactive. Thus, the end result is the directed insertional inactivation of the target gene. A number of modified *E. coli* plasmids have been utilized for this mutagenesis technique, often by replacing a β-lactamase ampicillin cassette for an appropriate selection marker. These include pCIV2 (40) and pSPC18 (41), which contain a kanamycin and spectinomycin resistance cassette, respectively.

The principal advantage to this method is that single recombination events are relatively quick and easy to generate because they require a single selection step rather than the multiple passages and screening required for construction of in-frame deletions using ts shuttle vectors (see below). This approach is also simple because it requires the cloning of only a single segment of the chromosome and can work with fragments as small as 0.25 kb. However, there are several disadvantages to the method. These include the possibility that the mutations are not necessarily stable because a second recombination event between the duplicated gene segments can result in excision of the plasmid vector and regeneration of a wild-type structure. Also, because the incoming plasmid does not replicate, it has only a limited period of time with which to undergo recombination for insertion into the chromosome. This latter limitation was addressed by Le Breton et al., who devised a two-plasmid system whereby a suicide plasmid (pSinS) lacking the pWVO1 RepA is complemented by a helper plasmid (pHlpK) that provides a ts RepA. The two plasmids are used to transform *S. pyogenes* at a permissive temperature, and a subsequent shift to a higher temperature prevents plasmid replication, selecting for plasmid integration

Downloaded From Vet-eBooks.com

(42). A final limitation to discuss is that the mutations generated by this technique are strongly polar. However, it is possible to modify the technique to directly assess the impact of polarity on the phenotype under investigation. In this case, an additional control strain is constructed, where instead of cloning a segment internal to the target gene, a segment is cloned that has its 5′ end anchored internal to the gene, but its 3′ end is anchored at a location distal to the 3′ end of the coding region of the gene. Integration of this construction into the target gene in a wild-type strain also results in a partial duplication. However, because the cloned segment overlaps the 3′ end of the gene, the first copy of the gene is regenerated

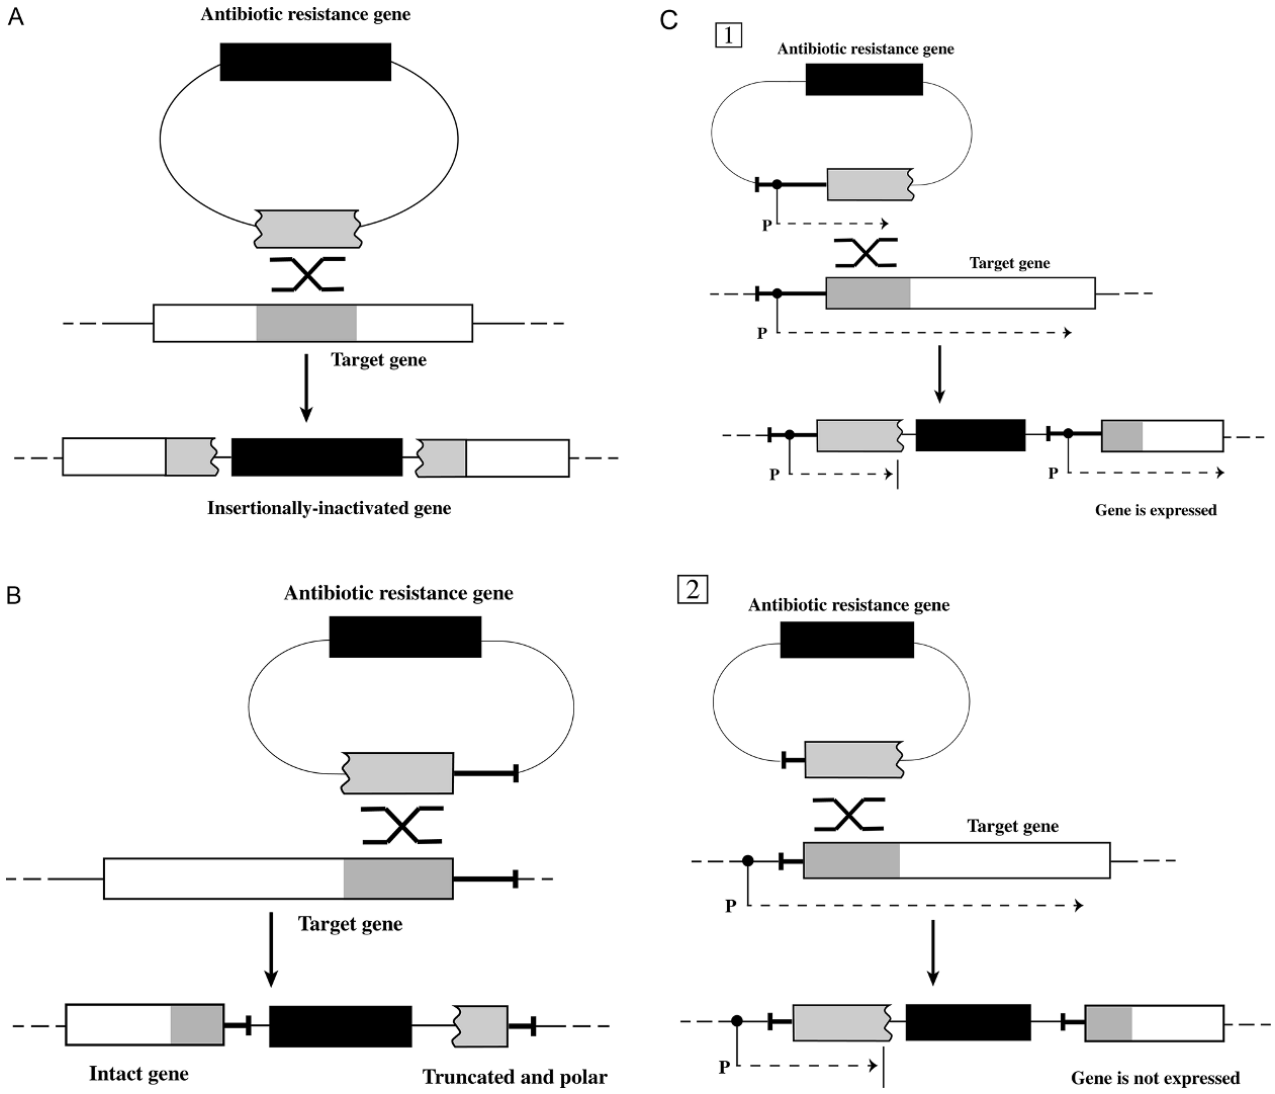

FIGURE 4 Directed insertional mutagenesis of targeted genes using circular DNA. (A) Insertional inactivation of the target gene. A DNA segment internal to the target gene (shown by the gray box enclosed by wavy lines) is cloned onto an *E. coli* plasmid which cannot replicate in *S. pyogenes*. The plasmid is introduced into an *S. pyogenes* host as a circular molecule (top of figure) with selection for a resistance marker on the plasmid. A single homologous recombination event between the chromosome and the circular molecule (shown by the "X") results in the integration of the plasmid into the chromosome, a partial duplication of the gene (the two regions shaded in gray) in which neither of the two copies are complete, resulting in gene inactivation. (B) Generation of a polar insertion 3′ to the target gene. If the segment of DNA cloned on the integrational plasmid includes the 3′ terminus and sequences downstream of the target gene (shown by the regions shaded in gray and the thick bar, respectively), homologous recombination (shown by the "X") results in a partial gene duplication in which the 5′ copy is intact but the 3′ copy is truncated, producing a polar effect on any downstream gene(s) which may share a promoter in common with the target gene. When compared with an insertion mutation that inactivates the target gene (Fig. 1 or Fig. 2), this strategy tests whether a phenotype is due to the loss of target gene function or to a polar effect on a distal gene. (C) Mapping the *cis*-acting control regions of the target gene. The technique is modified by constructing several plasmids representing a nested set of the chromosomal region extending various distances 5′ of the target gene. The plasmids are integrated into the target locus as described above, and the end-products are a partial duplication of the target gene in which the proximal copy is truncated and inactive. If the duplicated region includes the *cis*-acting control regions (represented by the broken arrow and the closed circle labeled "P"), the distal copy of the target gene will be expressed (scenario 1). In contrast, if the cloned segment does not include the *cis*-acting control regions, then the distal copy will not be expressed (scenario 2).

Downloaded From Vet-eBooks.com

and the integrated vector is located adjacent to this intact copy such that it is still polar on expression of any distal genes (Fig. 4B). If the phenotype under analysis is the result of a polar effect and the loss of expression of a distal gene, then this control strain should also demonstrate the mutant phenotype, even though it has an intact and functional copy of the target gene. On the other hand, an unaltered wild-type phenotype in the control strain indicates that the mutant phenotype is solely the result of insertional inactivation of the target gene (for example, see 43).

An additional modification of this method can be used to map the promoter and *cis*-acting control regions of a target operon. This is based on the technique developed by Moldover and colleagues (44) for analysis of promoters in *Bacillus subtilis* and is similar in concept to the method described above for placing a polar insertion downstream of a target gene. However, in this technique, the segment of DNA cloned into the integrational vector is anchored within the coding region at its 3′ end but is anchored upstream of the start of the gene at its 5′ end. Integration of this construct into the target locus again generates duplication. However, since the 3′ end of the cloned segment ends within the gene, the first copy is truncated and is inactive. This is followed by the integrated vector and then by the second intact copy of the target gene, which is now preceded exactly by the 5′ flanking region cloned into the vector. If this 5′ flanking region includes the promoter and other *cis*-acting control regions, the target gene will be expressed (Fig. 4C-1). If this segment lacks these elements, the target gene will not be expressed (Fig. 4C-2). By using a nested set of insertions containing different lengths of the upstream control region, it is possible to map the sequences required for expression and regulation of the target gene with a high degree of precision. This method has been used to examine regulation of *mga*, the regulator of the genes which encode the M proteins and the C5a peptidase (40).

In-Frame Deletion

Despite the increase in time and effort, the construction of in-frame deletions has become the standard for directed mutagenesis because they are stable and nonpolar. In-frame deletions have been constructed in the genes for many *S. pyogenes* virulence factors, including the C5a peptidase (16), the M protein, the cysteine proteinase (45), the *has* operon (46), and streptolysin O (47). Most in-frame deletion mutations were constructed by the method pioneered in the Cleary lab (16) that utilizes a derivative of the ts plasmid pG+host4. In this method, the gene of interest is cloned into the vector in *E. coli*. Standard molecular techniques are then used to delete a large central region of the gene, but at the same time preserve its reading frame. Alternatively, a set of four primers are designed to perform splicing by overlap extension (48) to directly generate the deletion construct and insert it into the shuttle plasmid, all via PCR and without the use of restriction digestion and ligation (49). The resulting construct is introduced into an *S. pyogenes* host at a temperature that is permissive for replication of the plasmid. The culture is then shifted to the nonpermissive temperature while maintaining selection for the resistance determinant of the plasmid. This selects for chromosomes into which the nonreplicating plasmid has been inserted by homologous recombination between the in-frame deletion allele and the resident wild-type allele. At this stage, the chromosome contains both the wild-type and deletion alleles. At some frequency, a second homologous recombination occurs which results in the excision of the integrated plasmid. Depending on the recombination junctions, either the wild-type or the deletion allele remains behind in the chromosome (Fig. 5). Shifting the culture back to the permissive temperature enriches for chromosomes from which the plasmid has been excised, since replication of the integrated plasmid creates a second origin of replication for the chromosome, which is usually deleterious to growth. The culture is once again shifted to the nonpermissive temperature, but this time in the absence of selection for the plasmid. This enriches for segregants, which have lost the excised and now nonreplicating plasmid. These segregants are plated as single colonies, which are then examined by streaking each colony onto agar plates in the presence or absence of antibiotic selection to identify clones which have lost the plasmid and thus are sensitive to the antibiotic used for selection. These are typically subjected to further screening by PCR and/or genome sequencing to identify chromosomes which contain the in-frame deletion allele. For a detailed description of this technique see Le Breton and McIver (12).

Counterselection Markers

The requirement for multiple passages at nonpermissive and permissive temperatures can make this method of in-frame deletion time-consuming. However, counterselection strategies that select against the retention of the plasmid can be used to expedite the recovery of chromosomes that have undergone plasmid excision and loss (50). One such strategy involves phenylalanyl tRNA synthetase (alpha-subunit) encoded by *pheS*. A single amino acid substitution in PheS (PheS*) confers relaxed substrate specificity and allows for the misincorporation of a toxic derivative of phenylalanine, 4-chloro-phenylalanine (4CP), into proteins. Here, a plasmid containing *pheS** is integrated into the chromosome. Subsequent culture in the presence of 4CP results in the death of cells that retain the *pheS**-containing plasmid, while those that have excised the plasmid survive (51). The addition of a second amino acid substitution in PheS* (defined here as PheS**) (52) confers even greater misincorporation of 4CP and higher counterselection efficiency and has been successfully used in *Streptococcus mutans* (53) and in *S. pyogenes* (Port and Caparon, unpublished) (Fig. 6). An alternative counterselection strategy involves introduction of the *rpsL* marker into the ts vector (54). This gene encodes ribosomal protein S12, and point mutations in *rpsL* which render the ribosome resistant to the antibiotic streptomycin arise spontaneously in *S. pyogenes* at a frequency of $\sim 10^{-9}$ cell^{-1} generation^{-1} (26). However, *in trans*, the wild-type allele is dominant, so when a ts vector containing wild-type *rpsL* is integrated into the chromosome of a streptomycin-resistant strain, the resulting partial diploid will be sensitive to streptomycin. Thus, the inclusion of streptomycin during the final passage at the nonpermissive temperature directly selects for chromosomes from which the integrated plasmid has excised and segregated. This method has been used to introduce mutant alleles of the virulence regulator Mga into the chromosome for functional analyses (54).

In-Frame Deletion Using CRISPR/Cas9

A drawback to the standard in-frame deletion method mentioned above is that it can be time-consuming, usually taking more than a week for the multiple passages that are required to enrich for chromosomes that contain the deletion allele (Fig. 5). This time period can be reduced through the application of a system using clustered regularly interspaced short palindromic repeats (CRISPR) and CRISPR-associated

Downloaded From Vet-eBooks.com

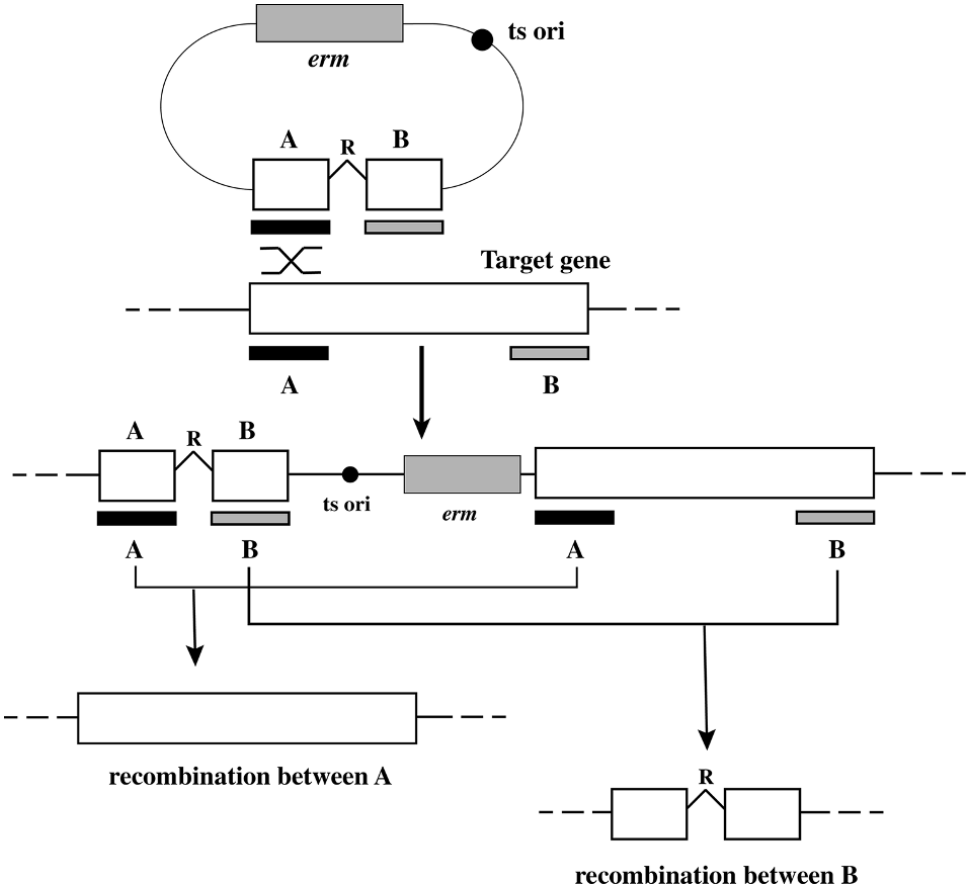

FIGURE 5 Construction of an in-frame deletion. Standard PCR-based methods are used to generate a deletion of the internal region of a copy of the target gene that has been cloned on an *E. coli*-streptococcal shuttle vector that is temperature-sensitive for replication (indicated by "ts ori"). The deletion is constructed so as to maintain the reading frame of the gene (represented as the bent line labeled "R," connecting the 5′ region labeled "A" and the 3′ region labeled "B"). Following its introduction into *S. pyogenes*, growth at a temperature that is nonpermissive for replication of the plasmid with selection for the antibiotic-resistant determinant of the plasmid (*erm*) selects for chromosomes in which the plasmid has integrated by homologous recombination (indicated by the "X"). The two regions of homology flanking the deletion are represented by the solid and gray bars labeled "A" and "B." Recombination between the A bars or, alternatively, between the B bars (shown by the brackets and arrows) results in excision of the plasmid and either the restoration of the wild-type structure or allelic exchange for the deletion allele (these products are illustrated below the second set of arrows). Growth at a temperature permissive for replication of the plasmid enriches for excisant chromosomes, presumably because if integrated, the plasmid origin of replication becomes active, resulting in misregulation of chromosomal replication. Presence of the wild-type or deletion allele in any isolate is easily determined by assay for the unique restriction site engineered into the deletion allele (indicated by the "R" above the bent line) or by PCR with primers flanking the region of interest.

protein 9 (Cas9). CRISPR/Cas9 was originally described in *S. pyogenes*, where it functions to confer an adaptive immunity against invading genetic elements, especially bacteriophages (55, 56). It does this by introducing double strand breaks at specific sequences that the Cas9 enzyme is programmed to recognize by incorporation of a small targeting RNA molecule (CRISPR RNA [crRNA]) that is encoded in the CRISPR array (55, 56).

To cleave a specific DNA site, the Cas9 nuclease associates with both a crRNA that has a short sequence complementary to the DNA target sequence (known as the protospacer) and with a separate trans-activating crRNA (trRNA, sometimes called tracrRNA) (57). The trRNA is partially complementary to the crRNA and is required for crRNA maturation from a primary transcript encoding pre-crRNAs. The crRNA and trRNA form a based-paired structure that is incorporated into Cas9 and targets the complex to a protospacer region located adjacent to a short motif known as the protospacer-adjacent motif, which for *S. pyogenes* Cas9 is NGG. Jinek et al. simplified the system by merging trRNA and crRNA into a single synthetic molecule known as the single guide RNA (sgRNA) (57). Due to its simplicity, requiring only Cas9 and sgRNA, the type II CRISPR/Cas9 system from *S. pyogenes* has found wide application for genome editing in many organisms, including higher eukaryotes (58). A derivative, "dead" Cas9 (dCas9), modified by site-

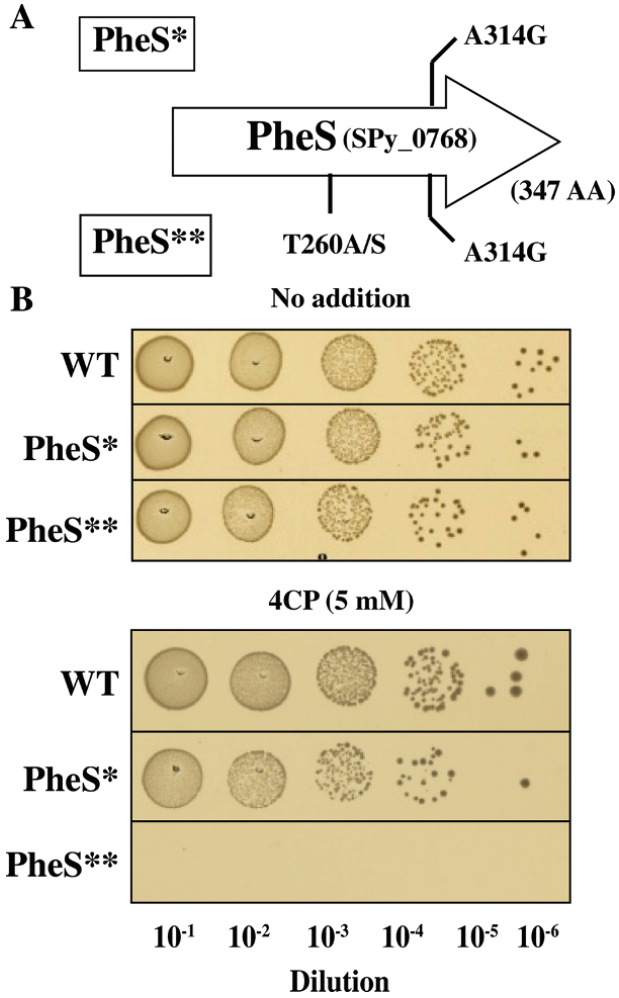

FIGURE 6 PheS**, a counterselectable marker. The phenylalanyl tRNA synthetase (alpha subunit) PheS catalyzes the attachment of phenylalanine onto its cognate transfer RNA. (A) Introduction of a single amino acid substitution (PheS*, A314G) confers relaxed substrate specificity and allows for the misincorporation of a toxic derivative of phenylalanine, 4-chloro-phenylalanine (4CP), into proteins. Addition of a second substitution at position 260 (PheS**, either T260A or T260S in combination with A314G) facilitates increased misincorporation of 4CP. (B) *S. pyogenes* containing a multicopy plasmid (pABG5) either as an empty vector (WT) or engineered to express PheS*, or PheS** was serial diluted and plated onto solid media in the absence (top panel) or in the presence (bottom panel) of 5 mM 4CP. Strains expressing PheS* show moderate sensitivity to 4CP toxicity, whereas strains expressing PheS** show enhanced sensitivity.

specific mutations that inactivate its two nuclease activities, can be used in a variety of approaches for silencing expression of specific genes (the CRISPRi method) (56, 59).

Cas9 can also be adapted for the efficient construction of in-frame deletions in *S. pyogenes* by providing a direct counterselection against strains that retain the wild-type allele. This method requires modification of the standard ts plasmid to contain Cas9 and an sgRNA in addition to the in-frame deletion allele (K.H. Cho, unpublished). The sgRNA should include a short ~20-nucleotide sequence complementary to a sequence in the targeted gene that will be eliminated by the deletion, which is adjacent to a suitable protospacer-adjacent motif. When the plasmid is introduced into *S. pyogenes* with the wild-type gene allele, only the strain with the in-frame deletion allele in its chromosome created by double-crossover survives, because it has eliminated the protospacer sequence. In contrast, any strain retaining the wild-type allele is killed due to the introduction of a double strand break of its chromosome by the Cas9 nuclease. This process is highly efficient, because unlike most eukaryotic organisms that can repair a double strand DNA break through nonhomologous end joining and homology-directed recombination (60), many prokaryotes use only homology-directed recombination to repair the double strand break. Thus, if no homologous DNA is available for repair, the double strand DNA break can be lethal (61). This method has been successfully used to create in-frame deletions in *Staphylococcus aureus*, *Streptococcus pneumoniae*, and *E. coli* (62, 63). It is anticipated that this method will be even more successful in *S. pyogenes*, because more than half of the *S. pyogenes* genomes (14 out of 20 completely sequenced and annotated strains available in GenBank at the time of this writing) already possess *cas9*. For these strains, just providing an sgRNA may be sufficient for selection of in-frame deletion mutants.

Considerations for Directed Mutagenesis

The multiple *in vitro* passages required for directed mutagenesis techniques have a tendency to enrich for spontaneous mutants with reduced expression of virulence factors (64), including the M protein and the hyaluronic acid capsule (65). It is therefore important to isolate and phenotypically test multiple independently derived mutants to confirm that they have a consistent phenotype, as well as to genetically complement any mutants to confirm that the targeted mutation is the cause of the observed phenotype. If the gene targeted for mutagenesis lies upstream of an essential gene, it may be difficult to select for the initial single crossover due to a polar effect. To counter this point, a larger DNA fragment encompassing the entire downstream gene can be utilized to ensure continued gene expression following the initial crossover (66). Finally, some mutants are less fit and have a slower growth rate than the wild type. Therefore, any deletion mutants that are generated are quickly outcompeted by their wild-type counterparts, making them difficult to recover following *in vitro* passage. In this case, an allelic replacement mutant can be made whereby a gene of interest is replaced by an antibiotic cassette, which allows for direct selection of the mutated chromosome (66).

TRANSPOSON MUTAGENESIS

The techniques described above have been extremely useful for the analysis of virulence in *S. pyogenes*. However, they require a detailed pre-existing knowledge of the target gene and thus are more suited for reverse genetics approaches applied to testing hypotheses which address the functions of previously identified and characterized genes or genes identified from whole-genome sequence information whose function is suggested by homology with a characterized gene. This approach is not well suited for a forward genetics approach for the identification of novel genes that contribute to virulence. This is most successfully done using a traditional unbiased genetic approach, in which a virulence phenotype is established and random mutations are generated to identify genes which influence this phenotype. In *S. pyogenes*, the

Downloaded From Vet-eBooks.com

most successful method of random mutagenesis has used the insertion of a transposable element at multiple loci in the chromosome. This section considers the various types of transposons that have been successfully used to identify novel genes in *S. pyogenes*, with particular focus on recently adapted transposon systems that allow for the characterization of high-diversity libraries, which include hundreds (signature tagged mutagenesis) or even thousands (TnSeq) of mutants during infection.

Tn*916*

The first transposable element used to identify novel virulence genes in *S. pyogenes* was Tn*916* (Fig. 7A). This element is the prototype of the family of transposons discovered by Clewell's group (29), which are now known as the conjugative transposons. They have the remarkable property that they are self-transmissible and transpose from a locus in a donor chromosome to a different locus in a recipient chromosome when these chromosomes are located in different cells. The conjugal transfer event requires cell-cell contact and can occur between very distantly related species and even between Gram-positive and Gram-negative hosts. This biology of these unique elements has been extensively investigated and is the subject of several excellent reviews (for example, 67) and thus will only be briefly mentioned here.

The advantage to using Tn*916* is that it can be applied to probably any isolate of *S. pyogenes*, including those which may be difficult to transform. The disadvantages are that Tn*916* is a large element for a transposon (over 18 kb in size), does transpose into preferred sites, and frequently generates chromosomes with multiple insertions. The transposon has served as a useful mutagenesis agent and has been used to identify novel genes involved in regulation (e.g., *mga* [7]), expression of streptolysin S (68–70), and production of the capsule (71, 72), among others.

Tn*917*

This transposable element was also originally described by Clewell's group in *E. faecalis* (73), highly engineered by Youngman and colleagues, and applied with great success to the mutagenesis of *Listeria monocytogenes* and *B. subtilis*. One characteristic of this family is that its members contain fairly large terminal repeats, although they are much smaller in size than the conjugative transposons. They produce stable insertions, generate a 5-bp target site duplication upon insertion, and transpose at high frequency and with a high degree of randomness. Their movement involves a replicative pathway, which requires that donor and recipient molecules undergo replication, and proceeds through the cointegration of donor and host molecules which contain two directly repeated copies of the transposon at the fusion junctions. Resolution of the cointegrate occurs via site-specific recombination catalyzed by a transposon-encoded enzyme called resolvase that recognizes a specific site in each copy of the transposon (the *res* site). The end result is that a single copy of the transposon is located at a random site in the recipient molecule. Scott's group (74) developed a mutagenesis vector (pJRS290) (75) that is based on pG+host4 and contains a highly engineered derivative of Tn*917* developed by Youngman and coworkers (76) (Tn*917*-LTV3) (Fig. 7B). This derivative of Tn*917* has several useful features, including an *E. coli* plasmid origin of replication that facilitates the direct cloning of chromosomal DNA adjacent to the inserted transposon. Using this vector, Tn*917*-LTV3 was found to transpose efficiently and with a high degree of randomness in *S. pyogenes*.

Tn*4001*

The transposable element Tn*4001* was originally isolated as an agent of transmissible gentamycin-resistance in *S. aureus* (77). It is a composite-type transposon and a member of the Tn*5* family. These transposable elements share a common structure in which directly repeated copies of an insertion sequence flank an antibiotic resistance gene. Each insertion sequence itself is bounded by short inverted repeats that flank a transposase gene, which is the only transposon-encoded gene required for movement. The individual insertion sequences themselves are usually capable of transposition independent of the entire element. For Tn*4001*, two copies of the insertion sequence IS*256* flank a central gentamycin-resistance gene. The transposition pathway for this class of elements involves a "cut and paste" mechanism catalyzed by the transposase, which recognizes as its substrates the short inverted repeats of the insertion sequences. Studies have shown that Tn*4001* has a broad host range, including staphylococci, oral streptococci, and mycoplasmas, and that it chooses its targets for insertion with a high degree of randomness. Since the cut and paste pathway does not require replication of the donor molecule, the element can easily be delivered into the host of choice via a nonreplicating suicide vector. However, a number of problems have limited its use. The most significant of these is that transposition of the entire element occurs at a somewhat low frequency relative to the frequency of transposition of the individual insertion sequences. As a result, a chromosome with a Tn*4001* will frequently also have multiple copies of IS*256* inserted at other loci. To address this problem, derivatives of Tn*4001* have been constructed that essentially contain only the inverted repeats of IS*256* oriented to flank the gene for transposase and a selectable marker (78). The resulting elements are relatively small in size (~2 kb) and transpose at a high frequency characteristic of an individual copy of IS*256*. The organization of the element also prevents independent transposition of the insertion sequence and ensures that the resulting population of insertions is homogeneous, although the resulting mutants may have insertions at two loci. A spectinomycin-resistant version of this transposon (called TnSpc for simplicity) (Fig. 7C) was used to identify novel genes required for expression of the SpeB cysteine protease of *S. pyogenes*, including a transcriptional regulator (*ropB*) and a chaperone (*rop*A) (78). Additional variants include the introduction of an erythromycin resistance gene and 1 of 12 unique 34-bp signature tags for application in signature-tagged mutagenesis studies. In this method, 12 independent pools of mutants are generated. Then, one mutant is taken from each of these pools, and they are combined to generate an inoculum with 12-fold complexity that is used as the input into an assay of virulence. The output pool is then analyzed by a PCR assay to conduct a census of the recovered sequence tags, which is then compared with the input pool to determine the relative fitness of individual mutants. Mutants with reduced fitness are putative virulence genes, and this method has been successfully applied to the identification of genes that promote pathogenesis in a zebrafish model of *S. pyogenes* infection (79, 80).

Tn*FuZ*

Since the terminal inverted repeats of IS*256* are quite short (26 bp), several specialized derivatives of the transposon have

Downloaded From Vet-eBooks.com

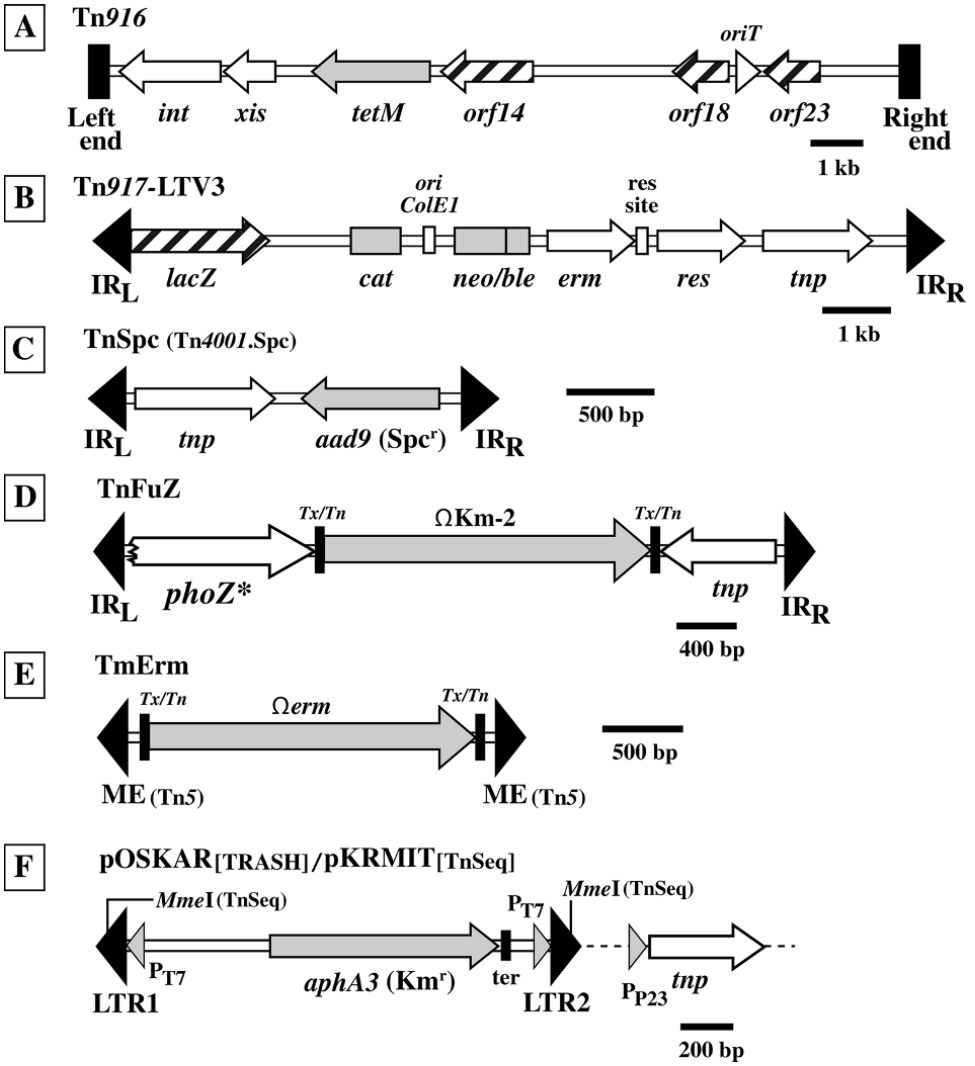

FIGURE 7 Transposon mutagenesis of *S. pyogenes*. The several transposons that have been used for mutagenesis of *S. pyogenes* are shown. Antibiotic resistance genes are represented by the gray bars, transposon ends and/or terminal inverted repeats are shown in black, genes that are essential for transposition are shown by white bars, and genes that are nonessential for transposition are represented by the stripped bars. (A) Tn*916* (GenBank accession no. U09422) is the prototype conjugative transposon and contains at least 24 different open reading frames. Of these, one is required for resistance to tetracycline, two are essential for transposition, and the rest are likely involved in conjugal transfer. (B) Tn*917*-LTV3 is a highly engineered derivative of the Tn*3*-like transposon Tn*917*. This element transposes via a replicative mechanism and has been modified to include a promoterless *lacZ* reporter gene to generate random transcriptional fusions and an *E. coli* ColE1 plasmid origin of replication to facilitate the cloning and analysis of inactivated loci. (C) TnSpc is a derivative of the Tn*5*-like transposon Tn*4001*, which transposes via a cut and paste mechanism and consists of the left and right inverted repeats and transposase of IS*256* and a spectinomycin resistance gene. (D) TnFuZ introduces the gene for the *E. faecalis* alkaline phosphatase (*pho*Z) altered by removal of the region encoding its signal sequence (broken line at the 5′ end of *phoZ**). TnFuZ acts as an "export signal sequence trap." Insertions into genes that encode a protein export sequence promote the secretion of PhoZ* enzymatic activity, which can be detected by a number of high-throughput assays for alkaline phosphatase activity. (E) TmErm is an engineered element that contains the right and left mosaic ends (ME) of Tn*5* flanking an erythromycin resistance marker (Ω*erm*) that includes strong transcription and translation stop sites (*Tx/Tn*). To apply transposome mutagenesis to *S. pyogenes*, the DNA fragment containing TmErm is purified, such that the resulting preparation does not include the ampicillin resistance determinant contained on the pMOD-2::Ω*erm* vector backbone. The purified DNA fragment containing TmErm is then reacted with transposase (EZ::TN, Epicentre Technologies) *in vitro* to form the transposome that is then used to transform *S. pyogenes* using electroporation. (F) pOSKAR and pKRMIT are transposon systems incorporated into the ts pWV01-based *E. coli*-streptococcal shuttle vector that utilize the highly active *mariner Himar1* transposable element (MarC9) under control of the P23 promoter from *Lactococcus lactis*. Both transposon systems include a kanamycin resistance gene (*aphA3*) flanked by long terminal repeats (LTR) whose promiscuous target insertion site requires only a TA dinucleotide sequence, leading to a highly random library of insertions. pOSKAR can be utilized for TraSH analysis through the use of outward-facing T7 promoters, while pKRMIT also includes an outward-cutting *MmeI* site for use with TnSeq analysis.

Downloaded From Vet-eBooks.com

been developed that place a reporter gene adjacent to the IS*256* end. The Tn*FuZ* (fusion to *phoZ*) reporter places a version of the *E. faecalis phoZ* alkaline phosphatase adjacent to the transposon inverted repeat (Fig. 7D). This reporter gene has been modified by removal of its endogenous export signal sequence to construct an "export signal sequence trap." In this method, insertion of the element into an open reading frame can result in the formation of a translational fusion with PhoZ (the use of PhoZ as a reporter gene is discussed below). If the donor open reading frame contains a secretion export signal, the chimeric PhoZ protein will be secreted. Since PhoZ is only active following its export across the cytoplasmic membrane, a simple and rapid colorimetric screen can be used to identify colonies arising from a mutant that contains an insertion in a gene that encodes a secreted protein. The Tn*FuZ* element has been used to identify secreted proteins whose expression is enhanced during aerobic growth (81). Another example of the versatility of IS*256*-based elements is those that have been modified to include genes encoding a bacterial luciferase (use of luciferase as a reporter gene is discussed below). Insertion into a transcription unit that directs transcription of the luciferase genes allows gene expression *in vivo* to be monitored noninvasively using specialized imaging cameras that can capture photons emitted by the streptococci in living host tissue (82).

Transposome Mutagenesis

In transposome mutagenesis, a stable complex between transposase and transposon DNA is formed *in vitro* and then introduced into a bacterium. The elevated concentration of Mg^{2+} in the bacterial cytoplasm activates transposase that then catalyzes transposition of the element to some random location in the bacterial chromosome. This method has been adapted for efficient mutagenesis of *S. pyogenes* (43). For this, a streptococcal erythromycin-resistance gene was introduced between the inverted repeats of a derivative of Tn*5* (EZ-TN5^{tm}) on the *E. coli* plasmid pMOD-2 (Epicentre Technologies) to construct TmErm (Fig. 7E) (43). Following digestion with a restriction endonuclease, the transposon (TmErm)-containing linear DNA fragment is reacted with a modified hyperactive transposase (EZ::TN, Epicentre Technologies) to generate the transposome. Following transformation of *S. pyogenes* using electroporation, erythromycin-resistant colonies were obtained at frequencies between 10^3 and 10^4 CFU/μg DNA (43). Mutations generated by this method have proven to be very stable even in the absence of erythromycin selection, possibly because the inserted transposon does not encode its own transposase.

Himar1-Based Mariner Transposon Systems

While the generation of a complex transposon library is relatively straightforward, mapping the location of the insertion site in the chromosome of any single mutant has historically been quite laborious. Prior to the development of rapid and relatively low-cost whole-genome sequencing technology, arbitrary PCR (78) was usually utilized to map the site of transposon insertion. An adaptation of this method for rapid screening using pools of mutants was a form of microarray-based analysis known as transposon site hybridization, utilizing a transposon with outward-facing T7 promoters at flanking ends (pOSKAR) (Fig. 7F) (83). Later, this transposon platform was modified to allow for analysis by high-throughput next-generation sequencing through the use of an outward-cutting restriction enzyme known as *Mme*I for the technique known as TnSeq (pKRMIT) (Fig. 7F) (84). Both of these transposon platforms utilize the highly active and promiscuous *mariner Himar1* transposable element, whose target insertion site requires only a thiamine-adenine (TA) dinucleotide sequence, leading to a highly random library of insertions.

Le Breton and McIver's group developed a Mariner-based system for use in *S. pyogenes* by introducing the *mariner* transposon into the ts pWV01 shuttle vector. Because the transposon is highly active, propagation of the shuttle vector in *E. coli* is unstable and requires careful screening of preparations of purified plasmid to ensure that the correct plasmid structure has been maintained prior to electroporation into *S. pyogenes* (12). Furthermore, transposition likely occurs quite rapidly relative to the rate of plasmid loss following growth at restrictive plasmid temperatures. Therefore, additional screening is required for the subsequent *S. pyogenes* mutant pools prior to phenotypic testing. Despite these technical limitations, multiple labs have used this transposon system for transposon site hybridization analysis utilizing the plasmid pOSKAR to screen for genes required for growth in human blood (25), to identify regulators of the Rgg quorum sensing system (85, 86), and for TnSeq analysis utilizing the plasmid pKRMIT for analysis of core essential genes required for growth *in vitro* (42) and for murine soft-tissue infection (87).

Analysis of Transposon Mutants

Regardless of the type of transposable element utilized, there are a number of additional tests that should be performed to ensure that the mutant phenotype is the direct result of insertion of the transposon. This involves determining the sequence of the locus into which the transposon has inserted via arbitrary PCR, inverse PCR after enzyme digestion and ligation, or whole-genome sequencing. With this data in hand, the next step is to construct a mutant in the locus in the wild-type parental strain using one of the strategies for directed mutagenesis outlined above. If the original insertion is responsible for the mutant phenotype, then it is expected that all isolates obtained via directed mutagenesis will also be mutants. It should also be kept in mind when interpreting results that transposon-generated mutations are also polar, so the gene(s) responsible for the observed phenotype may lie downstream of the interrupted gene.

ANALYSIS OF GENE EXPRESSION

Gene regulation phenomena play a key role in pathogenesis. The interaction between the host and the microbe is dynamic and often is a progression through a number of discrete steps. Each of these steps is characterized by the expression of specific sets of bacterial genes required for survival and multiplication and the host's response to the action of the products of these microbial genes. As a consequence, the microorganism is continually challenged to adapt to new and changing environmental conditions. Pathogens have taken advantage of the dynamic nature of this interaction and have evolved to recognize changes in specific environmental conditions as markers that define a particular host compartment or stage of infection. The pathogen uses this information to modulate expression of virulence genes required for survival in this host compartment. Thus, an understanding of the *in vitro* conditions that regulate expression of a specific virulence gene provides insight into how the gene contributes to virulence *in vivo* (for review see 88). Regulation of virulence genes often involves control at the level of transcription. For *S. pyogenes*, transcriptional

Downloaded From Vet-eBooks.com

regulation has often been analyzed through the use of reporter genes, particularly in studies designed to determine the specific conditions that activate or repress expression of a gene of interest.

The basic strategy for using reporter genes to analyze gene expression involves fusing the promoter for the virulence gene of interest to a reporter gene that encodes a gene whose product can easily be quantitated. This feature is of particular utility when the assays for quantitation of the product of the streptococcal gene under analysis are time-consuming, expensive, and/or cumbersome. The reporter gene lacks its own promoter, so its product becomes an accurate relative indicator of the steady state level of transcription initiation from the target promoter. It should be kept in mind that because the message is a chimera between the initiation signals of the target gene and the reporter gene, it is not subject to the same posttranscriptional and posttranslational controls. Furthermore, the half-life of the reporter gene's translation product does not reflect that of the native polypeptide. Thus, reporter genes are most appropriately used to quantitate the strength of initiation of transcription of the target promoter.

The reporter genes that have been successfully used in *S. pyogenes* include chloramphenicol acetyltransferase (Cat), β-galactosidase (Lac), β-glucuronidase (Gus), alkaline phosphatase (Pho), and bacterial luciferase (LuxAB). The products of all these genes are stable, highly active enzymes that are highly specific for their substrates. Their utility is enhanced by the availability of synthetic substrates with isotopic, colorimeteric, fluorogenic, or light-emitting properties that allow very sensitive detection. Also, the reporter genes encoding these enzymes are derived from Gram-positive bacteria or have been extensively modified to optimize their expression in Gram-positive hosts and differ extensively from their counterparts used for analysis in *E. coli*.

The most successful applications of Cat have employed *cat*86, originally isolated from *Bacillus pumilus*, which has been modified by the deletion of an attenuator sequence and the substitution of an adenine-thiamine-guanine (ATG) start codon for the native gene's thiamine-thiamine-guanine (TTG) start codon. The advantages of Cat are that *cat*86 is very stably maintained in *S. pyogenes* and that the assays for its enzymatic acetylation of chloramphenicol are very sensitive (89, 90). It has several disadvantages: the most sensitive assays involve radioactivity, are expensive, are somewhat labor-intensive relative to other reporter genes, and require the preparation of cell-free extracts. Both Lac and Gus utilize *E. coli* genes that have been modified by the introduction of ribosome binding sites recognized by Gram-positive bacteria (91, 92). The advantages to using these as reporters are that assays for their enzymatic activities are easy to perform and rapid and many samples can be analyzed simultaneously, that a wide variety of substrates is available, and that it is possible to analyze both permeabilized cells and cell extracts. Disadvantages are that they are not as sensitive or as stably maintained in *S. pyogenes* as *cat*86. Nevertheless, *gusA* has proven to be very useful in numerous applications, including identification of regulatory sites in the *hasA* promoter (93) and to find a regulator (*rocA*) that modulates transcription of the CovRS two-component global regulator of virulence and stress resistance (94).

The LuxAB bacterial luciferase, originally from *Vibrio fischeri*, has found utility in dissecting the mechanism of Rgg-associated signaling peptides in *S. pyogenes* (35). An advantage of a luciferase reporter is that the assay is extremely sensitive and quantitative, because exposure of bacterial cultures to volatile decyl aldehyde (decanal) for less than one minute can result in a measurable light output. A disadvantage of this reporter is that luciferase activity is growth phase sensitive due to the reaction's requirement for reduced flavin mononucleotide as a cofactor (95) and has been shown to fail in some bacteria during the stationary phase (82) or under conditions of low pH or oxidative stress (96).

A chimeric reporter protein based on fusion of two naturally secreted proteins has also been developed. This reporter contains as its enzymatic partner, the alkaline phosphatase of *E. faecalis* (PhoZ) (97). This enzyme is secreted from *E. faecalis* and is a lipoprotein that becomes tethered to the outer leaflet of the cell membrane. Fusing the enzymatic C-terminal domain of PhoZ, not including its lipoprotein secretion signal, to the nonlipoprotein N-terminal secretion domain of protein F of *S. pyogenes* results in a very stable, highly enzymatically active chimeric protein (PhoZF) (Fig. 1) which is freely secreted from the streptococcal cell into the surrounding medium (20). This feature makes quantitative analysis of the secreted chimeric protein in culture supernatant very simple and requires neither permeabilization nor preparation of cytoplasmic extracts. Due to the widespread popularity of alkaline phosphatase enzymes, an excellent selection of sensitive substrates with a variety of useful characteristics, including those with fluorescent and light-emitting properties, are inexpensive and are readily available.

Green fluorescent protein (GFP) has become a widely used reporter of gene expression because of its ease of detection and its utility for application in real-time assays for analyses *in vitro* and *in vivo* during infection. Numerous versions of GFP are available that have been modified to alter codon usage, stability, and spectral properties (98). The GFPuv variant has been used to examine regulation of the promoter for the hyaluronic acid biosynthesis gene cluster in streptococci recovered directly from infected tissues (99). This latter study also reported an important consideration for interpreting data derived from GFP-based reporters in that fluorescence is often not uniform among streptococcal cells in any population, including many cells that express no detectable fluorescence (99). It is likely that the microaerophilic or anaerobic conditions that are typically used for culturing *S. pyogenes* are not ideal for GFP maturation, since oxygen is required for GFP chromophore formation. However, a more stable variant known as superfolder GFP has shown utility in several applications in *S. pyogenes*, including monitoring subcellular localization of proteins (100).

Numerous strategies have been used to introduce reporter fusion constructs into *S. pyogenes* for analysis. Plasmid vectors have the advantage that they are easy to manipulate and can be used to generate and analyze a large number of permutations and variations of promoter structure to probe the *cis* and *trans*-acting control regions. A plasmid-based reporter is present in multiple copies, and this amplification increases the sensitivity of detecting the activity of the promoter under analysis. This latter feature can also make plasmid-based systems sensitive to multiple-copy-number-derived artifacts, such as titration of *trans*-acting regulatory components, when those components are only present in limiting quantities. Furthermore, any sequence-directed local effects of chromosomal structure on expression of a given promoter will not likely be replicated in a plasmid environment. Integration of reporter constructs into the chromosome can alleviate many of these latter types of potential artifacts but with a trade-off in ease of use and sensitivity. Integration is usually performed by introducing the reporter construct on a nonreplicating *E. coli*-based plasmid to target integration into the target gene's native locus by homologous recombination promoted by the

Downloaded From Vet-eBooks.com

cloned promoter segment. Alternatively, use of the integrating p7INT/p7INT* plasmid can reproduce a more native chromosomal environment through integration at the *attB* site (Fig. 2).

Next-generation sequencing approaches such as RNAseq for global analysis of the transcriptome coupled with quantitative real-time RT-PCR methods have recently become the standard for analysis of gene expression in *S. pyogenes*. Although it requires preexisting knowledge of the genome sequence, this disadvantage is more than offset by the facts that RNAseq does not require the laborious construction of reporter gene fusions, that it is fast and easy to perform, that it can directly analyze the entire transcriptome, including novel RNA species, and that it is not limited to the genes for which probes were designed. RNA analysis has been greatly facilitated by the development of technology for the simple and rapid purification of high-quality RNA from relatively small samples (101). In practical terms, quantitative real-time RT-PCR is used for validation expression of individual genes of interest from data developed from RNAseq analyses (102). In quantitative real-time RT-PCR, total RNA is purified and then converted to first-strand complementary DNA (cDNA) using reverse transcriptase. These cDNAs then serve as a template for real-time PCR using primers specific for the gene in question. Real-time thermocyclers are modified with a detection system that can continuously monitor the fluorescence of a probe that is sensitive to the quantity of DNA that is being synthesized by PCR, and the amplification cycle at which a detectable amplification product is first detected is a quantitative measure of the concentration of that message in the input cDNA pool. Data are typically reported as a ratio to a reference gene such as *recA* or *gyrA* whose expression is relatively constant under analysis conditions.

Techniques for Ectopic Expression

Structure-function studies of the role of putative virulence factors require techniques for ectopic expression, both to control the timing and relative levels of expression of a given gene and to study the structure-function relationships of specific domains of a given virulence-associated protein. The former case requires the availability of an ectopic promoter whose activity can be tightly, easily, and quantitatively controlled by some external factor. The latter case requires a method for the expression of various domains of the polypeptide under analysis into the context of an unrelated polypeptide. This allows an independent analysis of the functionality of that domain separate from other regions of the original polypeptide. Methods to accomplish both of these expression strategies have been developed for analysis of virulence in *S. pyogenes*.

An initial approach for using a regulated heterologous promoter to direct expression of the gene under analysis was based on the *nisA* promoter of *Lactococcus lactis*. In lactococci, the NisR/K two-component system controls the expression PnisA in direct response to nisin concentration. The method for using this regulated promoter involves the introduction of *nisK* and *nisR* into an *S. pyogenes* strain, while the gene of interest is introduced under control of the *nisA* promoter, which makes expression of the gene of interest sensitive to the concentration of exogenous nisin that is added to the culture. Tightly regulated expression of a *gusA* reporter gene and induction of up to 60-fold over background using a broad range of nisin concentrations has been reported for *S. pyogenes* (74). The NisR/K system has some drawbacks, including the stability of nisin (103) and a relatively high basal level of expression in the uninduced state, which makes conditional expression of putative essential genes difficult. A more tightly controlled inducible promoter is based on the tetracycline-inducible promoter P_{tet}. In this system, the *tet* repressor (TetR), binds to a 19-nucleotide palindromic sequence, referred to as the *tet* operator (*tetO*), between the -35 and -10 site of P_{tet}. In the presence of inducer, commonly tetracycline or nonantimicrobial analogs, including anhydrotetracycline (aTc), TetR binds to the inducer, reducing its binding affinity for *tetO* and thereby allowing for expression of the downstream open reading frame. Originally from *E. coli*, this system has been adapted for use in Gram-positive bacteria by the use of optimized promoter sequences and ribosome-binding sites and through addition of multiple *tetO* sites for enhanced dynamic range (104). A reverse TetR has been developed that has an enhanced, rather than reduced, affinity for *tetO* in the presence of inducer, and thereby the presence of inducer represses gene expression (105). P_{tet} has been used in *S. pyogenes* to control the expression of reporter genes (100) and to experimentally verify the essentiality of ribonucleases J1 and J2 (106). A third, and perhaps more widely used, conditional expression system is based on a theophylline-inducible riboswitch (32). In this system, a ribosome-binding site (RBS) for expression of the target gene has been engineered to become occluded and unavailable due to mRNA secondary structure. However, the binding of the theophylline ligand to the mRNA induces the formation of an alternative secondary structure, such that the RBS is free to bind ribosomes and translation is initiated. The native RBS located upstream of a gene of interest is thus replaced by the riboswitch for conditional expression studies. Two advantages of the theophylline-inducible riboswitch are less leaky expression than P_{tet} and the fact that riboswitches do not require accessory proteins. The theophylline riboswitch has been used to study the essentiality of the histone-like protein gene *hlp* (107), *gacA* (108), and several genes predicted to be essential from a saturating TNseq transposon screen (42).

Structure-function dissection of virulence protein function can benefit from ectopic expression methods that allow the analysis of defined subdomains of the polypeptide. This has proven particularly valuable for identification of the ligand-binding domains of adhesins that direct attachment of bacteria to various host cell receptors. In this approach, the subdomain under examination is expressed and displayed on the bacterial cell surface in the context of a heterologous protein. A technique developed for this strategy, which uses the framework of the M6.1 protein, was based on the work of Pozzi and coworkers (109), who demonstrated that the central domain of the M protein could be replaced with a heterologous sequence without affecting expression and surface presentation of the resulting chimera. Essentially, the heterologous domain is placed between the N-terminal secretion and C-terminal attachment domains of M protein to display the heterologous domain on the streptococcal cell surface. A successful application of this strategy involved analysis of the two distinct fibronectin-binding domains of protein F (110). For a more detailed explanation of this technique see Hanski et al. (39).

CONCLUDING REMARKS

Rapid progress has been made in recent years in the development of sophisticated techniques for genetic analysis in *S. pyogenes*. Much of this effort has been directed at the development of methods for the mutagenesis of known genes.

Downloaded From Vet-eBooks.com

Considerable progress has also been made in the development of strategies for the identification of novel genes. It is likely that the widespread application of these techniques to the virulence properties of *S. pyogenes* will enrich our understanding of streptococcal pathogenesis with insight at the molecular level and will help to establish and clarify the contributions of specific genes. Additional use and development of methods for the analysis of gene expression and heterologous expression will continue and will allow analyses of virulence factors at much higher levels of resolution than previously possible.

Molecular Mimicry, Autoimmunity, and Infection: The Cross-Reactive Antigens of Group A Streptococci and their Sequelae

MADELEINE W. CUNNINGHAM

7

INTRODUCTION

Cross-reactive antigens are molecules on the group A streptococci that mimic host molecules and during infection or immunization induce an autoimmune response against host tissues, leading to the autoimmune group A streptococcal sequelae (1–25). "Molecular mimicry" is the term used to describe immunological cross-reactivity between the host and bacterial antigens. Immunological cross-reactions between streptococcal and host molecules have been identified involving antibodies or T cells that react with streptococcal components and tissue antigens (6, 7, 22, 24, 25). The advent of monoclonal antibodies (mAbs) and T cell clones/hybridomas has greatly advanced the identification of the host and streptococcal antigens responsible for immunological cross-reactions associated with immunization, infection, and autoimmune sequelae. The identification of cross-reactive antigens in group A streptococci and important in our understanding of the pathogenesis of autoimmune sequelae, such as rheumatic fever including carditis (8, 11) and Sydenham chorea (7), which may follow group A streptococcal infection (3).

Molecular mimicry between host and bacterial antigens was first defined as identical amino acid sequences shared between different molecules present in tissues and the bacterium (26–28). The investigation of molecular mimicry through the use of mAbs has identified other types of molecular mimicry. The second type of mimicry involves antibody recognition of similar structures such as alpha-helical coiled-coil molecules such as streptococcal M protein, and the host proteins myosin, keratin, tropomyosin, vimentin, and laminin that share regions containing 40% identity or less and cross-reactive sites are not completely identical (4, 29–43). A third type of molecular mimicry is revealed in immunological cross-reactions between molecules as diverse as DNA and proteins (36, 40, 44) or carbohydrates and peptides (45–47). The three types of molecular mimicry are summarized in Table 1. Studies of the cross-reactive antigens of the group A streptococci have contributed greatly to our knowledge about molecular mimicry, autoimmunity, and infection and the antibody molecules involved. The antibody molecules described as polyreactive or cross-reactive indicate recognition of multiple antigens. As described, the basis of the immunological cross-reactions may be identical or homologous amino acid sequences shared between two different proteins or may be epitopes shared between two entirely different chemical structures.

A theme in molecular mimicry suggests antibody recognition of an internal biomarker, often a structural protein, which cross-reacts with the streptococcal antigen and a cell surface antigen leading to cytotoxicity or to functional cell signaling (6, 7). Through these mechanisms, tissue is altered and T cells are recruited to the site of attack (48).

HISTORICAL PERSPECTIVE

Cross-reactive antigens and antibodies were first found to be associated with acute rheumatic fever (ARF) and group A streptococci when it was discovered that rheumatic fever sera or anti-group A streptococcal antisera reacted with human heart or skeletal muscle tissues (15, 17, 19). Antibodies against group A streptococci in the serum of rheumatic fever patients were shown to be absorbed from the sera with human heart extracts, and in contrast, the antiheart antibodies were shown to be absorbed with group A streptococci or streptococcal membranes (49, 50). Rabbit antisera produced against group A streptococcal cell walls reacted with human heart tissue, and antibodies produced against human heart tissue reacted with group A streptococcal antigens (49, 51, 52). In rheumatic fever, heart-reactive antibodies appeared to persist in patients with rheumatic recurrences, and there appeared to be a relationship between high titers of antiheart antibodies and recurrence of rheumatic fever (15, 19). Heart-reactive antibodies were reported to decline within 5 years of the initial rheumatic fever attack.

Subsequent research on this early work by Kaplan and Suchy (49) implicated the streptococcal cell wall containing the M protein as the cross-reactive antigen recognized by the antiheart antibodies, while studies by Zabriskie and Freimer (15, 17) implicated the streptococcal membrane as the site of the cross-reactive antigen. Beachey and Stollerman (53) and Widdowson and Maxted (54–56) reported an M-associated non-type-specific antigen and an M-associated protein, respectively, which were thought to be associated with immunological cross-reactions in ARF. In 1977, van de Rijn

et al. demonstrated that highly purified peptides from group A streptococcal membranes reacted with the antiheart antibodies in rheumatic fever serum (57). Taken together, this evidence suggested that cross-reactive antigens were located in both the cell wall and membrane of the group A streptococci.

Evidence also supported the hypothesis that the group A polysaccharide was a cross-reactive antigen (58). Goldstein and colleagues showed that glycoproteins in heart valves contained the *N*-acetyl-glucosamine determinant that they proposed to be responsible for immune cross-reactivity of group A streptococci with heart tissues. Dudding and Ayoub demonstrated the persistence of anti-group A carbohydrate antibody in patients with rheumatic valvular disease (59). Lyampert in Russia also published studies suggesting that the group A streptococcal polysaccharide antigen induced responses against host tissues (60–62). McCarty suggested that the terminal O-linked *N*-acetyl-glucosamine might cross-react with antibodies against the group A carbohydrate and host tissues (63). Additional evidence suggested that the hyaluronic acid capsule of the group A streptococcus also might induce responses against joint tissues (64, 65). Administration of a peptidoglycan-polysaccharide complex prepared from group A streptococci to rats induced carditis and arthritis (66–71). The studies in the 1960s and 1970s left little doubt that group A streptococci induced autoantibodies against the heart and other host tissues and that streptococcal components could induce inflammatory lesions resembling arthritis and carditis in animal tissues.

CROSS-REACTIVE mAbs RECOGNIZE CARDIAC MYOSIN AND ALPHA-HELICAL COILED-COIL MOLECULES IN HEART AND BRAIN

mAbs cross-reactive with group A streptococci and human heart tissues were produced from mice immunized with streptococcal cell wall and membrane components (4, 33, 40, 72) and from rheumatic carditis patients (35). Figure 1 illustrates the cross-reactivity of an antistreptococcal mAb with myocardium. In 1985, Krisher and Cunningham identified myosin as a cross-reactive host tissue antigen that provided the link between streptococci and the heart (4). In 1987, it was demonstrated that cardiac myosin could induce myocarditis in genetically susceptible mice (73). Myosin is an alpha-helical coiled-coil molecule that was shown to be an important tissue target of the cross-reactive mAbs (72). Other host tissue antigens recognized by antistreptococcal mouse and human mAbs included the alpha-helical coiled-coil molecules tropomyosin (29, 40), keratin (29, 45, 74), vimentin (36), laminin (6, 30, 75), DNA (36), and *N*-acetyl-β-D-glucosamine (45–47), the immunodominant epitope of the group A polysaccharide. A summary of the cross-reactive antistreptococcal mAb host tissue targets is provided in Table 2. The tissue targets identified by the cross-reactive mAbs may be important in the manifestations of group A streptococcal rheumatic fever sequelae of arthritis, carditis, chorea, and erythema marginatum (76, 77). A summary of

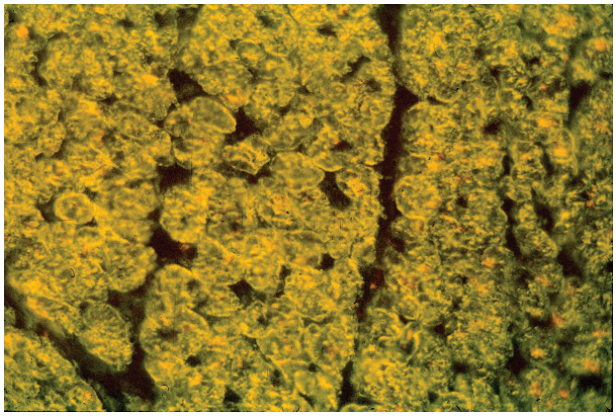

FIGURE 1 Reaction of mouse antistreptococcal mAb with a human tissue section of myocardium in a indirect immunofluorescence assay. Mouse IgM (20 μg/ml) was unreactive (not shown). mAbs were tested at 20 μg/ml. (Taken from reference 40 with permission from the *Journal of Immunology*.)

the cross-reactive human and mouse mAb specificities has been published in previous reviews (78–81).

The cross-reactive antibodies were divided into three major subsets based on their cross-reactivity with (i) myosin and other alpha-helical molecules, (ii) DNA, or (iii) *N*-acetyl-glucosamine. Figure 2 illustrates the subsets of cross-reactive antistreptococcal/antimyosin mAbs. All three subsets were identified among mAbs from mice immunized with group A streptococcal components, but in humans, the predominant subset reacted with the *N*-acetyl-glucosamine epitope and myosin and related molecules. This result is not surprising, since rheumatic fever patients do not develop antinuclear antibodies during the course of their disease. Elevated levels of poly-reactive antimyosin antibodies found in ARF sera (35) and in animals immunized with streptococcal membranes or walls (17, 49, 50, 52) most likely account for the reactivity of these sera with myocardium and other tissues. Similar types of cross-reactive mouse and human antibodies have been investigated by Lange and colleagues (82) and by Young and colleagues (83), respectively.

Poly-specific or cross-reactive autoantibodies have emerged as a theme in autoimmunity and molecular mimicry (36, 84–86). The V-D-J region genes of the human and mouse cross-reactive mAbs have been sequenced (29, 30, 87), but there is no consensus sequence to explain the molecular basis of poly-specificity and cross-reactivity. It is worth noting that the three groups of reactivities in mice do not have specific antibody V gene families or VH and VL gene combinations that correlate with a specific reactivity. However, higher-avidity cross-reactive antimyosin mAb (87) was associated with reactivity with laminin and

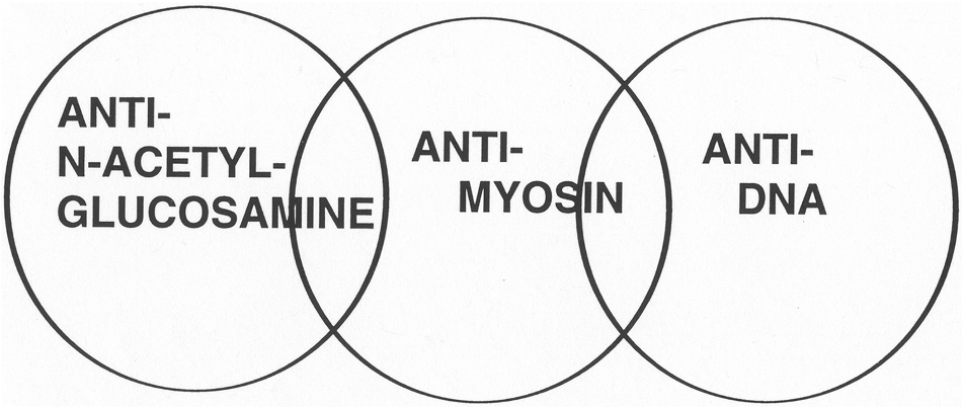

FIGURE 2 Human and murine antistreptococcal/antimyosin mAbs were divided into three subsets based on their reactivity with myosin and *N*-acetyl-glucosamine, the dominant group A carbohydrate epitope, with DNA and the cell nucleus, a property found among murine mAbs, and reactivity with myosin and a family of alpha-helical coiled-coil molecules. (Taken from reference 203 with permission from Indiana University School of Dentistry Press.)

complement-mediated heart cell cytotoxicity (30, 75). The V genes of cross-reactive human mAbs from rheumatic fever were encoded by a heterogeneous group of VH3 family genes (VH-3, VH-8, VH-23, VH-30) and a VH4-59 gene segment (29). Wu et al. reported a similar group of V gene sequences for their human antistreptococcal/antimyosin antibodies produced from Epstein-Barr virus-transformed B cell lines (83). Many sequences were found to be either in germline configuration or were highly homologous with a previously sequenced germline V gene. It has been proposed that a germline antibody may be poly-reactive due to conformational rearrangement and configurational change, permitting binding of diverse molecules (88).

Cytotoxic mouse and human mAbs have identified the extracellular matrix protein laminin as a potential tissue target present in basement membrane surrounding myocardium and valve surface endothelium (6, 30, 75, 89, 90). Cross-reactive antibodies may become trapped in extracellular matrix that may act like a sieve to capture antibody and lead to inflammation in host tissues. The cross-reactive antibodies in rheumatic heart disease, even though they react with cardiac myosin, target valve surface endothelium and laminin (6) as shown in Fig. 3 and 4 and initiate the inflammation at the endocardium, where T cells then target the activated valve endothelium and infiltrate the valve (48) as shown in Fig. 5 and lead to eventual scarring and neovascularization of the normally avascular valve. Vascular cell adhesion molecule-1 (VCAM-1) expression has been found on the valve surface endothelium that attracts very late antigen-4 (VLA-4) on the activated T cell (48).

mAbs IDENTIFY STREPTOCOCCAL CROSS-REACTIVE ANTIGENS

Introduction

The discovery leading to the development of mAbs (91) was transformative for the investigation of autoantibodies and their specificities, including the cross-reactivities of the antibodies of the group A streptococci (4). Because a single mAb can represent a minor specificity and not the antibodies represented in the disease, the sera from patients with the disease should be investigated to prove that the mAbs reflect the disease and potentially its pathogenesis. Antimyosin mAbs identified cross-reactive antigens in streptococcal membranes (36, 92) and walls (36). The streptococcal M protein was shown to react with the heart or myosin cross-reactive mAbs (40, 92). In addition, a 60-kDa protein present in the cell membrane (93, 94) was cross-reactive with myosin in the heart, and a 67-kDa protein that was immunologically similar to class II major histocompatibility molecules was also identified (95). The data suggested that cross-reactive antigens were present in both the wall and membrane of the group A streptococci. The data support previous evidence from both Kaplan (49–52, 96) and Zabriskie (15, 17, 19). Although these data were once thought to be conflicting, it is clear that the cross-reactive antibodies recognize more than one antigen in the streptococcal cell. The data

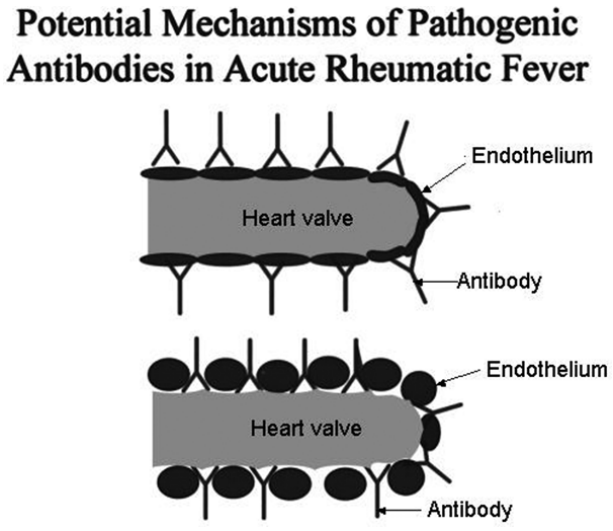

FIGURE 3 Diagram illustrating the potential mechanism of antibody in the pathogenesis of rheumatic heart disease. Cross-reactive antibody is shown binding directly to endothelium (top diagram) or binding to basement membrane of the valve (bottom diagram) exposed due to shear stress or damage by antibody and complement. FIGURE 4 Reactivity of antistreptococcal/antimyosin mAb 3.B6 with normal human valve endothelium and myocardium. Formalin-fixed human mitral valve (A) and myocardium (B) were reacted with mAb 3.B6 at 10 μg/ml. mAb 3.B6 binding was detected using biotin-conjugated anti-human antibodies and alkaline phosphatase-labeled streptavidin followed by fast red substrate. Control sections did not react with human IgM at 10 μg/ml (C,D). (Reproduced with permission from Lippincott Williams and Wilkins).

previously reported by Goldstein (58) are also supported by the evidence that a subset of cross-reactive mAbs recognized *N*-acetyl-β-D-glucosamine, the immunodominant epitope of the group A polysaccharide. *N*-acetyl-glucosamine is a major epitope of some of the cross-reactive mouse mAbs and virtually all of the human cross-reactive mAbs investigated (6, 45–47). The studies link together the cross-reactivity of the group A carbohydrate epitope, GlcNAc, human cardiac myosin, and streptococcal M protein. Antigenic redundancy due to cross-reactivity may be an important factor in triggering disease in a susceptible host. The cross-reactive antigens are now seen as separate entities recognized by mAbs that recognize more than one antigen molecule. Thus, the previous studies, which before seemed to be conflicting, were all correct. The use of mAbs has allowed dissection of the group A streptococcal cross-reactive antigens that would not have been possible using polyclonal sera. The following sections provide more evidence about the identification and analysis of the cross-reactive antigens of the group A streptococci. Table 2 summarizes the host tissue protein antigens targeted by antistreptococcal antibodies in disease and following immunization with group A streptococcal components. Table 3 summarizes the group A streptococcal cross-reactive antigens, of which the group A carbohydrate (6) and the M proteins (8, 97–101) are the most well investigated.

M Proteins and Rheumatic Fever

Investigation of the M proteins has provided important information about the sequence and primary structure of the molecule. The hypothesis that M proteins and myosin have immunological similarities was supported by the structural studies of Fischetti and colleagues (102–105) that demonstrated the seven-amino-acid-residue periodicity that is common among group A streptococcal M proteins and shared with proteins such as tropomyosin, myosin, desmin, vimentin, and keratin. Figure 6 illustrates the seven-residue periodicity and the homology characteristic of alpha-helical coiled-coil proteins such as tropomyosin and myosin. The cross-reactivity between group A streptococci and myosin was first identified by Krisher and Cunningham using mouse mAbs from mice immunized with group A streptococcal antigens (4). Subsequent studies by Dale, Beachey, Bronze, and colleagues using polyclonal sera and affinity purified antibodies further demonstrated immunological cross-reactivity between M proteins and myosin (37–39, 106). Studies using the cross-reactive mAbs also identified immunological cross-reactivity between streptococcal M proteins (both PepM [the N-terminal half of the molecule] and recombinant molecules) and cardiac and skeletal myosins (31, 36, 40).

Since streptococcal M proteins have been investigated for potential epitopes that were recognized by the cross-reactive mAbs, affinity purified antimyosin antibodies from ARF sera were reacted with peptides of streptococcal M5 protein. Affinity purified antimyosin antibodies from ARF reacted with an M5 amino acid sequence (residues 184 to 188) near the pepsin cleavage site (near the center of the molecule) in M5 and M6 proteins (40). The epitope, located in the B repeat region of M5 and M6 proteins, appeared to be a B cell epitope for antibody-mediated cross-reactivity with myosin (32, 40). An M5 peptide, containing the B repeat region epitope Gln-Lys-Ser-Lys-Gln (QKSKQ) was shown to inhibit antimyosin antibodies in ARF (40). Furthermore, an M5 peptide that contained the QKSKQ sequence induced antibodies in BALB/c mice against cardiac or skeletal myosins and the light meromyosin (LMM) fragment of myosin. This evidence further supported the previous findings

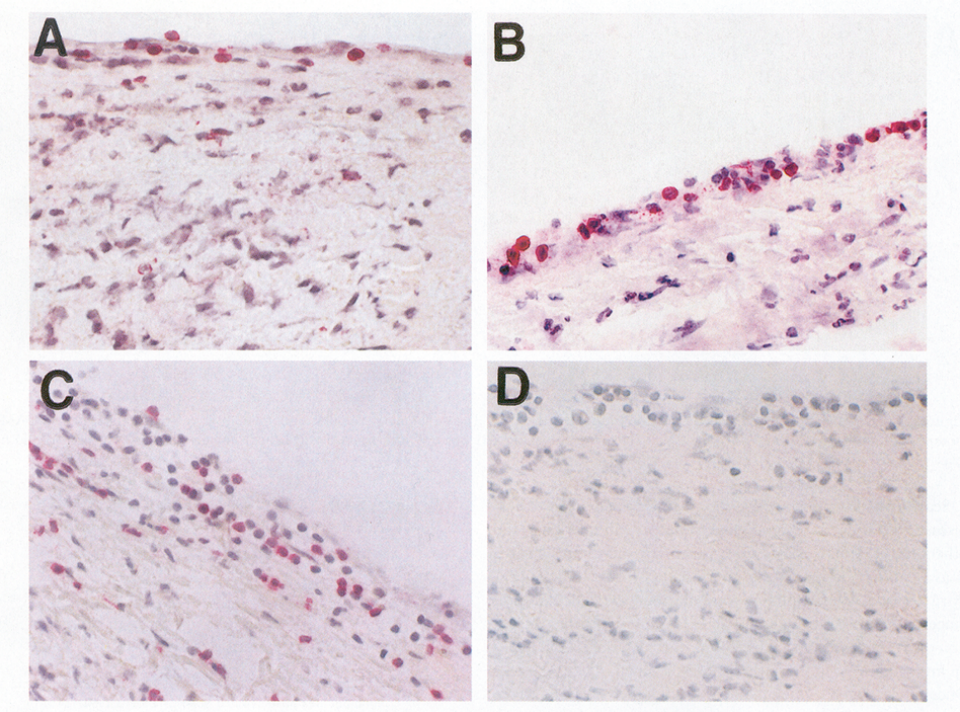

FIGURE 5 Adhesion and extravasation of T lymphocytes into an ARF valve in valvulitis. (A,B) Extravasation of $CD4^+$ lymphocytes (stained red; original magnification, 200× and 400×, respectively). (C) Extravasation of $CD8^+$ lymphocytes (stained red) into the valve through the valvular endothelium (magnification, 200×). An IgG_1 isotype control mAb (IgG_1) did not react with the same valve (not shown). (With permission from the *Journal of Infectious Diseases*, Chicago Press).

indicating that the QKSKQ sequence is important in the antibody-mediated cross-reactions with myosin in ARF (40). M5 residues 164 to 197 were demonstrated to induce antibodies against sarcolemmal membrane of heart tissue (107), and M5 residues 84 to 116 induced heart-reactive antibody and reacted with antimyosin antibody purified from ARF sera (40, 107). Studies by Kraus and colleagues (42) demonstrated a vimentin cross-reactive epitope present in the M12 protein, and M protein peptides containing brain cross-reactive epitopes were localized to the M5 protein sequence 134 to 184 and the M19 sequence 1 to 24 (98, 99). A summary of the currently known myosin cross-reactive B cell epitopes in M5 protein is shown in Fig. 7, which illustrates the A, B, and C repeat regions of M protein.

Immunization of BALB/c mice with each of 23 overlapping synthetic peptides of M5 protein has revealed that the M5 peptides NT3-NT7, B2B3B, and C1A-C3 induce antihuman cardiac myosin antibodies as shown in Fig. 8. Similar overlapping synthetic peptides spanning the M5 protein molecule have been reported elsewhere (32). Titers of the anti-M5 peptide sera were 10 times greater against cardiac myosin than against skeletal myosin, tropomyosin, vimentin, and laminin (32). Certain M5 peptides appeared to induce a cardiac myosin-directed response in BALB/c mice. Furthermore, BALB/c mice developed mild myocarditis when immunized with M5 peptides NT4, NT5, NT6, B1A, and B3B (32). Peptides from the C-repeat region of M5 protein did not produce myocardial lesions when administered to BALB/c mice.

67-kDa antigen

The C-repeat region of class I M proteins contains the class I epitope, which is identified by reactivity with anti-M protein mAb 10B6 (108–111). Class I M protein serotypes were streptococcal strains associated with pharyngitis and rheumatic fever. Responses against the class I epitope were stronger in patients with rheumatic fever than in those with uncomplicated disease (112, 113). mAb 10B6, which recognizes the C-repeat epitope, also reacted with skeletal and cardiac myosins and the heavy meromyosin subfragment of myosin (112). The C-repeat class I epitope in M5 contains the amino acid sequence KGLRRDLDASREAK, which shares homology with RRDL, a conserved amino acid sequence found in cardiac and skeletal myosins. The myosin sequence RRDL is located in the heavy meromyosin subfragment of the cardiac and skeletal myosin heavy chain (112).

It was reported that reactivity of IgG from ARF sera was greater to the class I peptide sequence than IgG from uncomplicated pharyngitis (112). This was confirmed in a study by Mori and colleagues (114). However, the lower immune response to the class I epitope in uncomplicated pharyngitis most likely occurred because the patients with uncomplicated pharyngitis had been treated with penicillin (115). Antibodies against the class I epitope were affinity purified from ARF sera and shown to react with myosin (112).

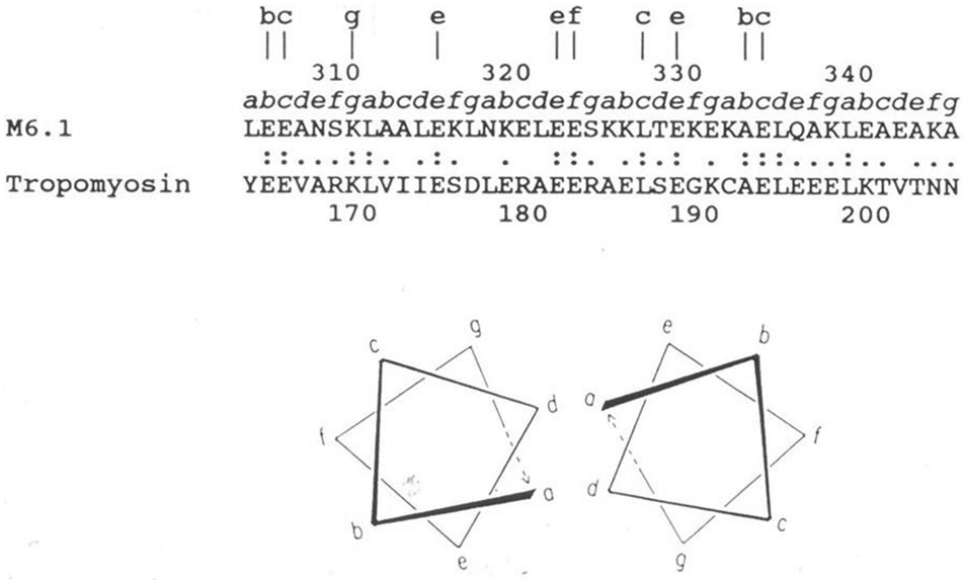

FIGURE 6 Sequence alignment of streptococcal M6 protein and human cardiac tropomyosin in a region exhibiting significant homology. Lowercase letters a to g directly above the sequence designate the position of these amino acids within the seven-residue periodicity in both segments. Lowercase letters at the top of the figure designate identities at external locations in the heptad repeat. Double dots indicate identities, and single dots indicate conservative substitutions. Within this segment of the streptococcal M6 molecule, 31% homology is observed with tropomyosin. Since both molecules are alpha-helical coiled-coil proteins, they contain the seven-residue repeat pattern where positions a and d are usually hydrophobic. Similar homologies are seen between M proteins and myosin heavy chains and any of the three laminin chains. (Reproduced from reference 40 with permission from the *Journal of Immunology*.)

Studies by Huber and Cunningham demonstrated that streptococcal M5 peptide NT4 containing the amino acid sequence GLKTENEGLKTENEGLKTE could produce myocarditis in MRL/++ mice, an autoimmune-prone strain (116). The studies demonstrated that the myocarditis was mediated by $CD4^+$ T cells and class II major histocompatibility complex molecules. Antibodies against the IA^k major histocompatibility molecule or antibody against $CD4^+$ T cells abrogated the myocarditis (116). Amino acid sequence homology between the NT4 peptide of M5 and human cardiac myosin demonstrates 80% identity. Figure 9 illustrates the homology between the M5 peptide NT4 sequence and the cardiac myosin sequence. The mimicking sequence in NT4 is repeated four times in the M5 protein and is present in myosin only once. Repeated regions of the M protein that mimic cardiac myosin may be important in breaking tolerance in the susceptible host and producing autoimmune disease. The data support the hypothesis that epitopes in streptococcal M5 protein that mimic cardiac myosin may be important in breaking tolerance to this potent autoantigen. Table 4 summarizes the M protein amino acid sequences observed to induce inflammatory myocardial lesions in mice.

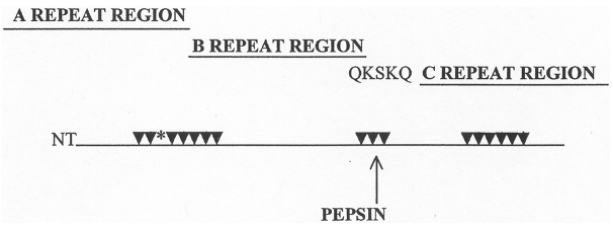

FIGURE 7 Antimyosin antibody cross-reactive sites in M5 protein A, B, and C repeat regions of the molecule. Arrows point to sites determined to induce human cardiac myosin cross-reactive antibody (32). The asterisk (*) marks the location of peptide NT4 containing several repeats of an epitope in cardiac myosins that causes myocarditis in MRL/++ and BALB/c mouse strains (32, 116). Site QKSKQ is the epitope determined to react with antimyosin antibody in ARF sera (40). (Reproduced from *Effects of Microbes on the Immune System* with permission from Lippincott Williams and Wilkins.)

Streptococcal M proteins not only mimic epitopes in cytoskeletal proteins, but they mimic epitopes in other strong bacterial and viral antigens, namely, heat shock protein (Hsp-65) (117) and coxsackie viral capsid proteins (31, 116, 118, 119). These immunological cross-reactions may be vital to the survival of the host and suggest that antibody molecules may recognize and neutralize more than a single infectious agent. Such antibodies may be an important first line of defense and would be highly advantageous for the host. Multiple pieces of evidence from experiments using synthetic peptides have shown that sites in the M protein mimic a site(s) in the VP1 capsid protein of coxsackie virus (31, 120). Further evidence demonstrated that some of the antistreptococcal/antimyosin mAbs neutralized enteroviruses and were cytotoxic for heart cells (31). This was extremely interesting because coxsackie viruses cause autoimmune myocarditis in susceptible hosts (121–123). The Hsp-65 antigen has been shown to play a role in the development of arthritis and diabetes (124, 125). Cross-reactive epitopes shared between streptococcal M proteins and Hsp-65 play a role in arthritis sequelae. Antibodies against heat shock protein 60

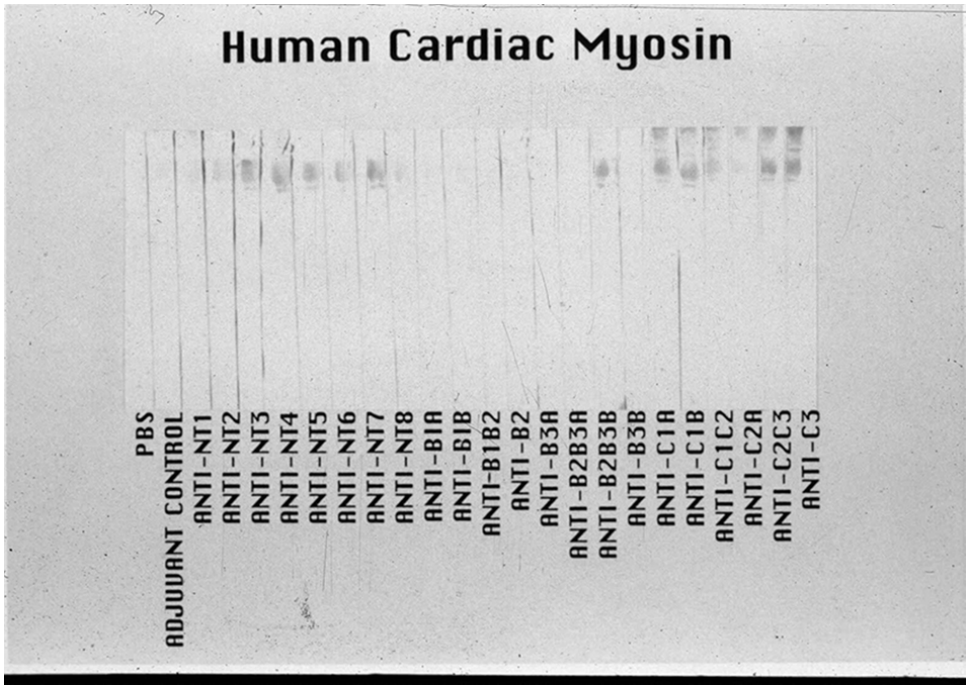

FIGURE 8 Reactivity of the antistreptococcal M5 peptide sera in a Western immunoblot of human cardiac myosin. The 200-kDa protein band of the purified human cardiac myosin, shown in the stained portion of the Western blot, reacted most strongly with antipeptide sera from mice immunized with the M5 peptides NT3-7, B2B3B, C1A, C1B, C2C3, and C3. Sera were tested at a 1:1000 dilution. A control antimyosin mAb CCM-52 (a gift from William Clark, Cardiovascular Research Institute, Michael Reese Hospital and Medical Center, Chicago, IL) reacted with the 200-kDa band present in our purified preparation of human cardiac myosin heavy chain. Purification of the human cardiac myosin heavy chain to homogeneity was previously described by Dell et al. (204). The Western blot confirms the data seen in the enzyme-linked immunosorbent assay with human cardiac myosin. (Reproduced from reference 32 with permission from ASM Press.)

have been implicated in cytotoxicity against endothelium (126). Shared epitopes among pathogens may be important in molecular mimicry, may break tolerance to cryptic host molecules, and may influence the development of autoimmune diseases. Table 5 summarizes bacterial and viral proteins that have immunological similarities with M protein.

Identification of the Molecular Basis of Mimicry in the Streptococcal M Protein

Studies were undertaken to crystallize a portion of the streptococcal M1 protein (127) to evaluate its virulence properties when portions of the amino acid sequence were mutated, but also to investigate regions and structures responsible for eliciting or reacting with cross-reactive antibodies that participate in molecular mimicry. The structural study revealed irregularities and instabilities in the coiled coil of the M1 fragment crystal. Similar structural instabilities and irregularities occur in myosin and tropomyosin that had previously been demonstrated to cross-react with the streptococcal M proteins (37–40). Stabilization of the irregularities of the M protein structure, by creating mutants of the M protein gene to alter specific amino acids, enhanced the stability of the coiled coil and diminished the virulence properties of the M1 protein, including decreased cross-reactivity with autoantibodies that cross-reacted with heart tissues, cardiac myosin, and group A streptococcal M proteins (127). Loss of the heart or tissue cross-reactivity of the streptococcal M protein improves its potential for use as a vaccine antigen.

M Proteins and Cross-Reactive T Cells

M proteins have also been shown to stimulate human T lymphocyte responses (97, 128–135), including cytotoxic T lymphocytes from ARF patients (128, 136). PepM protein

(pepsin-extracted M protein fragment) has been reported to be a superantigen that stimulated Vβ2, Vβ4, and Vβ8 bearing T cell subsets (133–135, 137). Other reports show that neither recombinant nor native forms of M proteins are superantigenic (138–140). A superantigenic site reported for the M5 protein has been localized to the amino acid sequence located in M5 residues 157 to 197 (KEQENKETIGTLKKILDETVKDKLAKE QKSKQNIGALKQEL) in the B3 repeat region (137). The site has a significant amount of sequence homology with other superantigens. The role of M protein or other superantigens in ARF may be to activate large numbers of T cells, including some that are cross-reactive and may lead to ARF.

Studies of T cell epitopes in rheumatic fever and in animal models focus on the M5 protein molecule because serotype M5 has often been associated with ARF outbreaks (141). T and B cell epitopes of the M5 protein were defined in earlier studies by Robinson and colleagues (131, 132), by Good and colleagues (129, 130), and in my laboratory (32).

Guilherme et al. isolated cross-reactive T cells from mitral valves, papillary muscle, and left atrium of rheumatic fever patients previously infected with M5 group A streptococci (97). T cell lines were responsive to several peptides of the streptococcal serotype M5 protein and proteins from heart tissue extracts. Sequences from the A and B repeat regions of M5 protein that stimulated the valvular T cells are shown in Table 6. In BALB/c mice using synthetic peptides, myosin-cross-reactive T cell epitopes from the A, B, and C repeat regions of the M5 protein were identified (32). Six dominant myosin cross-reactive T cell epitopes were located in the M5 molecule (32). Table 6 summarizes (i) the dominant myosin cross-reactive T cell epitopes of M5 protein in BALB/c mice (32), (ii) the M5 sequences recognized by T cell clones from rheumatic heart valves (97), and (iii) the M5 peptides reported by Good and colleagues to stimulate human T cells from normal controls and rheumatic fever patients that were responsive to myosin peptides (129, 130). An important correlation seen in Table 6 indicates that M5 peptides NT4/NT5 (GLKTENEGLKTENEGLKTE and KKEHEAENDKLKQ QRDTL) and B1B2/B2 (VKDKIAKEQENKETIGTL and TIGTLKKILDETVKDKIA), which were dominant cross-reactive T cell epitopes in the BALB/c mouse, contain sequences similar to those reported to be recognized by T cells from rheumatic valves (97). Peptides NT4 and NT5 produced inflammatory infiltrates in the myocardium of animals immunized with those peptides (32). The collective evidence on cross-reactive T cells suggests that amino acid sequences in M5 protein that share homology with cardiac myosin may break tolerance and promote T cell-mediated inflammatory heart disease in animals and humans (32).

Group A streptococcal carbohydrate

T cells isolated and cloned from the peripheral blood or from human rheumatic mitral valves of human rheumatic heart disease patients recognized streptococcal M5 peptides and LMM peptides (21, 22, 25). The cross-reactive T cells taken from ARF and RHD rheumatic heart disease heart valves mainly recognize three regions (residues 1 to 25, 81 to 103, and 163 to 177) of the amino-terminal region of M5 protein, several valve-derived proteins, and peptides of the β-chain of the human cardiac LMM region, which is the smaller of two subunits produced by tryptic digestion of human cardiac myosin (21, 22, 25, 97). Mimicry between M proteins and cardiac myosin stimulates cross-reactive T cells in the peripheral blood of the host (25, 142, 143). The T cells then travel to the valve once the endothelium of the valve becomes activated and inflamed (48). This extravasation event at the valve endocardium allows the cross-reactive T cells to enter the valve, where they recognize and proliferate to valvular proteins such as vimentin (89), which may include cardiac myosin from papillary muscle. T cells that remain in the valve survive if they continue to be stimulated by host alpha helical proteins within the valve. The activated cross-reactive T cells when continually stimulated within the valve become pathogenic for the host and produce the TH1 mechanism of pathogenesis with scarring in the valve. Figure 10 illustrates the events in rheumatic carditis that result from immune responses against the cross-reactive antigens of the group A streptococci (144).

The granulomatous Th1 cell response and the presence of interferon-γ (IFNγ) have been reported as dominant in rheumatic valves (145). Studies of rheumatic heart disease have suggested that Th17 cells in peripheral blood are elevated in rheumatic heart disease with concomitant down-regulation of the Treg phenotype (146). In ARF and rheumatic heart disease, elevated numbers of Th17 cells, high interleukin-17A (IL-17A) levels, and decreased T regulatory cells were reported in peripheral blood (146). Although less is known about Th17 cell responses in rheumatic heart disease, Th17 cells are important in group A streptococcal infections and have been identified in nasopharyngeal and tonsillar lymphoid tissues in streptococcal infection animal models (147–149). Different routes of bacterial infection may induce long-lived Th1 memory cells and short-lived Th17 cell responses (148). IL-17 triggers effective immune responses against extracellular bacteria, such as promoting neutrophil responses (150–153).

The Lewis rat model of rheumatic heart disease also suggests the presence of IL-17A in the pathogenesis of experimental valvulitis induced by immunization with group A streptococcal antigens (13, 101). This finding does not preclude Th1, which is often found in tandem with Th17 responses in autoimmune disease models and in human autoimmune diseases (148). Although both Th1 and Th17 are proinflammatory, Th17 responses have been found to be more damaging in the chronic stages of disease leading to

fibrosis, and IL-17A was dispensable in the earlier proinflammatory stages of myocarditis in mice (154) but promoted fibrosis in later stages and was associated with heart failure in humans (155).

A New Model of Valvular Heart Disease Induced by Group A or Group G Streptococcal M Proteins in the Lewis Rat

A new model of experimental autoimmune valvulitis and rheumatic heart disease was developed by Quinn et al. by immunization of the Lewis rat model with the recombinant M6 protein (23). The lesions that developed demonstrated characteristics of rheumatic heart disease in humans with verrucae (Fig. 11C) (23), Anitschkow cells, and edema with cellular infiltration into the endocardium of the valve (Fig. 11A and B) (8, 23). T cell lines from the model proliferated to both the rM6 protein and cardiac myosin. The model appeared to be very similar in appearance to the VCAM-1 activation (Fig. 11D) in humans and infiltration of $CD4^+$ T cells into the VCAM-1 positive endothelium/endocardium (not shown) of the valve in rheumatic heart disease (48) (Fig. 12). More recent studies identified A and B region peptide epitopes of M5 protein that induced valvulitis in the Lewis rat (8). Repeat region peptides NT4, NT5/6, and NT7 (see Table 6) induced valvulitis similar to the intact pepsin fragment of M5 protein, PepM5. T cell lines from rats with valvulitis proliferated to M5 peptides NT5/6 and NT6. Passive transfer of an NT5/6-specific T cell line into naive rats produced valvulitis characterized by infiltration of $CD4^+$ cells and upregulation of VCAM-1 in valvular endothelium, while another NT6-specific T cell line did not target the valve (8). Thus, the infiltrating T cell line appeared to be important in the induction of inflammation in the valve.

Recent studies have used the Lewis rat model to demonstrate the induction of valvular heart disease by the C repeat region peptides of group A streptococcal M5 protein (12, 13). T cells from the model proliferated to M protein and cardiac myosin. Further studies by Ketheesan and colleagues demonstrated that exacerbation and increasing severity of valvulitis followed repeated group A streptococcal immunizations with group A streptococcal M protein (156). Lewis rats were immunized with group A streptococcal recombinant M5 protein and boosted once, twice, or three times. Anti-cardiac myosin antibodies and T cell responses increased with the booster immunizations. More severe lesions were observed in the repetitively immunized Lewis rats (156). Thus, the model demonstrates increased cardiac damage as seen in humans after repeated streptococcal infections. Immunization of the Lewis rat model with M protein from group G streptococci also led to valvular lesions (101). In the experimental autoimmune valvulitis model, both group A and group G M proteins and cardiac myosin induced proliferation of the T cells. IL-17A and IFNγ were found to be upregulated in the model (101). Thus, roles for IL17A in ARF and rheumatic heart disease are supported by the studies of patients with carditis.

Human Cardiac Myosin Peptide Epitopes in Rheumatic Heart Disease in Human Populations and Their Use in Monitoring Progression of Disease

Studies of humans with rheumatic fever and rheumatic heart disease have identified disease-specific epitopes of human cardiac myosin in the development of rheumatic carditis in humans (24). Immune responses to cardiac myosin were similar in rheumatic carditis among a small sample of worldwide populations, in which serum IgG targeted disease-specific human cardiac myosin epitopes in the S2 subfragment hinge region within S2 peptides containing amino acid residues 842 to 992 and 1164 to 1272 (Fig. 13) (24). Analysis of the anti-cardiac myosin autoantibodies in rheumatic carditis in a Pacific Islander family further confirmed the specific responses against cardiac myosin in rheumatic heart disease and confirmed the presence of potential rheumatogenic epitopes in the S2 region of human cardiac myosin (24). The study suggested that cardiac myosin epitopes targeted in rheumatic carditis were in the S2 hinge region of cardiac myosin and that the anti-cardiac myosin responses were

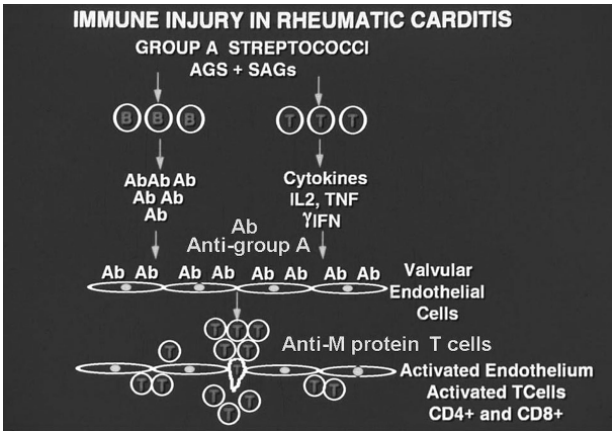

FIGURE 10 Diagram representing the proposed immunopathogenesis of poststreptococcal rheumatic heart disease. Initially, B and T cells are activated by specific streptococcal antigens and superantigens, leading to strong immune responses against streptococcal and host antigens. The development of pathogenic clones of B and T lymphocytes is important in the development of the disease. Initially, antibodies develop against the group A carbohydrate, which are cross-reactive with the valve surface, and glycoproteins such as laminin and bind to the valve surface endothelium (endocardium), leading to inflammation and upregulation of cell adhesion molecules such as VCAM-1 on activated surface endothelium of the valve. M protein-reactive T cells enter the valve through the surface endothelium by binding to cell adhesion molecules such as VCAM-1 and extravasate into the valve (48). The formation of scar tissue in the valve followed by neovascularization allows the disease to continue in the valve. The specificity of the T cells in blood (25) and T cells entering the valve have been shown to react to M protein (22, 97, 144). T cell subsets include Th1 (IFNγ) (145) in the pathogenesis of proinflammatory responses and the development of the scarred and fibrotic valve. IL-17A has also been associated with rheumatic heart disease in humans and animal models, suggesting that Th17 cells are involved in disease (101, 146, 149).

similar among populations with rheumatic carditis worldwide regardless of the infecting group A streptococcal M protein serotype.

Further study of cardiac myosin peptide epitopes revealed that Australian patients with active rheumatic heart disease reacted significantly more to peptides from the S2 or LMM regions of human cardiac myosin than did healthy controls (11). Comparison of serum from active rheumatic heart disease patients to serum from patients treated for over a year with antibiotics revealed that the treatment led to a reduction in the anti-cardiac myosin peptide autoantibodies (11). Thus, identifying the immune response against the cardiac myosin peptides may monitor progression of rheumatic heart disease and may also determine effective treatment with a concomitant decline of the autoantibodies to cardiac myosin.

M Proteins and Poststreptococcal Acute Glomerulonephritis

Kefalides and colleagues showed that sera from patients with acute poststreptococcal glomerulonephritis contained antibodies against laminin, collagen, and other macromolecules found in the glomerular basement membrane (157). The epitope recognized in collagen was identified and shown to be located in the 7-S domain of type IV collagen (158). Streptococcal antigens, immunoglobulins, and complement were detected in the kidney glomeruli in acute poststreptococcal glomerulonephritis (159). Studies by Lange and Markowitz suggested that the glomerular basement membrane shared antigens with streptococcal M12 protein (160) and/or between the group A streptococcus and glomeruli (41, 161–163). Kraus and Beachey discovered a renal autoimmune epitope (Ile-Arg-Leu-Arg) in M protein (43). Evidence has suggested that certain M protein serotypes are associated with nephritis and that molecular mimicry or immunological cross-reactivity between glomeruli and M protein could be one mechanism by which antiglomerular antibodies are produced during infection. In animal models of nephritis induced by nephritogenic streptococci (M type 12), antiglomerular antibodies eluted from kidney glomeruli reacted with the type 12 streptococcal M protein (164). Furthermore, an antiglomerular mAb reacted with the M12 protein (163). These studies support immune-mediated mechanisms in poststreptococcal acute glomerulonephritis (AGN). Streptococcal and renal antigens may be an important source of mimicking antigen present in the kidney and play a role in binding immunoglobulin and complement with production of nephritis.

Novel Cross-Reactive Protein Antigens in Group A Streptococci

Antimyosin antibodies from ARF were used to identify group A streptococcal cross-reactive antigens other than M proteins. The cross-reactive antigens were detected in a *Streptococcus pyogenes* strain that had spontaneously lost its *emm* gene. The affinity purified antimyosin antibodies were used to screen gene libraries and the antigen preparations from this M protein-deficient streptococcus. A 60-kDa streptococcal actin-like protein (165), a 60-kDa wall-membrane protein (93, 94), and a 67-kDa protein from a cloned gene product (95) were identified. All of the antigens were unique and interesting. The 60-kDa actin-like molecule behaved biochemically like an actin and produced actin-like filaments observed by electron microscopy (165). The 67-kDa cloned gene product recognized by antimyosin antibody from ARF sera was novel in that it shared enough sequence homology with major histocompatibility molecules that it reacted with sera against mouse major histocompatibility complex class II molecules and exhibited a hydrophilicity plot almost identical to that of major histocompatibility complex class II molecules (95). The gene for the 67-kDa protein was present only in pathogenic streptococcal groups A, C, and G (95). This gene was not found in other streptococcal groups, *Escherichia coli*, or staphylococci when they were screened for hybridization with the gene probe. The role of the 67-kDa protein as a potential virulence factor in the pathogenesis of streptococcal infections or sequelae is not yet known.

IMMUNE RESPONSES TO *N*-ACETYL-B-D-GLUCOSAMINE, DOMINANT EPITOPE OF GROUP A POLYSACCHARIDE, IN THE PATHOGENESIS OF RHEUMATIC HEART DISEASE AND SYDENHAM'S CHOREA IN ARF

Immunological Cross-Reactivity Between Carbohydrates and Peptides

The structure of the group A polysaccharide is a polymer of rhamnose with *N*-acetyl-β-D-glucosamine linked to the rhamnose backbone. The *N*-acetyl-glucosamine is the immunodominant epitope of the group A carbohydrate that

distinguishes *S. pyogenes* from other streptococcal species. The *N*-acetyl glucosamine and the group A polysaccharide have been identified in cross-reactions between streptococci and heart tissues (58, 61, 62). Recently, Shikhman, Adderson, and others reported that a subset of cross-reactive antimyosin/antistreptococcal mAbs from immunized mice and virtually all human mAbs from rheumatic carditis patients reacted strongly with an *N*-acetyl-glucosamine epitope of the group A streptococcal carbohydrate (29, 45–47). Furthermore, synthetic peptides from keratin (45, 47), coxsackie virus (46), and human cardiac myosin (29) reacted with mAbs against *N*-acetyl-glucosamine and myosin as previously described. In addition, a synthetic cytokeratin peptide, SFGSGFGGGY, mimicked *N*-acetyl-glucosamine in its reaction with antibodies to *N*-acetyl-glucosamine and lectins. Mimicry between the group A carbohydrate epitope and peptide molecules is a form of mimicry between chemically diverse molecules. Based on results with peptides altered at a single amino acid residue, it was deduced that aromatic and hydrophobic interactions were important in cross-reactive anticarbohydrate antibody binding to the peptide. Our data as well as that of others (166, 167) clearly link anticardiac myosin and anti-*N*-acetyl-glucosamine responses with antiheart cross-reactivity.

Rheumatic Heart Disease

Dudding and Ayoub described the elevation and persistence of anti-group A polysaccharide antibody in rheumatic valvulitis (59). Studies of the human antistreptococcal/antimyosin mAbs that reacted strongly with *N*-acetyl-glucosamine have revealed that one of the mAbs was cytotoxic for human endothelium and reacted with valvular endothelium in tissue sections of a human valve (6). The cytotoxic mAb recognized the extracellular matrix protein laminin that is part of the basement membrane underlying the valvular endothelium. These data suggest that human antibody cross-reactivity with valve tissues is established through antimyosin/anti-*N*-acetyl-glucosamine/antilaminin reactivity. Antibodies that react with valve endothelium may lead to inflammation at the valve surface and promote T cell infiltration of the valve in rheumatic heart disease. Based on our current knowledge as

Downloaded From Vet-eBooks.com

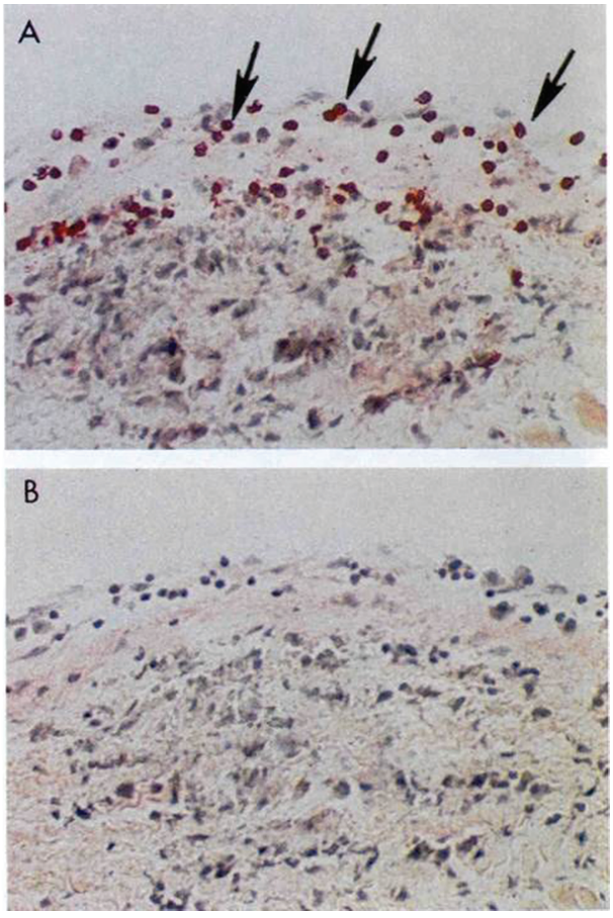

FIGURE 12 Extravasation of $CD4^+$ lymphocytes into valve above Aschoff's body in the subendocardium of the left atrial appendage. Original magnification, 200×. (A) Stained with anti-CD4 Mab; (B) stained with antibody isotype control. (Taken from Roberts et al. [48]).

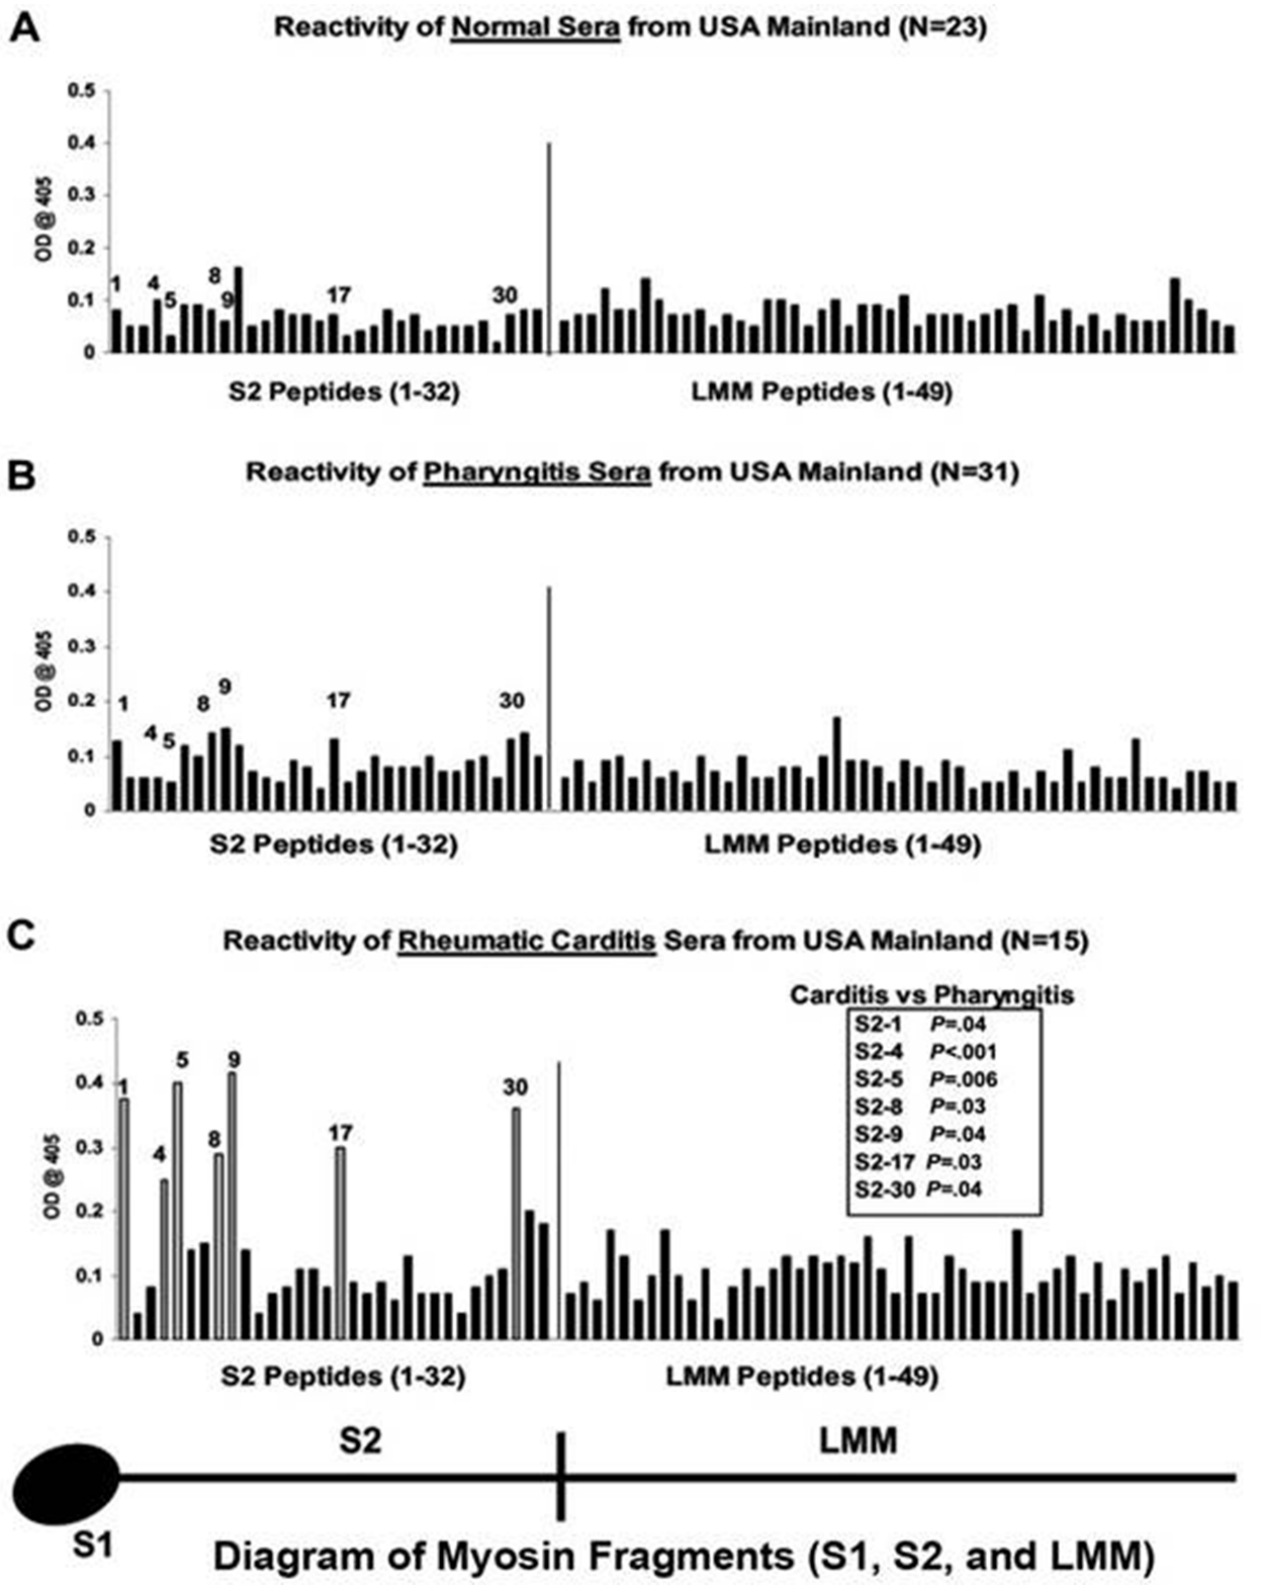
illustrated in Fig. 10 (143, 144), the proposed events in rheumatic valvulitis/carditis involve both antibodies and T cells. Cross-reactive antibodies target the valve and are believed to act against the group A carbohydrate and valve endothelium based on several lines of evidence described herein (6, 58, 59, 89, 96). T cells are cross-reactive with streptococcal M proteins and homologous alpha helical protein antigens such as myosin, laminin, tropomyosin, or vimentin and become activated and extravasate through activated endothelium into the valve, where they differentiate into $CD4^+$ TH1 cells producing IFNγ and valvular scarring (21, 48, 97, 142–144, 168). VCAM-1 was upregulated on valve endothelium (endocardium) in rheumatic carditis, indicating that the endothelium of the valve in rheumatic carditis was activated (48). Evidence strongly supports the cross-reactive T cell component of the disease, where T cells are shown to penetrate the valve endothelium into an originally avascular valve (21, 32, 48, 97, 136, 142, 143, 168–174). T cells in peripheral blood of patients (24) and the valve (21, 22, 97, 175) have been shown to be cross-reactive with M protein and cardiac proteins, including cardiac myosin epitopes, and they are both $CD4^+$ and $CD8^+$ phenotypes, but the $CD4^+$ phenotype and Th1 cells dominate. The development of scarring and fibrosis in the valve is part of the pathogenesis caused by IFNγ (3, 145, 175) production and IL-17A (101, 146), since the scarring promotes neovascularization and development of a blood supply into normally avascular valve tissue. T cells can subsequently enter the valve through blood vessels developed in the scar. The valve becomes predisposed to cellular infiltration through both the activated valve endocardial surface and the neovascularized scar tissue. Although antibodies develop against collagen in rheumatic heart disease (176, 177), they have not been found to be cross-reactive but may contribute to the pathogenesis of disease (178) once mimicry damages the valve and collagen is exposed to the immune system.



Recent reviews on rheumatic heart disease describe the collective studies and proposed pathogenesis of molecular mimicry in the disease (1–3, 179–184). Initial damage at the chordae tendineae would be sufficient to begin the process of damage to the endothelium of the valve (25) where T cells infiltrate and congregate as they recognize laminin and other valvular proteins that are part of the basement membrane (185). These mechanisms lead to the upregulation of inflammatory molecules such as VCAM-1 (48), which allows the valve to be infiltrated by the T cells, and then the continual damage of the valve with every repetitive streptococcal infection. Treatment with antibiotic prophylaxis as part of the guidelines from the American Heart Association for treatment of rheumatic fever is an important deterrent to the development of rheumatic fever and heart disease in children.

Sydenham Chorea and Pediatric Autoimmune Neuropsychiatric Disorder Associated with Streptococcal Infection (PANDAS)

Sydenham chorea is the major neurological manifestation and movement disorder of rheumatic fever. Human mAbs produced from disease were compared with sera from Sydenham chorea and used to identify the potential antibody targets as well as provide a better understanding of pathogenesis. Human Sydenham chorea-derived mAbs and serum IgG demonstrated specificity for mammalian lysoganglioside and the group A streptococcal carbohydrate epitope *N*-acetyl-β-D-glucosamine (7). Chorea-derived mAbs and acute serum antibodies, as well as cerebrospinal fluid from Sydenham chorea, reacted with lysoganglioside and targeted the surface of human neuronal cells. These antibodies also induced elevated calcium/calmodulin-dependent protein kinase II activity (CaM kinase II) (7). Although the mAbs were IgM, the serum antibodies that triggered the cell signaling in human neuronal cells were IgG. IgG can penetrate the blood-brain barrier when breached by bacterial components or other molecules such as epinephrine (186–188), and the IgG can reach brain tissues, where it can target specific cells in the brain tissue and produce disease.

Thus, the human chorea mAb 24.3.1 IgG was shown to penetrate the brain when the genetic information for the chorea antibody V genes were expressed in a transgenic mouse model (189). The antibody was expressed by B cells in the transgenic model and was produced by B cells and specific IgG accumulated in mouse serum. Once the blood-brain barrier was broken, the antibody that was tagged with a specific mouse allotype was observed in the basal ganglia, where the allotype-tagged chorea antibody IgG penetrated dopaminergic neurons in the ventral tegumental area or the substantia nigra as shown in Fig. 14 (189). The chorea antibodies were then shown in tritiated thymidine experiments to lead to production of excess dopamine by neuronal cells that could lead to the symptoms of chorea. Other animal models demonstrated that antibodies induced by streptococcal immunization led to deposition in the basal ganglia and the

Colocalization of Tg 24.3.1 IgG1a (anti-IgG1a Ab; left panel) and tyrosine hydroxylase antibody (anti-TH Ab; middle panel). TH is a marker for dopaminergic neurons. The left-hand panel shows IgG1a (labeled with fluorescein isothiocyanate [FITC]), the center panel shows TH Ab (labeled with tetramethylrhodamine isothiocyanate [TRITC]), and the right-hand panel shows a merged image (FITC-TRITC). Brain sections (basal ganglia) of VH24.3.1 Tg mouse (original magnification, 320×), showing (A) FITC-labeled anti-mouse IgG1a, (B) TRITC-labeled anti-TH Ab, and (C) the merged image. Controls treated with secondary antibody are negative. (Figure taken with permission from Cox et al. [189].)

development of behaviors characteristic of Sydenham chorea, such as holding a food pellet or holding on to a beam or demonstrating obsessive compulsive grooming after water spray to fur (190, 191). Passive transfer of the autoantibodies to animals also led to behaviors characteristic of neuropsychiatric symptoms and obsessive compulsive disorders (192–194).

Studies collectively demonstrated that the IgG from Sydenham chorea targeted a group of cross-reactive antigens in the brain (7–9, 195, 196). These include lysoganglioside, as mentioned above, and they also target tubulin, an intracellular protein abundant in the brain. More importantly, the cross-reactive antibodies have been shown to react with and signal the dopamine receptors D1 and D2 that have led to the characterization of Sydenham chorea as a dopamine receptor encephalitis where the autoantibodies signal the D2 receptor (189). The autoantibodies have been found in both serum and CSF of patients with Sydenham chorea, and the IgG autoantibodies as well as human mAbs signal human neuronal cells and activate CaMKII, which is an important signaling molecule in the brain. These cross-reactive antistreptococcal chorea-derived antibodies lead to the production and release of excess dopamine by neuronal cells in the basal ganglia that ultimately leads to chorea.

FIGURE 13 Reactivity of serum samples originating from the United States with human cardiac myosin peptides from the S2 and LMM regions in the enzyme-linked immunosorbent assay (1:100 serum dilution). (A) Mean reactivity of normal serum samples from control donors with no evidence of streptococcal infection or heart disease on the U.S. mainland against S2 and LMM peptides. These samples rarely reacted with any S2 or LMM peptide at an optical density of 0.2. (B) Mean reactivity of serum samples from patients with streptococcal pharyngitis in the United States against S2 and LMM peptides. These samples rarely reacted with any S2 or LMM peptide at an optical density of 0.2. (C) Serum immunoglobulin G from patients with rheumatic carditis in the United States. Serum samples from patients with rheumatic carditis from the United States reacted predominantly with peptides S2-1, S2-4, S2-5, S2-8, S2-9, S2-17, and S2-30, compared with the reactivity of serum samples from patients with pharyngitis in the United States against those same peptides (B). (C) Unadjusted Mann-Whitney *P* values for the comparison between carditis and pharyngitis on the United States mainland. The comparison for S2-4 is statistically significant on the basis of a two-sided alpha level adjusted to preserve the false-discovery rate at 5%. (Taken from Ellis et al. [24] with permission from the *Journal of Infectious Diseases*).

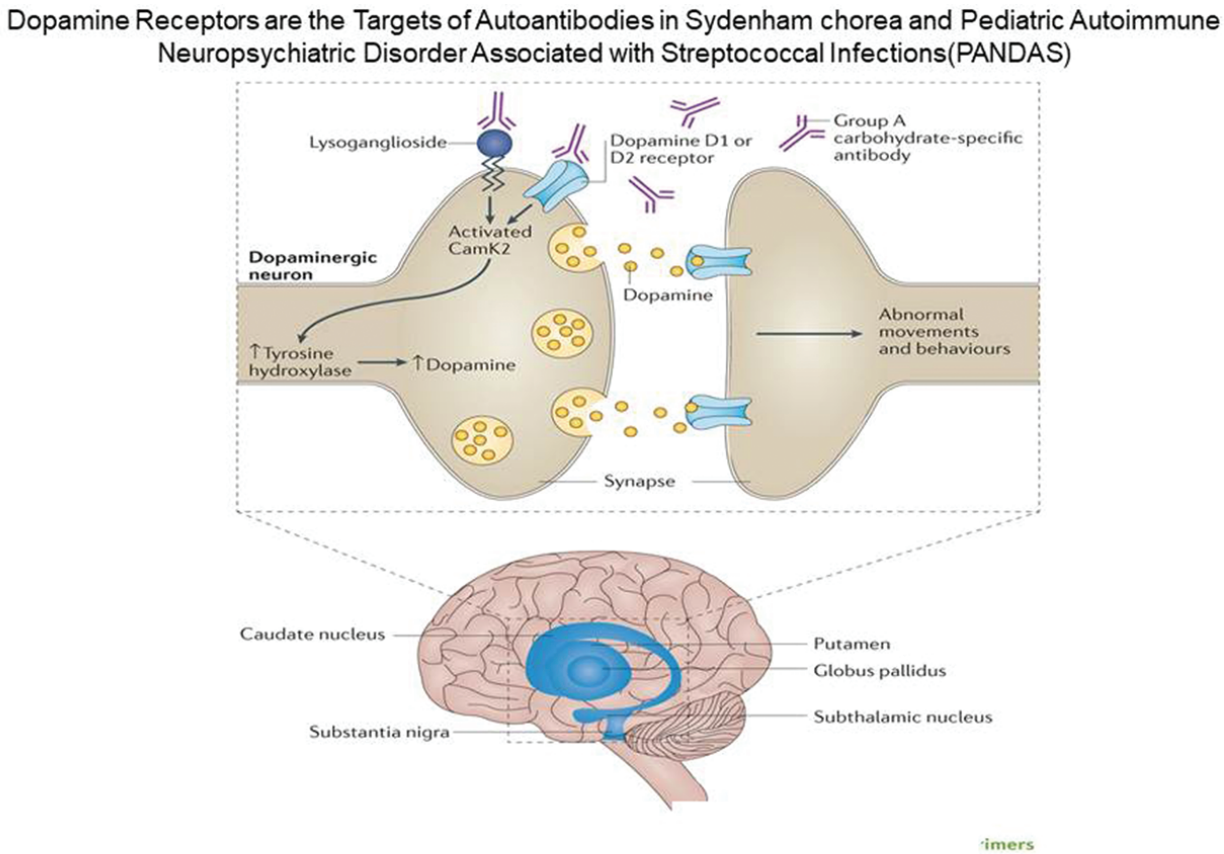

FIGURE 15 Diagram of proposed events leading to the group A streptococcal sequelae Sydenham chorea and PANDAS. Autoantibodies against brain tissues in Sydenham chorea and PANDAS with piano-playing choreiform movements cross-react with the group A streptococcal carbohydrate, lysoganglioside, and dopamine receptors D1R and D2R. The antibodies in Sydenham chorea and PANDAS react with the surface of neuronal cells and trigger cell signaling events, leading to upregulation of calcium/calmodul-independent protein kinase II (CaMKII) and excess dopamine release that leads to the involuntary movements in Sydenham chorea or PANDAS with piano-playing choreiform movements. Both Sydenham chorea and PANDAS are likely to be a dopamine receptor encephalitis based on our data (189, 205) and those of Dale et al. (197, 198). (Taken from *Nature Reviews Disease Primers* with permission).

Similar antineuronal autoantibodies and autoantibody-mediated neuronal cell signaling are elevated in serum and CSF from PANDAS with the choreiform movements. In both Sydenham chorea and PANDAS, the presence of abnormally elevated antidopamine receptor autoantibodies suggests a dopamine receptor encephalitis (197, 198). Studies of mice infected intranasally with group A streptococci illustrated the importance of infection and its role in opening the blood-brain barrier that must be broken to allow IgG to penetrate the brain. Studies by Agalliu and Cleary and colleagues show that intranasal group A streptococcal infection leads to activated Th17 cells that traverse the olfactory bulb and open the blood-brain barrier to proteins such as IgG (199, 200). Upon opening the blood-brain barrier, IgG antineuronal autoantibodies can penetrate the brain and potentially lead to Sydenham chorea and PANDAS.

The studies suggest (i) that the antibodies against streptococci and brain in Sydenham chorea and related diseases produce central nervous system dysfunction through a neuronal signal transduction and subsequent excess dopamine release mechanism and (ii) that the molecular targets of the chorea antibodies include lysoganglioside and the dopamine receptors in neuronal cell membranes. The antineuronal autoantibodies also target the group A streptococcal carbohydrate epitope *N*-acetyl-β-D-glucosamine present on the rhamnose backbone of the carbohydrate and present in the cell membrane and wall of the group A streptococci as well as the intracellular brain protein tubulin. The diagram in Fig. 15 illustrates proposed events of how antineuronal autoantibodies against lysoganglioside and the dopamine receptors D1 and D2 may function in Sydenham chorea and PANDAS (3).

CONCLUSIONS

The theme in mimicry, as found in the above-described studies, suggests that cross-reactive antibodies target an intracellular biomarker such as myosin in the heart and tubulin in the brain, but for the antibodies to be pathogenic, they must target a cell surface antigen such as the extracellular matrix protein laminin in the valve endocardial basement membrane or dopamine receptors present at the surface of neu-

Downloaded From Vet-eBooks.com

ronal cells, leading to the initiation and manifestations of disease. In general, the autoantibodies present as a group of specificities in disease include the cross-reactive antigens recognized by the autoantibodies in disease sera. The cross-reactivity found in individual sera from the disease has been characterized using human mAbs that reflect the serum IgG in the disease.

Cross-reactive antibodies and cross-reactive T cells against group A streptococci are important in the pathogenesis of autoimmune sequelae that characterizes rheumatic fever following streptococcal infection. Cross-reactive antibodies have been defined as those that recognize host tissue alpha-helical coiled-coil antigens such as myosin, tropomyosin, keratin, vimentin, and laminin in the heart (79) and tubulin, lysoganglioside, and dopamine receptors in the brain (9). Cross-reactive antistreptococcal antibodies recognize peptide sequences in alpha-helical proteins such as the M protein virulence determinant of the group A streptococci as well as the *N*-acetyl-glucosamine molecule, the dominant epitope of the group A streptococcal carbohydrate (45–47). Glycosylated proteins are expected to be targets of the cross-reactive antistreptococcal antibodies. Historically, Goldstein et al. determined autoantibody reactivity with carbohydrates on heart valves (58), and Dudding and Ayoub demonstrated that the group A carbohydrate autoantibodies were an indicator of poor prognosis in valvular heart disease (59). This evidence supports our findings and confirms the importance of the autoantibodies against streptococcal antigens in the development of cross-reactivity that is the basis of the initial disease processes in rheumatic fever and rheumatic heart disease.

In rheumatic heart disease, laminin, an extracellular matrix molecule present in the basement membrane of the valve, may trap cross-reactive anticarbohydrate autoantibodies at the endocardial cell surface and lead to damage or inflammation of the endothelium. Activated endothelium leads to subsequent extravasation of streptococcal M protein/myosin-cross-reactive T cells into the valve (8, 48, 97, 142, 168). Cross-reactive group A streptococcal antigens with apparent roles in the pathogenesis of rheumatic heart disease include the M proteins and the group A polysaccharide. Amino acid sequences of streptococcal M5 protein that have been shown to be pathogenic in animals have also been reported to be recognized by T cells from rheumatic heart valves (21, 97, 142, 143, 168). The identification of human cardiac myosin cross-reactive B and T cell epitopes of M5 protein has been a step forward in understanding the cross-reactive epitopes that produce disease in animals and humans (32) and are hallmarks of molecular mimicry.

In Sydenham chorea, mimicry between the *N*-acetyl-glucosamine molecule of the group A carbohydrate and brain gangliosides potentially leads to antibodies that bind to the surface of neuronal cells and triggers induction of dopamine in the disease (7). In the pathogenesis of chorea, the development of IgG responses and higher-affinity cell surface reactive antibody that can bind strongly enough to alter host tissues may lead to disease. In carditis, T cells can enter the valve, but only those that are consistently stimulated with local antigens retain a strong immune response. The Th1 T cell subset and its proinflammatory IFNγ cytokine are dominant in valves with a potential role also for IL-17A and the Th17 subset of T cells in fibrosis and scarring.

Although the identity and pathogenic mechanisms of cross-reactive antigens and their cross-reactive antibodies and T cells is much clearer now than in the past, there will always be new lessons to be learned about the pathogenesis of the autoimmune sequelae of ARF and how cross-reactivity and mimicry of host tissues by the group A streptococci leads to autoimmune sequelae following streptococcal disease.

My work was supported by grants HL35280 and HL56267 from the National Heart, Lung, and Blood Institute (NHLBI) and intramural funds from the National Institute of Mental Health (NIMH). M.W.C. is the recipient of an NHLBI merit award.

Deep appreciation is expressed to my students, postdoctoral fellows, and colleagues who contributed to the studies reviewed in this chapter.

Extracellular Matrix Interactions with Gram-Positive Pathogens

SVEN HAMMERSCHMIDT, MANFRED ROHDE AND KLAUS T. PREISSNER

8

The adherence to and invasion of eukaryotic cells are the main strategies pathogenic bacteria use for colonization, evasion of immune defense, survival, and causing disease in their mammalian hosts. Most Gram-negative bacteria use pili to achieve adherence and invasion (1), while only a few Gram-positive species are equipped with these structural elements (2, 3). Hence, Gram-positive pathogens express specific cell surface components called adhesins, or MSCRAMM (microbial surface components recognizing adhesive matrix molecules), which directly or indirectly facilitate the adherence of the bacteria to host tissues, thereby mediating not only colonization but also invasion of microbes (4, 5). Bacterial adhesins of several Gram-positive pathogens, including *Staphylococcus aureus*, *Streptococcus pyogenes*, and *Streptococcus pneumoniae*, are of utmost importance to enable their attachment to adhesive glycoproteins of the host extracellular matrix (ECM) as well as their adherence to host epithelial or endothelial cells, utilizing this strategy also to trigger immune evasion mechanisms (5–7).

The structure and composition of the eukaryotic ECM as a major noncellular component of the host is rather diverse in structure to provide the connective tissue with tensile strength and elasticity and to meet the functional demands at various sites in the body. In addition, the ECM affects the cellular physiology of the host organism and is vital for adhesion, migration, proliferation, and differentiation of many cell types. The ECM not only serves as a structural scaffold for host cells but also provides support for infiltrating pathogens to colonize and invade, particularly under conditions of injury and trauma. Cell-surface adhesive components of the host are often recognized by pathogenic bacteria in a tissue- or cell-specific manner. Pathogens also bind a variety of humoral adhesive components in body fluids that serve as molecular glue for microbial binding to the host tissue, leading to the activation of cellular mechanisms to promote the invasion of pathogens.

The diverse interactions of bacteria with host ECM components therefore represent important pathogenicity mechanisms in microbial infection. The identification and characterization of host ECM molecules and complementary bacterial adhesins would contribute not only to a better understanding of the molecular aspects of pathogenesis but also to the design of novel strategies to control and manage infectious diseases (8). In this article we describe the interactions of ECM components with adhesins of Gram-positive pathogens. The first section introduces the structure and function of ECM proteins, and the second part deals with the interactions of Gram-positive pathogens with such ECM components and the biological consequences thereof. Examples of these interactions with *S. pneumoniae* and *S. aureus* are depicted in Tables 1 and 2.

EXTRACELLULAR MATRIX

In mammals the ECM comprises more than 300 proteins, designated as the core matrisome (9), whereby a large number of ECM-modifying enzymes, growth factors, and other glycoproteins are associated with these protein polymer networks of varying compositions. The different ECM scaffolding proteins and ECM-associated components cooperate to assemble and remodel connective tissues at various sites in the body in close contact to cells through adhesion receptors, particularly integrins (10). Together with receptors for ECM-bound growth factors, they provide multiple inputs into cells to control the survival, proliferation, differentiation, shape, polarity, and motility of cells, culminating in the quote "Without this bit of glue, you wouldn't look like you."

The major structural components of eukaryotic ECMs are different types of collagens that form various interstitial and basement membrane networks (11). The interstitial ECM is largely comprised of fibril-forming collagens (types I, II, and III) together with fibril-associated collagens (types IX and XII), whereas basement membranes contain a two-dimensional collagen type IV network that is often interconnected with a laminin network. Other components, such as collagenous and noncollagenous glycoproteins, elastin, proteoglycans, hyaluronan, growth factors, and proteases, become associated with ECM, giving rise to their specialized structure and function at various tissue locations in the body (12). The main portion of interstitial ECM is produced and deposited by embedded connective tissue cells such as fibroblasts in the dermis, smooth muscle cells and fibroblasts in the vasculature, and osteoblasts and chondroblasts in bone and cartilage. In addition, melanocytes, fat, skeletal muscle, nerve and epithelial cells, and circulating blood cells, such as macrophages, granulocytes, and lymphocytes, participate in the synthesis and secretion of ECM material and thereby determine the specific character of a given tissue or organ.

Bacterial protein	Acronym	ECM ligand(s)
Choline-binding proteins		
Choline-binding protein E	CbpE/Pce	Fibrinogen, laminin
Choline-binding protein F	CbpF	Elastin
Choline-binding protein I	CbpI	Elastin
Choline-binding protein L	CbpL	Collagen, elastin
Pneumococcal surface protein C	PspC	Vitronectin, thrombospondin-1
LPxTG-anchored proteins		
Complement factor H-binding protein	Hic/PspC 11.4	Vitronectin, thrombospondin-1
Neuraminidase A	NanA	Fibrinogen, collagen IV
Plasmin- and fibronectin-binding protein A	PfbA	Fibronectin, plasmin
Plasmin- and fibronectin-binding protein B	PfbB	Fibronectin, plasmin
Pneumococcal adhesion and virulence factor B	PavB	Fibronectin, plasminogen, Thrombospondin-1
Pneumococcal protease A	PrtA	Collagen IV
Pilus 1 subunit	RrgA	Fibronectin, collagen I, laminin
Zinc metalloprotease	ZmpB	Collagen IV
Nonclassical surface proteins		
Pneumococcal adhesion and virulence factor A	PavA	Fibronectin
Endopeptidase O	PepO	Fibronectin, plasminogen, C4bBP
Enolase-1	Enolase	Plasminogen, C4bBP
Glyceraldehyde 3-phosphate dehydrogenase	GAPDH	Plasminogen
Phosphoglycerate kinase	PGK	Plasminogen

During embryonic development, the ECM is constantly rearranged, which is necessary for regulating morphogenesis in an active and dynamic fashion. Likewise, the time-dependent modification and rebuilding of ECM at various locations in the body is essential for inflammation and wound healing. At these sites, the provisional ECM may provide bacterial entry and colonization, and soluble proteolytic fragments of ECM proteins are indicators of matrix turnover, particularly at sites of tissue remodeling or tumor cell invasion (11). Specific circulating fragments of type XVIII collagen (endostatin) (13) or type IV collagen (tumstatin) (14) were shown to exert potent antiangiogenic activities on vascular cells (15). Their respective interactions with microbes, however, have not been explored.

Structure and Function of ECM Molecules

Collagens

Twenty-eight types of collagen, encoded by more than 45 genes, have been defined on a molecular basis. Collagens are divided into (i) fibril-forming collagens, (ii) fibril-associated

TABLE 2 *Staphylococcus aureus* surface proteins that recognize ECM molecules

Bacterial protein	Acronym	ECM ligand(s)
Adhesins (MSCRAMM[a])		
Bone sialoprotein-binding protein	Bbp	Bone sialoprotein, fibrinogen
Clumping factor A	ClfA	Fibrinogen
Clumping factor B	ClfB	Fibrinogen
Collagen adhesin	Cna	Collagen
Fibronectin-binding protein A	FnBPA	Fibronectin, fibrinogen, elastin

collagens with interrupted triple helices, (iii) network-forming collagens, and (iv) transmembrane collagens. A major subfamily of collagens is formed by the fibril-forming types, such as I, II, III, V, and XI, that are produced and assembled, e.g., during wound healing processes (16). These collagens are characterized by large stretches of triple-helical protein strands and are distinct from the fibril-associated collagens and the third subfamily, the network-forming collagens, of which types IV and X are prominent examples. All collagen types are expressed in a tissue- and/or cell-specific manner and contribute to the appearance and mechanical properties of a given connective tissue, thereby also determining its cellular environment.

Network-forming collagens, such as different isoforms of type IV, determine the structure of basement membranes as a specialized ECM, present at all tissue borders in connection with the diverse forms of epithelial cells. An intercalated laminin network that can exist independently is linked to type IV collagen via nidogen/entactin proteins. Basement membranes serve quite distinct functions in the body, such as linking epithelia to the underlying interstitial ECM, covering skeletal myotubes with basal lamina, or serving as a solute filtration barrier in the kidney glomerulae or at sites of gas exchange in the lung alveolae. Heparan sulfate proteoglycans, usually perlecan, and adhesive glycoproteins such as fibronectin are embedded into these supramolecular arrays as well (11). The majority of structural components are in direct contact via (adhesion) receptors with epithelial, endothelial, striated muscle, fat, and nerve cells, which produce the individual components and deposit them in a polarized fashion toward the cellular basolateral side of a given epithelium.

Laminins

Laminins are major constituents of basement membranes and are the first ECM proteins to be produced during embryogenesis. Because of their specific interactions with type IV collagen, proteoglycans, and other ECM components, as well as with several adhesive cell types, laminins play an important structural and functional role within basement membranes. Laminins are heterotrimeric molecules and have a characteristic flat, cross-shaped appearance with a molecular mass of 900 kDa. They are composed of three chains, α (400 kDa), β (200 kDa), and γ (200 kDa), which are linked to each other by disulfide bridges. There are five α chain, three β chain, and three γ chain isoforms identified in humans. In total, 15 laminin molecules (heterotrimeric isoforms) are classified on the basis of different combinations of the chains (17–19), which are expressed in a tissue-specific manner. Laminins are heavily glycosylated proteins with a 12 to 27% carbohydrate content that is often represented by complex-type carbohydrates (20). Laminins are in close contact with a variety of cell types, including muscle, adipocytes, neurons, and endothelial and epithelial cells, and are involved in the promotion of cell proliferation, attachment, and chemotaxis, as well as neurite outgrowth and enhancement of angiogenesis (21).

Elastin

Another specialized structural protein of the ECM in specific tissues is elastin, which is the main component of elastic fibers. These fibers are responsible for the elasticity of lung, skin, and other tissues, as well as blood vessels. Elastin is a highly cross-linked polymer of the nonproteolytically modified, hydrophobic precursor tropo-elastin. During fibrogenesis, secreted tropo-elastin is transformed into insoluble polymeric elastin by intermolecular covalent bonds between lysines into desmosine and isodesmosine cross-links through the copper-dependent enzyme lysyl oxidase (22, 23). The rubber-like mechanical properties of elastin result from repetitive hydrophobic domains of tropo-elastin subunits.

Matricellular Glycoproteins

Adhesive glycoproteins constitute specialized structural and functional components of the ECM. For example, upon vessel wall injury, particularly at sites of wound healing, the initial adhesion of platelets and their subsequent aggregation are dependent on the adhesive glycoproteins von Willebrand factor, fibronectin, thrombosponin-1, and vitronectin that are present in the subendothelial ECM and stored inside platelets before they are secreted during the initial phase of hemostatic plug formation. Adhesive glycoproteins not only promote the attachment and spreading of cells via their transmembrane integrin receptors (10), but also perform multiple functions by interacting with other ligands, such as heparan sulfate, collagens, proteases or mediators of humoral defense mechanisms (24). These proteins also exist as soluble forms in the blood circulation, which may differ from those in the subendothelium as well as in α-granules of platelets owing to alternative splicing, differences in the state of polymerization, different conformations, or the transition into self-aggregating proteins. The partitioning of these "matricellular" proteins between humoral and cell surface or ECM phases, together with inducible receptor sites on platelets or inflammatory cells, indicates that these adhesive glycoproteins are important players in tissue remodeling (such as in tumors) or defense mechanisms (25). Thus, the matricellular adhesion proteins not only provide versatile molecular links mediating the adhesive processes and responsive reactions at localized tissue sites, but are also of major importance for the initial adherence phase of pathogens to the host tissue.

Fibronectin

Fibronectin is a ubiquitous adhesive protein that is essential for the adhesion of almost all types of cells. It is abundant at various ECM sites as well as in the blood circulation and has a concentration in the range of 200 to 700 μg/ml (26). This high-molecular-weight adhesive glycoprotein has a broad spectrum of functions ranging from its contribution in ECM formation, cell growth, and differentiation to wound healing and tumor progression. It exists in two forms in the human body: as a soluble 440-kDa compact dimer in plasma (so-called cold-insoluble globulin) and as a multimeric fibrillar form in connective tissue and basement membranes (26, 27). The characteristic dimeric form of the molecule in solution is generated by disulfide bridging at the carboxy-termini of two similar subunits, each with a molecular mass of about 220 kDa (28). In addition to approximately 30 intrachain disulfide bonds, two free sulfhydryl groups per subunit are involved in the formation of high-molecular-weight polymers of fibronectin, which are predominantly found in tissues. The heterogeneity observed in fibronectin molecules isolated from plasma or tissue is due to a variation in both the amino acid sequence and posttranslational modifications. Although only one fibronectin gene has been identified, variations in the carbohydrate content or structure, phosphorylation, sulfation, and acetylation are responsible for the additional heterogeneity of the protein.

The multidomain fibronectin molecule contains three types of repetitive domains with independent three-dimensional modular structures, whereby each monomer is typically composed of 12 type I repeats (40 amino acids each), 2 type II repeats (60 amino acids each) and 15 to 17 type III repeats (~90 amino acids each) (29). Owing to the

Downloaded From Vet-eBooks.com

presence of intramolecular disulfide bonds, type I and type II repeats are structurally rigid, in contrast to the conformationally flexible β-barrels of type III repeats, which are devoid of these linkages, thus enabling them to be involved in fibronectin polymerization (30). The sensitivity of fibronectin to proteolytic degradation has been used to identify the structure-function relationships of independent domains. The 30-kDa amino-terminal fragment contains the major acceptor site for factor XIIIa (transglutaminase)-mediated cross-linking and bears the binding sites for heparin, fibrin, and bacteria, including *S. aureus* (31). The well-known property of fibronectin to bind collagen or gelatin and to complement C1q is contained within the adjacent 40-kDa fragment, while the central portion of the molecule has no well-defined binding functions.

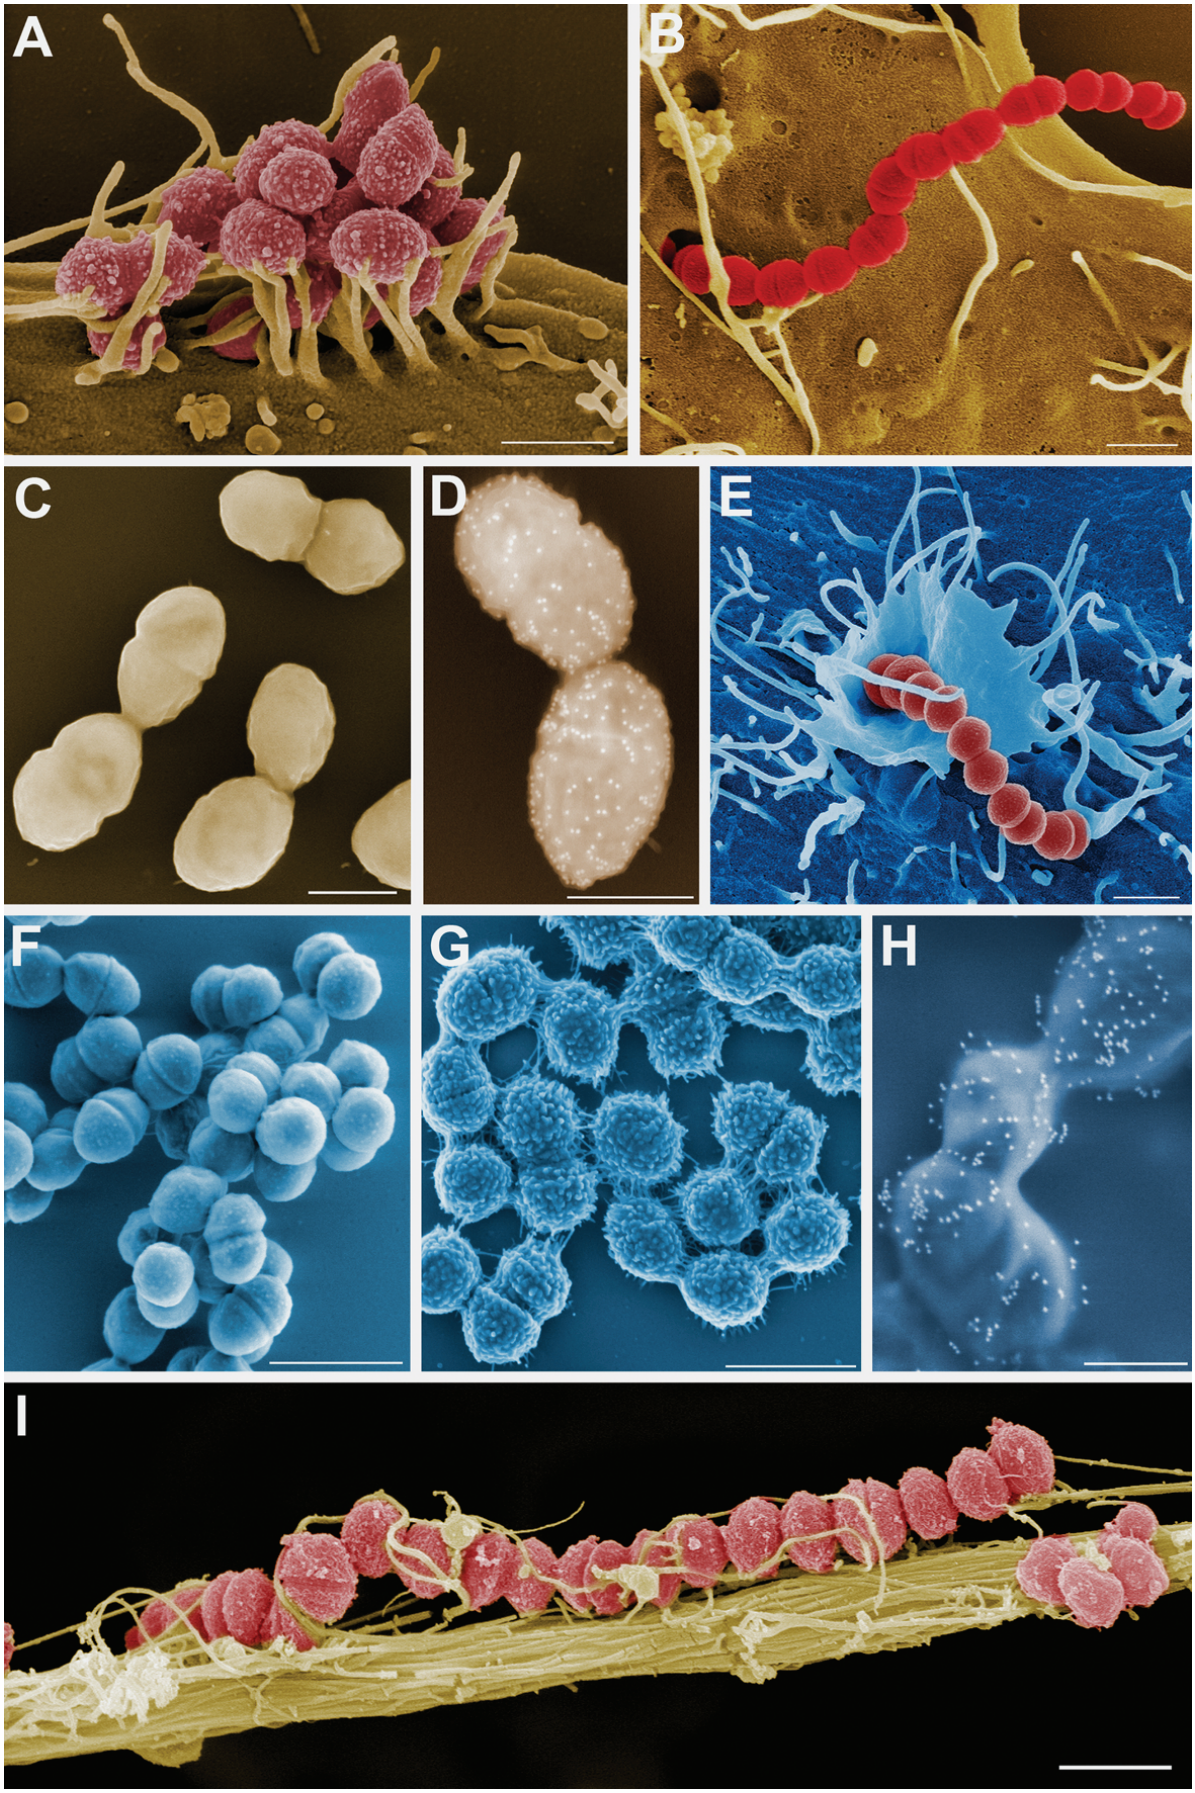
The versatile recognition sequence Arg-Gly-Asp (RGD) for integrins was first recognized in the type III-10 repeat of fibronectin (32) and has been found in a large number of adhesive and nonadhesive proteins as well. Additional heparin-binding and fibrin-binding domains are located within the carboxy-terminal portion of the fibronectin molecule. Together with the RGD-containing cell attachment site, the heparin-binding domain is crucial for the establishment of integrin-mediated stable focal adhesions in many cell types, as has been demonstrated in fragment complementation assays. The transformation from the compact soluble to the extended fibrillar form of fibronectin, a highly regulated process termed fibrillogenesis, requires the application of mechanical forces generated by cells: these bind and exert forces on fibronectin through their integrin receptors, which mechanically couple the intracellular actin cytoskeleton to the ECM via an elaborate adhesion complex (33). The accumulation of fibronectin into an insoluble form is potentiated by disulfide bridge formation, as well as by covalent cross-linking, catalyzed by transglutaminase/factor XIIIa.

Vitronectin

Another adhesive glycoprotein, vitronectin, circulating in human plasma as a folded monomer of 75 kDa, exists either as a single-chain protein or as a two-chain disulfide-linked polypeptide (65 + 10 kDa) and exerts multiple functions in the complement, fibrinolytic, and blood coagulation systems (34, 35). In contrast, in its multimeric, unfolded form, vitronectin can efficiently bind to glycosaminoglycans such as heparin and becomes incorporated into the ECM of various human tissues, supporting cell adhesion and differentiation as well as regulating ECM composition and stability. Several immunofluorescent and histochemical studies suggest the deposition of vitronectin in a fibrillar pattern in loose connective tissue in association with dermal elastic fibers in skin and with renal tissue (36, 37). The interaction sites for several binding proteins are located in different vitronectin domains: the N-terminal part comprises a somatomedin B domain and an RGD motif that allows attachment of vitronectin to the integrin receptors $\alpha_v\beta_3$, $\alpha_v\beta_1$, and $\alpha_v\beta_5$ (38). In addition to four hemopexin-type repeats, vitronectin consists of three heparin-binding domains (HBD1: amino acids 82–137; HBD2: amino acids 175 to 219; HBD3: amino acids 348 to 361), the latter of which mediates binding to proteoglycans and is involved in ligand-induced multimerization of the protein (34, 39).

Moreover, the accumulation of terminal complement complexes along elastic fibers later in life, the association of vitronectin with keratin bodies during keratinocyte programmed cell death (apoptosis), and colocalization of vitronectin with deposits of the terminal complement complex in kidney tissue from patients with glomerulonephritis suggest a role for the complement inhibitor vitronectin in preventing tissue damage in proximity to local complement activation. Although the mechanism of deposition of exogenous matricellular vitronectin alone or in association with other proteins into different tissues remains unclear, it may occur in a fashion similar to that for fibronectin; thus, both proteins are prominent candidates for promoting the adherence of bacteria at various accessible ECM sites. The interaction of vitronectin with glycosaminoglycans or different types of native collagens and basement membrane-associated osteonectin and the cross-linking of vitronectin by transglutaminase/factor XIIIa are reactions that are likely to occur in the ECM *in vivo* as well (40, 41). Finally, several Gram-negative and -positive pathogenic bacteria recruit plasma vitronectin as a humoral complement inhibitor of the lytic membrane attack complex to prevent its assembly and to protect the microbes against lysis (42).

Fibrinogen



The adhesive glycoprotein fibrinogen is a major plasma glycoprotein that mediates the aggregation of activated platelets via their $\alpha_{IIb}\beta_3$-integrins in the early phase of hemostasis and is converted into insoluble fibrin by the key protease of the blood clotting cascade, α-thrombin. The primary structure of fibrinogen (43) together with biophysical studies indicate that the 350-kDa molecule is composed of two identical sets of three polypeptide chains, Aα, Bβ, and γ, which are disulfide-bridged and organized in an antiparallel fashion, representing a symmetrical dumbbell-shaped quaternary structure (44). Upon selective and specific proteolytic attack by α-thrombin, two pairs of fibrinopeptides, A and B, are sequentially released, and the appearance of these peptides in the circulation is an indicator of thrombin activity *in vivo*. Covalent stabilization of the forming fibrin clot is mediated by factor XIIIa-dependent cross-linking between γ and α chains of fibrin. Together with invading cells and aggregating platelets, the fibrin clot constitutes the majority of the initial provisional ECM network during the wound healing process (45).

Fibrinogen is a multifunctional protein capable of binding to collagen, fibronectin, components of the fibrinolytic system, and a variety of eukaryotic cells, as well as to bacteria. While the fibrin clot is being organized during normal wound healing, it may already serve as a cofactor surface for tissue plasminogen activator-dependent plasminogen formation, ultimately leading to clot lysis. Cell surface integrin receptors for fibrinogen have been identified on platelets ($\alpha_{IIb}\beta_3$) (required for platelet aggregation) and on mammalian cells (46). Integrin $\alpha_M\beta_2$ (complement receptor 3) on phagocytes may also recognize fibrinogen during wound healing and defense when phagocytic clearance of fibrin(ogen)-associated clot or cell fragments is required. The recognition of the distal end of the γ-chains of fibrinogen and of two RGD-containing sites by different integrins indicates that fibrinogen may serve as a bridging component between surface receptors on different cells or other extracellular sites once they become exposed (47).

Thrombospondin

Thrombospondins are multifunctional 420-kDa homotrimeric, multidomain glycoproteins with multiple functions that are synthesized and secreted by various cell types such as endothelial cells, smooth muscle cells and macrophages (48–50). In addition, thrombospondin-1 is stored in platelet α-granules to become secreted in the initial phase

Downloaded From Vet-eBooks.com

Downloaded From Vet-eBooks.com

of hemostasis, whereby the released thrombospondin may strengthen fibrin network formation and becomes incorporated into the repair thrombus. The plasma concentration of circulating thrombospondin-1 ranges between 20 and 300 ng/ml and increases temporarily upon activation-induced platelet α-granule release up to 30 μg/ml (50). The level of thrombospondins in the circulation and other body fluids (produced by vascular cells or secreted by activated platelets) and their distribution in tissues appears to vary in correlation with different pathological states.

Thrombospondins belong to a family of structurally unrelated members of the tenascin protein family, including osteonectin and osteopontin. These matricellular proteins regulate divergent cellular functions including cell adhesion and signaling, proliferation of different cell types, as well as angiogenesis and immune responses (51–53). Owing to their highly regulated biosynthesis, induced by various hormones and cytokines during embryonic development, nerve regeneration, and vascular remodeling related to angiogenesis, these proteins become sequestered in the ECM and thereby mediate cell recruitment via different cell surface receptors, including integrins. Thrombospondin specifically promotes cell attachment and spreading via α_v-integrins in the vascular system but may also lead to destabilization of focal adhesions (54). Human thrombospondin-1 monomers each consist of a globular N-terminal, a heparin-binding domain, a von Willebrand factor-binding domain, three properdin-like type I repeats, three epidermal growth factor-like type II repeats, eight calcium-binding type III repeats, and a globular C-terminal domain (48, 55). These domains interact with a wide range of host molecules in the ECM (designated the "interactome"), including structural proteins, cytokines, and proteases (56), resulting in scaffolding of these factors and modulating their functions.

INTERACTIONS OF GRAM-POSITIVE PATHOGENS WITH ECM MOLECULES

Collagens and Gram-Positive Pathogens

Many staphylococcal and streptococcal species specifically interact with collagenous proteins (Fig. 1), and several examples of these specific interactions will be discussed. It has been proposed that these interactions might be important in the pathogenesis of various diseases, such as osteomyelitis and infective arthritis. For example, Switalski et al. (57) isolated a surface protein of 135 kDa from *S. aureus* and tentatively identified it as a collagen receptor, while Patti et al. (58) cloned and sequenced a gene, *cna*, encoding a collagen-binding protein from *S. aureus*. This collagen-binding protein exhibits all the main features of a sortase-anchored surface protein of Gram-positive bacteria. The ligand-binding domain of the *S. aureus* protein is localized in the A region of collagen (58). So far, only a single gene has been identified for staphylococcal collagen-binding protein, although proteins of different molecular sizes have been reported from different strains, probably owing to strain-to-strain variation in the number of repeats. The collagen-binding protein from *S. aureus* is involved in the adherence of bacteria to cartilage. This interaction is specific for collagen because synthetic beads coated with collagen mediate the adherence to cartilage, whereas the beads coated with fibronectin show no adherence (57).

Animal pathogenic streptococci interact with different collagens to promote serious pathologies. For example, in infectious endocarditis, which is most commonly caused by streptococci and characterized by the formation of septic masses of platelets on the surfaces of heart valves, collagen-like platelet aggregation-associated protein of *Streptococcus sanguis* and direct interactions with host ECM collagens enhance platelet accumulation and subsequent bacterial colonization. *Streptococcus anginosus* isolated from an endocarditis specimen also binds collagen I and IV, and in addition to SspA and SspB, which are members of the antigen I/II family, CshA and FbpA are involved in the binding of collagen I and II (58).

A study showing the involvement of collagen in acute rheumatic fever, a serious autoimmune sequela of *S. pyogenes*, underlines the pathogenetic relevance of this interaction (59). *S. pyogenes* serotypes M3 and M18 isolated during outbreaks of rheumatic fever have the unique capability to bind and aggregate collagen type IV. While M18 isolates bind collagen through capsule structures, M3 protein was identified as a collagen-binding factor of M3 serotypes, recognizing collagen IV via the PARF (peptide associated with rheumatic fever) domain (60, 61). Immunization of mice with purified M3 protein resulted in the generation of anticollagen type IV antibodies. These findings suggest a link between collagen binding and the presence of collagen reactive antibodies, which may provide a pathomechanistic basis for rheumatic fever. Furthermore, M1 of pneumococci bind to collagen VI in the lamina propria underneath the epithelial basement membrane of the upper and lower airways and plays a relevant role for host-pathogen interplay during respiratory tract infection (62).

As another example, *Streptococcus mutans* interacts with collagen type I via a 16-kDa binding protein with high affinity, as shown by the adherence of bacteria to a collagen-coated surface. Furthermore, collagen mediates the attachment of *S. mutans* to dentin in the oral cavity, thereby playing a role in the pathogenesis of root surface caries (57). The collagen-binding protein of *S. mutans*, designated Cnm protein, represents a new strain-specific member of the collagen-binding adhesin family (63). Moreover, the binding of collagen to the antigen I/II family of polypeptides of oral streptococci has been reported to facilitate the invasion of bacteria into root dentinal tubes (64), which further

FIGURE 1 (A) Adhesion of SfbI (streptococcal fibronectin binding protein I)-expressing GAS to an epithelial cell (HEp-2) mediated by fibronectin, which serves as a bridging molecule between streptococci and host cell integrins. (B) Invasion of SfbI-expressing streptococci (red) into an epithelial cell through the formation of invaginations by coopting host cell caveolae, fibronectin, and integrins. (C) *Streptococcus gordonii* expressing SfbI protein without exposure to fibronectin; this serves as a control to (D) *S. gordonii* expressing SfbI after incubation with fibronectin and subsequent labeling with antifibronectin antibodies and protein A gold-nanoparticles; note the strong binding of fibronectin to the surface of the bacteria via SfbI protein (white gold-nanoparticle dots). (E) Invasion of non-SfbI-expressing streptococci (red) into an epithelial cell (HEp-2) through signal induction of membrane ruffling of the host cell. (F) *S. gordonii* expressing SfbI on its surface after incubation with type IV collagen alone; note the smooth bacterial surface. (G) Preincubation of SfbI-expressing *S. gordonii* with fibronectin, followed by exposure to type IV collagen, results in a drastic accumulation of collagen on the bacterial surface. (H) Detection of type IV collagen on the surface of SfbI-expressing *S. gordonii*, following incubation with fibronectin and collagen IV (white gold-nanoparticle dots). (I) Direct binding of M3 serotype streptococci (red) to mouse type I collagen (derived from the mouse tail). Bars represent 1 μm in panels A, B, and E to I and 0.5 μm in panels C and D.

Downloaded From Vet-eBooks.com

underlines the importance of collagen-bacteria interactions for tissue site-specific diseases.

Some *S. pyogenes* strains, which do not interact with collagen directly, are able to recruit collagen by prebound fibronectin and the SfbI protein, a major fibronectin-binding protein (FnBP) (59). Fibronectin-mediated recruitment to sites of ECM-collagen thereby represents a mechanism for the aggregation, colonization, and immune evasion of *S. pyogenes*. A similar process is hypothesized for collagen I and its interactions with M proteins (65). Cpa, an adhesin of the group A streptococci (GAS) pilus and located at its tip, is a collagen I-binding protein, but the exact role in the infection process is still elusive (3, 66). However, the discovery of internal thioester bonds in the pilus tip adhesin Cpa of *S. pyogenes* raises the possibility of pathogen-encoded covalent adhesion (67, 68), such as for the host opsonin complement C3b. A subset of pneumococci express type I pili and the adhesin RrgA that both interact with collagen I as well (2), stressing the principle of bacterial adhesin expression for effective microbial colonization of host tissues.

Laminin and Gram-Positive Bacteria

Exposure of laminin to pathogenic bacteria is usually seen in damaged or inflamed tissues, as specifically detected for the binding of *S. pyogenes* to laminin (69). Human monoclonal antibodies, which have been developed from rheumatic heart disease patients, have also been found to recognize laminin, among other proteins. These autoantibodies are generally cross-reactive with a variety of *S. pyogenes* components and are poly-specific in nature. It has been proposed that autoantibodies recognizing myosin in the heart muscle and laminin in the heart valve are centrally involved in the pathogenesis of rheumatic heart disease (70). Thus, laminin plays an important role at least in the pathogenesis of *S. pyogenes*-mediated autoimmune diseases. Streptococcal-induced damage of the epithelial cell surfaces or entry through skin sores may thereby provide access to basement membrane laminin and the surrounding tissue for colonizing bacteria. To this end, two streptococcal laminin-binding proteins (Lbp) have been described, including streptococcal pyrogenic exotoxin B. This protein, which is ubiquitously expressed by *S. pyogenes* strains, is a secretable cell surface cysteine protease, degrades host ECM components, and activates interleukin-1β (71). This 34-kDa Lbp was found to be present and highly conserved in all *S. pyogenes* strains examined and mediates microbial attachment to HEp2 cells (72). Moreover, Lmb protein from *Streptococcus agalactiae* has been identified as another Lbp, and the structures of these binding proteins of group B streptococci and GAS have been elucidated (73, 74). Their structures indicate that these proteins belong to the ABC-transporter family of bacterial metal-binding receptors and are the substrate-binding proteins for zinc and iron ions. Lmb-mediated attachment of *S. agalactiae* to laminin may be essential for the bacterial colonization of damaged epithelium and translocation of bacteria into the blood stream (75). In addition, Lmb expression is upregulated during meningitis, implying that binding of laminin is crucial for group B streptococcal meningitis (76). ShrA of GAS is another Lbp and contributes to GAS adherence and subsequent infection (77). In addition, the streptococcal collagen-like protein-1 of *S. pyogenes* binds to laminin and fibronectin, and these interactions were proposed to facilitate bacterial internalization as well (78).

While the binding of laminin and other ECM proteins to *S. mutans* and *S. anginosus* has been reported (79), a more specific interaction between laminin and a *Streptococcus gordonii* strain isolated from a patient with infective endocarditis was mediated by a 145-kDa cell wall protein whose production was regulated in the presence of laminin (80). Moreover, sera from patients with infective carditis contained antibodies against this protein, whereas no significant recognition was seen with sera from patients with valvulopathies, suggesting an increased expression of this Lbp during infective endocarditis. Although a few streptococcal strains isolated from the oral cavity, including viridian streptococci, expressed this protein, the majority of strains isolated from patients with endocarditis expressed binding protein(s) for laminin, indicating that this ECM component might be an important factor in the pathogenesis of viridans endocarditis.

Elastin and Gram-Positive Bacteria

The specific binding of elastin was described for a number of *S. aureus* strains, whereby a major high-affinity-binding component was identified as a 25-kDa staphylococcal surface protein termed EbpS. The particular binding to elastin is mediated by a discrete domain defined by a short peptide sequence in the amino terminal extracellular region of EbpS (81). EbpS is located at the bacterial surface as an integrated membrane protein, and its expression was correlated with the ability of bacteria to grow to a higher density in liquid cultures, indicating that EbpS may have a role in regulating bacterial cell growth (82). It has also been postulated that EbpS might contribute to infection in organs containing elastin, such as lung, skin, and blood vessels, yet no specific studies have been performed so far. Finally, *S. aureus* FnBPs can also bind to elastin, which may be relevant in bacterial adhesion to connective tissue *in vivo*. In addition, several bacteria can capture plasminogen, which can be activated to plasmin by host and bacterial plasminogen activators, whereby bacterial cells become armed with a host protease which destroys ECM proteins such as elastin, opsonins, and other proteins that may contribute to immune evasion and promote microbial spreading and invasion during skin infection (83).

Fibronectin and Gram-Positive Pathogens

The adhesive glycoprotein fibronectin not only acts as a major substrate for eukaryotic cell adhesion but also serves as the prototype of adhesive ECM proteins to specifically bind to microorganisms (84) (Fig. 1). The molecular interactions, structural requirements, and functional consequences of fibronectin binding to Gram-positive bacteria have been extensively studied in several bacterial species. In particular, most *S. aureus* isolates, as well as various streptococcal strains, specifically bind and adhere to fibronectin, mediated by several different bacterial adhesins (85–87) with highly homologous recognition motifs for the host protein. Two genes, *fnbpA* and *fnbpB*, that encode the FnBP of *S. aureus* have been described. The gene products exhibit typical features of Gram-positive surface proteins, and the binding domain was localized to a 38-amino-acid repeat sequence of these proteins. FnBPA has been shown to induce the aggregation of platelets as well and may play a role in *S. aureus*-associated infective endocarditis (88).

A number of FnBPs, which serve as pleiotropic virulence factors in streptococci (89), have been identified in *S. pyogenes*, including the SfbI, also referred to as protein F, encoded by the gene *prtF*, which mediates the adherence of GAS to epithelial cells (90, 91). SfbI protein consists of

Downloaded From Vet-eBooks.com

638 amino acids and comprises five structurally distinct domains (92). The N-terminal signal peptide is followed by an aromatic domain and four proline-rich repeats, which are flanked by nonrepetitive spacer sequences. A second repeat region, distinct from the proline repeats, is located in the C-terminal part of the protein. Fibronectin binding was located in the C-terminal repeat region as well as in the nonrepetitive spacer sequence. Functional analysis showed that the repetitive sequence is essential for adherence, whereas both repeat and spacer sequences are required for the invasion of streptococci into eukaryotic cells (93). SfbI therefore represents a highly evolved prokaryotic protein that exploits fibronectin not only for extracellular targeting but also for its subsequent activation that leads to efficient cellular invasion.

Consequently, synthetic beads coated with SfbI serving as a model for bacteria were readily internalized by epithelial cells, indicating that SfbI alone is sufficient for microbial invasion (4, 94). SfbI triggers cellular invasion through caveolae and participates in organelle formation to avoid intracellular killing (95). This process may also contribute to the mechanisms of intracellular survival and persistence of *S. pyogenes*. The functional domains of SfbI were highly conserved in isolates belonging to different serotypes (92), such that pathogenic bacteria are attached to human fibronectin through tandem β-zippers (96), indicating that SfbI is the first defined invasin of GAS. The cellular receptor responsible for SfbI (protein F)-mediated microbial invasion has been identified as host $\alpha_5\beta_1$-integrin capable of recognizing fibronectin-bound bacteria (97). Unlike streptococcal M protein, SfbI does not show any cross-reactivity with host proteins (98).

Besides its involvement in adherence and invasion, SfbI has also been shown to be a strong mucosal adjuvant (94), since mice immunized intranasally with ovalbumin coupled to SfbI evoked a substantially higher immunoglobulin A response in lung lavage than did mice immunized with ovalbumin alone. SfbI also evoked a protective immune response in mice because animals immunized with SfbI protein were protected against the lethal challenge of GAS belonging to different serotypes (99). These findings underline the importance of SfbI in vaccine development.

"Serum opacity factors" of GAS (termed SfbII and SOF22) also specifically interacted with fibronectin, whereby their fibronectin-binding domain was located in the C-terminal repeat region of each protein that is not involved in the serum opacity factor activity. Yet, the role of its interaction with fibronectin is not yet clear, since as a soluble protein it may compete with bacteria-integrated FnBP for binding to fibronectin. In *in vivo* experiments, however, synthetic beads coated with the repeat region of serum opacity factor showed significant adherence to epithelial cells (100).

Another FnBP, Sffbp12, was described in GAS with no homology to SfbI or SfbII (101), but Sffbp12 shares a high degree of homology with fibronectin- and fibrinogen-binding proteins of *Streptococcus dysgalactiae* and *S. aureus*, respectively. An additional FnBP, designated F2, functions as a major adhesin in a subset of *S. pyogenes* strains and has been reported to be an important factor for both early and late pathogenic stages of superficial infections (102). Two other FnBPs from *S. pyogenes*, Fba and FbaB, have been identified (72); Fba has been shown to promote bacterial entry into epithelial cells, while FbaB is etiologically involved in the development of invasive streptococcal disease. *S. agalactiae* also binds fibronectin via a C5a peptidase, which cleaves the complement anaphylatoxin C5a to destroy its chemotactic function, which is necessary for the recruitment of inflammatory host cells (103).

The diversity of fibronectin-bacteria interactions can be further extended: fibronectin also binds to animal-pathogenic streptococci, facilitating their adherence to host vascular endothelial cells and promoting the infectious process via the blood circulation (104). In this regard, the cattle pathogen *S. dysgalactiae* expresses two binding proteins, FnbA and FnbB (105), whereby their fibronectin binding domains are located in the repeat region of both proteins that do not show any sequence homology. Despite the differences in the amino acid sequences of repeats for various FnBPs, they were capable of cross-inhibiting the binding of fibronectin to *S. aureus*, *S. dysgalactiae*, and *S. pyogenes*, respectively (106). The repeat motif of SfbI therefore conforms to the consensus sequence previously reported for FnbA, FnbB, and FnbpA. In *S. aureus* the FnBPA triggers invasion of bacteria into host cells, and the multiple repeats ($n = 11$) are essential to trigger invasion (107). Within the stretch of repeats the *in vivo* relevance of six high-affinity repeats was indirectly documented by the presence of antibodies in patients with *S. aureus* infections, recognizing complexes of these repeats together with bound fibronectin (108).

Fibronectin binding has also been observed with coagulase-negative staphylococci (109), but unlike other Gram-positive cocci, they only interact with immobilized fibronectin, allowing them to colonize artificial devices such as intraocular lenses, prosthetic cardiac valves, vascular grafts, prosthetic joints, and intravascular catheters. Fibronectin incorporated into fibrin thrombi is also the cause of infection at sites of blood clots or damaged tissue (110). Moreover, the ECM-binding protein (Embp) of *S. epidermidis* mediates a specific interaction between the bacteria and fibronectin to immobilize the adhesive glycoprotein, thereby establishing the first step of biofilm formation. Here, the binding of microbial Embp to fibronectin is assigned to its type III repeat 12 in the C-terminal region (111).

S. pneumoniae also produces an arsenal of FnBPs for interactions both with soluble fibronectin and with the fibrillar multimeric form of the host protein (112, 113). In contrast to GAS or *S. aureus*, but similar to *S. epidermidis*, pneumococci recognize the C-terminal heparin-binding domain of fibronectin (86, 113). Here, the virulence factor A (PavA) was the first FnBP identified among pneumococci to be relevant for bacterial adherence. PavA is located on the pneumococcal surface, despite lacking a signal peptide and a motif for anchoring (114). PavA also plays a direct role in the pathogenesis of pneumococcal infections, since isogenic PavA mutants are substantially attenuated in virulence (less than 1% of wild type) in a mouse sepsis model or in experimental meningitis (114, 115). This FnBP shares about 70% sequence identity with the FnBPs FBP54 of *S. pyogenes* and FbpA of *S. gordonii* (87, 116). Interestingly, PavA lacks the typical fibronectin-binding repeats described, e.g., for SfbI of *S. pyogenes* or for FnBPA of *S. aureus* (117–119). Antibodies targeting the 42-kDa N-terminal part of PavA did not block pneumococcal binding to immobilized fibronectin, suggesting that the C-terminal part of PavA recognizes fibronectin (115). Moreover, pneumococci lacking PavA still possess 50% of wild-type fibronectin-binding activity, pointing to the expression of additional FnBPs on these bacteria. In fact, the choline-binding protein CbpG, the sortase-anchored pilus adhesin RrgA, and the binding protein for plasmin and fibronectin (PfbA) have been characterized as FnBP as well, the latter serving as a bacterial adhesion and antiphagocytosis factor (120).

Downloaded From Vet-eBooks.com

In addition, the pneumococcal adherence and virulence factor B (PavB) was shown to specifically bind to fibronectin (2, 112, 121, 122). PavB is highly conserved among pneumococci, and orthologous sequences to PavB were confirmed in other streptococci such as *S. agalactiae*, *S. gordonii*, and *S. mitis*, whereas an orthologue is absent in *S. mutans*, *S. aureus*, enterococci, and other relevant human pathogens. The core domain of PavB consists of approximately 150-amino-acid-long repetitive sequences, referred to as streptococcal surface repeats (SSUREs). The number of SSUREs in PavB proteins among pneumococcal isolates is strain dependent but serotype independent (8, 112). PavB interacts via its SSURE domain with fibronectin but also with other host proteins such as plasminogen or thrombospondin-1 (112, 123). Importantly, the efficiency of PavB binding to immobilized fibronectin or plasminogen increases with the number of SSUREs. This finding is in agreement with the interaction model established for other FnBPs, demonstrating that repetitive units independently interact with type III repeats of fibronectin.

Thus, a high-affinity interaction between a particular FnBP and fibronectin is only achieved via synergistic interactions of repetitive units, while individual repeats only provide low-affinity binding. To demonstrate the mode of interactions between PavA or PavB and fibronectin, binding studies have been conducted using type III fibronectin domains. Although the two FnBPs differ in amino acid sequence and overall structure, they interacted with at least 13 out of 15 type III repeats of fibronectin (124). It appears that such binding mechanisms are somehow related to those described for classical FnBPs of GAS or *S. aureus*, in which the interactions are mediated via tandem β-zippers (96). Remarkably, the interactions of pneumococcal proteins PavA and PavB are different from those of *S. epidermidis* Embp, although both bacterial species only interact with the C-terminal part of fibronectin. While PavA and PavB bind to several fibronectin type III repeats, Embp preferentially recognizes fibronectin type III repeat 12 (111).

Vitronectin and Gram-Positive Bacteria

Vitronectin has equivalent effects on host cell adhesion and bacterial binding as was demonstrated for fibronectin, but owing to the limited expression of vitronectin and its deposition in the periphery, specific interactions with bacteria are likely to occur in damaged or altered tissues (Fig. 1). Specific binding of vitronectin to various strains of staphylococci, pneumococci, and groups A, C, and G streptococci have been identified (125). The binding of vitronectin to group G streptococci and pneumococci but not to group A and C streptococci, is inhibited by heparin, indicating the diversity of vitronectin-binding proteins among streptococci. As with fibronectin, binding to vitronectin mediates the adherence of Gram-positive bacteria to host cells and the ECM (104, 126, 127). Bacterial vitronectin-binding proteins therefore represent additional adhesins of Gram-positive bacteria. The adhesin of *S. aureus* responsible for vitronectin has striking similarity to a heparan sulfate-binding protein from the same strain, suggesting that the host protein undergoes multiple interactions with different bacterial surface recognition sites as well (128).

Of the four vitronectin-binding proteins expressed by *S. epidermidis* (129), a dominant vitronectin-binding protein of *S. epidermidis* and of *S. aureus* is their major autolysin Atl (130). This bacterial adhesin constitutes a surface-associated protein, whereby AtlE of *S. epidermidis* and AtlA of *S. aureus* share sequence homology and domain organization. The full-length proteins are proteolytically cleaved in their amidase and glucosaminidase domains. Importantly, the amidase domain contains two repetitive regions, termed R1ab and R2ab, which are responsible for the interaction with vitronectin and thrombospondin-1 (130). Also, interactions of vitronectin with multiple recognition sites of the *S. epidermidis* wall surface may strengthen bacterial colonization (129). This is supported by the fact that AtlE contributes to the adherence of *S. epidermidis* to a polystyrene surface, to heat shock cognate protein Hsc70, or to other plasma proteins (131). Distant sequence homology exists between vitronectin and the heme-binding plasma protein hemopexin, whose ligand-binding properties strongly depend on its conformational flexibility. In addition to RGD- and heparin-dependent interactions with Gram-positive bacteria, hemopexin-type repeats in vitronectin and in hemopexin itself have been proposed to function as target sites for group A streptococci (132), mediating microbial adherence and colonization in the blood vessel wall.

Pneumococci exploit host-cell-bound vitronectin for their adherence to cells of the respiratory tract and probably also to endothelial cells, although this has not been demonstrated experimentally. Pneumococcal adhesins interact with vitronectin bound to $\alpha_v\beta_3$-integrin and thereby activate signaling pathways, which induce a reorganization of the actin cytoskeleton. This in turn leads to the formation of micro-spikes and tight binding of pneumococci to the host cells (126). The multifunctional adhesin PspC, which earlier was shown to interact with the ectodomain (secretory component) of the polymeric immunoglobulin receptor (pIgR) and complement inhibitor factor H, has been identified as pneumococcal vitronectin-binding protein as well (133). Vitronectin binds preferentially to PspC subtypes, which contain two R (repetitive) domains, formerly shown to be relevant for binding of the secretory component of pIgR. The C-terminal heparin-binding domains of vitronectin serve as interaction sites for PspC, thus confirming that heparin inhibits pneumococcal interactions with the multimeric form of vitronectin.

Since vitronectin is an important inhibitor of the terminal complement cascade, it was not surprising that vitronectin bound to pneumococcal PspC is functionally active and inhibits complement-mediated membrane lysis (133), thereby protecting these bacteria against the host innate immune system. PspC is produced by almost all pneumococcal serotypes, with the exception of serotype 3 strains, which produce a PspC-like protein referred to as Hic (factor H-binding inhibitor of complement) (class II PspC, PspC11.4). Hic, originally identified as a factor H-binding protein, was also shown to bind to vitronectin (130), whereby the central core of Hic (amino acids 151 to 201) was identified as a target domain for vitronectin. This region is different from the factor H binding domain (amino acids 38 to 92) of Hic, and consequently, Hic is able to bind two inhibitors of the complement cascade at once, thereby evading immune responses and facilitating invasive infectious disease caused by serotype 3 pneumococci (130).

Fibrinogen and Gram-Positive Bacteria

Together with invading cells and aggregating platelets, the fibrin clot represents the predominant initial provisional ECM network for the early phase of wound sealing (45). At sites of trauma and injury, fibrinogen therefore serves as a major host substrate for bacterial adhesion. Various

Downloaded From Vet-eBooks.com

fibrinogen-binding proteins mediating bacterial colonization in wounds or catheters have been described, of which those expressed by *S. aureus* are the best characterized (134). In particular, "clumping factor" serves to recognize the carboxy-terminal portion of fibrinogen γ-chain in a manner analogous to $\alpha_{IIb}\beta_3$-integrin binding. Moreover, the homology between metal ion-dependent adhesion sites of integrin α_{IIb}- and α_M-subunits or clumping factor and an integrin-like protein from *Candida albicans* (135) indicates common mechanisms of fibrinogen binding to mammalian cells, lower eukaryotes, and prokaryotes. Staphylocoagulase serves as an additional fibrinogen-binding factor that is not involved in bacterial clumping but, owing to prothrombin binding and proteolytic conversion, helps to promote fibrin formation or bacterial attachment onto fibrinogen-coated surfaces (136). As another example, the adherence of *S. aureus* to endothelial cells is mediated predominantly by fibrinogen as a bridging molecule leading to acute endovascular infections (137). Although platelet aggregation via a fibrinogen-dependent mechanism can be induced by this pathogen, this process is independent of the aforementioned principal platelet $\alpha_{IIb}\beta_3$-integrin binding to fibrinogen (138). *S. aureus* colonizes skin lesions in more than 90% of patients with atopic dermatitis, and fibrinogen appears to play a major role in the enhanced binding of *S. aureus* to atopic skin tissue.

In GAS, M protein is a cell surface structure principally responsible for binding fibrinogen, contributing to the known antiopsonic property of M protein (139). Fibrinogen binding to streptococci of groups C and G also leads to the inhibition of complement fixation and subsequent phagocytosis, indicating a relevant role of this interaction for bacteria to evade immune defense (140, 141). Furthermore, bacterial colonization was reduced in a mouse mastitis model by vaccination with *S. aureus* fibrinogen-binding proteins (142), providing a new concept for antimicrobial therapy. Another fibrinogen-binding protein, FbsB, has been reported in *S. agalactiae*. This protein plays an essential role in the overall process of host cell entry by these bacteria, whereby the treatment of lung epithelial cells with FbsB fusion protein blocked *S. agalactiae* invasion of epithelial cells in a dose-dependent fashion, indicating that FbsB may serve as a target for antimicrobial intervention (143).

Alongside its role as a major FnBP in mediating fibronectin-related adhesion of *S. pyogenes* to different tissues, SfbI also interacts with fibrinogen. Upon binding, a cryptic thioester of SfbI can undergo trans-esterification such that SfbI can form a covalent bond with fibrinogen (reminiscent of the reaction between complement C3b and bacterial surfaces) (144). The mutated form of SfbI lacking the internal thioester was unable to interact with fibrinogen or human cells. Interestingly, *in silico* analysis identified a high number of bacterial proteins (including proteins of the human pathogen *S. pneumoniae*) containing cryptic thioesters as well. These data point to the fact that certain bacterial adhesins function as chemical harpoons and can irreversibly link microbes to host molecules. Likewise, using atomic force microscopy, the mechanical stability of the interaction between the prototypical staphylococcal adhesin SdrG and the short peptide epitope of the fibrinogen B β-chain resembles the strength of a covalent bond. Thus, adhesins can attach to their target host proteins with exceptionally resilient mechano-stability (145).

In addition to staphylococcal or streptococcal surface proteins that interact with ECM components, proteins released by these bacterial species can directly influence fibrin formation or dissolution and thereby influence the wound healing process. While staphylocoagulase binds and activates prothrombin to thrombin, staphylokinase and streptokinase interact with plasminogen by forming a stoichiometric complex to produce plasmin, eventually resulting in thrombolysis. These strategies apparently allow effective fixation and subsequent penetration of these bacteria within wound areas of the host.

Thrombospondin and Gram-Positive Bacteria

The high-affinity interactions of human thrombospondin-1 with *S. aureus* strains and pneumococci, as well as other Gram-positive bacteria such as *S. epidermidis* (130, 146, 147), have been explored in the context of wound repair as well. Binding to thrombospondin-1 mediates the adherence of staphylococci to tissues via activated platelets during inflammation or infection. A large number of protein A-negative and protein A-positive staphylococcal isolates bind to thrombospondin-1-coated artificial surfaces, indicating that microbial adherence is significantly promoted as a function of immobilized thrombospondin-1. Moreover, bacterial adhesion to epithelial and endothelial cells is increased in the presence of host cell-bound thrombospondin-1, which functions in this scenario as a molecular bridge between the microbe and the host cell (147). Human thrombospondin-1 also facilitates the interaction between *S. aureus* or pneumococci and platelets, resulting in their irreversible activation (123, 148–150). Strikingly, the vitronectin-binding proteins AtlE, AtlA, and Eap from *S. epidermidis* and *S. aureus* and pneumococcal PspC and Hic have also been identified as thrombospondin-1-binding proteins in this regard. Moreover, the pneumococcal adhesin PavB, which interacts via its SSURE domains with plasminogen and fibronectin, was shown to act as a binding partner for thrombospondin-1 (123, 130, 148). The importance of pneumococcal PavB and PspC in this regard was confirmed by using PavB- and PspC-negative strains, with the result that thrombospondin-1-mediated pneumococcal adherence to human epithelial cells was significantly reduced (123).

The binding of thrombospondin-1 to coagulase-negative streptococci may contribute to bacterial adherence on biomaterial surfaces (151), and specific binding of thrombospondin-1 to groups A, C, and G streptococci has been reported in this regard. As for *S. aureus*, the binding component in streptococci is resistant to trypsin. Thus, Gram-positive bacteria, particularly pathogenic microorganisms, produce a plethora of proteinaceous adhesins that interact with human thrombospondin-1 or in combination with other ECM proteins, thereby enhancing the interaction of bacteria with platelets and nonprofessional host cells, e.g., for effective wound infection.

Degradation of ECM by Gram-Positive Pathogens

The invasion of bacteria into tissues requires the degradation of matrix proteins for proper microbial colonization to occur. This is accomplished by various bacterial enzymes as well as by host-derived plasmin that becomes generated preferentially on the surface of bacteria with the help of host plasminogen activators (Fig. 2). In extravascular tissues, urinary-type plasminogen activator (uPA) is the predominant enzyme responsible for pericellular plasmin formation, while endothelium-derived tissue-type plasminogen activator (tPA) is the major intravascular plasmin-generating enzyme and acts in a fibrin-dependent manner. A number of bacteria, such as groups A, C, and G streptococci and

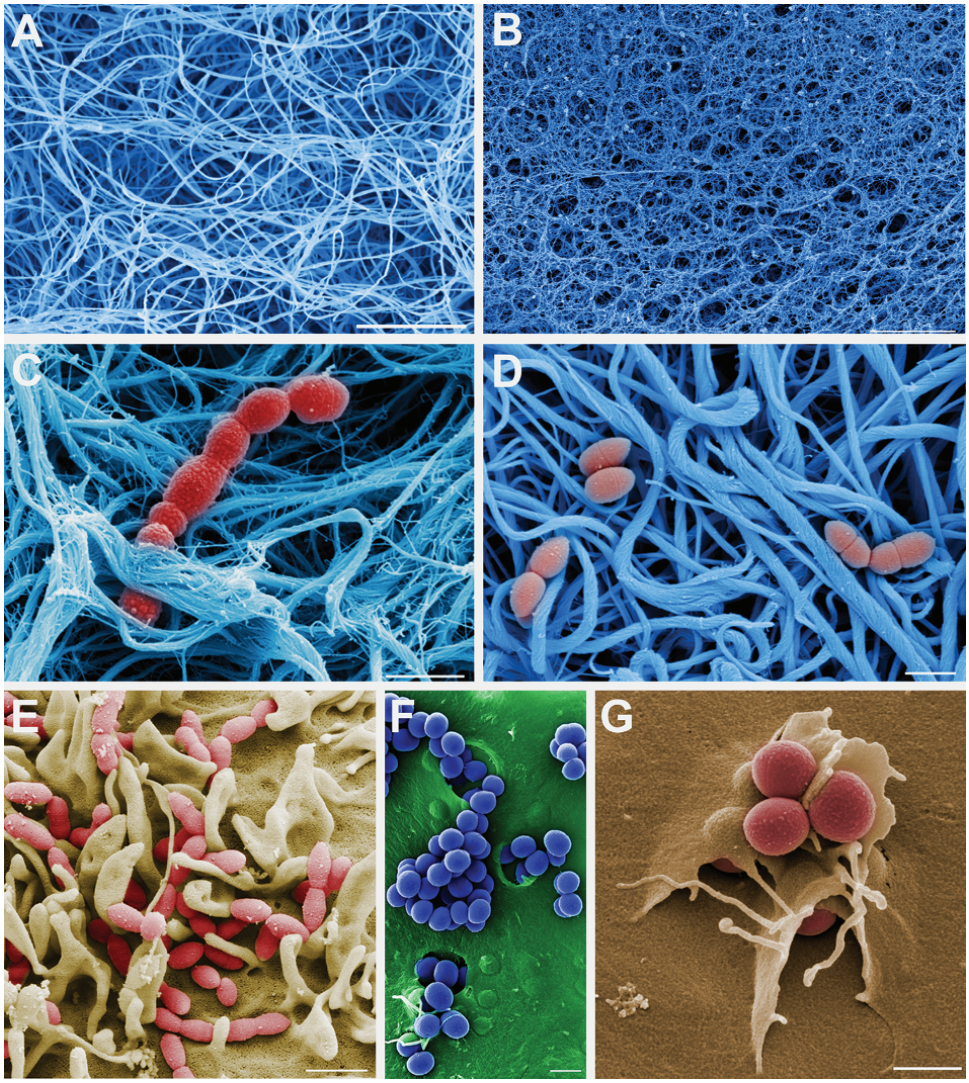

FIGURE 2 (A to D) Dissolution of a fibrin clot by *Streptococcus pneumoniae* (D39, serotype 2). (A) *In vitro* fibrin clot after fixation with aldehydes, dehydration with acetone, and critical-point drying that was subsequently exposed to *S. pneumoniae* in the presence of host-derived plasminogen activator and plasminogen; no dissolution of the fixed fibrin clot. (B) Following binding of plasminogen to its bacterial binding protein α-enolase and addition of plasminogen activator and plasminogen, the formed plasmin degrades native fibrin bundles. (C) Higher magnification of the process shown in panel B to demonstrate the dissolution of thick fibrin bundles (compare with panel D). (D) The same process as shown in panel C, except that a plasmin inhibitor was added to prevent the degradation of fibrin bundles. (E) Adhesion and initial invasion of *S. pneumoniae* (serotype 35A) to a Detroit 562 human nasopharyngeal carcinoma cell, mediated by bacterial binding of vitronectin and its interaction with host cell integrins, inducing a signaling cascade via integrin-linked kinase. (F, G) Two invasion mechanisms of methicillin-resistant *Staphylococcus aureus* into epithelial cells (HeLa): (F) via the formation of large invaginations and (G) by inducing rearrangements of the actin cytoskeleton of the host cell, i.e., membrane ruffling. Bars represent 10 μm in panel A, 200 μm in panel B, and 1 μm in panels C to G.

pneumococci express surface receptors for plasmin(ogen) that facilitate pericellular proteolysis and microbial invasion (152–154). A plasmin-binding protein (PAM) has been isolated from GAS, which belongs to the M protein family and binds to the characteristic kringle domains of plasminogen. This binding was blocked by a lysine analog, indicating that lysine residues in the M-like protein significantly contribute to the interaction (155).

As another example, plasminogen binding to *S. pyogenes* is responsible for bacterial adherence and pericellular invasion of human pharyngeal cells (154). Plasminogen binding has also been associated with the skin infections caused by *S. pyogenes* (156). The critical role of plasminogen in GAS infections has further been demonstrated in a study using transgenic mice overexpressing human plasminogen with markedly increased mortality when infected with GAS (157).

Downloaded From Vet-eBooks.com

Moreover, the structural similarity of plasminogen kringle motifs to neutrophil-derived polypeptides ("defensins") (158) suggests that their antimicrobial activity can be related to interference with plasmin formation, thereby preventing the spreading of infection. Finally, once bound to the streptococcal surface, plasmin was found to be protected from inactivation by the host serine protease inhibitor α_2-antiplasmin.

Another group of bacterial plasminogen-binding proteins, including the glycolytic enzymes α-enolase, glyceraldehyde-3-phosphate dehydrogenase, and phosphoglycerate kinase, fulfill their job as "moonlighting factors" and essentially contribute to plasminogen recruitment on the surface of *S. pneumoniae* and hence to pneumococcal pathogenesis (12, 152, 159, 160). The subsequent activation of surface-bound plasminogen via host-derived tPA or uPA endows pneumococci with proteolytic activity, which is then exploited by these microbes for degradation of fibrin thrombi, components of the ECM (including basement membrane proteins), and activation of matrix-metalloproteinases (152). Moreover, during the initial steps of bacterial colonization, host cell-bound plasminogen may facilitate penetration of microbes into tissues. In contrast, recruitment of soluble plasminogen to microbes reduced their attachment to epithelial or endothelial cells but increased their interaction with neutrophil granulocytes (153). These mechanisms are reminiscent of eukaryotic α-enolase-dependent recruitment of plasminogen to host immune or tumor cells, which thereby become equipped for effective tissue invasion (161).

Several bacteria express and secrete enzymes that interact with plasminogen to convert it into active plasmin. These include group A, C, and G streptococci and *S. aureus* that produce streptokinase and staphylokinase, respectively. These proteases form complexes with plasminogen, and the promoted conformational changes in the enzymogen induce plasmin formation. Moreover, staphylokinase requires fibrin as a cofactor and may induce immunogenic antibody responses, thereby provoking proliferation of T lymphocytes (152). Although staphylokinase and streptokinase had been applied as thrombolytic agents for use in thrombolysis of patients with, e.g., acute myocardial infarctions and arterial thrombosis (160), these treatments are no longer feasible and safe, also due to the unwanted immunogenicity of the bacterial enzymes.

As an acute-phase reactant in host defense, the circulating broad-spectrum proteinase inhibitor α_2-macroglobulin serves to eliminate spent proteinases via receptor-mediated endocytosis and may do so with microbial enzymes as well (162). Interestingly, various strains of streptococci exhibit specific binding to α_2-macroglobulin (163). A protein of 78 kDa was purified from GAS that interacted specifically with native α_2-macroglobulin. Although this protein does not possess any proteolytic activity, its interaction with α_2-macroglobulin provoked a conformational change similar to that observed in α_2-macroglobulin-protease complexes (164). Through their interaction with α_2-macroglobulin via the streptococcal surface protein GRAB, streptococci might gain access to host tissues, possibly via the α_2-macroglobulin receptor (165). In fact, mice infected with a GRAB mutant exhibited a longer survival and expressed less bacterial dissemination, emphasizing the role of α_2-macroglobulin in the virulence of *S. pyogenes* (166).

CONCLUSIONS

Infections by Gram-positive pathogens are still a major cause of serious human diseases. The rapid emergence of resistance to antibiotics in various Gram-positive cocci and (with the exception of pneumococci) the fact that no vaccine is available against most of these microorganisms make these Gram-positive pathogens a major health hazard. A better understanding of the pathogenic mechanism of Gram-positive infections is a prerequisite to improve existing suboptimal vaccines or to develop effective new ones. In addition, knowledge of the pathophysiologic processes of microbe-host interactions at different phases of infection is essential to design novel strategies for the prevention and treatment of these diseases.

The adherence and invasion of microbes are the first crucial, disease-causing mechanisms of Gram-positive pathogens. Since diverse molecular interactions of pathogens with the components of host ECM and cell surfaces are involved in both bacterial adherence and invasion, an understanding of the underlying mechanisms is of the utmost importance to design novel antimicrobial and therapeutic strategies. For example, bacterial adhesins, including the pleiotropic virulence factors of streptococci (89) that specifically interact with host ECM components, can be considered as drug targets for an antiadherence or anti-invasion strategy, e.g., utilizing the knowledge of specific interaction sites documented in this chapter. However, the problems with this strategy are that not all adhesin genes are present in every bacterial strain, there is antigenic variation of these adhesins, and environmental factors can also affect the expression of these genes. Moreover, since each microorganism can employ multiple adhesins and attachment mechanisms to initiate infection, effective antiadhesion drugs may contain cocktails of various inhibitors.

A classic example of the potential use of bacterial cell-surface components interacting with ECM is documented by the FnBP SfbI from *S. pyogenes*. SfbI protein acts as both an adhesin and an invasin of GAS. Mice immunized with this protein not only show reduced pharyngeal colonization but are also protected against lethal streptococcal challenge. Since SfbI is highly conserved in its functional domains in streptococcal isolates from different geographical regions, it does not cross-react with the host proteins, is highly immunogenic, and represents a promising vaccine candidate. Besides its role in adhesion and invasion, SfbI is a strong mucosal adjuvant, and because of its nontoxic nature, it has an advantage over the toxin-based adjuvants. In addition, immunization with *S. aureus* fibrinogen-binding proteins leads to reduced colonization in a mouse mastitis model. Synthetic peptides representing the fibronectin-binding domain of *S. aureus* adhesins as well as antibodies against this protein domain were successful in blocking *S. aureus* colonization on implanted foreign material. These examples clearly demonstrate that components involved in the interactions of ECM with Gram-positive pathogens can serve as potential drug targets and justify further research in this field.

The authors' work referred to in this chapter was supported by grants from the Deutsche Forschungsgemeinschaft, Bonn, Germany (DFG GRK 1870, DFG TRR34 project C10, DFG TRR240 project A11, DFG HA 3125/4-2 to S.H. and DFG TR84 project A2 to K.T.P.).

In recognition and memoriam to G. Singh Chhatwal for his outstanding work in the field of bacteria-host cell interactions of streptococci and his contribution to the previous edition of this chapter and in recognition and memoriam to Georg Peters for his outstanding work in the field of staphylococci as well as his dedication in supporting young investigators in medical microbiology.

Group A *Streptococcus*-Mediated Host Cell Signaling

VIJAY PANCHOLI

9

INTRODUCTION

Bacteria must adhere to, colonize, and invade the target tissue while evading host protective immune responses to be successful pathogens. A pathogen sequentially engages (adheres to) its surface-exposed adhesins with complementary host receptors to successfully colonize and infect the targeted cell. Group A *Streptococcus* (*Streptococcus pyogenes*) is one of the most successful pathogens and is a model organism used to understand various aspects of pathogenesis. The latter may be related to toxins, horizontal gene transfer, mammalian protein binding, cellular invasion, intracellular proliferation, immune evasion, innate immunity, programmed cell death, and/or autoimmunity. *S. pyogenes* displays a remarkable tissue tropism for the human pharynx and the skin, causing a variety of diseases (1–3). Initial *S. pyogenes* infection can easily be treated with penicillin, and there is no known emergence of penicillin-resistant strains. Despite important advances in hygiene and modern methods of prevention, *S. pyogenes* still ranks among the 10 deadliest human pathogens, causing an estimated more than 500,000 deaths annually (4, 5).

The surface of *S. pyogenes* presents an array of proteins that perform a variety of functions (6–8). Beyond this multifunctional nature, the complex makeup of *S. pyogenes* pathogenesis is attributed to several other factors. These include the prevalence of several *S. pyogenes* serotypes, strain-specificity within one serotype, individual-based differential immune responses, the ability of several proteins in concert to perform one particular function, and cultural and host (extracellular and intracellular) environment-based differential gene expression levels (3, 9–11). With the availability of complete genome sequence analyses of several hundred *S. pyogenes* strains (https://www.ncbi.nlm.nih.gov/genome/?term=streptococcus+pyogenes), it is easy to predict the number of different surface proteins, which may serve as potential adhesins during initial interactions with host cells. However, it is unknown how many of them remain expressed during the adherence process and serve as adhesins for specific cell-surface receptors. The complex dynamic relationship among these proteins is unknown because the expression of many of these proteins is environmentally regulated (3, 9–11). Further, many of the surface proteins are differentially regulated only when the bacteria reach the intracellular environment (12–14). Similarly, the interaction of bacteria with their host cells may up- or downregulate the expression of host cell receptors and may accordingly modulate intracellular signaling events (13, 15, 16). Bacterial adhesion-host receptor interactions studied *in vitro* may vary with polarized cells versus nonpolarized cells, normal versus established cells, and professional phagocytes versus nonprofessional phagocytic cells (17–19). The dynamics of these interactions in the early events of streptococcal infection are multifactorial and extremely complex.

Despite many obvious missing links in our understanding of the precise signal transduction pathways evoked by these organisms in their host cells, the available literature suggests a common paradigm (20). Through their surface proteins, pathogenic Gram-positive cocci interact with specific receptors on the target cell and induce a series of biochemical signals. These signals, which are characterized by the induction of phosphokinase enzymes and phosphorylation of several intracellular proteins, ultimately target the nucleus and lead to either generalized or specific gene activation. Activation of some of these genes may result in the modulation of interleukins or other cytokines, which may then initiate a proinflammatory response. These induced signals, and subsequently the resulting products, could have several effects on the invasion of bacteria. *S. pyogenes* can produce infections in virtually every human organ and tissue. Mild to severe inflammation is the key immune response during infection. Thus, although initial interactions may involve pharyngeal and skin cells, subsequent interactions of *S. pyogenes* after evasion or invasion of host innate immune responses invariably involve neutrophils as the first responders of the host defense and other host cells, including macrophages, mast cells, dendritic cells, and endothelial and other myeloid cells. Numerous studies have laid a sound foundation for our understanding of the cross talk between Gram-negative bacteria and host cells, thereby unraveling their basic virulence mechanisms (20–23). The information available on the cell biology of *S. pyogenes*-infected human/mouse pharyngeal cells, skin cells, neutrophils, macrophages, and endothelial cells in the past decade has contributed substantially to a better understanding of the *S. pyogenes* pathogenesis. These studies highlight the fact that unlike many Gram-negative pathogens, which take advantage of deficient or failed immune systems of immunocompromised hosts, *S. pyogenes* causes invasive diseases in the immunocompetent host because it is endowed with the ability to thwart human innate immune responses (24–27). This ability encompasses evading host complement deposition and activation, impairing phagocyte recruitment and activation, resisting the microbicidal activities of antimicrobial peptides (AMPs) and reactive

doi:10.1128/microbiolspec.GPP3-0021-2018

Downloaded From Vet-eBooks.com

oxygen species (ROS), escaping neutrophil extracellular traps (NETs), and causing programmed cell death (autophagy, apoptosis, pyroptosis, or necroptosis). Several excellent reviews on these aspects of *S. pyogenes* inflammation and sepsis have been published in recent years (24, 26–34). The field of the cellular microbiology of pathogenic streptococcal infection is, however, continuously expanding as the newer CRISPR/CAS9 (clustered regularly interspaced short palindromic repeat)-based technology, reagents, and knockout mouse strains have become available. In this article, the past and recent reports on signaling events initiated primarily by *S. pyogenes* infection are summarized along with relevant complementery information on other Gram-positive streptococci, where necessary.

INITIAL INTERACTIONS OF *STREPTOCOCCUS* WITH MUCIN ON PHARYNGEAL CELL MUCOSA

Situated on top of the human respiratory epithelial cilia is a viscous layer of mucus that continuously flows toward the pharynx. The anatomical disposition of respiratory mucus requires that all mucosal pathogens interact first with mucin before they adhere to a host cell receptor on the epithelial cell. Mucins are a highly complex class of glycoproteins found in both secretory and bound forms and are expressed by several genes (35–37). The structural diversity among the mucin family increases due to the posttranslational O-glycosylation and sulfation modifications that contribute to more than 50% of the molecular mass of the mucin molecule (35). Although mucin may serve as an initial protective barrier from invading pathogens, overproduction of mucin has been shown to exacerbate the pathological symptoms of diseases such as bacterial pneumonia and cystic fibrosis (38–40). While several reports have described the role of mucin in the pathogenesis of Gram-negative bacterium-associated cystic fibrosis and, similarly, of oral streptococcus-mediated diseases (38, 39, 41), the information available about the interaction of mucin with pathogenic Gram-positive bacteria and its implication in the disease process is very limited (42–45). The mucin-binding property of *S. pyogenes* is regulated by the *mga* gene (46). The M protein and a 39-kDa *S. pyogenes* cell wall-associated surface protein (streptococcal surface dehydrogenase [SDH]) are the first reported surface proteins that mediate streptococcal binding to salivary/tracheobronchial mucin (47). The binding of *S. pyogenes* to mucin also increases streptococcal adherence to and invasion of cultured human pharyngeal cells (47). Pullulanase, a 129-kDa *mga*-regulated *S. pyogenes* surface protein also binds to submaxillary mucin and serves as a surface adhesin (48). Pullulanase possesses carbohydrate-degrading activities and may facilitate direct bacterial interaction with host cells (48). *S. pyogenes* also adheres to the salivary proline-rich protein of pharyngeal epithelial cells via the GrpE chaperon protein (49). Additional mucolytic enzymes such as streptococcal neuraminidase (45) or other extracellular proteases (50–52) may play a similar role in facilitating bacterial migration through the viscous mucin layer and allowing them to target the epithelial surface-specific receptor before the invasion.

Certain types of mucins such as MUC2 and MUC5AC are overexpressed in human bronchial explant and epithelial cell cultures in response to interactions with culture supernatants of Gram-negative (e.g., *Pseudomonas aeruginosa*) and Gram-positive (*Staphylococcus aureus*, *S. pyogenes*, *Staphylococcus epidermidis*) bacteria (53). This expression is found to be tyrosine-phosphorylation dependent (53), indicating that a specific type of mucus production may be the result of the induction of specific intracellular signaling events. Although respiratory cell-bound mucins, such as MUC1, are thought to be involved in cell adhesion (54–56), their cytoplasmic domains have been shown to play a role in cytoskeletal rearrangements in certain disease conditions (57). An asymptomatic carrier stage of *S. pyogenes* infection with little or no immune response in school-age children is very common (58). During this stage, the interaction of *S. pyogenes* with pharyngeal mucosal cells demands special attention. In adults, the mucins MUC5B (originally named MG1) and MUC7 (originally MG2) have been detected in saliva from the minor salivary glands and the submandibular and sublingual glands (59, 60). MUC5AC is considered to be the predominant mucin in airway mucus (61). During the first year of infancy, the salivary concentration of MUC5B increases and MUC7 decreases (62). MUC7 seems to play a role in mediating the interaction between bacteria and neutrophils (63). Similarly, the amount of mucins also seems to decline as people age (64). This observation may have a clinically important underlying reason for the lower frequency of *S. pyogenes* infection in infancy and old age. Thus, the tight regulation of mucin production is critical to maintaining a required balance between beneficial and detrimental outcomes. While not much information is available on mucin-associated signaling events during *S. pyogenes* infection, the suppression of the p21-activated kinase-Janus kinase signaling pathway has been shown to act as an inducer for *S. pneumoniae* pneumolysin-induced MUC5AC mucin transcription (65).

BINDING OF STREPTOCOCCAL ADHESINS TO HOST CELL RECEPTORS AND INTRACELLULAR SIGNALING EVENTS IN TARGET CELLS

The role of staphylococcal and streptococcal exotoxins, which function as superantigens, in the induction of mitogenic and inflammatory responses is well established and is characterized by the release of a variety of chemokines and cytokines from peripheral blood monocytes (30, 66–70). Although the release of a variety of inflammatory cytokines/inflammatory mediators, including AMPs (31), prostaglandin E2, leukotrienes B4, and chemokines, triggered by streptococcal superantigens plays an important role in invasive *S. pyogenes* disease, individuals infected with the same strain may develop very different manifestations (70). Kotb et al. (67) proposed that leukocyte antigen class II allelic variation contributes to differences in severity of invasive streptococcal infection through the ability to regulate the production of the cytokines tumor necrosis factor-β (TNF-β), interferon-γ (IFN-γ), and interleukin 4 (IL-4) mediated by streptococcal superantigens. In particular, patients with the DRB1*1501/DQB1*0602 haplotype mount significantly reduced responses and hence are less likely to develop severe systemic disease (67). Beyond the ability of superantigens to directly activate T cells, resulting in overzealous inflammatory responses, it was recently recognized that the essential role of *S. pyogenes* superantigens is to promote nasopharyngeal colonization and infection in a Vβ-specific T-cell-dependent manner. Thus, in the absence of accessible T cell receptor or the presence of neutralized superantigens, *S. pyogenes* infection cannot be established (71, 72). A similar study with *S. aureus* superantigen, which also activates mucosa-associated invariant CD8+ T cells as a substantial source of initial cytokine responses has indicated that only in the presence of

Downloaded From Vet-eBooks.com

such initial cytokine responses does colonization of mucosa by *S. pyogenes* or *S. aureus* occur (73).

In addition to superantigens, an important role of the M protein in excessive plasma leakage from vasculature leading to life-threatening hypotension and multiorgan failure was recently recognized (74). Herwald et al. (74) reported that the ability of the M protein to bind fibrinogen (75, 76) allows the M protein/fibrinogen complex to interact with β2-integrins and activate neutrophils. As a result, neutrophils release heparin-binding protein, an inflammatory mediator that induces vascular leakage and a massive inflammatory response, leading to toxic shock. More evidence is available that confirms the ability of target epithelial cells or blood monocytes to release certain interleukins and TNF as a result of their interaction with intact Gram-positive bacteria in a CD14-independent manner (77, 78). The examination by Wang et al. (78) of keratinocyte responses to adherent versus nonadherent *S. pyogenes* revealed a distinct pattern of expression of several proinflammatory molecules. This study further reported that both adherent and nonadherent streptococci are capable of inducing IL-6 and prostaglandin E_2; however, only adherent streptococci are able to induce IL-1α, IL-1β, and IL-8. Similarly, only adherent streptococci are capable of damaging the keratinocytes. Since the production of cytokines and the damage to the keratinocytes are considerably reduced in streptolysin O (SLO)-deficient *S. pyogenes* mutants, it is rational to conclude that streptococci also utilize some of their secretory products to induce a proinflammatory response (78).

The C-repeat region of streptococcal M protein binds to CD46, a membrane-bound complement regulatory protein related to factor H, which serves as a cellular receptor for *S. pyogenes* on human keratinocytes (79). CD46 belongs to a family of proteins that contain four structurally related short consensus repeat domains and regulate the activation of the complement components C3b and C4b (80). A major M protein-binding site is located within short consensus repeats 3 and 4, probably at the interface of these two domains (81). The hyaluronic acid capsule also modulates the M-protein-mediated adherence and acts as a ligand for attachment of *S. pyogenes* to CD44 on human keratinocytes (82). CD44 is also reported to be a receptor for *S. pyogenes* colonization of the pharynx (83). It was also proposed that this streptococcal-host cell intimate contact, mediated by the M protein CD46, may initiate proinflammatory responses from keratinocytes during infection (78). In fact, CD44-dependent *S. pyogenes* binding to polarized monolayers of human keratinocytes induces marked cytoskeletal rearrangements, resulting in membrane ruffling and disruption of intercellular junctions. The signal transduction induced after binding of *S. pyogenes* to the keratinocyte surface via CD44 involves a small signaling GTPase (Rac1) and the cytoskeleton linker protein ezrin, as well as tyrosine phosphorylation of cellular proteins (84). Studies of bacterial translocation in two models of the human skin have indicated that cell signaling triggered by the interaction of the hyaluronic capsule of *S. pyogenes* with CD44 opens intercellular junctions and promotes tissue penetration by the bacteria through a pericellular route (84).

The evidence that streptococci may regulate intracellular signaling events upon contact with their target cells, such as pharyngeal cells, was first suggested when a novel multifunctional protein, SDH was identified on the surface of streptococci (85). SDH, which shows binding activity to a variety of mammalian proteins such as fibronectin, myosin, plasmin, and actin, is also a cysteine-residue targeting the ADP-ribosylating enzyme (86, 87). ADP-ribosylation plays an important role in intracellular signaling events and is the mechanism by which many bacterial toxins show their deleterious effects on target cells (88). SDH does not serve as a toxin, but its direct contact with human pharyngeal cells (both polarized and nonpolarized) results in DNA condensation and apoptosis (89, 90). Interestingly, SDH belongs to a novel class of surface-expressed, anchorless housekeeping enzymes and is now well established as a virulence factor for pathogens (90, 91). Like SDH, another metabolic enzyme, streptococcal surface enolase (SEN), has also been shown to be present on the surface of *S. pyogenes* and *Streptococcus pneumoniae* functioning as a strong plasminogen receptor (92, 93). Human enolase has been shown to be expressed on the surface of a variety of cells, such as hematopoietic, neuronal, endothelial, and epithelial cells, and serves as a receptor for plasminogen (94–97). SDH binds to four membrane-associated proteins (89), two of which (47 kDa and 55 kDa) have been characterized as the human enolase and urokinase plasminogen activator receptors (uPAR), respectively (98). The report describing increased adherence of *S. pyogenes* to human pharyngeal cells in the presence of plasminogen indicates that this molecule may serve as a molecular bridge between human enolase expressed on the surface of pharyngeal cells and the SEN molecule expressed on the surface of *S. pyogenes* (97). Binding of plasminogen by *S. pyogenes* through SEN or other enolase-binding proteins facilitates the pericellular invasion of the host cell by *S. pyogenes* (97). Since SDH binds directly to human enolase and SEN (98) and is associated with the M protein and M-like protein (99), it is conceivable that both human enolase and uPAR can serve as potential receptors for *S. pyogenes*-mediated signaling events. uPAR is the native receptor of uPA, which is primarily responsible for recruiting plasmin during the infection process. uPAR is a glycosylphosphatidylinositol-anchored protein that is internalized via endocytosis in a clathrin-independent manner (100–102). It is likely that the binding of SDH to uPAR may contribute to the induction of downstream signaling events (103–105), the activation of the fibrinolytic system, and *S. pyogenes* internalization and invasion. Mice expressing human plasminogen *in trans* are significantly more susceptible to invasive *S. pyogenes* diseases than the $uPA^{-/-}$ mice, since in the latter the dissemination of *S. pyogenes* is significantly poor due to the lack of plasmin accumulation (106).

The putative receptor of SDH also includes two additional proteins, the 30- to 32-kDa protein 14-3-3, and the 80-kDa protein moesin (98). The 14-3-3 protein is an important regulatory protein that plays a diverse regulatory role in cell signaling (107–109) and serves as a gatekeeper of phosphorylation (110). While the roles of SDH and the 14-3-3 protein in *S. pyogenes* infection have not been explored, the 14-3-3 protein has been shown to play a determining role in parasitic and chlamydial infections (111, 112). Moesin is a member of the ezrin, radixin, moesin (ERM) protein family and plays a key role in membrane cortex integration and epithelial organization; thus, this protein is involved in endothelial barrier integrity and neutrophil functions (113–117). Similar to SDH, the *S. pyogenes* streptococcal inhibitor of complement (Sic) protein has also been shown to bind to moesin (118). By binding to moesin, the Sic protein enhances bacterial survival by enabling *S. pyogenes* to avoid the intracellular environment, resulting in pathogen abundance at the site of infection (118). Like Sic, SDH may contribute to *S. pyogenes* abundance during human infection and the subsequent dissemination of *S. pyogenes* to the community. Similar to the secreted Sic protein, the cell-associated streptococcal C5a peptidase (ScpA) protects *S. pyogenes* from

Downloaded From Vet-eBooks.com

phagocytosis by enzymatically cleaving complement C5a and thus interrupting host defenses (119, 120). Terao et al. (121) reported that unlike ScpA, which binds C5a with low affinity (equilibrium dissociation constant [K_D] = 7.25 mM) and cleaves C5a, SDH binds to C5a on neutrophils with a very high affinity (K_D = 0.409 μM) and inhibits its activation, thus contributing to *S. pyogenes* evasion from human neutrophils. The ability of ScpA to cleave C5a may contribute to its low binding affinity. Thus, both ScpA and SDH are required for the inactivation of C5a. On the other hand, the extracellularly released glyceraldehyde-3-phosphate dehydrogenase (GAPDH) from *S. pneumoniae* binds to C5a with a much higher affinity (K_D = 3.4 nM); however, this binding activates C5a (122). It is not clear whether this contrasting finding is caused by the absence of ScpA in *Pneumococcus* and is associated only with the secreted form of pneumococcal GAPDH (121). The mechanism that underlies the pneumococcal GAPDH-mediated activation of C5a is unknown. SDH, like whole streptococci, is capable of activating both tyrosine and serine/threonine kinases that phosphorylate several proteins in human pharyngeal cells (89). A recently characterized low-molecular-weight protein, tyrosine phosphatase (SP-PTP), secreted from *S. pyogenes* has a dual specificity for phosphorylated serine/threonine and tyrosine and plays a significant role in virulence (123). *S. pyogenes* mutants lacking SP-PTP are completely attenuated and when cocultured with human respiratory cell lines show a significantly high number of tyrosine-, as well as ser/Thr-phosphorylated proteins compared to the wild type and the *sp-ptp*-complemented *S. pyogenes* strains (123). The increased number of phosphorylated proteins indicates the ability of SP-PTP to interact with host cells directly and to interfere with intracellular signaling events (123).

ROLE OF INTEGRINS IN STREPTOCOCCAL-MEDIATED SIGNALING EVENTS

Integrins are large αβ heterodimeric membrane proteins found on the surface of a wide variety of mammalian cells (23, 124). The integrins seem to be involved in promoting adhesion to extracellular matrix proteins such as fibronectin, collagen, and laminin. Several fibronectin-binding proteins on the surface of *S. pyogenes* have been described and include protein-F/Sfb1 (125, 126), protein F2 (127), serum opacity factor (128), protein H (129), streptococcal glyceraldehyde-3-phosphate dehydrogenase (surface dehydrogenase, SDH) (85), Fbp54 (130), and M1 (131). Sfb1, protein F, and protein F1 have been found, at least in part, to mediate streptococcal invasion of HEp2 or HeLa cells (126, 132). Similarly, the M1 protein efficiently binds to the human lung epithelial cell lines, A549, in the presence of fibronectin via α5β1 integrin and mediates *S. pyogenes* invasion (131). This integrin-mediated interaction seems to play a critical role in signaling events that regulate streptococcal invasion. While recognizing the importance of α5β1 integrin-mediated streptococcal invasion of epithelial cells, the study emphasizes that the ability of fibronectin to mediate invasion varies considerably depending on the source of the integrin preparation (130, 131). *S. pyogenes* invasion is also reported to be mediated by laminin (133), which recognizes α1β1, α2β1, α3β1, α6β1, or α7β1 integrins on the cell surface (23, 124, 134). Both entry of *S. pyogenes* via protein F1 and uptake of fibronectin-coated beads into HeLa cells are blocked by anti-B1-antibody (132, 135). Thus, during the invasion of epithelial and endothelial cells, the streptococci and many other Gram-positive pathogens may attach to different components of extracellular matrix and use one or more integrins. By creating invasion-resistant xylose-transferase-deficient Chinese hamster ovary cell lines using CRISPR/Cas9 technology, Esko's group recently showed that the cellular invasion of *S. pyogenes*, *S. agalactiae*, and *S. aureus* is mediated primarily through the L4A domain of laminin α2 subunits (136).

Bacterial invasion of a target epithelial cell is a dynamic process which involves the active participation of the cytoskeletal structure (21, 22, 137). It is thus reasonable to predict that binding to integrins allows streptococci to communicate with the cytoskeletal structure of the cell and regulates streptococcal entry into the cell. Studies showing the inhibition of streptococcal invasion of Detroit pharyngeal cells in the presence of the tyrosine- and serine/threonine kinase inhibitors, genistein, and staurosporine indicate that the rearrangement of cytoskeletal structure, which facilitates bacterial entry, is substantially regulated by the activation of these intracellular signaling enzymes (89). In HeLa cells, the endocytosis of a highly invasive type M1 *S. pyogenes* strain is associated with polymerized actin and Lamp1 glycoprotein of the lysosomal vacuole (138). The M1 protein either directly or indirectly via bound fibronectin initiates signals that depend on the phosphatidylinositol 3-kinase (PI-3) pathway as in the presence of PI-3 inhibitors, (such as LY294002, wortmannin) and the actin polymerization, the streptococcal invasion of host cells is significantly decreased (139). Similarly, protein F1 also mediates recruitment of *de novo* tyrosine-phosphorylated focal adhesion kinase (140). Src kinases such as yes, paxillin, and Fyn proteins enhance the efficiency of *S. pyogenes* uptake but are not an absolute requirement. Also, Rac and Cdc42 are also activated, indicating that there are at least two independent pathways, which converge to trigger actin rearrangement and endocytosis/bacterial uptake (140). The fibronectin-binding M type-12 *S. pyogenes* strain A40 invades following membrane invagination at the level of the bacterium-cell (HEp-2) contact area. The non-fibronectin-binding M type-5 strain A8, on the other hand, recruits elongated microvilli upon bacterial contact, which then fuse to surround bacteria, leading to the formation of a large pseudopod-like structure that engulfs bacteria (135). The invasion of HEp-2 cells by strain A40 but not A8 is inhibited by treatment of cells with cholesterol-depleting agents, such as methyl-B-cyclodextrin and filipin, indicating that caveolae may act as an entry port for strain A40 (141). Whether caveolin protein serves as a receptor for streptococci is not known.

Unlike type M1 *S. pyogenes*, type M3 *S. pyogenes*, which lacks the SFB1 and PrtF1 proteins, activates Src family PTKs (protein tyrosine kinase) and GTPase Rac1, and accumulates actin nucleation complex Arp2/3 at the point of entry in endothelial cells in a PI3-kinase-independent manner (84, 142). In all published reports, the fibronectin-binding property of *S. pyogenes* is said to have a primary role in initial adherence to, colonization of, and subsequent invasion of respiratory epithelial cells (126, 131, 143, 144). It is reasonable to speculate from these studies that integrin-mediated signaling events play a critical role in streptococcal dissemination in the tissue. In contrast to this view, it seems that dissemination of *S. pyogenes* occurs more efficiently only in mice lacking plasma fibronectin, because F1-defective/negative *S. pyogenes* strains and transgenic mice lacking plasma fibronectin are less virulent as a result of limiting bacterial spread (145). Thus, the fibronectin-binding ability may be viewed as the bacterium's deliberate attempt to decrease its virulence and form an unassuming but more advantageous coexistence with its human host.

Rac1 GTPAses that are activated by the *S. pyogenes* type M3 strain bind to and activate the mixed-lineage kinases (MLK1,2,4), a group of mitogen-activated protein kinases that contain in their N-terminal region a GTPase recognition, a Cdc42/Rac interactive binding motif (CRIB) (142, 146, 147). This event leads to activation of mitogen-activated protein kinase kinases which regulate the c-Jun N-terminal kinase. The activation of p21-activated kinase by Rac allows the activation of inhibitory kappa B kinase, which phosphorylates IKB (the inhibitor of the nuclear factor NF-κB), promoting IKB ubiquitination and its degradation by the proteasome and allowing NF-κB to translocate into the nucleus and target gene expression (148, 149) (Fig. 1). In humans, the activated NF-κB dimers consist mainly of the Rel family protein p50 and p65 subunits, which then bind to responsive κB sites in the promoters and enhancers of the target genes (150). Like NF-κB, STAT molecules (signal transducer in the cytoplasm and activator of transcription in the nucleus) are also latent cytoplasmic transcription factors activated by cytokine stimulation via tyrosine phosphorylation (151). The binding of cytokines to their receptors results in autophosphorylation of receptor-associated JAK kinases that phosphorylate and activate STATs (152). The simple external binding of *S. pyogenes* has been shown to be sufficient to induce NF-κB activity in human epithelial and hematopoietic cells (27, 70, 153–155). This is consistent with the fact that neither cytochalasin B (156) nor protein synthesis inhibitor (157), which prevents bacterial internalization, abolishes NF-κB production. *S. pyogenes* also induces STAT1, STAT3, and IFN regulatory factor-1 DNA-binding activity and the formation of IFN-α-specific transcription factor complex and IFN-stimulated gene factor-3 in human primary macrophages (157). Streptococcus-mediated STAT activation is, however, cycloheximide sensitive (157), suggesting that prior activation and production of cytokines is required for STAT activation. These earlier studies thus shed light on the molecular mechanisms of interaction between streptococci and host cells that lead to different inflammatory responses.

Initial binding of *S. pyogenes* to host epithelial cells *in vitro* and *in vivo* through the activation of several intermediary signaling events as described above induces the secretion of several proinflammatory cytokines such as IL-1α, IL-1β, IL-2, IL-6, TNF-α, RANTES/CCL5 (Regulated upon activation, normal T cell expressed and secreted/chemokine [C-C motif] ligand 5) and IFN-β (70, 71, 158, 159). The induction of these proinflammatory responses in nasal-associated lymphoid tissue is the outcome of initial transforming growth factor-beta-, IL-6-, IL-21-, IL-1β-, and IL-23-dependent differentiation of Th17 cells from naive T cells (160). IL-1α or IL-1β in synergy with IL-23 promotes IL-17 secretion from memory T cells (161). The main function of *S. pyogenes*-induced nasal lymphoid tissue-associated IL-17-secreting T cells is to mediate inflammation by stimulating the production of inflammatory cytokines, such as TNF- α, IL-1β, and IL-6, and a variety of inflammatory chemokines that promote the recruitment of neutrophils and macrophages (160). The cytokines released from infected epithelial cells and resident macrophages, similar to nasal lymphoid tissues induce the expression of P, E, and L selectins of endothelial cells. Blood leukocytes (mainly neutrophils) then temporally bind to individual selectins (first P and E selections, followed by L selectins) via their surface integrins and rolls along the endothelial layer to populate the site of infection through transendothelial migration (162, 163). Selectins play an active role in the initiation of the intracellular signaling pathway (TNF-α, IL-8, respiratory burst) in leukocytes and cell-cell interaction. Vascular dysfunction and ischemic destruction during *S. pyogenes* necrotizing fasciitis, characterized by the platelet/neutrophil complex, are mediated essentially by platelet-P selectin (164–166).

INITIAL INTERACTION OF *S. PYOGENES* WITH NEUTROPHILS AND NEUTROPHIL EXTRACELLULAR TRAPS (NETS)

Neutrophils recruited at the site of *S. pyogenes* infection through the extravasation process, as described above, phagocytose the invading pathogen. The *S. pyogenes* is then engulfed by a phagosome and killed by AMPs, such as cathelicidins (LL-37), α-defensins, neutrophil elastase, lysozyme, or ROS (167). AMPs, which are hydrophobic molecules composed of ~10 to 50 amino acid residues with net positive charge, interact with the net negative charge of the bacterial surface. This strong electrostatic interaction allows AMP to insert into the cytoplasmic membrane, causing membrane rupture (168). ROS kill bacteria by oxidizing microbial proteins and lipids through the action of induced cytosolic NOX2, NADPH enzymes, and the conversion of the resulting reactive oxygen (superoxide $O_2^{\bullet-}$) to deleterious hydrogen peroxide (H_2O_2) and hypochlorous acid (HOCl) (169). *S. pyogenes* still overcomes this hostile environment and successfully colonizes 5 to 25% of humans through its endowed stealth behavior (29, 31).

A relatively newly discovered neutrophil innate immune function is attributed to the extracellular discharge of fibril matrix and formation of extracellular traps, known as neutrophil extracellular traps (NETs) (170). The NETs contain DNA fibrils along with histone proteins, neutrophils granules, neutrophil elastase, myeloperoxidase, lactoferrin, gelatinase, and cytoplasm but not actin or tubulin. NET activation and release allows neutrophils to kill extracellular pathogens and minimize damage to the host cells; the process is also called NETosis (171). Bacterially induced NETosis involves activation of NADH oxidase (Nox), which generates superoxide ion ($O_2^{\bullet}$) and hence is also called Nox-dependent NETosis. A similar process that occurs in mast cells is called METosis, or MCETs (172). Like neutrophils, other myeloid cells, including mast cells (172), macrophages (173), basophils (174), and eosinophils (175), also extrude DNA/histone-based extracellular traps. Hence, the common terminology for these phenomena observed in many myeloid cells types, ETosis, has been suggested as the novel cell death pathway (176). The accumulation of histone H4 and CXCL10 detected in biopsies from patients with necrotizing fasciitis caused by *S. pyogenes* has have been reported (177). The histone H4 specifically targets monocyte in human blood and evokes the mobilization of Toll-like receptor 4 (TLR4)-dependent chemotactic chemokines CXCL9 and CXCL10 and helps maintain the proinflammatory response (177, 178). The significance of histone in the NETs is specifically attributed to its antibacterial activity, which was first observed by Hirsch on several Gram-negative and Gram-positive bacteria, including *S. pyogenes* (179). *In vitro* and *in vivo* mouse skin infection models have shown that mast cells also play an important role in *S. pyogenes* skin infection (172). The *in vivo* skin infection model using mice deficient in mast cells showed a lack of LL-37, an important component of mast cell extracellular traps (172). A characteristic of mast cell activation is the release of histamine. SLO and SpeB of *S. pyogenes* have been shown to induce histamine from mast cells upon *in vitro* infection (172). NETosis is a highly dynamic process

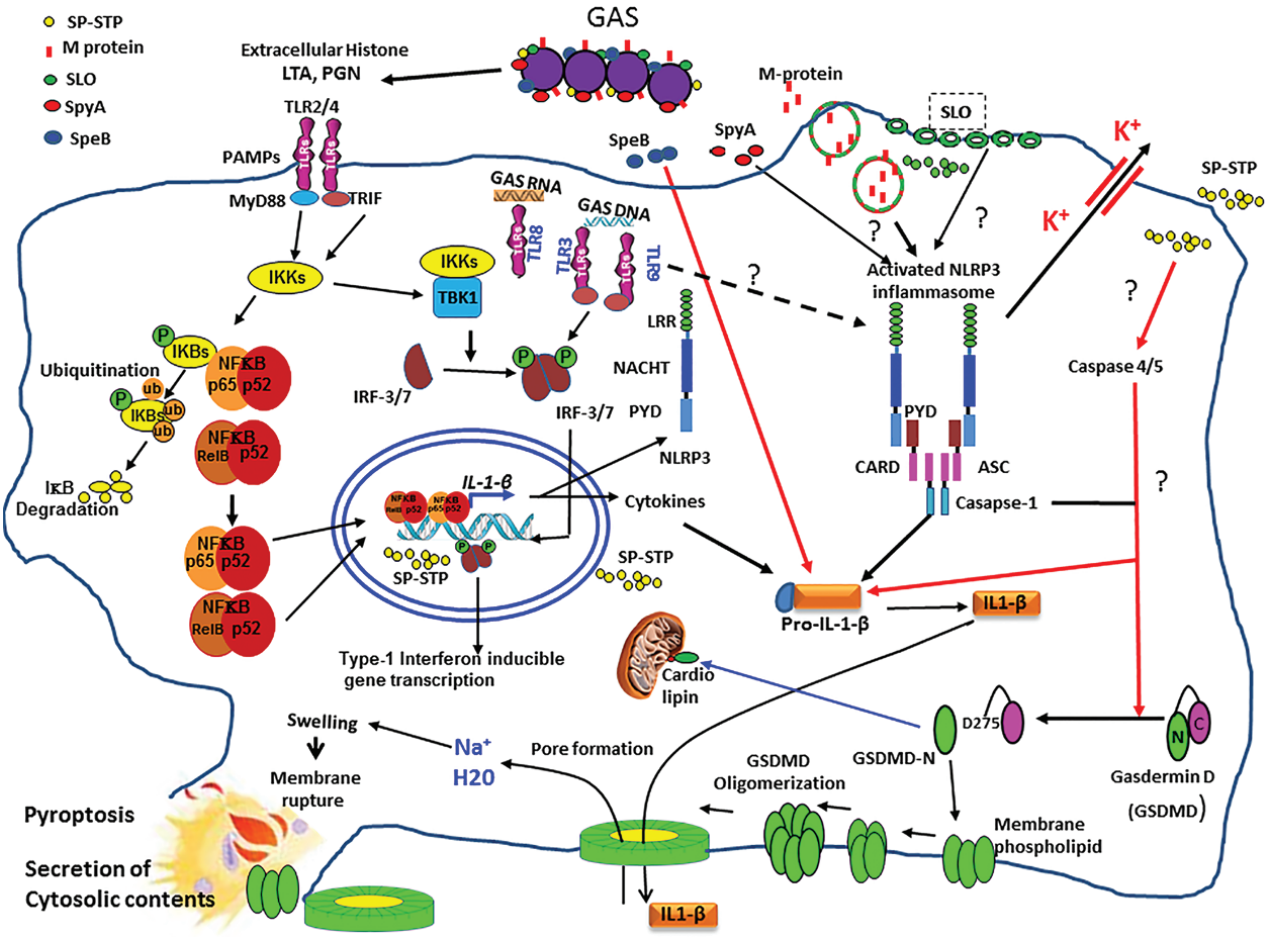

FIGURE 1 Group A *Streptococcus*-mediated signaling events responsible for inflammation. A group of cytosolic protein complexes called inflammasomes contributes to *S. pyogenes*-mediated inflammation. *S. pyogenes* activates NLRP3 inflammasomes. The activation of NLRP3 inflammasomes occurs in two steps. The first step involves transcriptional priming of inflammation. There are at least four well-studied receptors (uPAR, enolase, CD44, CD46) that directly interact with the surface proteins of *S. pyogenes*. Fibronectin, fibrinogen, and other lectin-like proteins play a crucial bridging role in the binding of *S. pyogenes* surface proteins to integrins of eukaryotic cells. These initial interaction-mediated signaling events help *S. pyogenes* invade the host cells. *S. pyogenes* lipoteichoic acid and peptidoglycan fragments, which serve as PAMPs/DAMPs, initiate inflammation by binding to the Toll-like receptors TLR-2/4, which serve as an external pattern-recognition receptor (PRR). *S. pyogenes* DNA and RNA can initiate inflammation via binding to intracellular PRRs (TLR3, TLR8, TLR9). These PRR/PAMP interactions occur in a MyD88-dependent or independent manner via Toll/interleukin-1 receptor-domain-containing adapter-inducing interferon-β (TRIF). MyD88-dependent signaling activates NF-κB and the NF-κB-mediated induction of IL-1β, NLRP3, and other cytokines. TRIF activates type 1 IFN and the IFN-induced chemokines. The second step (activation), not known of until recently in *S. pyogenes*-mediated inflammasome activation, is initiated by the SpeB-removed or secreted M-protein, which enters the cell via clathrin-coated pit-mediated endocytosis followed by activation of NLRP3 inflammasomes. Other factors, such as SLO and NADase may cooperatively make holes in eukaryotic cells and inject bacterial product in them to exploit intracellular signaling events and activate inflammasomes. Streptococcal ADP-ribosyl transferase (SpyA) seems also to activate NLRP3 inflammasomes. The assembly of the NLRP3 inflammasome complex is formed by NLRP3 (NACHT, LRR, and PYD domain-containing protein 3), the adaptor ASC (apoptosis-associated speck-like protein containing a caspase recruitment domain), and caspase-1. The activated NLRP3 inflammasome cleaves and converts inactive pro-IL-1β to active and proinflammatory IL-1β. This signaling is called canonical IL-1β-dependent inflammasome activation. The mediators of noncanonical IL-1β-activation (red arrows) include SpeB, which may enter the cell after SLO/NADase-mediated pore formation and cleave Pro-IL-1β to active IL-1β in an NLRP3-independent manner. SP-STP may have a role in activation of the human homolog of caspase-11, the caspase-4/5 which triggers both caspase-1-dependent and -independent production of the inflammatory cytokine IL-1β. The inflammasome activation is associated with K+ efflux. The activation of inflammasome resulting in proinflammatory responses ultimately leads to pyroptosis, a phenomenon characterized by membrane blebbing, swelling and lysis of the cell, and release of cytosolic content. Although not shown in *S. pyogenes* infection, pyroptosis is caused by the cleavage of gasdermin D (GSDSMD) to its N-terminal P30 fragment, which migrates to the membranes, binds to phospholipid, oligomerizes, and forms pores. The activated IL-1β is secreted out, and salts and water enter the cell through these pores, leading to swelling and rupture of the cell. The released contents then start another cycle of proinflammatory responses in adjacent cells.

Downloaded From Vet-eBooks.com

considering the short life (minutes to hours) of neutrophils. As the NETosis activation pathway has emerged, it has become clear that the level of transcription activity ("transcriptional firing") reflects the degree of DNA condensation occurring during NETosis since inhibition of transcription and the translation suppresses both types of NETosis (180). This is true for both NADPH oxidase (NOX2)-dependent (suicidal) and NOX2-independent NET formation. NOX2-independent NETs are induced by calcium ionophore and are also called vital NETosis. Extensive citrullination of histone in multiple loci occurs only during calcium-mediated NOX2-independent NETosis (180). Vital NETosis is completed in minutes, unlike suicidal NETosis, which takes hours. During vital NETosis, the neutrophils are not dead but are without DNA and are still capable of phagocytosing and killing the engulfed bacteria. Suicidal NETosis is characterized by the rupture of the plasma membrane along with extrusion of DNA content into the extracellular space.

Recent *in vitro* and *in vivo* findings from the Nizet group elegantly revealed how *S. pyogenes* evades NETosis-mediated proinflammatory signaling events in and killing by neutrophils and macrophages (27). Streptodornase degrades DNA in the NETs, allowing *S. pyogenes* to escape NETosis (181). SclA, a surface protein, inactivates LL-37 and inhibits myeloperoxidase release (182). High-molecular-weight hyaluronan capsule engages human immunoglobulin-like transmembrane protein Siglec-9 lectin possessing an immunoreceptor tyrosine-based inhibitory motif, dampening neutrophil activation (183–185). Encapsulated *S. pyogenes* resists phagocytosis and contributes to H_2O_2 resistance. Superoxide dismutase, NADPH oxidase, and alkyl hydroperoxide reductase reduce the H_2O_2 accumulation and detoxify H_2O_2 (29). Recent findings have shown that the resistance of *S. pyogenes* to NETs is also due to antiphagocytic M protein, because its N-terminal portion strongly binds to histone and inactivates the antimicrobial activity of histones (186). The B-repeats of the M protein also bind to immature LL-37 (hCAP-18), or murine cathelicidin-related AMP (mCRAMP), and sequester them from being active (187).

IL-1β/INFLAMMASOME SIGNALING PATHWAYS AND *S. PYOGENES* INFECTION

Inflammatory responses are meant to resolve inflammation, limiting tissue damage. Such immune responses are rapid and destructive but self-resolving and specific as seen for most, if not all, mild extracellular *S. pyogenes* infections. However, upon tissue invasion and establishment of an intracellular niche in epithelial cells and macrophages, some *S. pyogenes* strains survive intracellularly and propagate within the cytoplasm, resulting in damage and destruction of the host tissues, sepsis, organ failure, and often death (188, 189). The orchestration of such calculated inflammatory responses, which determine the fate of infection, is initiated with the binding of pattern recognition receptors (PRRs) on the host and pathogen (danger)-associated molecular patterns (PAMPs/DAMPs) on the pathogens (190, 191). IL-1 plays a pivotal role in inflammation caused by *S. pyogenes* and other Gram-positive streptococcal pathogens (34). The inflammation, in general, is mediated by inflammasomes. The inflammasome is a high-molecular-weight protein complex that requires assembly of PRRs and PAMPs/DAMPs, which in turn activate inflammatory caspases and cytokines of the IL-1 family (IL-1 and IL-18) and the induction of inflammation-associated cell death (pyroptosis) (192). IL-1 exists in two forms: membrane-bound IL-1α and the soluble form, IL-1β, both of which initiate a variety of signaling events via binding to the IL-1 receptor (193). The role of the induced level of IL-1α in *S. pyogenes* infection is not clear. However, IL-1β plays a significant role in the defense against *S. pyogenes* and infection by other Gram-positive pathogens by attracting neutrophils at the site of infection (34). Increased levels of another cytokine of the IL-1 family, IL-18, which contributes to the induction of IFN-γ and natural killer cells, also has been reported during *S. pyogenes* infection (194, 195), but its precise function as a protective or pathological agent is not clear. The conversion of IL-1 to IL-1β is not dependent solely on the inflammasome, because several other pathways are also responsible for its activation. *S. pyogenes*'s SpeB (cysteine protease) and proteases of other pathogens which are capable of cleaving IL-1β may contribute to the alternative (noncanonical type; see details below) inflammasome-independent pathways (34) (Fig. 1).

There are 13 mammalian Toll-like glycoprotein receptors (TLRs) that have been recognized for their ability to sense a wide variety of microbial PAMPS at the cell surface and within endosomes (196). Additional PRRs include nucleotide-binding and oligomerization domain-like receptors (NLRs) and the retinoid acid-inducible gene-I-like receptors (RIG1) that recognize PAMPS/DAMPS intracellularly (197, 198). The presence of both extracellular and intracellular PRRs suggests that even though microbes may evade surveillance by extracellular PRRs, they are subsequently encountered by another line of PRRs in the cytosol. The detection of PAMPS/DAMPS by these PRRS activates multiple proinflammatory signaling pathways or the inflammasome pathway. The ability of *S. pyogenes* to activate inflammasomes is dependent on the cell type, M type *S. pyogenes* strains, as well as *in vitro* versus *in vivo* experimental conditions. Fundamentally, inflammasome activation in monocytes differs from that in macrophages (193, 199). In monocytes, including neutrophils, caspase-1 is constitutively expressed, leading to activation of pro-IL-1 and release of active IL-1β after single stimulation with a bacterial ligand. On the other hand, macrophages (THP-1 cells) require two distinct stimuli, one (priming step) that stimulates transcription and translation of pro-IL-1β and a second stimulus such as ATP, and other factors that are required for caspase-1 activation with bioactive IL-1β production and its secretion (193). Thus, irrespective of the cell type, IL-1β production is dependent on the assembly of an inflammasome complex. The first step of priming could be mediated by TLRs, the IL-1 receptor, or the TNF receptor. While TLR-mediated priming occurs via the myeloid differentiation primary response gene (MyD88) (196), the NLR-RIP2 (receptor-interacting-serine/threonine-protein kinase 2, RIPK2 or RIP2) complex resulting in the NF-κB activation to induce IL-1β, the IL-1 receptor, and the tumor necrosis factor receptor is activated via binding to secreted soluble IL-1β and TNF-α (197) (Fig. 1).

Streptococci commonly recognize only two main inflammasome complexes: NLRP3 and AIM2 (absent in melanoma 2) multi-protein complexes (34). NLRP3 stands for NACHT, LRR and PYD domains-containing protein 3, wherein NACHT stands for NAIP [nucleotide-binding and oligomerization domain-like protein family apoptosis inhibitor protein], CIITA [C2TA or major histocompatibility complex (MHC) class II transcription activator], HET-E [incompatibility locus protein from *Podospora anserina*], and TEP1 [TP1 or telomerase-associated protein]) domain; LRR stands for leucine-rich repeat; and PYD stands for pyrin domain)-containing protein 3. *S. pyogenes* (M1 strain SF370)

Downloaded From Vet-eBooks.com

has been shown to activate type 1 interferons and induces p38 mitogen-activated protein kinase, NF-κB, TNF-α, and IL-6 in bone marrow-derived mouse macrophage in a TLR2 (receptor for lipoteichoic acid)-, TLR4 (receptor for lipopolysaccharide)-, and/or TLR9 (receptor for bacterial DNA containing unmethylated CpG sequence)-independent but MyD88-dependent manner (200). The fact that this *S. pyogenes*-mediated induction occurs even in the absence of *S. pyogenes* SLO or streptolysin S (SLS) indicates that these virulence factors do not participate and regulate inflammatory responses in mice. However, an encapsulated *S. pyogenes* strain, 950771, induces NF-κB in mouse bone-marrow-derived macrophage in an SLO-dependent manner (201).

S. pyogenes strain- and host cell-dependent variations as described above are also observed for inflammasome activation. Thus, *S. pyogenes* strain SF370 and the isogenic mutants lacking SLO and SLS have revealed the induction of IL-1β, IL-10, TNF-α, and CXCL-10 via activation of the NALP3/NLRP3 inflammasome complex in *S. pyogenes*-infected human peripheral blood-derived macrophage (202). Encapsulated live *S. pyogenes* strain 950771 and its SLO, however, activate caspase 1 and NLRP3 in bone marrow-derived macrophages of C57BL/6J mice in a TLR2-independent manner (201). In general, the cells that are exposed to TLR ligands require the second stimulation of purinergic receptor P2X7R by ATP to activate NLRP3 inflammasomes (193). However, *S. pyogenes*/SLO-mediated NLRP3 stimulation occurs independently of P2X7R and ATP (201). The mechanism of NLRP3 activation remained unknown until the recent report from the Nizet laboratory which unraveled the second stimulus initiated by the M1 protein. *S. pyogenes* M1 protein alone can promote IL-1β signaling in THP-1 macrophages but not in epithelial cells, neutrophils, or monocytes. The ability of M proteins from various M types to promote IL-1β signaling specifically in macrophages parallels their ability to cause cell death. Thus, an M28 protein, which does not cause cell death/pyroptosis, is unable to induce IL-1β. Although in this study THP-1 cells were stimulated using lipopolysaccharide, an SLO mutant and an M1 mutant were unable to activate NLRP3 or IL-1β *in vitro*. These findings were substantiated by revealing the induction of IL-1β in mice after injecting the purified M1 protein in a thioglycollate-induced experimental peritonitis model. Interestingly, the B-repeat of the M protein which plays a key role in various other immune evasion functions (186, 187) has been shown to be specifically involved in the induction of inflammasomes, because the M1 protein lacking a B-repeat is unable to propagate IL-1β signaling in both *in vitro* and *in vivo* experiments (203). The specificity of the M1 protein-mediated second stimulus directed to its B-repeat indicates that a host-specific receptor likely recognizes the M1 protein located in clathrin-coated pits since the internalization of the M protein, and subsequent induction of NLRP3 inflammasome, is inhibited by a specific inhibitor of the clathrin-mediated endocytosis process (203). This study confirms the previous report on the inhibition of *S. pyogenes*-induced inflammasomes by dynamin-dependent endocytosis using an endocytosis inhibitor, Dynasore (202). Dynamin is a GTPase protein and plays an essential role in membrane fission during clathrin-mediated endocytosis and caveolae from the cell membrane and formation of polymerization of actin (204). *S. pyogenes* ADP-ribosyl transferase toxin SpyA has also been shown to simulate protective caspase-dependent IL-1β production in mouse bone marrow-derived macrophages, ultimately causing their apoptosis (194). This stimulation and apoptosis are mediated through the activation of the NLPR3 inflammasome (194). In the absence of SpyA, such a protective role of IL-1β is abrogated, resulting in increased intracellular survival within the macrophages and higher mortality in a mouse infection model. SpyA thus acts independently of TLRs.

Purified DNA isolated from *S. pyogenes* can induce IFN-β and TNF-α, indicating the potential role of TLR9 in its activation from the cytoplasm (205, 206). INF-α plays an important role in protecting against Gram-positive bacterial infection in general (207). *S. pyogenes* streptodornase-mediated DNase activity diminishes intracellular TLR9-dependent IFN-α and TNF-α secretion by murine bone marrow-derived macrophages. This promotes resistance to the intracellular macrophage killing both *in vitro* and *in vivo*, thus providing another mechanism of microbial innate immune evasion and promoting necrotizing skin infection (205). Like DNA, *S. pyogenes* ribosomal RNA (23S) is also recognized by mouse TLR13 upon phagocytosis by murine macrophages (208). TLR13 is, however, present in mice and a few mammals but absent in humans. TLR8 recognizes *S. pyogenes* 23S RNA following phagocytosis of *S. pyogenes* by human monocyte-derived macrophages (209). Together, these findings indicate that *S. pyogenes* nucleic acids may play an important role in immune recognition during infection.

NONCANONICAL INFLAMMASOME

In addition to caspase-1, caspase-11 (human caspase-4 and caspase-5) has also been shown to process IL-1β via NLRC4 and NLRP1 (210–212). The original caspase-$1^{-/-}$ mouse strain that was used in many earlier studies to understand the function of caspase-1 in the production of IL-1β during Gram-negative bacterial infections was later identified as the caspase-$1^{-/-}$-$11^{-/-}$ double knockout genotype (210). These findings kindled questions about the possible role of casapse-11 in the pathogenesis of bacterial infections. Caspase-$11^{-/-}$ mice are resistant to lipopolysaccharide-induced toxic shock. Mice deficient in both caspase 1 and caspase-11 are more resistant to salmonella and shigella infections (212). The importance of caspase-11-dependent pyroptosis thus becomes more obvious to restrict intracellular bacterial replication. It is, however, believed that caspase-11 forms a noncanonical inflammasome in response to Gram-negative bacteria but not Gram-positive bacteria, although this has not been thoroughly tested. Caspase-4 and caspase-5 (which are absent in mice) are the human orthologs of caspase-11 in mice (211). From the available knowledge, the secreted PP2C-type eukaryote-like serine/threonine phosphatase (SP-STP) from *S. pyogenes* is the only protein which has been reported to induce 2- to 4-fold mRNA expression of caspase-4 and caspase-5 in the Detroit 562 human pharyngeal carcinoma cell line after treatment for 24 h (13) (Fig. 1). It is noteworthy that SP-STP is the only known streptococcal protein that enters the human respiratory epithelial cells and transmigrates to the nucleus of host cells and causes apoptosis of the Detroit pharyngeal cells (13). Since there has been no follow-up study regarding the role of these caspases in the induction of IL-1β *in vitro* or *in vivo* in *S. pyogenes* infection models, it is currently unknown whether such an induction involves a novel noncanonical inflammasome and whether the induced mRNA expression alone is sufficient for autoactivation. Further, an M1T1 *S. pyogenes* mutant lacking SP-STP is completely attenuated, and the lung alveolar epithelial cells of mice infected with this mutant show a significant decrease in apoptosis (13). Further studies of this protein in relation to the activation of caspase-4, -5, and -11 may reveal a new mechanism of *S. pyogenes* pathogenesis.

Downloaded From Vet-eBooks.com

Although earlier reports indicated that caspase-11 was not induced during *Listeria monocytogenes* infection and had no role in *L. monocytogenes*-mediated inflammation (213), the lipoteichoic acid of *L. monocytogenes* and *S. aureus* was recently shown to promote caspase-11 cleavage and activation via NLRP6 activation (214). Similarly, recombinant *S. pneumoniae* pneumolysin and *S. aureus* α-toxin have also recently been shown to activate caspase-4 and caspase-11 in A549 (human lung adenocarcinoma) cell lines (215). Another example of noncanonical inflammasome activation, which occurs in parallel with a classical inflammasome during *S. pyogenes* infection, is the ability of *S. pyogenes* SpeB to directly cleave pro-IL-1β into functionally active IL-1β via its cysteine protease activity (216). Expression levels of SpeB vary among different M types due to naturally occurring mutations in the CovR/S regulatory system and host environmental regulation (25, 217). Thus, differentially regulated SpeB expression, and other secondary stimuli such as M protein, SLO, and SpyA, activates or inactivates canonical or noncanonical inflammasomes that mediate IL-1 activation in a tightly regulated manner, resulting in the resolution of infection, hyperinflammation, and uncontrolled sepsis.

CAUSE OF PYROPTOSIS

Recently, the ultimate cause of inflammasome-activated caspase-1, -4, -5, and -11 leading to pyroptosis via activation of IL-1β was reported to be the cleavage of gasdermin D (GSDMD) (218, 219), but activation of GSDMD has not been reported in *S. pyogenes*-infected monocytes/macrophages. GSDMD is a member of the gasdermin family, which regulates epithelial cell proliferation and acts as a tumor suppressor (220). Upon cleavage of cytoplasmic GSDMD at Asp275, its N-terminal portion translocates and binds to phospholipids of the cell membrane as well as cardiolipin of mitochondria (221) (Fig. 1). Multimeric GSDMD-N then assembles in the membrane in the form of pores, allowing the efflux of IL-1β as well as an influx of water, resulting in cell swelling and eventual rupture and the release of cytosolic contents (222, 223). The extracellular release of the GSDMD-N may also bind to the outer membrane lipid of extracellular bacteria, causing extracellular *in trans* bactericidal activity, but without harming neighboring mammalian cells. The lack of plasma membrane disruption is the result of lipid-binding specificity. GSDMD does not bind to nonphosphorylated phosphatidylinositol, phosphatidylethanolamine, or phosphatidylcholine, found on the inner leaflet of the cell membrane (224).

S. PYOGENES-MEDIATED AUTOPHAGY (XENOPHAGY) AND AUTOPHAGIC SIGNALING

The group A *Streptococcus* has evolved with several strategies for its perpetual existence as a successful pathogen. Like many intracellular pathogens (225–229), *S. pyogenes* also survives and often multiplies intracellularly, especially within macrophages (230). Intracellular *S. pyogenes* is either killed by the endosomal vacuole content of the host cell or survives and causes cell death. Autophagy is a cellular homeostatic mechanism by which cytoplasmic contents are engulfed by a characteristic double-membrane autophagosome. The autophagosomes subsequently fuse with lysosomes (autophagolysosome), and the contents are eventually degraded and recycled in an orderly fashion. Autophagy thus is a homeostasis mechanism that contributes significantly to the innate immune system (231).

The role of autophagy in *S. pyogenes* infection was first demonstrated in HeLa cells infected with strain JRS4, an M6 *S. pyogenes* (232). This report revealed the temporal increases in the colocalization of *S. pyogenes* with the LC3 protein and lysosome-associated membrane protein 1, a marker for autophagosomal vacuoles and vacuolar membrane proteins. Autophagy also is known as xenophagy (autophagy of infectious particles), which also involves membrane traffic and fusion. Further kinetic studies of M6 *S. pyogenes* strain-mediated autophagy also showed that Rab GTPases/Rab proteins localize at distinct intracellular membranes and vesicles and function as GTP-bound "on" or GDP-bound "off" forms. During the membrane fusion process, Rab proteins (GTPase) play a significant role in membrane trafficking and autophagosome formation in *S. pyogenes*-infected HeLa cells (233). Among many Rab GTPases, the autophagosome-associated Rab5 and Rab7 determine *S. pyogenes* invasion, endosome fusion, and intracellular fate. Additional Rab GTPase regulatory proteins, Rab9a, Rab23, and Rab17, have also been shown to participate in the later stages of *S. pyogenes*-containing vacuolar enlargement, lysosomal fusion, and membrane recycling (233, 234) (Fig. 2). The fusion of recycling endosomes with *S. pyogenes*-containing autophagosome vacuoles was recently revealed to be mediated by the SNARE (soluble *N*-ethyl-maleimide-sensitive factor attachment protein) receptor complex formed by STX6 and VTI1B (vesicle transport through interaction with t-SNAREs homolog 1B)-VAMP3 (vesicle-associated membrane protein 3) proteins (235). Beclin 1, another protein encoded by the BECN1 gene, is a mammalian ortholog of the yeast autophagy protein, Atg6, which plays a critical role in autophagy and cell death (236). Upon engagement of pathogen receptor CD46 with *S. pyogenes* (M types 6 and 49), possibly via the M protein (79), Beclin1/VPS34-mediated autophagic killing occurs (237). The possible pathway leading to autophagy likely occurred through Cyt-1/GOPC signaling (237). GOPC is a trans-Golgi-associated protein that interacts with its single PDZ domain (post synaptic density protein [PSD95], Drosophila disc large tumor suppressor [Dlg1], and zonula occludens-1 protein [zo-1]) with a variety of cell surface receptors, such as CD46, that possess a cytoplasmic tail containing tyrosine residues (Cyt-1) (238). Recently, the mechanistic role of Beclin-1 in *S. pyogenes*-mediated autophagic killing was defined more clearly. In *S. pyogenes*-infected cells, the antiapoptotic prosurvival proteins Bcl-2 and Bcl-xL as well as class III PI3 kinase directly interact with Beclin-1 and suppress the Beclin-1-regulated autophagy (239). Beclin-1, on the other hand, binds to the UV resistance-associated gene protein (UVRAG) and ATG14L, which together stimulate autophagy (240). UVRAG also interacts with the vacuolar protein complex (VPS11, VPS16, and VPS18) and facilitates the activation of Rab7- and Rab5-tagged vacuoles during maturation of endosomes and autophagosomes (241). Upon endocytosis of *S. pyogenes* into epithelial cells, Bcl-xL inhibits *S. pyogenes*-induced autophagy directly by suppressing autophagosome-lysosome fusion and indirectly by suppressing internalization of *S. pyogenes* through interaction with Beclin-UVRAG (242). NLRP4 also has been shown to directly interact with Beclin1 via the VPS-UVRAG complex (243). The association of *S. pyogenes* with autophagosomal vacuoles and the autophagic process increases when NLRP4 but not NLRC4 is knocked down (243). Interaction of NLRP4 in *S. pyogenes*-infected cells revealed that NLRP4 is accumulated in *S. pyogenes*-containing phagosomes and transiently dissociates from Beclin 1 after *S. pyogenes* infection and thus modulates

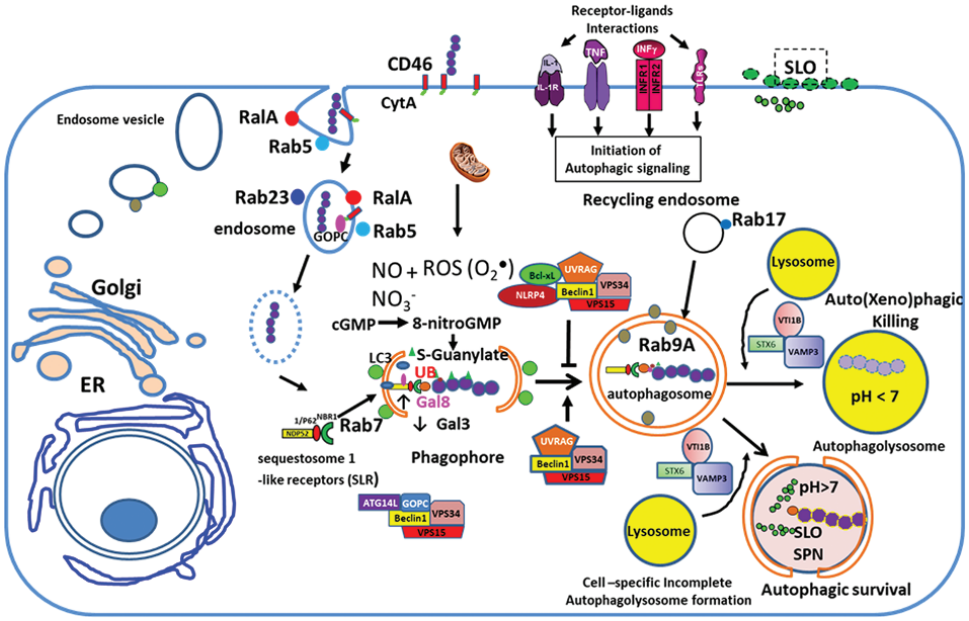

FIGURE 2 Intracellular signaling associated with autophagy/xenophagy of *S. pyogenes*. *S. pyogenes* invades host epithelial cells by one of two mechanisms, invagination at the point of bacterial contact with host cells or massive induction of microvilli, which form membrane ruffling for engulfment of bacteria (filopodia). Cytoskeletal rearrangements involve induction of the PI-3 kinase pathway or RAS/CDC42(Rat Sarcoma oncogene receptor family small GTPases/cell division control protein 42)/tyrosine kinase activation. Autophagy (self-eating) or xenophagy (eating of a nonself particle, e.g., bacteria) is controlled by Ser/Thr kinases and by the lipid kinase activity of PI-3 kinase and ATG14-like protein (ATG14L). Initial entry of *S. pyogenes* happens through endocytosis, which is tightly regulated by several Rab GTPases. Typical donors of endosome membranes are endoplasmic reticulum, Golgi apparatus, mitochondrion, and plasma membrane. For physiological autophagy Rab1, 5, 7, 24, and 33B act in a regulated fashion to form autophagolysosome, which is the stepwise culmination of the fusion of a double-membrane phagophore with endosome with *S. pyogenes* (phagosome) to form autophagosome followed by fusion of a double-membrane autophagosome with a lysosome. Upon endocytosis of *S. pyogenes*, the infection-specific Rab GTPases Rab23, Rab7, Rab9a, and Rab17 act in a sequential manner for the initiation, elongation/closure, maturation, and maintenance of autophagic/xenophagic vacuole to degrade intracellular *S. pyogenes*. *S. pyogenes* is killed only when autophagosome is fused with a lysosome. During the initial phase of *S. pyogenes* autophagy, the lipid kinases VPS34, Beclin1, GOPC (Golgi-associated PDZ and coiled-coil motif-containing protein), and ATG14L are involved in forming phagophore. Subsequently, ATG14L is replaced with UVRAG (UV resistance-associated gene protein) in the VPS34-Beclin1 complex to form autophagosome. During the final maturation of autophagosome containing *S. pyogenes* to autophagolysosome, the SNARE protein STX6, VTI1B, and VAMP3 are involved. NLRP4 and Bcl-XL serve as a negative regulator of the autophagy of *S. pyogenes*. Additional factors that are involved in the autophagy of *S. pyogenes* are a sequestosome-1-like protein complex constituted by nuclear dot protein (NDP52), neighbor of BRCA1 gene 1 protein, and 1/P62 proteins that decorate the inner membrane of phagophore via binding to the LC3 protein. One of these SLR proteins, NDP52, directly interacts with E3 ligase, which ubiquitinates bacteria. Galectin 8 also plays an important role in the attachment of SLR with which ubiquitinated *S. pyogenes* is associated. Phosphorylated SLR protein then multimerizes within phagophore and matures into autophagosome and retains *S. pyogenes* within the autophagosomes. In keratinocytes infected with *S. pyogenes*, autophagosomes do not mature to autophagolysosome, possibly because of the secretion of SLO/NADase, while in some cells, such as HeLa and HEP-2 cells, complete autophagolysosome occurs and *S. pyogenes* is killed. Incomplete formation of autophagolysosome remains defective in acidic pH, which does not allow *S. pyogenes* to be killed. A failure to maintain low pH may differentially regulate virulence gene expression, which in turn may affect bacterial survival. In response to *S. pyogenes* entry, host cell systems also generate second messenger cyclic GMP and nitric oxide as well as ROS. Oxygen radical and nitric oxide together may form reactive peroxynitrite, which may then target cysteine residues of the *S. pyogenes* surface protein to S-guanylate *S. pyogenes*. As indicated, only S-guanylated *S. pyogenes* is ubiquitinated and subsequently subjected to xenophagic killing. Endothelial cells are defective in the S-guanylation process. Endothelial cells also express relatively less specific galectin-8 than galectin-3, which results in abrogation of xenophagic killing and intracellular multiplication of *S. pyogenes*. Xenophagic killing and survival of *S. pyogenes* are strain specific (with variable SpeB expression and related protease activity, which degrades ubiquitin and SLR protein complex) and cell type specific (normal versus established cancer cell line, epithelial, macrophage versus endothelial).

the autophagic bactericidal process (243). Cumulative studies have revealed that in HeLa cells, autophagy plays an important role in the intracellular degradation of type M6 *S. pyogenes*, and a number of autophagy-associated proteins dynamically play a role as well.

However, in contrast to the M6 *S. pyogenes* strain JRS4, which is defective in SpeB production, an M1T1 *S. pyogenes* strain, which produces SpeB, has been shown to survive and multiply within the host cells (Hep-2 cells) and avoid autophagy and endosomal degradation (244). This observation is attributed to the ability of the M1T1 strain to avoid the ubiquitination process of the autophagy protein. For selective autophagy, ubiquitination of *S. pyogenes* via LC3-adaptor proteins, p62, neighbor of BRCA1 gene 1 protein, NDP52

Downloaded From Vet-eBooks.com

(sequestosome 1/p62-like receptors, or SLRs), and recognition by the autophagy marker LC3 is a critical step (245). SpeB degrades host ubiquitin-LC3-adaptor proteins and ubiquitinated proteins of the host cells (244). Thus, the M1T1 mutant lacking SpeB that is associated with ubiquitin-LC3-adaptor protein and found in autophagosomes is killed similarly to the JRS4 strain (244). Likewise, the JRS4 M6 *S. pyogenes* strain complemented with the *speB* gene behaves like the M1T1 *S. pyogenes* strain and avoids autophagy (244). The role of SLO in the autophagic killing of *S. pyogenes* by HeLa cells (232), keratinocytes (246), or endothelial cells (247, 248) is continuously evolving. While earlier reports (232) indicated that the autophagic killing in HeLa cells is dependent on SLO, results obtained using keratinocytes (buccal palate-derived primary cells) infected with unencapsulated M3 and JRS4 M6 strains and their isogenic mutants lacking SLO, SLS, and NAD glycohydrolase (NADase) have revealed that SLO enhances *S. pyogenes* survival (246).

The survival of S. *pyogenes* within autophagosomes is also dependent on the intracellular pH of the cell. Low pH quickly suppresses the growth of pathogens, including *S. pyogenes*. In a low-pH environment, the expression of many virulence factors (SLO and SLS) is significantly downregulated, and at high pH the expression of SpeB is upregulated (249). Thus, although SpeB-defective M6, M49, and M89 strains are efficiently targeted by autophagy and effectively cleared by epithelial cells, they do multiply within autophagosomes of human microvascular endothelial cells (HMEC-1) that are defective in acidification (247). It seems that survival and elimination of *S. pyogenes* within autophagosomes is more relevant to the pH environment than is the ability of bacteria to express SpeB (247). SpeB contributes only moderately (~25%) to the survival and growth of *S. pyogenes* within host cells. Even increasing the pH of endothelial cells or using an *S. pyogenes* mutant lacking SpeB does not alter the growth (247). *S. pyogenes* streptolysin-O or NAD glycohydrolase (NADase) prevents phagolysosome acidification and thus enhances *S. pyogenes* survival (250).

A recent report attributed the differences in the *S. pyogenes* multiplication patterns in epithelial cells and those in endothelial cells to the relative presence of galectin-3 in these cells (251). Galectins are beta-galactosidase-binding proteins. GAL-8 and GAL-3 have been identified as two of the proteins associated with invasive bacteria (i.e., *Salmonella* spp. and *Neisseria meningitis*) for autophagy targeting (252, 253). Although the direct role of galectin in autophagy is unknown, it has been found that higher expression of Gal-3 and lower expression of Gal-8 in endothelial cells compared to epithelial cells may contribute to the observed differential *S. pyogenes* multiplication (251). Gal-3 also promotes *S. pyogenes* replication and suppresses the recruitment of Gal-8 and ubiquitin. This study also revealed that upon knockdown of Gal3 in endothelial cells, the colocalization of Gal8, ubiquitin E3-ligase (parkin), and ubiquitin-decorated *S. pyogenes* are significantly increased. Similarly, upon inhibition of Gal-8 in epithelial cells, recruitment of parkin, ubiquitin, and *S. pyogenes* elimination are severely affected.

The activation of inflammasomes invariably generates ROS that activate autophagy (254–256). Like ROS, nitric oxide (NO) is a short-lived reactive species that plays a significant role in cell signaling (257). Superoxide and NO together form peroxynitrite, which nitrosylates many molecules. ROS/NO-mediated nitrosylation of cGMP (8-nitro-cGMP) has been found to be an inducer of autophagy (258). In particular, in the presence of this endogenous nitrated nucleotide, selective clearance of invasive *S. pyogenes* occurs via polyubiquitylation. The Lys-63-linked polyubiquitination has been found to be targeted specifically to S-guanylated *S. pyogenes*, which is internalized into autophagosomes and subsequently eliminated. Interestingly, one of the guanylated and ubiquitinated surface proteins of intracellular *S. pyogenes* is SDH (85, 258). The increased multiplication of *S. pyogenes* within endothelial cells compared to epithelial cells is also attributed to its intrinsically defective xenophagic mechanism (248). In particular, endothelial cells, despite being capable of inducing autophagy (i.e., association with the autophagosome LC3 marker) upon *S. pyogenes* endocytosis, are unable to form double-membrane structures, a crucial step required for xenophagy. Further, endothelial cells are not efficient enough to ubiquitinate *S. pyogenes* because of poor recruitment of Atg proteins as well as in the induction and production of 8-nitro-GMP as described above (248). Together, these findings indicate that NOS-mediated posttranslational modification and ubiquitination of *S. pyogenes* within the host cell plays a pivotal role in pathophysiology associated with xenophagy (Fig. 2).

In the host cell, mono- and poly-ubiquitylated proteins are deubiquitinated by CYLD (cylindromatosis) deubiquitinases (259–261). Normal cells express CYLD in much higher quantities than cancer cells or established cell lines. Hence, bacteria may remain less ubiquitinated. SLS mediates xenophagic recognition of *S. pyogenes* in keratinocytes via galectin-8 but in a ubiquitin-independent manner (246). It is not known whether, in addition to the SLS activity of *S. pyogenes*, the increased quantity of CYLD also plays a role in the lack of association of *S. pyogenes* with ubiquitin. The regulatory role of CYLD-mediated deubiquitination in protection against lethal infection by *S. pneumoniae* (262) and *Haemophilus influenzae* (263) and other pathogens (262, 264) is now well established. Whether CYLD-mediated modulation of posttranslational modification plays a role in *S. pyogenes* needs further verification. Thus, the observed differences in autophagy-mediated intracellular killing can be attributed to the intracellular expression levels of deubiquitinase enzymes, in addition to the other factors described above.

GROUP A *STREPTOCOCCUS*-MEDIATED APOPTOSIS AND APOPTOTIC SIGNALING

Streptococci can also induce apoptosis, or programmed cell death (265, 266). Apoptosis is crucial for proper organismal development, maintenance of cell number homeostasis, and elimination of diseased or otherwise harmful cells (267, 268). Apoptotic cell death in response to bacterial infection is believed to delete infected and damaged epithelial cells and to restore epithelial integrity, which is distorted during infection (269). Thus, apoptosis may contribute to the resolution of bacterial infection. The ability of host cells to undergo apoptosis is considered the host defense strategy to keep the pathogen at a disadvantage by not providing a target for adherence, invasion, and subsequent proliferation. However, the ability of the bacterium to direct the host cell to undergo apoptotic cell death, thus allowing it to escape from phagocytic activity, may be an important virulence factor. Apoptosis of few epithelial cells directed by bacteria not only helps these bacteria escape from one of the host's lines of defense, but it also facilitates penetration to the next cellular barrier. Tsai et al. (265) and Nakagawa et al. (266) showed that M type 1, 6, and 49 *S. pyogenes* strains induce apoptosis in 10 to 20% of the upper and lower respiratory cell lines, HEp-2 laryngeal and A-549 lung alveolar, respectively. In particular, the cells with internalized bacteria show increased expression

Downloaded From Vet-eBooks.com

of the Bax protein, which translocates to mitochondria (266), resulting in cytochrome C release. At the same time, the expression of prosurvival gene products, such as Bcl-2 and Bcl-X_L, is significantly decreased in mitochondria (Fig. 3). Caspase-9 activation and inhibition of apoptosis of these cells in the presence of caspase inhibitors indicate that caspase activation is likely an important mediator which triggers apoptosis (265, 266).

SpeB may play a direct role in causing this limited apoptosis by activating matrix metalloproteinase and release of first apoptosis signaling and TNF-α (265). Another study showed that NAD+-glycohydrolase of an M type-3 clinical isolate gains access to the keratinocyte cytoplasm by enhancing SLO-dependent damage of keratinocyte cell membranes (270). Once inside the cell, NAD+ glycohydrolase inhibits *S. pyogenes* internalization by keratinocytes and

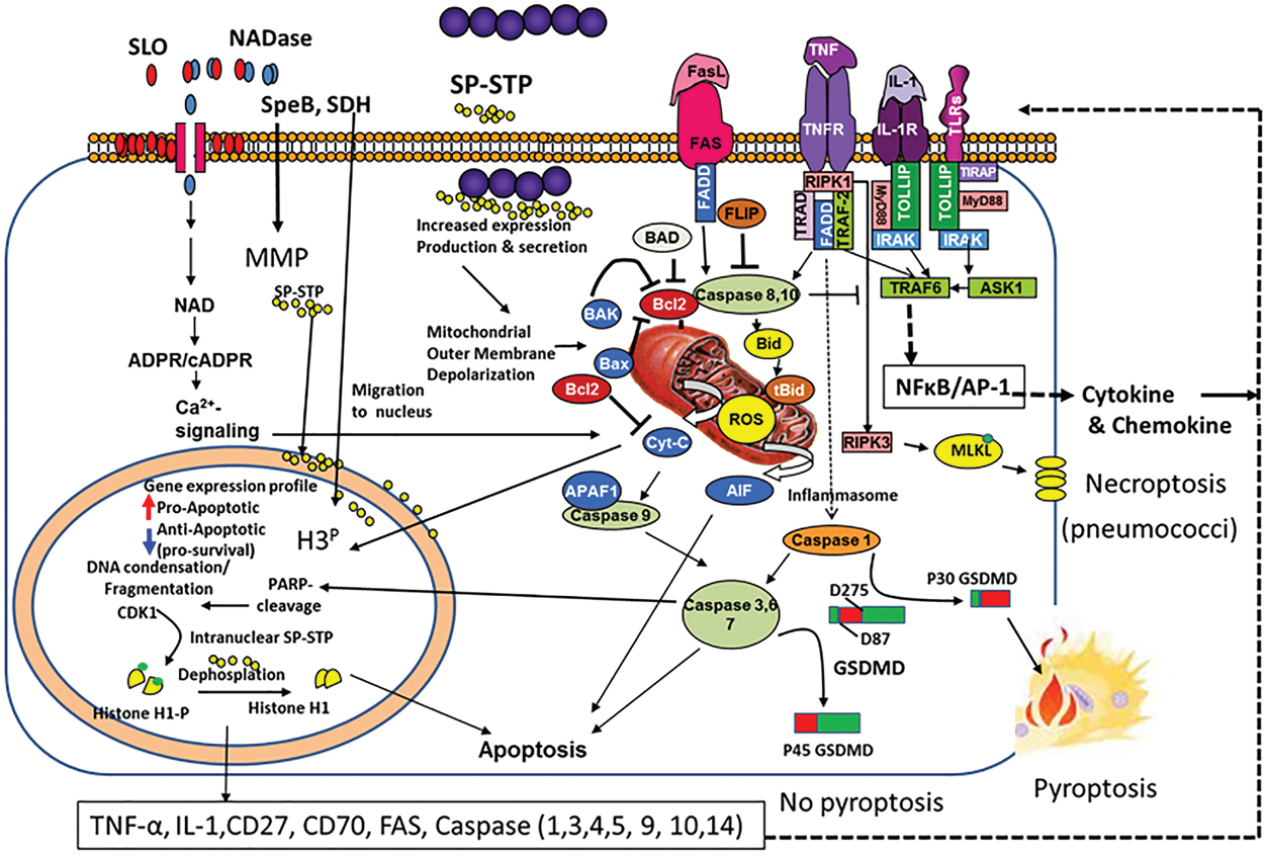

FIGURE 3 Cell-signaling events that regulate *S. pyogenes*-mediated programmed cell death. *S. pyogenes* infection-mediated cell death of the host cells depends on the cell type and is triggered extracellularly and intracellularly as shown. Epithelial cells infected with *S. pyogenes* undergo apoptotic cell death characterized by DNA fragmentation, cytochrome release, BAX (BCL2-Associated X apoptosis regulator protein) translocation to mitochondria, and inhibition of BcL2, Bcl-XL (B-cell lymphoma-extra large). *S. pyogenes*-induced apoptosis is also characterized by increased expression of IL-1β; caspase-1, -9, -3, -4, -5, -6, and -14; cytochrome C oxidase; and protein involved in Ca^{++}-signaling. At least five purified proteins have been shown to contribute to *S. pyogenes*-mediated apoptosis of host cells. SpeB causes apoptosis of Hep2-cells by activating matrix metalloproteinase (MMP) and induction of first apoptosis signal molecule (FAS) and TNF-α. SLO facilitates *S. pyogenes*-mediated apoptosis by allowing NADase into the cell and cleaving NAD to ADP-ribose (ADPR) and possibly cyclic ADPR, which in turn activates calcium signaling, and mitochondrial membrane depolarization, releases reactive oxygen radical, IL-1β, and activates caspases in human and mouse macrophages. SDH and SP-STP induce apoptosis of human respiratory epithelial cells (Detroit 562 and A549) in part by inducing nuclear condensation via histone H3 phosphorylation and/or H1 dephosphorylation and by upregulating mRNA expression of several proapoptotic genes and downregulating prosurvival genes. SP-STP induces caspase-4 and caspase-5, crosses two membrane barriers, and transmigrates to the nucleus, where it dephosphorylates CDK1 phosphorylated histone H1 protein. SP-STP induces apoptosis both extracellularly and intracellularly. SP-STP expression increases several-fold in intracellular *S. pyogenes* and is secreted in the cytoplasm and causes apoptosis possibly by modulating several intracellular signaling events within the cytoplasm and in the nucleus. Apoptosis and pyroptosis are both modulated by GSDMD. Caspase-3 activation inhibits pyroptosis, while caspase-1-mediated cleavage of GSDMD results in P30 GSDMD that multimerizes in the form of pore in the membrane that causes pyroptosis (see Fig. 1). GSDMD P45 resulting from the cleavage activity of caspase-3 is inactive and prevents pyroptosis but allows apoptosis. GSDMD is ultimately responsible for pyroptosis. Caspase-8 inhibition can lead to receptor-interacting serine/threonine-protein kinase 1 (RIPK1)-dependent activation of RIPK3, which upon phosphorylation of mixed-lineage kinase domain-like pseudokinase (MLKL), leads to necroptosis, the phenomenon which is observed in pneumococcus-infected or purified pneumolysin-treated eukaryotic respiratory cells and human cardiomyocytes.

Downloaded From Vet-eBooks.com

together with SLO induces apoptosis (270, 271). The precise signaling events are not known, but it is postulated that NAD+ glycohydrolase may enzymatically hydrolyze NAD, resulting in the accumulation of nicotinamide, ADP-ribose (ADPR). The cyclic ADPR may stimulate Ca^{2+} signaling pathways, including those leading to apoptosis (270–272). SLO alone can cause apoptosis of murine macrophage, possibly through mitochondrial membrane depolarization and the disruption of phagolysosomal membrane, resulting in uninterrupted *S. pyogenes* multiplication and eventual caspase-1 dependent apoptosis (273). Global transcriptional regulation in neutrophils after phagocytosis of *Borrelia hermsii*, *L. monocytogenes*, *Burkholderia cepacia*, *S. aureus*, and *S. pyogenes* has shown that *S. pyogenes* induces unique changes in neutrophil gene expression (274). More specifically, phagocytosis of *S. pyogenes* results in up- and downregulation of 393 genes (168 upregulated, 225 downregulated), 71 of which are apoptosis-related genes that include upregulation of AP-1, FOSL1, FOSB, JUNB, and TNFRSF5 (CD40), and downregulation of at least 26 genes involved in the response to IFN. The downregulated genes include IFN-responsive genes (IFIT1, IFIT4, IFITM2, IFI16, IFN regulatory factor-1, MX1, and ADAR) and transcription factor-related genes (STAT1, STAT3, STAT5B, STAT6, JAK1, RELA, and RELB) representing the JAK-STAT survival pathway. Interaction of streptococcal SDH with human pharyngeal cells (Detroit 562) resulting in nuclear condensation indicates that SDH may play a role in *S. pyogenes*-mediated apoptosis (89, 275). Interaction of SDH with pharyngeal cells also induced *de novo* phosphorylation of histone H3 protein. Phosphorylation of H3 plays a decisive role in transcription regulation during growth and development (276–278). *S. pyogenes* interaction mediated H3 phosphorylation, and nuclear condensation is an important marker of cells undergoing apoptosis (275, 279). An application-targeted gene array study showing the upregulation of proapoptotic genes and downregulation of important anti-apoptotic genes along with 30 to 40% of apoptosis in human pharyngeal cells after 12 h coculturing with SDH indicated that it significantly contributes to the *S. pyogenes*-mediated apoptosis of pharyngeal cells (280). Eukaryotic GAPDH is known to localize into the nuclear compartment and cause apoptosis (281–283). GAPDH of group B *Streptococcus* (*S. agalactiae)* causes apoptosis of murine macrophages (284).

Recently, SP-STP, a novel virulence factor, has been found to cause apoptosis of human respiratory cells (13). SP-STP is secreted in the *S. pyogenes* culture supernatant and is highly expressed in the intracellular *S. pyogenes* population of Detroit cells infected with *S. pyogenes*. SP-STP shares significant homology with eukaryotic PP2C (Ser/Thr phosphatase), which is known to promote apoptosis of neuronal and endothelial cells (13). Purified SP-STP has also been found to cause apoptosis of human respiratory epithelial cells when exogenously added or when ectopically expressed within the cytoplasm. Enzymatically active STP from *Enterococcus faecalis* is, however, unable to cause apoptosis when added exogenously and cocultured with respiratory epithelial cells. Interestingly, enzymatically active STP of *E. faecalis* and enzymatically inactive SP-STP have a similar tertiary structure based on circular dichroism (CD)-spectra analysis (13). Enzymatically inactive SP-STP is unable to cause apoptosis, indicating that SP-STP enters the cell in a receptor-specific manner. Ectopically expressed SP-STP causes apoptosis in >95% of epithelial cells within 12 h of incubation. Microarray and reverse transcription-quantitative PCR analyses of SP-STP-treated human pharyngeal cell lines have revealed upregulation of several proapoptotic genes (TNF-α; IL-8; caspase-1, -3, -4, -5, and -9; GADD45a [growth arrest and DNA-damage-inducible protein]; CD40; and CD27) and downregulation of antiapoptotic prosurvival genes (BCl2, BCLxL, MCL-1). Exogenously added or ectopically expressed SP-STP also has been shown to transmigrate to the nucleus and dephosphorylate CDK-phosphorylated H1. Transmigration of SP-STP in the nucleus results in apoptosis of the cell. Dephosphorylation of the phosphorylated histone H1 is known to be associated with cell apoptosis, indicating that SP-STP causes apoptosis through a novel mechanism (285). Together, these studies indicated that host cell death caused by *S. pyogenes* occurs through various mechanisms (Fig. 3).

During pneumococcal meningitis, neuronal injury arises indirectly from the bacteria and excessive immune response by the host. In experimental meningitis, concentrations of several caspases are significantly elevated, and active caspase-3 is present in the dentate gyrus (286). However, intrathecal treatment with broad-spectrum caspase inhibitor rescues only around 50% of the neurons of experimental mice with acute pneumococcal meningitis (287). In a microglial neuronal cell tissue culture system, pneumococcal infection results in rapid damage of mitochondria followed by the release of cytochrome C and apoptosis-inducing factor (288). Anti-apoptosis-inducing factor antibody also inhibits apoptosis in a significant number of cells infected with pneumococci, indicating that neuronal damage during pneumococcal meningitis occurs both as caspase-dependent and caspase-independent (mitochondrial pathway) manners (287, 288). Unlike in neuronal cells, pneumococci induce apoptosis of human alveolar and broncho-epithelial cells by caspase-6 and noncaspase protease but not by caspase-3 (289). *S. pneumoniae* also translocates into the myocardium and causes necroptosis via the RIPK1/RIPK3/MLKL signaling pathway, which is activated as a result of the suppression or downregulation of caspase-8 (290–293). *S. pneumoniae* strains that cause low activation of NF-κB in macrophage have been shown to cause severe pneumonia associated with necroptosis (294, 295).

The term "apoptosis" is defined essentially based on the morphology. As the biochemical changes occurring during this event leading to cell death have become evident, they have been differentially and appropriately recognized with corresponding differential microscopic morphological characteristics. Inflammasome-associated cell death (pyroptosis) and apoptosis are distinct yet related phenomena and engage in bidirectional cross-talk in macrophages (296). Active caspase-1, -4, and -5 typically cleave GSDMD at the Asp 275 residue, releasing p30 GSDMD, which causes rapid cell death or pyroptosis. However, the active caspase-1-activated caspase-3 and caspase-7 cleave GSDMD at Asp87, rendering it inactive, which prevents pyroptosis and causes apoptosis (296). Thus, pyroptotic stimuli can activate apoptosis, but apoptotic stimuli inactivate pyroptosis (Fig. 3). A recent study showed that DPP8/9 (postproline cleaving serine protease) inhibition by Val-boroPro (Talabostat-PT-100) stimulates the mammalian immune system and causes pro-caspase-1-dependent pyroptosis of macrophages and monocytes (297). Interestingly, this inhibitor does not cleave apoptotic caspase-3 or caspase-7 and renders GSDMD uncleaved, yet causes pyroptosis and not apoptosis in an active pro-caspase-1-dependent manner (297). Inflammasomes can also cause GSDMD-independent secondary pyroptosis and IL-1 release even in the absence of caspase-1 protease activity (298).

In conclusion, *S. pyogenes* manipulates the host cell to survive, proliferate, and spread to other cells, and the

Downloaded From Vet-eBooks.com

programmed cell death (noninflammatory autophagic, apoptotic, and inflammatory pyroptotic, and necroptotic) process controls pathogen replication and host inflammation (299). However, recent studies using transgenic mice overexpressing the prosurvival Bcl2 protein found minimal impact on the clearance of *S. pyogenes* and *Legionella* during *in vitro* bone-marrow-derived macrophage infection and *in vivo* intranasal/subcutaneous infection (300). Hence, it is rational to conclude that the most important role of programmed cell death during *S. pyogenes* infection is to minimize inflammation and increase host resilience and not to help clear or prevent *S. pyogenes* proliferation (300).

CONCLUDING REMARKS

The direct and indirect evidence of the consequences of streptococcal interaction with target epithelial cells suggest that streptococcal adherence is not merely a static process but is highly regulated, dynamic, and complex. The foundation of this dynamic process is intracellular signaling events that ultimately determine the fate of the targeted cell and subsequently that of adjacent cells. While together, these events allow streptococci to disseminate in tissues, the biochemical changes resulting from cascades of signaling events in affected cells determine the clinical picture of streptococcal disease. Thus, *S. pyogenes* and other streptococcus-mediated intracellular signaling events play a critical role in the disease process and outcomes.

The study of *S. pyogenes*-mediated signaling events is so far based on established and known cell lines *in vitro*, and hence such studies may not provide an answer to the severity of *S. pyogenes* infections *in vivo*. Limited attention has been given to the genetic basis of populations that are prone to develop frequent and severe *S. pyogenes* infections. Given the easily accessible and powerful CRISPR/CAS9, genome sequencing technologies, and the human genome database, the future holds promise to develop *in vitro* and *in vivo* infection models reflecting the targeted population to help us understand with precision why certain populations are more susceptible than others to *S. pyogenes* infection. Such studies may help develop novel host-directed therapeutics. Therapeutic targeting of the relevant host cell signaling events may hold promise to counteract severe, invasive, and often fatal *S. pyogenes* diseases more effectively. Approaches to reprogramming cellular functions have already been implemented for many septic shock and inflammatory diseases, despite persistent obstacles (301–306).

Vaccine Approaches To Protect against Group A Streptococcal Pharyngitis

VINCENT A. FISCHETTI

10

INTRODUCTION

Streptococcus pyogenes (Lancefield group A) is a human pathogen responsible for a wide range of diseases, the most common of which are nasopharyngeal infections (or strep throat) and impetigo. More than 25 million cases of group A streptococcal infections occur each year in the United States at a cost of over $1 billion to the public in addition to losses in productivity. In recent years, an increase in streptococcal toxic shock and invasive infections (particularly, necrotizing fasciitis) has been reported with certain strains of group A streptococci, resulting in rapid fatalities in up to 30% of the cases (1, 2). Since there have been no reports of penicillin resistance in group A streptococci, streptococci-related diseases can be successfully treated with this antibiotic; however, with erythromycin, the second drug of choice for these bacteria, resistance is currently observed. Before treatment, group A streptococcal infections are usually associated with fever, significant discomfort, and generalized lethargy mostly due to the wide range of toxic substances secreted. About 3% of individuals with untreated or inadequately treated streptococcal pharyngitis develop rheumatic fever and rheumatic heart disease, a sequela of the streptococcal infection resulting in cardiac damage, particularly of the mitral valve. While in the United States outbreaks of rheumatic fever are usually sporadic and infrequent, affecting only local areas of the country (3), in developing countries as many as 1% of school-age children are estimated to have rheumatic heart disease (4). Because of this, and the concern that penicillin-resistant strains may appear, there is a strong incentive to develop a safe and effective vaccine against group A streptococcal pharyngitis.

Although more prevalent during the winter months, at any given time up to 30% of asymptomatic humans carry group A streptococci in their pharynx. Except under unusual circumstances and one serotype, there is no animal reservoir for these organisms. Thus, the eradication or significant reduction in the carriage of group A streptococci in the human pharynx would have a profound effect on the dissemination of this organism in the population and on the initiation of streptococcal disease. Even in the case of the highly invasive strains of streptococci, there is no evidence that they have their origins in other than pharyngeal sources.

Lancefield (5) showed more than 50 years ago that the surface M protein would be a prime candidate for a vaccine to protect against streptococcal infection. However, we have learned since that time that protection incurred by serum immunoglobulin G (IgG) to the M molecule is type specific, and antibodies directed to the N-terminal type-specific region induce protection against only that M type among the >250 M protein types (refer to the CDC website: https://www.cdc.gov/streplab/groupa-strep/index.html). More recent studies have revealed that broad protection against streptococcal infection may be achieved by the induction of a local secretory response to exposed conserved sequences found within the M molecule. The approach prevents streptococcal colonization of the upper respiratory mucosa in a mouse model.

It has been known for decades that patients with rheumatic fever have serum IgG to human smooth muscle tissue at levels three to four times that found in normal serum. While these antibodies have also been found to react with streptococcal cell wall, membrane, and M protein N-terminal determinants, their role, if any, in the pathogenesis of rheumatic fever has not yet been proven. The fact that rheumatic fever and further cardiac damage occur around the time of the streptococcal infection, and not between infections when cross-reactive antibodies are still elevated (6), argues against the direct involvement of these antibodies in the disease process. Despite this, and until proved otherwise, it will be important to minimize the induction of cross-reactive antibodies in streptococcal vaccine preparations. This article concentrates on the progress to date toward the development of a vaccine to protect against streptococcal nasopharyngeal infection. For a more detailed review of the subject see reference 7.

M PROTEIN STRUCTURE AND FUNCTION

Protective immunity to group A streptococcal infection is achieved through antibodies directed to the M protein (8), a major virulence factor present on the surface of all clinical isolates. M protein is a coiled-coil fibrillar protein composed of three major segments of tandem repeat sequences that extends nearly 60 nm from the surface of the streptococcal cell wall (8) (Fig. 1). The A- and B-repeats located within the N-terminal half are antigenically variable among the >250 known M protein types, with the N-terminal nonrepetitive region and A-repeats exhibiting hypervariability. The more C-terminal C-repeats, the majority of which are surface

Downloaded From Vet-eBooks.com

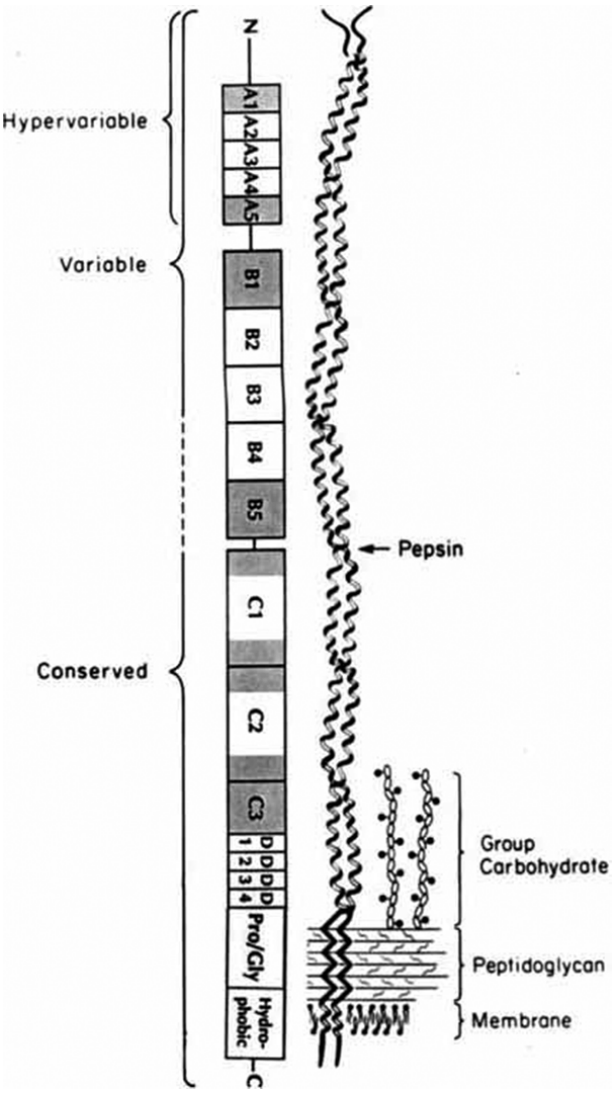

FIGURE 1 Proposed model of the M protein from M6 strain D471 (29, 85). The coiled-coil rod region extends about 60 nm from the cell wall with a short nonhelical domain at the NH2 terminus. The Pro/Gly-rich region of the molecule is found within the peptidoglycan (86). The membrane-spanning segment is composed of predominantly hydrophobic amino acids, and a short charged tail extends into the cytoplasm. Data suggest that the membrane anchor may be cleaved shortly after synthesis (86). The A-, B-, and C-repeat regions are indicated along with those segments containing conserved, variable, and hypervariable epitopes among heterologous M serotypes. Pepsin designates the position of a pepsin-susceptible site near the center of the molecule.

exposed, contain epitopes that are highly conserved among the identified M proteins (9). Because of its antigenically variable N-terminal region, the M protein provides the basis for the Lancefield serological typing scheme for group A streptococci, the M serotype (8), and a more contemporary molecular approach to typing group A streptococci, the *emm* type (10), referring to the sequence of the first 80 or so amino acids at the N-terminus of the M protein gene.

The M protein is considered the major virulence determinant because of its ability to prevent phagocytosis when present on the streptococcal surface and thus, by this definition, all clinical isolates express M protein. This function may in part be attributed to the specific binding of complement factor H to both the conserved C-repeat domain and the fibrinogen bound to the B-repeats (11), preventing the deposition of C3b on the streptococcal surface. It is proposed that when the streptococcus contacts serum, the factor H bound to the M molecule inhibits or reverses the formation of C3b,Bb complexes and helps to convert C3b to its inactive form (iC3b) on the bacterial surface, preventing C3b-dependent phagocytosis. Studies have shown that antibodies directed to the B- and C-repeat regions of the M protein are unable to promote phagocytosis. This may be the result of the ability of factor H to also control the binding of C3b to the Fc receptors on these antibodies, resulting in inefficient phagocytosis. Antibodies directed to the hypervariable N-terminal region are opsonic, perhaps because they cannot be controlled by the factor H bound to the B- and C-repeat regions. Thus, it is possible that through evolution the streptococcus has devised a method to protect its conserved region from being used against itself by binding factor H to regulate the potentially opsonic antibodies that bind to these regions.

TYPE-SPECIFIC PROTECTION

The M protein has been a prime vaccine candidate to prevent group A streptococcal infections since Lancefield showed clearly that M protein-specific human and animal antibodies have the capacity to opsonize streptococci in preparation for phagocytic clearance. In general, serum IgG directed to the hypervariable amino-terminal portion of M protein leads to complement fixation and phagocytosis by polymorphonuclear leukocytes of streptococci of the homologous serotype (12). Antibodies directed to other antigens on the surface of group A streptococci do not allow for phagocytosis, suggesting that besides the M protein, no other streptococcal surface antigen is able to induce antibodies to override the antiphagocytic effect of the M protein. Fox (13) has reviewed the early attempts at M protein vaccine development. Since the early 1970s few human trials have been realized (14, 15). This is partially because of problems with hypersensitivity reactions found with the acid-extracted M protein preparations of the time and the fact that only type-specific protection was observed. In addition, repeated attempts to separate heterologous protein contaminants from the type-specific determinants proved unsuccessful.

In 1979, Beachey et al. (16) used pepsin-extracted M24 protein (PepM24, the N-terminal half of the native M24 molecule) (Fig. 1) to immunize human volunteers. Unlike earlier acid-extracted products (13), this highly purified fragment was found to be free of non-type-specific reactivity and did not induce delayed-type hypersensitivity tests in the skin of the 37 adult volunteers. Immunization with alum-precipitated PepM24 protein led to the development of type-specific opsonic antibodies in 10 of 12 volunteers, none of whom developed heart-reactive antibodies as determined by immunofluorescence. These studies clearly indicated that M protein vaccines free of sensitizing antigens could be produced but further emphasized the type specificity of the immune response.

Using these studies as a starting point, Beachey and coworkers (17) began to develop a type-specific epitope-based vaccine strategy to protect against streptococcal disease (for a recent review see 18). It was soon learned that the complete PepM24 fragment was not necessary, but peptides representing the first 20 or so N-terminal amino acids of the M24

Downloaded From Vet-eBooks.com

protein also evoked type-specific opsonic antibodies to M24 streptococci. Experiments with synthetic peptides of the N-terminus of the M1, M5, M6, and M19 proteins resulted in the same conclusions. When a hybrid peptide was chemically synthesized representing the N-terminal sequence of both the M24 and M5 proteins and injected into animals with complete Freund's adjuvant, opsonic antibodies were produced to both M5 and M24 streptococci (19). Opsonic antibodies to three M proteins were obtained when the N-terminal sequences of three M protein sequences (M5-M6-M24) were synthesized in tandem and injected into rabbits.

MULTIVALENT TYPE-SPECIFIC VACCINE

After the untimely death of Edwin Beachey, James Dale in the Beachey laboratory improved on Beachey's approach and used recombinant technology to prepare a tandem oligonucleotide array representing the N-terminal sequence of four serotypes (M24-M5-M6-M19) (Table 1) (20). When the recombinant tetravalent fusion protein was purified and used to immunize rabbits, antibodies were raised against all four M proteins with variations in both the enzyme-linked immunosorbent assay titer and opsonic activity to the four respective streptococcal types. These studies were subsequently repeated using an octavalent construct (21); however, in these studies, opsonic antibodies were produced against six of the eight serotypes used in the vaccine construct (less reactivity being observed with the serotypes represented at the ends). To help overcome this, a 26-valent vaccine was subsequently developed comprising four peptides in which the serotype at one end was duplicated at the other (22). It was designed to contain the N-terminal region of M proteins from epidemiologically important serotypes, including those responsible for pharyngitis in children and those historically responsible for rheumatic fever. The antibodies produced in rabbits to this mixture of peptides were found to be 69% opsonic in one of the three rabbits immunized. Using a 50% reduction in growth of streptococci as an endpoint in a bactericidal assay, 92% (24/26) of the serotypes induced an opsonic response. Whether a 50% reduction is sufficient to block human infections still remains to be tested. As with the other vaccine studies using N-terminal sequences, none of the rabbits developed tissue cross-reactive antibodies to human tissues, including cardiac tissues.

TABLE 1 List of vaccine candidates

Vaccine type	Antigen used	Primary reference(s)
M-protein, type specific	N-terminal multivalent	27, 87
M-protein, conserved region	Whole C-repeat region	38, 88
	Single epitope	89
	T- and B-cell epitopes	49
Group carbohydrate	*N*-acetyl-glucosamine	90
Others (non-M protein)	C5a peptidase	79
	Serum opacity factor	83
	T-antigen (pili)	91
	Fibronectin binding (SfbI)	84
	Serine protease	92, 94
	Conserved proteins	93

In a subsequent phase I safety study, a hexapeptide was generated containing the N-terminal region of M1, M3, M5, M6, M19, and M24 proteins and used to immunize 28 human volunteers intramuscularly (23). After three immunizations, significant antibody levels were produced to all six proteins. After a 1-year follow-up, the vaccine was well tolerated with no evidence of tissue cross-reactive antibodies. Based on epidemiological data (24–26), Dale et al. subsequently engineered a 30-valent vaccine that would represent 98% of pharyngitis cases in the United States and Canada and >80% of invasive disease in these countries (27). The vaccine was shown to induce antibodies to all vaccine serotypes present in the vaccine, which was an improvement over the 26-valent construct (22). These studies confirm and extend the earlier experiments of Beachey and colleagues and reveal that such an approach may be useful for the prevention of infection by specific streptococcal serotypes.

An important factor to consider in the development of a type-specific epitope-based vaccine is the potential of the streptococcus to generate new M serotypes by changing the amino-terminal portion of the M protein. For example, in the type 6 M protein of strain D471, type-specific opsonizing antibodies are directed against epitopes located both at the amino-terminal end (residues 1 through 21) and within the A-repeat block (28), which begins at amino acid 27 and continues to residue 96 in the 441-amino acid M6 molecule (29). High-frequency, intragenic recombinational events within the A-repeat block can lead to a significant loss in the opsonizing ability of monospecific antibodies directed to this region (30). For instance, an opsonic antibody generated to the D471 parental strain showed some or no opsonizing activity to size-variant derivatives of this strain or other M6 streptococci isolated from patients. In addition, Harbaugh et al. (31) showed that sequence variation also occurs within the nonrepeating N-terminal end of the M protein sequence from strains of the same serotype and that these changes ultimately affect the binding of opsonic antibodies. More recently, Penney et al. (32) showed a significant degree of sequence variation within the N-terminal hypervariable region of several strains identified serologically as M1. In all, these findings strongly indicate that opsonic antibodies induced by M protein N-terminal sequences from a given vaccine strain may prove to be ineffective or weakly effective against other strains of the same serotype as a result of antigenic drift. Therefore, a type-specific vaccine necessary to protect against a streptococcal infection would require a multivalent antigen corresponding to stable immunodeterminants on serotypes that together account for the majority of the nasopharyngeal isolates prevalent within the population at a given time. Thus far, this region has not been identified. For a detailed review of the type-specific approach and other approaches see Dale et al. (33).

MUCOSAL VACCINE FOR NON-TYPE-SPECIFIC PROTECTION

At its peak incidence, 50% of children between the ages of 5 and 7 years suffer from streptococcal infection each year. Furthermore, the siblings of a child with a streptococcal pharyngitis are 5 times more likely to acquire the organism than one of his or her parents. This decreased occurrence of streptococcal pharyngitis in adults might be explained by a nonspecific age-related host factor resulting in a decreased susceptibility to streptococci. Alternatively, protective antibodies directed to antigens common to a large number of group A streptococcal serotypes might arise as a consequence of multiple infections or exposures experienced during

Downloaded From Vet-eBooks.com

childhood. This could result in an elevated response to conserved M protein epitopes. This latter hypothesis is partly supported by studies of the immune response to the M protein in which it was found that the B-repeat domain (Fig. 1) was clearly immunodominant. When rabbits were immunized with the whole M protein molecule, the first detectable antibodies were directed to the B-repeat region, which rose steadily with time. It was only after repeated M protein immunizations that antibodies were produced against the hypervariable A- and conserved C-repeat regions.

Early human trials by Fox and colleagues (15, 34) strongly suggested that mucosal vaccination with M protein was protective. Using highly purified acid-extracted M protein (which contains type-specific and conserved region fragments of M protein), volunteers were immunized either intranasally or subcutaneously. When they were challenged orally with virulent streptococci, the intranasally immunized volunteers displayed lower rates of both nasopharyngeal colonization and clinical illness compared with placebo controls. Volunteers immunized subcutaneously displayed only a reduction in clinical illness and showed no reduction in nasopharyngeal colonization.

Unlike antibodies to the N-terminal region of the M molecule, it was clear that antibodies directed to the exposed C-repeat region were not opsonic. Because of this, experiments were performed to explore whether mucosal antibodies directed only to the conserved region of M protein could be responsible for protection against streptococcal infection. Taking advantage of the pepsin site in the center of the M molecule (separating the variable and conserved regions) (Fig. 1), the recombinant M6 protein was cleaved, and the N- and C-terminal fragments were separated by sodium dodecyl sulfate-polyacrylamide gel electrophoresis and Western blotting. When the blots were reacted with different adult human sera, all adults tested had antibodies to the C-terminal conserved region, while as expected, only sera that were opsonic for the M6 organisms reacted with the N-terminal variable region. Similar studies performed with M protein isolated from five common serotypes (M3, M5, M6, M24, M29) revealed that sera from 10 of 17 adults tested did not have N-terminal-specific antibodies to these M types, while only two sera reacted with two serotypes and the remaining five sera reacted with only one serotype. However, all sera tested reacted to the C-terminal fragment of the M molecule. Similar results were seen when salivary IgA from adults and children were tested in an enzyme-linked immunosorbent assay against the N- and C-terminal halves of the M6 molecule (V.A. Fischetti, unpublished data). In all, this is further evidence that the relative resistance of adults to streptococcal pharyngitis is clearly not due to the presence of type-specific antibodies to multiple M serotypes of streptococci but may be due to the presence of antibodies to conserved determinants.

From these findings it was reasoned that an immune response to the conserved region of the M molecule might afford protection by inducing a mucosal response to prevent streptococcal colonization and ultimate infection. In view of the evidence that the conserved C-repeat epitopes of the M molecule are immunologically exposed on the streptococcal surface (35), it should be possible to generate mucosal antibodies that are reactive to the majority of streptococcal types, using only the conserved region antigen for immunization.

PASSIVE PROTECTION

Secretory IgA (sIgA) is able to protect mucosal surfaces from infection by pathogenic microorganisms despite the fact that its effector function differs from those of serum-derived immunoglobulins. When streptococci are administered intranasally to mice, they are able to cause death by first colonizing and then invading the mucosal barrier, resulting in dissemination of the organism to systemic sites. Using this model, a study was conducted to determine if antigen-specific sIgA, delivered directly to the mucosa, plays a role in protecting against streptococcal infection. Live streptococci were mixed with affinity-purified M protein-specific sIgA or IgG antibodies and administered intranasally to the animals (9). The results clearly showed that the anti-M-protein sIgA protected the mice against streptococcal infection and death, whereas the opsonic serum IgG administered in the same way was without effect. This indicated that sIgA can protect at the mucosa and may preclude the need for opsonic IgG in preventing streptococcal infection. This study was one of the first to compare purified, antigen-specific sIgA and serum IgG for passive protection at a mucosal site.

In the Dale laboratory, passive protection against streptococcal pharyngeal colonization was also shown by the oral administration of purified lipoteichoic acid (LTA) but not deacylated LTA before oral streptococcal challenge in mice (36). The addition of anti-LTA by the same route also protected mice from oral streptococcal challenge. While several *in vitro* studies showed the importance of M protein and LTA in streptococcal adherence, these *in vivo* studies together with those presented above using sIgA suggest that both M protein and LTA may play a key role in the colonization of the mouse pharyngeal mucosa. However, it is uncertain whether this is also true in humans.

ACTIVE IMMUNIZATION WITH CONSERVED REGION PEPTIDES

To determine whether a local mucosal response directed to the conserved exposed epitopes of M protein can influence the course of mucosal colonization by group A streptococci, peptides corresponding to these regions were used as immunogens in a mouse model (37). Overlapping synthetic peptides of the conserved region of the M6 protein were covalently linked to the mucosal adjuvant cholera toxin B subunit (CTB) and administered intranasally to the mice in three weekly doses. Animals were challenged intranasally with live streptococci (either homologous M6 or heterologous M14) 30 days later, and pharyngeal colonization by the challenge organism was monitored via throat swabs for 10 to 15 days. Mice immunized with the peptide-CTB complex showed a significant reduction in colonization with either M6 or M14 streptococci compared with mice receiving CTB alone (38) (Fig. 2). Thus, despite the fact that conserved-region peptides were unable to evoke an opsonic antibody response (12), these peptides have the capacity to induce a local immune response capable of influencing the colonization of group A streptococci at the nasopharyngeal mucosa in this model system. These findings were the first to demonstrate protection against a heterologous serotype of group A streptococci with a vaccine consisting of the widely shared C-repeat region of the M6 protein.

Confirmation of these findings was later published independently using a different streptococcal serotype as the immunizing and challenge strains (39, 40). In a separate study, Pruksakorn et al. (41), using a different criterion for streptococcal opsonization than those previously published (i.e., stationary-phase organisms were used instead of organisms in logarithmic phase [42, 43]), found that when a peptide derived from the conserved region of the M protein, termed 145, was used to immunize mice, it induced antibodies capable of opsonizing type 5 streptococci and streptococci

Downloaded From Vet-eBooks.com

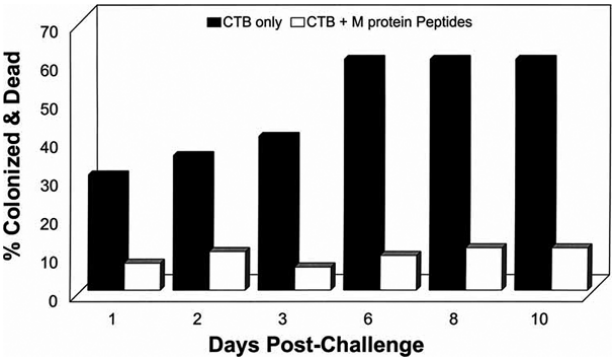

FIGURE 2 The extent of colonization and death of mice challenged with group A streptococci after oral immunization with M-protein conserved-region M6 peptides linked to CTB. The throats of orally immunized mice were swabbed each day after challenge with M14 streptococci, and the specimens were plated on blood plates to determine the extent of colonization compared with that of mice vaccinated with CTB only. Plates showing group A streptococci were scored as positive.

isolated from Aboriginal and Thai patients with rheumatic fever. These findings are in sharp contrast to those from the studies of Jones and Fischetti (12), who showed that antibodies to the conserved region of M protein are not opsonic. To further reduce the size of the 145 peptide to avoid possible tissue cross-reactivity, a 12-amino acid B-cell epitope was constructed called J8 (44). In an attempt to maintain the alpha-helical conformation of the J8 peptide as found in the native M molecule, the flanking regions were substituted with nonstreptococcal sequences with high helix potential (45). In an immunogenicity study this chimeric peptide was linked to diphtheria toxoid (J8-DT) and found to be immunogenic in mice immunized nasally, resulting in a mucosal IgA response and a systemic IgG response (46–48). When these peptides were used to immunize mice intranasally in a protection study, significant protection was observed after streptococcal challenge by the same route (40), resulting in similar protection as unmodified peptides (38). Thus, in addition to a mucosal response, if these conserved-region chimeric peptides do in fact induce an opsonic response in humans (41, 42), they may offer added protection against streptococcal infection. While it was reported that the J8-DT peptide completed phase 1 clinical trials in human volunteers (the safety phase) in 2013, the results of that trial have yet to be reported. The developers of this vaccine found that delivery by either the subcutaneous or intranasal routes was effective in protecting mice from streptococcal infection (49, 50). Another candidate vaccine, called StreptInCor, is a 55-amino acid peptide derived from the conserved C-repeat region of the M5 protein (51). While the smaller J8 peptide described above contains a single B-cell epitope, the StreptInCor vaccine incorporates both a T- and B-cell epitope. Also, being larger, it retains the alpha-helical conformation of the native molecule, resulting in proper T-cell activation (49, 52). In a study of *S. pyogenes* strains isolated in Sao Paulo Brazil, the authors estimated that the StreptInCor vaccine would cover about 71% of the infections (53, 54).

PILUS-BASED VACCINE

One of the major immunogenic proteins on *S. pyogenes* described by Lancefield is termed the T-antigen (55), a molecule used to subclassify *S. pyogenes* into immunologically distinct T types (56, 57). Subsequently, the T-antigens were determined to be pili, flexible rod-like structures on the surface of *S. pyogenes* (58). Pili are heteropolymers made up of a major backbone subunit-forming the shaft of the pilus and two minor subunits at either end of the shaft (AP1 and AP2), the genes of which are located on the FCT (fibronectin-collagen-T-antigen) pathogenicity island (59). A detailed analysis of *S. pyogenes* disease strains and the sequence of T-antigens they carried revealed that 12 T types could represent >90% of the *S. pyogenes* causing disease in Europe and the United States (60, 61). As with the multivalent M protein vaccine, the modular structure of the T-molecule (62) may allow for a similar design of a pili-based vaccine for *S. pyogenes*.

VACCINIA VIRUS AS A VECTOR

To further verify the validity of using the M protein conserved region as a streptococcal vaccine, experiments were repeated in a vaccinia virus vector system. In these studies, the gene coding for the complete conserved region of the M6 molecule (from the pepsin site to the C terminus) was cloned and expressed in vaccinia virus producing the recombinant VV::M6 virus (63). Tissue culture cells infected with this virus were found to produce the conserved region of the M6 molecule. Animals immunized intranasally with only a single dose of recombinant virus were significantly protected from heterologous streptococcal challenge compared with animals immunized with wild-type virus (Fig. 3). When the extent of colonization was examined in animals immunized with the wild type or the VV::M6 recombinant, the VV::M6-immunized animals showed a marked reduction in overall colonization, indicating that mucosal immunization reduced the bacterial load on the mucosa in these animals. Animals immunized intradermally with the VV::M6 virus and challenged intranasally showed no protection.

The approaches described above again proved that induction of a local immune response was critical for protection against streptococcal colonization and that the protection was not dependent on an opsonic response. However, in the event that the streptococcus was successful in penetrating

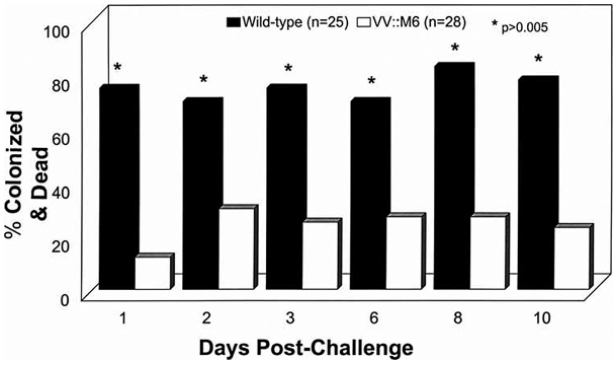

FIGURE 3 The extent of colonization and death of mice challenged with group A streptococci after oral immunization with recombinant vaccinia virus containing the gene for the whole conserved region of the M6 protein. The throats of orally immunized mice were swabbed each day after challenge with M14 streptococci, and the specimens were plated on blood plates to determine the extent of colonization compared with that of mice vaccinated with wild-type vaccinia only. Plates showing group A streptococci were scored as positive.

Downloaded From Vet-eBooks.com

the mucosa and establishing an infection, only then would type-specific antibodies be necessary to eradicate the organism. This idea may explain why adults sporadically develop a streptococcal pharyngitis. The success of these strategies not only forms the basis of a broadly protective vaccine for the prevention of streptococcal pharyngitis but may also offer insights for the development of other vaccines. For instance, a vaccine candidate previously shown to be ineffective by the parenteral route may prove to be successful by simply changing the site of immunization. Furthermore, these results emphasize the fact that in some cases antigens need to be presented to the immune system in a specific fashion to ultimately induce a protective response.

THE USE OF GRAM-POSITIVE COMMENSALS AS VACCINE VECTORS

The CTB-linked peptide and vaccinia systems mentioned above, although successful for protection against streptococcal infection, are not ideal. The CTB system requires large quantities of purified peptide and a linkage protocol that allows no more than two peptides per CTB molecule to enable the proper binding of CTB to GM_1 ganglioside (38). Although possible to achieve, these requirements would make this type of vaccine relatively expensive to produce, even if recombinant technology were used to prepare the fusion molecules. Given the fact that such a vaccine ultimately must be administered in developing countries, the cost would likely be prohibitive. The vaccinia virus vector, on the other hand, is inexpensive but unlikely to gain approval from the Food and Drug Administration since oral/intranasal administration, which could result in serious complications, is required for effectiveness. Because of these limitations, a safer and cheaper mucosal vaccine delivery system was developed.

While several nonliving systems of delivering antigen to mucosal sites have been developed (37, 64–66), live vectors may afford a better and more natural response without the need to reimmunize to gain higher antibody titers. In most instances, live antigen delivery vectors are derived from bacteria (usually Gram negative) (67) or viruses (68) that are normally considered mammalian pathogens. Perhaps this is due in part to our better understanding of these organisms, making genetic manipulations easier. Usually, these organisms have been extensively engineered to reduce their pathogenicity yet maintain certain invasive qualities (e.g., to invade the M cells of the gut mucosa) to induce a mucosal immune response. To circumvent some of the safety and environmental issues inherent in the wide-scale dissemination of engineered pathogens, a nonpathogenic Gram-positive bacterial vaccine vector was developed (69). In this system, foreign antigens are displayed on the surface of Gram-positive human commensal organisms that colonize the niche invaded by the pathogen (oral, intestinal, or vaginal). Colonization generates both an enhanced local IgA response to the foreign antigen and systemic IgG and T-cell responses. Unlike many other live bacterial systems, in which the foreign antigen is either retained in the cytoplasm, translocated to the periplasm, or in some cases secreted, the Gram-positive vector anchors the foreign antigen to the cell for surface display (69). Since the cell wall peptidoglycan of the Gram-positive cell is a natural adjuvant, an enhanced response is obtained when the engineered organisms are processed for antibody induction. The ability to accomplish this is based on the discovery that surface molecules from Gram-positive bacteria that anchor via their C termini (of which >200 have now been sequenced) have a highly conserved C-terminal region that is responsible for cell attachment (70, 71).

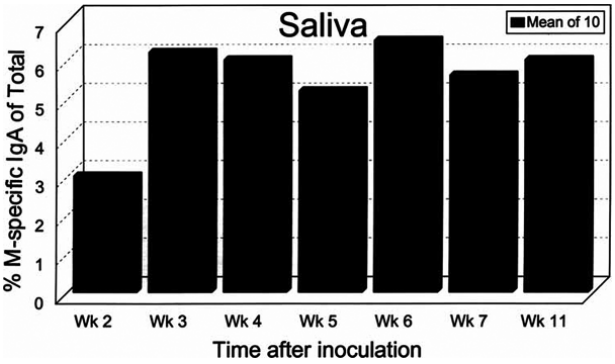

FIGURE 4 M protein-specific salivary IgA in rabbits colonized with *S. gordonii* expressing the conserved region on the cell surface. Salivary samples were taken after pilocarpine induction and tested in an enzyme-linked immunosorbent assay against the M protein.

A NEW-GENERATION STREPTOCOCCAL VACCINE

Based on successful mouse studies examining the immune response to a recombinant antigen expressed on the surface of *Streptococcus gordonii*, a recombinant *S. gordonii* was engineered that comprised the C-terminal half of the M protein containing the exposed conserved region of the molecule. This segment was similar to that used successfully in the vaccinia virus experiments (see above) (72). *S. gordonii* expressing this segment of the M protein on its surface successfully colonized for up to 12 weeks all of the 10 rabbits that were immunized. During this time, the animals raised a salivary IgA (Fig. 4) and serum IgG (Fig. 5) response to the intact M protein. The amount of M protein-specific sIgA was up to 5% of the total IgA in the saliva of these animals. The IgA and IgG induced by this method did not cross-react with human heart tissue, as determined by an immunofluorescence assay, or with tropomyosin, myosin, or vimentin as determined by Western blotting. As an added feature of the live vector system, Byrd et al. constructed *S. gordonii* which coexpressed immunomodulatory molecules such as interleukin-2 and interferon-gamma along with the M protein conserved region (73). They found that in the coexpression constructs, the cytokines modulated the systemic immune response compared to control constructs without cytokines.

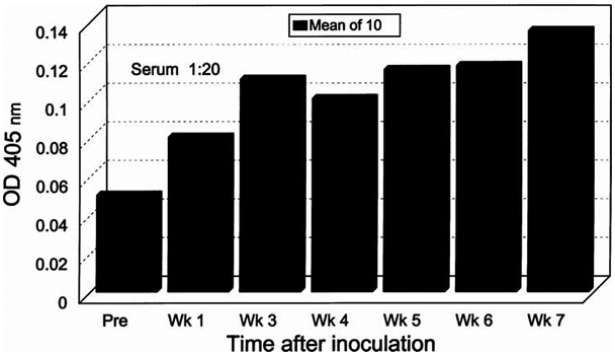

FIGURE 5 M protein-specific serum IgG in rabbits colonized with *S. gordonii* expressing the conserved region on the cell surface. Blood samples were taken at weekly intervals and tested in ELISA against the M protein.

Downloaded From Vet-eBooks.com

The commensal delivery system would be ideal for developing countries if it proved to be effective. Because it is a live vector, it would be easy to administer and not likely to require additional doses. Also, since Gram-positive bacteria are stable for long periods in the lyophilized state, a cold chain would not be required. Early studies showed that, when reintroduced into the human oral cavity, *S. gordonii* is capable of persisting for over 2 years and is transmitted to family members. For a developing country this factor could be ideal, since rarely is the whole population able to be immunized. However, it remains to be determined if this approach will induce a protective immune response in humans (74).

NON-M-PROTEIN APPROACHES TO PROTECT AGAINST STREPTOCOCCAL INFECTION

Other approaches have been developed recently that may serve an alternative to using M protein as a vaccine candidate (75). Cleary and coworkers (76) have identified a group A streptococcal protease that specifically cleaves the human serum chemotaxin C5a, preventing its binding to polymorphonuclear neutrophils. It was suggested that the surface-exposed streptococcal C5a peptidase prevents the influx of phagocytes to a streptococcal infection by destroying this chemotaxin. As proof, cleavage of C5a has been shown to reduce the influx of inflammatory cells at the site of a streptococcal infection (77). Expanding this finding, it was found that delivery of a defective form of the streptococcal C5a peptidase molecule intranasally to mice showed promise in protecting against challenge from heterologous M serotypes (78). In these studies, immunized animals cleared the challenge streptococci from the throat more rapidly than did control animals. To support this approach, human sera were tested for the presence of C5a peptidase antibodies in acute and convalescent sera from children with streptococcal pharyngitis (79). The authors found that C5a peptidase was highly immunogenic.

Using a different strategy, Musser and his group (80) have been working on the group A streptococcal cysteine protease known as streptococcal pyrogenic exotoxin B (SpeB). The gene for this protein is found in virtually all strains of group A streptococci, and in most cases its product is secreted from these organisms. Since cysteine proteases have been implicated in bacterial pathogenicity, Kapur et al. (80) found that a protease-negative SpeB mutant lost nearly all of its ability to cause death in mice when compared with wild-type organisms. They showed that mice passively immunized with rabbit IgG to cysteine protease exhibited a longer time to death than did control animals. Active immunization with cysteine protease gave the same result. Thus, while this vaccine approach prolonged the time to death, it did not prevent death.

N-acetyl-glucosamine, a polysaccharide component of the streptococcal cell wall, is the group-specific antigen for group A streptococci. Since most people infected by streptococci develop anti-*N*-acetyl-glucosamine antibodies, Zabriskie and colleagues attempted to determine if these antibodies have any effect on protecting against streptococcal infection. Using a modified *in vitro* phagocytic assay and a low bacterial inoculum, they found that anticarbohydrate antibodies specific for the *N*-acetyl-glucosamine were phagocytic. Comparing human and rabbit opsonic sera, they concluded that very high titers of anti-*N*-acetyl-glucosamine-specific antibodies were necessary to be effective in opsonization and phagocytosis of *S. pyogenes* (81).

As for other candidates, serum opacity factor, a cell wall-associated and -secreted protein of class II group A streptococci (82), has been shown to produce a protective immune response to heterologous streptococcal serotypes (83). The fibronectin binding domain of SfbI, a fibronectin binding protein of *S. pyogenes*, when used to immunize the upper respiratory mucosa of mice, was found to induce a protective mucosal response after challenge with streptococci by the same route (84).

In conclusion, while several viable vaccine antigens exist as candidates to protect against *S. pyogenes* infections (Table 1), no single antigen has yet risen to be commercially developed. Some of the reasons include (i) the inability to conclusively identify the antigen responsible for inducing the heart cross-reactive antibodies, (ii) the expense involved in determining if the vaccine antigen responsible for protection will not induce rheumatic fever because of the low frequency of the disease, and (iii) the lack of resistance seen in *S. pyogenes* to penicillin-based antibiotics. All this complacency will change the first time an *S. pyogenes* strain is isolated that is found to be resistant to penicillin.

The Bacteriophages of *Streptococcus pyogenes*

W. MICHAEL McSHAN, KIMBERLY A. McCULLOR AND SCOTT V. NGUYEN

11

OVERVIEW

The year 2015 was the centenary of the discovery of bacteriophages (phages) by Frederick Twort (1), and the first associations of phages with *Streptococcus pyogenes* (group A streptococcus) were made by Cantacuzene and Boncieu in 1926 (2) and by Frobisher and Brown in 1927 (3), both groups showing that the "scarlatina toxin" (erythrogenic toxin, pyrogenic exotoxin A) could be passed to a new strain after exposure to a sterile filtrate from a toxigenic isolate. Additional studies by Evans in the 1930s and 1940s documented the prevalence of group A streptococcal phages, linked them with virulence, and provided early additional evidence for lysogeny (4–8). More studies followed of both lysogenic and lytic streptococcal phages (9–15), but the link between lysogeny and the transmission of the erythrogenic toxin was not made until the landmark study by Zabriskie in 1964 (16); the phage-encoded toxin structural gene (*speA*) was subsequently identified by Weeks and Ferretti (17, 18) and independently by Johnson and Schlievert (19). The history and contributions of these and other early workers to our knowledge of the bacteriophages of *S. pyogenes* are covered elsewhere (20). Following these studies, a significant body of research has shown that phages contribute to the success and virulence of their host streptococci by acting as vectors for genes encoding virulence factors and through their ability to disseminate streptococcal genes from one cell to another through transduction. Since group A streptococci are not thought to be normally competent for transformation, except possibly under certain conditions (21), and since Hfr-type conjugal transfer of chromosomal genes has not been observed, it is easy to argue that the bacteriophages of *S. pyogenes* play a major role in the genetics and molecular biology of this pathogen.

LYTIC PHAGES OF GROUP A STREPTOCOCCI

Biology and Distribution of Lytic Phages

Bacteriophages typically may be grouped by their life cycle into two categories: lytic phages and lysogenic (temperate) phages. Lytic phages infect their host cell and begin the viral replicative cycle within a short time frame. At the end of replication and assembly, the host bacterial cell typically lyses and releases the newly formed bacteriophage particles. The five decades following the discovery of phages saw numerous investigations of lytic phages of *S. pyogenes*, which included studies of their host range, their basic biology, and their ability to mediate general transduction. In contrast to lysogenic phages, lytic phages do not alter the phenotype of the host streptococcal cell by a long-term genetic relationship, but they can shape the host population by eliminating susceptible cells in a population or by facilitating genetic exchange by transduction.

Bacteriophage A25

The best-studied lytic phage of *S. pyogenes* is bacteriophage A25, which was originally isolated in the early 1950s from Paris sewage (11, 12) and was found to mediate generalized transduction in *S. pyogenes* (22). Phage A25 is also referred to in the literature as phage 12204, its designation by the American Type Culture Collection (ATCC 12204). The genome sequence of A25 has been determined to be 33,900 bp with a GC content of 38.44%, very close to the predicted size (23) and GC content (24) reported previously. The sequence is available from GenBank (accession no. KT388093.1). Electron microscopy shows that it belongs to the *Siphoviridae* with an isometric, octahedral head measuring 58 to 60 nm across and a long flexible tail that measures 180 to 190 nm in length and 10 nm in diameter (25, 26). The tail of this phage is composed of 8-nm circular subunits and terminates in a transverse plate with a single projecting spike that is about 20 nm long (26, 27). In contrast to many lysogenic phages, the genome sequence shows that A25 does not encode a hyaluronidase (hyaluronate lyase) as part of its tail fiber. It does, however, encode a lysin that has activity against groups A, C, G, and H streptococci (28).

One-step growth experiments showed that phage A25 has an average burst size that may vary depending upon the host strain, with reported average burst sizes of 30 PFU/cell when propagated with strain K56 (29) and 12 CFU/cell using strain $T25_3$ (30). Peptidoglycan is the cell receptor for A25, and treatment of the cells with the group C streptococcus phage C1 lysin (PlyC) destroyed the receptor binding (31). Phage A25 has a broad host range, being adaptable to group G streptococci after passage (31). This broad host range is reflected by the mosaic nature of the A25 genome, which contains genetic modules shared with bacteriophages from *S. pyogenes*, *Streptococcus pneumoniae*, *Streptococcus suis*, *Streptococcus dysgalactiae* subsp. *equisimilis*, *Streptococcus iniae*, and *Streptococcus equi* subsp. *zooepidemicus* (32).

doi:10.1128/microbiolspec.GPP3-0059-2018

Downloaded From Vet-eBooks.com

Wannamaker and coworkers showed that A25 also could infect 48% of group C strains tested (33). Other *S. pyogenes* lytic phages in the same study could also infect group C strains at frequencies ranging from 34 to 47%. The possibility that A25 and other lytic *S. pyogenes* phages can infect multiple species of streptococci may contribute to horizontal transfer of both host and prophage genes via transduction. Phylogenetic analysis of the terminase suggests that A25 uses *pac* style packaging of its genome (32), and low-stringency *pac* site recognition has been associated with high-frequency transduction in phages (34). The efficiency of transduction by A25, discussed below, suggests that its packaging of DNA sequences is not highly stringent.

The genome sequence of A25 revealed that, remarkably, this bacteriophage was very likely an escaped lysogen containing a remnant lysogeny module that retained a *cro*-like antirepressor and operator sequence but no longer contained a cI-like repressor or integrase (32). The genome has a modular genetic arrangement similar to many *S. pyogenes* genome prophages (Fig. 1) with regions associated with regulation, DNA replication, endonucleolytic cleavage, DNA packaging, head and head morphogenesis genes, tail genes, and lysis. In contrast to most genome prophages, however, no identifiable virulence genes were found. An extended region of high DNA homology with the lysogeny module of a number of genome prophages is present (shaded gray in Fig. 1), and the shared operator sequence between these prophages and A25 appears to be a mechanism of A25 resistance for these prophages, allowing their Lambda-like repressor proteins to silence A25 expression and abort its replication. The key role of this repressor was confirmed by transferring a plasmid-encoded copy of this gene into susceptible strains of *S. pyogenes*, leading to high-level resistance to A25 infection (32). The remainder of the A25 genome shows little homology to known *S. pyogenes* prophages, instead having regions of homology to phages from other streptococcal species as described above. Streptococcal phage Str01, sequenced after A25, showed near identical homology to the A25 genome except for the presence of a cI-like repressor and integrase gene. Interestingly, homology to this portion of the Str01 genome was found to prophages from group G streptococci. This suggests that lysogenic escape was a more distant event then rescued by the acquisition of integrase and cI-like repressor from a group G streptococcal phage, further implicating multispecies genetic transfer within streptococci and streptococcal phages.

Transduction in *S. pyogenes*

Transformation, conjugation, and transduction are common means of genetic exchange in bacteria. In *S. pyogenes*, natural transformation may occur when the cells live in a biofilm (35), but such exchange has not been seen under typical laboratory conditions. Conjugative transposons are frequent elements in *S. pyogenes*, but they are not associated with transfer events seen with the F plasmid of *E. coli*. Generalized transduction, by contrast, occurs in *S. pyogenes* and is mediated by both lytic and lysogenic phages.

Transduction in *S. pyogenes* was first reported in 1968, detailing how five phages, three lytic and two lysogenic, were able to transduce streptomycin resistance (22). Of this group of phages, phage A25 (phage 12204) was able to transduce antibiotic resistance at the highest frequency (1×10^{-6} transductants per PFU). Transfer was DNase resistant but sensitive to antiphage serum, supporting generalized transduction as the mechanism of genetic exchange. The capsule of *S. pyogenes* is composed of hyaluronic acid, which was

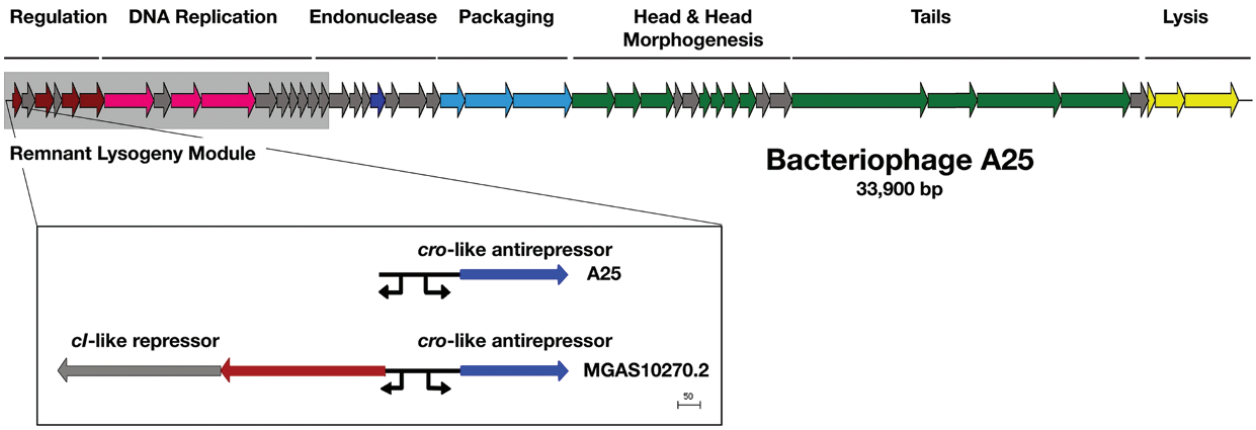

FIGURE 1 The genome of bacteriophage A25 reveals an escape from lysogeny. The 33,900-bp generalized transducing phage A25 is shown. The portion of the chromosome included in the shaded box is the high homology region that contains the remnant lysogeny module and other genes that A25 shares with prophages from genome strains MGAS10270 (M2), MGAS315 (M3), MGAS10570 (M4), and STAB902 (M4). Unlike these complete lysogens, A25 only has the operator and antirepressor from the lysogeny module (shown in expanded view below the map), apparently having lost the integrase and repressor for lysogeny some time in the past. This A25 expanded region is compared to the homologous region from genome prophage MGAS10270.2, which contains these elements as well as the upstream genes including the *cI*-like repressor. Promoters are shown as directional arrows. Introduction of the MGAS10270.2 repressor into an A25-sensitive *S. pyogenes* strain results in its conversion to a high level of A25 resistance (32). The genome follows a typical modular arrangement, with the predicted function for A25 genes indicated by color: regulation, dark red; DNA replication, pink; encode endonucleases, dark blue; genome packaging, light blue; structural, green; and lysis, yellow. The figure is redrawn from McCullor et al. (32).

Downloaded From Vet-eBooks.com

found to be a barrier to A25 infection (11). Lysogenic phages often encode a hyaluronidase, but phage A25 lacks such a gene since this enzymatic activity has not been associated with nor was a gene identified by genome sequencing (32). The state of *S. pyogenes* encapsulation can vary during the growth phase (36), and some strains, such as the recently described M4 isolate from Australia (37), do not express capsule at all. Therefore, the susceptibility of cells to phage-mediated transduction probably varies by growth state and genetic background, both of which could influence horizontal transfer.

A number of strategies have been used to improve transduction frequencies. Malke showed that transduction frequencies could be improved by using specific A25 antiserum to block unabsorbed or progeny phages from infecting transductants resulting from the initial adsorption (38). In theory, this phenomenon leading to higher transduction frequencies can occur in nature, particularly with infections of strains containing resident prophages with high homology to A25 within the lambda-type regulatory region. As discussed above, superinfection immunity represses A25 gene expression but does not impede initial phage adsorption and injection of DNA material. This mechanism protects the infected cell from lysis by A25 infection and allows for survival of transduced cells. Increased levels could also be obtained by the use of temperature-sensitive mutants of phage A25 (29), as could UV irradiation of transducing lysates prior to adsorption to the host streptococci (38–40).

Lysogenic bacteriophages of *S. pyogenes* are capable of mediating transfer of antibiotic resistance by transduction. Strains with bacteriophage T12-like prophages can produce transducing lysates capable of transferring resistance to tetracycline, chloramphenicol, macrolides, lincomycin, and clindamycin following lysogen induction. Generalized transduction transfer of erythromycin and streptomycin resistance following mitomycin C treatment of endogenous prophages has also been observed (41).

Transduction may play a role in the dissemination of genes among related streptococcal species. Some bacteriophages isolated from groups A and G streptococci can infect serotype A, C, G, H, and L strains; some were capable of infecting multiple serotypes (42). The same study showed that phage A25 could transduce streptomycin resistance to a group G strain. Wannamaker and coworkers further showed that streptomycin resistance could be transferred to *S. pyogenes* strains by a temperate transducing phage isolated from group C streptococcus (33). The wealth of *S. pyogenes* genome data supports the idea that horizontal gene transfer has been important in the evolution of this pathogen (43), and transduction is assumed to play an important role in this process. However, the molecular mechanisms that would drive this process are little understood. The majority of the studies into streptococcal transduction were done before the advent of modern techniques of molecular biology and genomics, and therefore this may be an opportune time to reexamine this phenomenon. A better understanding of streptococcal transduction may prove key to understanding the flow of genetic information in natural populations of *S. pyogenes* and the horizontal transfer of information from other genera. In addition, better understanding of gene transfer mediated by phage transduction could translate to better molecular tools for manipulation of *S. pyogenes* genomes, which currently remains a more challenging feat compared to other streptococcal species. More efficient genetic manipulation, in turn, could further our understanding of gene function within *S. pyogenes*.

LYSOGENIC PHAGES OF GROUP A STREPTOCOCCI

Genome Prophages, their Distribution, and Attachment Sites

Lysogenic bacteriophages are defined by their ability to integrate their DNA into the host bacterium's chromosome via site-specific recombination, becoming a stable genetic element that can be passed to daughter cells following cell division. Studies from the pregenomics era suggested that lysogeny was common in *S. pyogenes* (9, 10, 44–47), but it was genome sequencing, starting with the first sequence completed and confirmed by almost every subsequent sequenced genome, that demonstrated that toxin-carrying prophages were not only common but prominent genetic features that shaped the fundamental biology of this bacterial pathogen (Table 1). The number of lambdoid prophages or phage-like chromosomal islands found in a given genome strain has ranged from a low of one (MGAS15252) to as many as eight (MGAS10394), with three to four elements being common. These prophages are found integrated into multiple sites on the *S. pyogenes* genome, being found in each quadrant (Fig. 2 and Table 2). The majority of the genome prophages (72%) are found integrated into genes encoded on the lagging strand (relative to *ori*C). No prophages have been found to target genes in the hypervariable regions that include the M-protein (*emm)* or the streptococcal pilus. Some sites are frequent targets for prophage integration; the genes for DNA binding protein HU, transfer messenger RNA (tmRNA), and DNA mismatch repair (MMR) protein MutL are commonly occupied by a prophage or prophage-like chromosomal island.

Integration of prophages occurs via homologous exchange between sequences shared between the phage and host chromosomes (*attP* and *attB*, respectively); this process is mediated by a phage-encoded integrase. These duplications between the phage and host DNA can be as little as a few nucleotides to over 100 bp, often including coding regions of the bacterial genome (48–50). In *S. pyogenes*, the identifiable duplications between *attB* and *attP* range from 12 bp (MGAS10394.1) to 96 bp (T12). An extensive survey of bacterial genome prophages found that prophages usually integrate into a gene open reading frame (ORF) (69% of identified prophages), while integration into an intragenic region, such as seen in coliphage Lambda, is less common, accounting for only 31% of prophages (50). Gene targets included tRNA genes (33%), tmRNA (8%), and various other genes (28%). Examples of each target site are observed in the *S. pyogenes* genome prophages (Table 2). Most commonly, the duplication occurs between the phage and the 3′ end of the host gene, and integration leaves the ORF intact via the duplicated sequence (50, 51). In *S. pyogenes*, however, the 5′ ends of genes are frequently targeted for integration, which potentially could lead to altered expression of the host gene (Table 2). The best-characterized system of altered host gene expression is the control of MMR in strain SF370 by *S. pyogenes* chromosomal island, serotype M1 (SpyCIM1), where the expression of genes for MMR, multidrug efflux, Holliday junction resolution, and base excision repair are controlled by this phage-like chromosomal island in response to growth (51–54). Similarly, the phage-like transposon MGAS10394.4 (also known as Tn*1207.3* [55]) separates the DNA translocation machinery channel protein ComEC operon proteins 2 and 3, potentially creating a polar mutation that silences protein 3. A number of other

streptococcal genes are targeted at their 5′ ends by prophages, including genes encoding the recombination protein RecX, a HAD-like hydrolase, and DNA-binding protein HU (Table 2). Other prophages integrate into the promoter region preceding the ORF in dipeptidase Spy-713, *yesN*, and a gamma-glutamyl kinase. In the case of dipeptidase Spy0713 that is targeted by members of the SF370.1 family, integration separates the ORF from the predicted native promoter and may replace it with a phage-encoded promoter found immediately upstream of the coding region following integration (Fig. 3). This phage-encoded promoter is preceded by a canonical CinA box (56), suggesting that this putative alternative promoter may also change the transcriptional program of the gene. In another example, two serotype M3 prophages were found integrated into a clustered regularly interspaced short palindromic repeat (CRISPR) type II system direct repeat; remarkably, this event may have led to the loss of CRISPR function in these cells. In all of these examples, the integration of a phage or phage-like element into the 5′ end of a gene has the potential to alter streptococcal gene expression by blocking transcription or providing an alternative promoter, and the frequency of such transcription-altering prophages may be an important regulatory strategy in *S. pyogenes*.

Not all *S. pyogenes* prophages inactivate host genes following integration. Those that integrate into the 3′ ends of genes typically preserve gene function through the shared DNA sequence between the DNA molecules, and a number of examples are found in the genome prophages (Table 2). Bacteriophage T12 integrates by site-specific recombination into what was initially identified as a gene for a serine tRNA (57) but was correctly identified as a tmRNA gene after the completion of genome sequencing. Genes encoding tmRNA are frequently used as bacterial attachment sites (*attB*) for prophages that infect a range of bacterial species, including *Escherichia coli*, *Vibrio cholerae*, and *Dichelobacter nodosus* (50, 58). Besides the tmRNA gene, other 3′ gene targets used by genome prophages include the histone-like protein HU, dTDP-glucose-4,6-dehydratase, a putative SNF family helicase, and recombination protein *rec*O.

Morphology and Genome Organization

Tailed phages with double-stranded DNA genomes (*Caudovirales*) are abundant in the biosphere, perhaps being the most frequent form of life on Earth (59). Of the *Caudovirales*, the phage subset *Siphoviridae* (icosahedral heads with long, noncontractile tails) make up about 60% of the total (60) order. A bacteriophage survey from the pregenomics era found that 92% of phages of the genus *Streptococcus* were *Siphoviridae* by the current classification (61), and the few early electron micrographs published reflect this prevalence (13, 25, 26, 38). Figure 4 shows the typical *Siphoviridae* morphology of two well-studied *S. pyogenes* phages, SF370.1 and T12. The tail fibers of SF370.1, which contain the hyaluronidase (hyaluronate lyase) used for capsule penetration during phage infection (62), are seen in the micrograph. The lytic transducing phage A25 also has typical *Siphoviridae* morphology (25, 38). While lysogenic phages may be found to be mostly members of the *Siphoviridae*, given their probable common pool of genetic modules (see below), other phage morphotypes may be found in the lytic phages, such as the *Podoviridae* C1 phage of the related group C streptococci

Downloaded From Vet-eBooks.com

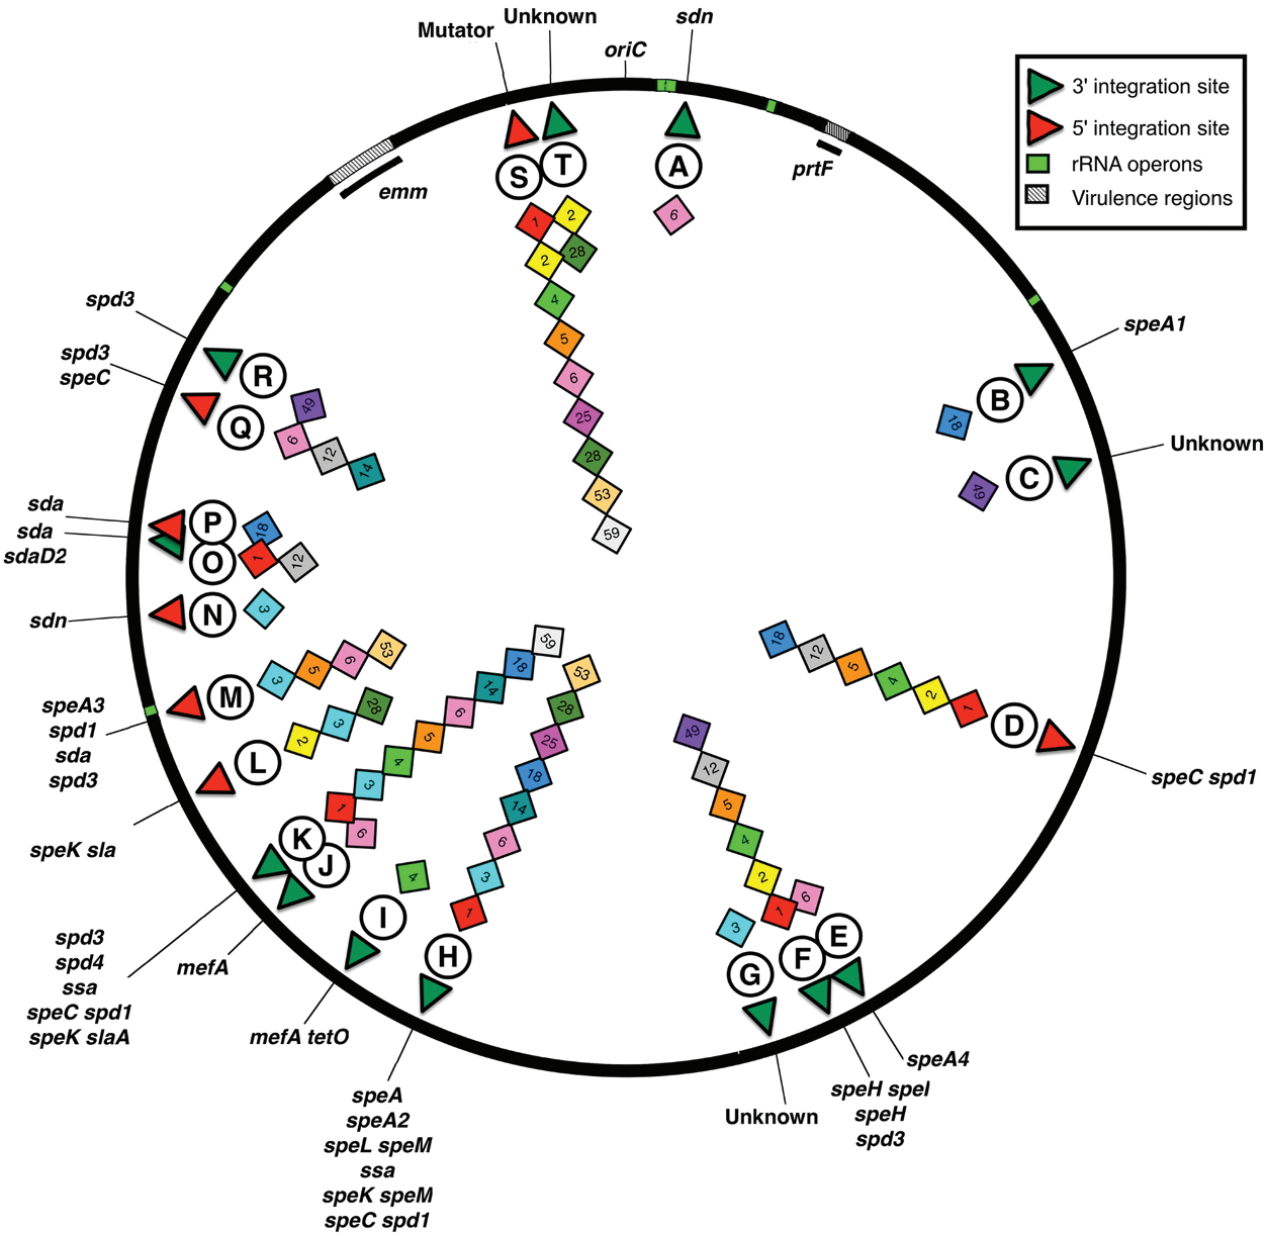

FIGURE 2 Prophage attachment sites in the *S. pyogenes* genome. The locations of the genome prophages are shown as a generalized chromosome backbone based on the SF370 M1 genome; each diamond represents a genome prophage identified at that site. The M type of the host for each prophage is indicated by the number within the diamond, and the circled letter is the identifier linked to Table 2 for *attB* gene identification, the integration target within that gene (5′ or 3′), and associated prophage virulence genes. The rRNA operons are indicated as green blocks, and the hypervariable regions containing virulence genes associated with *emm* or *prtF* are hatched. The origin of replication is indicated (OriC).

(63). The coliphage Lambda has been the prototype for lysogenic prophages, and the genetic organization of most group A streptococcal genome prophages follows a similar general plan (64, 65), having identifiable genetic modules for integration and lysogeny, replication, regulation, head morphogenesis, head-tail joining, tail and tail fiber genes, lysis, and virulence (Fig. 5).

Lysogeny module

Temperate phages are defined by their carriage of genes that establish and maintain a stable condition within a host cell, usually via site-specific integration. Minimally, lysogeny requires genes encoding an integrase (recombinase) and excisionase to mediate prophage DNA integration and excision as well as genes encoding repressor and antirepressor proteins to direct and control this process following the pattern seen in coliphage Lambda (66). Phage integrases typically mediate a recombination event between an identical sequence shared between the circular form of the prophage genome (*attP*) and the bacterial chromosome (*attB*), and the recognition of these DNA sequences is inherent in a given integrase protein (49, 67, 68). Most lambdoid phages usually have integrases that

Downloaded From Vet-eBooks.com

belong to the tyrosine integrase family, and the integrases of genome *S. pyogenes* prophages belong to this group. The excisionase gene in Lambda and many other Gram-negative host phages is positioned upstream of integrase, but in the lactic acid bacteria and other Gram-positive bacteria its genome location is variable (69, 70). Indeed, since excisionase proteins often show little conservation (71), the identification of the correct ORF in a given prophage is often difficult. Some excisionase genes may be provisionally identified in the *S. pyogenes* genome prophages by homology to other phages (64); however, to date, none have been confirmed experimentally.

DNA replication and modification

Following the lysogeny module is a region that shows considerable diversity between individual prophages and that encodes genes involving DNA replication and modification. Homologs of DNA polymerases, replisome organizer, restriction-modification systems, and primase genes are present in these regions as well as potential sequences that may function as origins of phage DNA replication (64, 65). Inspection of the genome annotations of these regions also shows that while many genes are unique to group A streptococcal phages, others have close homologs in phages from other streptococcal species such as *Streptococcus thermophilus* or *S. equi*, suggesting that a pool of genetic material is shared by a diverse group of phages (discussed below).

DNA packaging, capsid structural genes, and host lysis genes

The next region of prophage genomes is typically dedicated to the genes encoding the proteins for the assembly of phage heads and tails as well as the proteins needed to package the phage DNA into the heads and join this complex to the tails. The function of many of these genes has been inferred by homology to known phage proteins or sequences or by presumption of function due to their relative order in the chromosome. However, with the exception of the hyaluronate lyase (hyaluronidase) gene found in some *S. pyogenes* phage tail fibers (45, 62, 72), most of these genes have not been characterized experimentally, and these function assignments remain provisional. Following the capsid genes are the typical holin-lysin genes that are employed at the end of the lytic phase to lyse the infected bacterial cell and release the newly formed phage particles.

Virulence genes

Finally, at the distal end of the phage chromosome are the genes for host conversion that encode a range of virulence factors; prominent are exotoxins that are often superantigens and DNases such as streptodornase (Table 2). The origin of phage-encoded toxins remains unclear, but the fact that these toxin genes play no known role in the replication of the phage suggests that such genes were acquired at some point late in the phage's evolutionary history. It has been proposed that virulence factors may be acquired by phages by imprecise excision events (73), but finding known phage-associated virulence genes independently on the bacterial chromosome has not occurred. Some superantigen genes are not associated with prophages (74, 75), but whether these genes are a genetic source of prophage superantigens is unclear. Lateral gene capture of virulence genes has undoubtedly been important in their dissemination (76), and such exotoxins may have evolved *de novo* as elements to increase bacterial host cell fitness (77). Decayed prophage remnants with superantigen domains may be seen in the *S. pyogenes* genome (65), and these regions may serve as a genetic reservoir for virulence genes. Similarly, host-range variants of phages from different bacterial species or even genera are another potential reservoir for toxin genes; for example, the *speA* gene of *S. pyogenes* and the enterotoxins B and C1 of *Staphylococcus aureus* show a significant degree of homology and thus may share a common origin (18).

Diversity of Lysogenic Phages

Structural genes dominate phylogenic relations

Botstein, in a seminal 1980 paper, proposed that the product of bacteriophage evolution is not the individual virus but a pool of interchangeable genetic modules, each of which carries out a biological function in the phage lifecycle; natural selection therefore acts at the level of these individual modules (functional units) (78). Phylogenetic analysis of the Lambdoid *S. pyogenes* prophages predicts that several prominent groups exist (Fig. 6). Within each branch, considerable group diversity may exist in terms of targeted bacterial attachment site and encoded virulence factors (Table 2). Inspection of each group shows that phylogeny is driven by large shared blocks of genes encoding proteins for DNA packaging, heads and tails, and host lysis (Table 3); for example, see the analysis of the group of prophages containing phage T12, where all members of the group minimally share these structural genes (Fig. 7). However, others, such as the SF370.1 group, are much more clonal, all sharing the same virulence and lysogeny modules. Therefore, the phylogeny of individual functional modules (such as toxin genes) may be unrelated to other regions of the genome (such as the lysogeny module or capsid genes). The apparent shuffling of the individual modules may be driven by both homologous and nonhomologous recombination (64, 79–82). The actual driving force behind this engine of prophage diversity in *S. pyogenes* remains poorly understood, but some clues have emerged. In a survey of 21 toxin-carrying *S. pyogenes* strains, 18 were found to carry a highly conserved ORF adjacent to the toxin genes (83). This ORF, which was named paratox, may help promote homologous recombination between phages so that toxin genes may be exchanged, leading to phage diversity. Some genome phages or phage-like elements do not readily fall into any group: MGAS10394.2, HKU16.1, NZ131.1, m46.1, and MGAS10394.4 are phylogenetic outliers that have little commonality with other prophages. When the prophages are clustered by the M type of their host cell, some patterns do emerge (Figure 8). There appears to be a pool of phages shared by M1 and M12 *S. pyogenes* strains, for example. M3 strains have some phages that appear more frequently within this serotype, but the current sample size is too small to draw any definite conclusions. Indeed, more genomic data will be required to get a clearer picture of prophage distribution by serotype.

Prophage hyaluronidase (hyaluronate lyase)

A subset of genome prophages encode a hyaluronidase (hyaluronate lyase, hyaluronoglucosaminidase) gene (Table 3). Two alleles (*hylP* and *hylP2*) of this gene were originally identified (45, 72), and subsequent studies show that this gene exists in multiple alleles mainly distinguished by single nucleotide polymorphisms and by collagen-like domain indels in some variants (84, 85). The phage hyaluronidase gene found in the genome sequences also shows considerable diversity that may have resulted from recombination (45, 72, 84, 85). It had been suggested that phage hyaluronidase was a

potential virulence factor, but the crystallization and structural analysis of HylP1 from phage SF370.1 suggested that the function of this enzyme is to introduce widely spaced cuts in the bacterial hyaluronic acid to cause a local reduction in capsule viscosity and aid phage invasion during infection (62). Similar structural properties were observed in the hyaluronidase proteins encoded by prophages SF370.2 and SF370.3 (86).

Horizontal transfer of genes from other species

One observation to come from extensive genome sequencing is that the lysogenic phages of *S. pyogenes* share a gene pool with other streptococcal species, including those that are closely related (e.g., *S. equi*) as well as those more distantly related (*S. pneumoniae*). These shared genes include ones essential to the basic phage life cycle, such as capsid proteins, and virulence genes such as exotoxins and superantigens. For example, *S. equi* prophages share many superantigens or virulence genes with *S. pyogenes* phages, including *slaA*, *speL*, *speM*, *speH*, and *speI* (87). This study found that phage Seq.4 from *S. equi* strain Se4047 was very closely related at the DNA level to *S. pyogenes* Manfredo phage Man.3, including the two phage-encoded exotoxins. Similarly, *Streptococcus agalactiae* phage JX01, isolated in milk from cattle with mastitis, shares extensive homology with *S. pyogenes* prophage MGAS315.2 in the modules controlling DNA replication, tail, head-tail connector, head capsid, and DNA packaging, with over 97% amino acid identity between their terminase subunits; however, no virulence-associated genes were identified in this phage (88). The temperate phage MM1 of *S. pneumoniae* also draws from a common pool of structural genes, sharing the DNA packaging, the head-to-tail joining, and the tail genes with phage SF370.1 (89). Further, this phage and MGAS315.4 share tail and tape measure genes. Some of the oral streptococci also have phages that contribute to this common pool. The portal, terminase, major capsid protein, major tail protein, and tape measure protein of *Streptococcus mitis* phage SM1 share homology with prophage SF370.3 and a number of other phages of low-GC Gram-positive hosts (90). While acquisition of these phage structural genes from other streptococcal species may not directly impact virulence the same way that a novel exotoxin would, these capsid genes may help to expand the host range within the group A organisms. The dairy

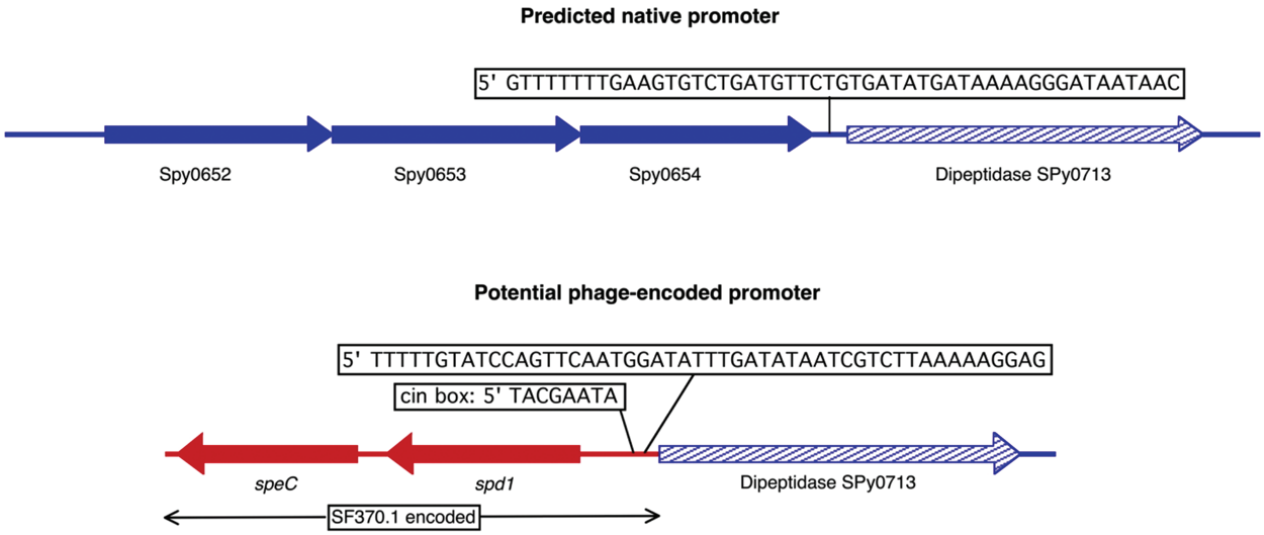

FIGURE 3 Integration of prophage SF370.1 may provide an alternative promoter for dipeptidase Spy0713. In strains lacking an integrated prophage at this site, the native promoter for dipeptidase Spy0713 is downstream of the uncharacterized gene Spy0654; the predicted sequence is shown above. Integration of phage SF370.1 into Spy0713 separates this gene from that of the native promoter, and a predicted promoter encoded by the prophage is now positioned in front of the dipeptidase ORF. This phage-encoded promoter is preceded also by a canonical CinA box (56), which is not part of the native promoter. Transcription of prophage virulence genes *spe*C and *spd1* is from the opposite strand and should not influence transcription of Spy0713. Promoter predictions were done using the online tool at http://www.fruitfly.org/seq_tools/promoter.html (110).

species *Lactococcus lactis* also is included in this pool of shared phage genes since prophage SF370.3 closely resembles the cos-site temperate phage r1t of *L. lactis* (64, 91).

S. PYOGENES PROPHAGES AND THE HOST PHENOTYPE

Prophages as Vectors for Virulence Genes

As described above, the link between bacteriophages and virulence in *S. pyogenes* may be traced to the earliest days of bacteriophage research. A considerable range of virulence-associated genes are carried by these prophages and prophage-like elements, including superantigens (*spe*A, *spe*C, *spe*G, *speH*, *speI*, *speJ*, *speK*, *speL*, SSA, and variants), DNases (*spd1*, MF2, MF3, and MF4), phospholipase A2 (*sla*), and macrolide resistance (*mef*A). It is quite common for a given prophage to carry more than one virulence gene, such as phage SF370.1, which contains both *spe*C and *spd1*. The number and diversity of prophage-associated virulence genes in *S. pyogenes* argues that these frequently play an important role in pathogenesis.

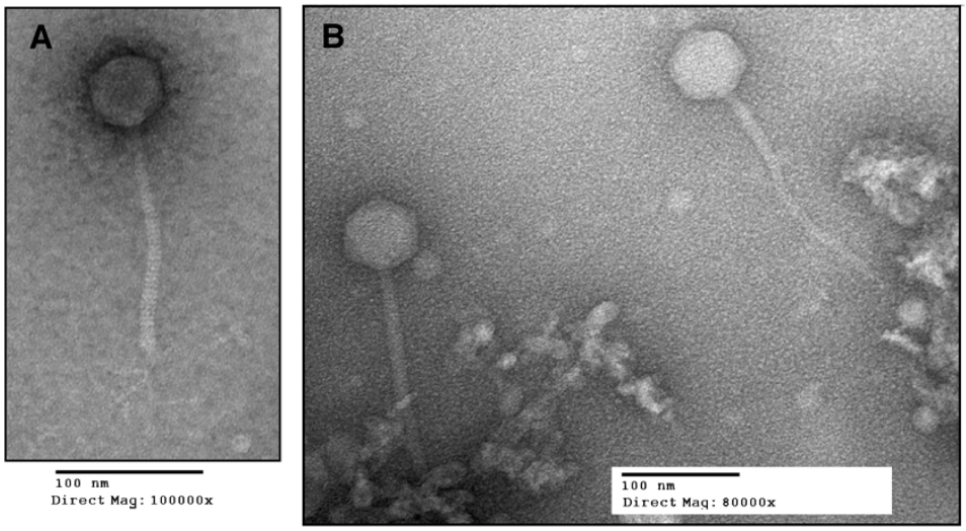

FIGURE 4 Morphology of streptococcal lysogenic phages. Prophages SF370.1 (A) and T12 (B) release typical *Siphoviridae* virions following induction. The SF370.1 head is about 55 nm across and the tail is 168 nm in length in this micrograph. In this image, the tail fibers that contain hyaluronate lyase (hyaluronidase) are visible. The T12 capsid has similar dimensions, with the head being about 66 nm and the tail length 196 nm. Electron micrographs provided by W.M. McShan and S.V. Nguyen.

[a]Contains a hyaluronate lyase (hyaluronidase) as a component of the tail fiber.

The expression of phage-encoded virulence genes, rather than an autonomous event, may be linked to the host streptococcal cell genetic background (92) or physiological state (93). For example, the reception of signals from co-cultured human cells influences *S. pyogenes* prophage virulence gene expression. Human pharyngeal cells release a soluble factor that stimulates expression of pyrogenic exotoxin C (SpeC) and phage DNase Spd1 as well as induction and release of phages by *S. pyogenes* grown in coculture (94, 95). Similar results were observed independently where the expression of prophage-encoded toxins SpeK and Sla was enhanced by coculture with pharyngeal cells (96). Eukaryotic cells also provide an environment that promotes the transfer of toxin-producing phages from a lysogen to a new host; this phenomenon can occur in either *in vitro* culture or a mouse model (97). However, the genetic background of the streptococcus influences whether the acquisition of a new prophage expressing DNase results in enhanced pathogenic potential of the resulting lysogen (92). Some of these bacterium-phage interactions appear to be linked to the cellular regulatory networks; for example, the *S. pyogenes* global regulator Rgg can control the expression of the phage-encoded DNase Spd3 by interacting with phage promoters of that gene (93). Alteration of streptococcal gene expression may also impact the levels of phage toxins released during an infection. Employing a murine subcutaneous chamber model, Aziz and coworkers showed that the expression of *S. pyogenes* protease SpeB diminished after extended colonization in the mouse; this loss of protease activity occurred with simultaneous enhancement of phage-encoded exotoxin SpeA and streptodornase expression (98). Interestingly, these altered expression patterns were independent events.

Phage-Like Elements that Carry Antimicrobial Resistance Genes

S. pyogenes harbors a number of genetic elements that appear to have phage sequences combined with sequences from transposons or plasmids and are vectors for antibiotic resistance. One example is Φm46.1, the main *S. pyogenes* element carrying the *mef*A and *tet*O genes (99). The chromosome integration site of Φm46.1 is a 23S rRNA uracil methyltransferase gene, and this phage has high levels of amino acid sequence similarity to Φ10394.4 of *S. pyogenes* strain MGAS10394.4 and λSa04 of *S. agalactiae* A909 (100, 101). The antibiotic resistance cassette of the PhiM46.1 family may be a recent acquisition: the lysogeny module appears split due to the insertion of a segment containing *tet*O and *mef*A into the phage DNA (99). Phage Φm46.1, besides being found frequently in *S. pyogenes*, has a broad host range that allows it to transduce antibiotic resistance to strains of *S. agalactiae*, *Streptococcus gordonii*, and *S. suis* (102). All of these species share a highly conserved *attB* site, which undoubtedly facilitates dissemination of this phage. Further, within GAS, Φm46.1 appears to be able to infect a wide range of M types (103). The ability of this phage family to mediate transfer of antibiotic resistance shows again how frequently *S. pyogenes* prophages modify the phenotypes of their host to improve fitness.

Prophages, Phage-Like Elements, and Regulation of Host Gene Expression

The impact of prophages on the host phenotype extends beyond toxigenic conversion. One early report noted the possible control of M protein and serum opacity factor expression

FIGURE 6 Phylogenetic relationships of *S. pyogenes* prophages. An unrooted phylogenetic tree was created by DNA alignment of the genome prophages. Prophages MGAS10394.2, HKU16.1, NZ131.1, m46.1, and MGAS10394.4 were so dissimilar from the other prophages that each occupied an independent branch; consequently, for clarity, they are not shown on the tree. The alignment organized the remaining prophages into six major branches, and the encircled letter identifier by each prophage refers to its associated attachment site (*attB*) described in Table 2; each identifier is colored to facilitate viewing. The groups are defined by shared modules for structural genes (Table 3). The tree was created using the software packages Clustal-omega and TreeGraph 2 (111, 112).

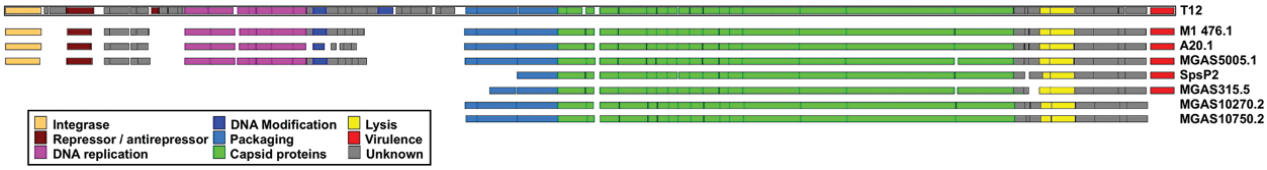

FIGURE 7 Shared genetic modules of the T12-related prophage family. The top line is the simplified genetic map of bacteriophage T12 colored by gene or genetic module for the integrase, repressor-antirepressor, DNA replication, DNA modification, DNA packaging, capsid proteins, lysis, and virulence (*speA*). Regions of unknown or uncertain function are colored gray. Beneath T12 is shown the genetic maps of the other genome prophages that share the extended region dedicated to packaging, capsid proteins, and lysis. DNA regions that are divergent from T12 are not shown. The figure illustrates that a structural gene module can be associated with divergent attachment sites or virulence genes. The alignment was derived from the phylogenetic tree presented in Fig. 5.

by a prophage or other extrachromosomal element that could be cured upon passage. In light of our current understanding of global transcriptional regulators, such a change suggests that the identified prophage could be interacting with or substituting for a regulator to mediate the changes reported in the older literature. The regulator Rgg has been shown to interact with several prophage-encoded genes. In addition to the DNase Spd3 mentioned above (93), Rgg has been shown to bind prophage-encoded promoters controlling genes for an integrase and a surface antigen (104). Recent studies suggest that the two-component regulatory system CovRS may also be influenced by prophage carriage. Many invasive strains of *S. pyogenes* often have mutations in *covRS*, and a subset of these invasive strains produce no detectable capsule at 37°C but produce capsule at sub-body temperatures. Brown and coworkers reported that the presence of prophage PhiHSC5.3 could rescue capsule production independent of temperature in a *covR*-defective strain but that this spontaneous capsule production was eliminated by curing of this prophage (105). Thus, in this case a prophage appears to act as a thermoregulator, possibly repressing capsule production at 37°C.

A mobile element frequently found in *S. pyogenes* genomes is the phage-like SpyCI, which integrates into the 5′ end of the MMR gene *mutL* (Fig. 9A) (52–54). The SpyCIs share integrase modules with related phage-like chromosomal islands from *Streptococcus anginosus*, *Streptococcus canis*, *S. dysgalactiae* subsp. *equisimilis*, *Streptococcus intermedius*, and *Streptococcus parauberis* (Fig. 9B) (52). The DNA replication module is even more widespread among other species, and in addition to the ones named above, is found in related chromosomal islands found in *S. agalactiae*, *S. mitis*, *S. pneumoniae*, *Streptococcus pseudopneumoniae*, *S. suis*, and *S. thermophilus* (52). The remarkable defining characteristic of SpyCIs is how they regulate MMR and the other genes in the operon (major facilitator family efflux pump *lmrP*, Holliday junction resolvase *ruvA*, and base excision repair glycosylase *tag*). The best-studied member of this family, SpyCIM1 from strain SF370, is a dynamic element that excises from the bacterial chromosome during early logarithmic growth and replicates as a circular episome (54). As the bacterial population reaches the end of the logarithmic phase and enters the stationary phase, SpyCIM1 reintegrates into the unique attachment site at the beginning of *mutL* ORF (Fig. 9A, insert). The result of this cycle is that SpyCIM1 acts as a growth-dependent molecular switch to control the expression of MMR, causing SF370 to alternate between a mutator and wild-type phenotype in response to growth: during rapid cell division and DNA replication, the integrity of the genome is maintained by an active MMR system, while during periods of infrequent cell division, mutations may accumulate at a higher rate (53, 54). Preliminary studies suggest that the SpyCIs, which lack identifiable structural genes, may employ a helper prophage for packaging and dissemination in a fashion similar to the well-characterized *S. aureus* pathogenicity islands (106).

More recent studies have shown that SpyCIM1 and related phage-like chromosomal islands also act as global regulators for host genes. The elimination of SpyCIM1 shifted the expression of over 100 bacterial genes involved in virulence and metabolism (107). These shifts in global expression occurred at both the logarithmic and stationary phases, upregulating some genes while repressing the expression of others. Some of the virulence genes with increased expression included the antiphagocytic M protein (*emm1*), streptolysin O (*slo*), capsule operon (*hasABC*), and streptococcal pyrogenic exotoxin (*speB*) (107). Other genes, such as the regulator *ropB*, arginine deiminase, and l-lactate oxidase, were depressed in expression in either early or late logarithmic growth or both. Several uncharacterized SpyCIM1 genes are predicted to encode proteins with helix-turn-helix domains, which could possibly act as DNA regulatory elements to control host genes. Further work will be needed to understand the molecular mechanism of SpyCIM1 as a regulator. Thus, phage-like chromosomal islands in *S. pyogenes* appear not only to mediate a growth-dependent mutator phenotype but also to be global regulators. This remarkable evolutionary adaption may help promote survival of *S. pyogenes* when faced with changing environments.

Prophages as Agents of Genome Plasticity

Our understanding of the role of prophages in shaping the biology of *S. pyogenes* continues to evolve. In *S. pyogenes* and many other bacterial species, symmetric genome rearrangements have been observed, and often these genome rearrangements from *S. pyogenes* patient isolates are associated with invasive infections. A hypervirulent M23 serotype strain, M23ND, was found to have a unique and extensive asymmetric rearrangement in its genome, these rearrangements being mediated by competence genes (rRNA-*comX*), transposons (IS*1239*), and conserved prophage genes (*hylP*) (108, 109). While these rearrangements did not affect genome integrity, some rearrangements did recluster a broad set of CovRS regulated genes to the same leading strands, suggesting a potential selective advantage to *S. pyogenes* by clustering genes for virulence, growth, and/or survival. An approximately 400,000-bp inversion was found to have occurred through shared hyaluronidase genes (*hylP*) between two different genome prophages; this inversion was predicted to prevent normal excision of either prophage due to the spatial disruption of the attachment site sequences. Remarkably, induction with mitomycin C led to reversal of the large inversion, allowing induction of these prophages to the lytic cycle. A subpopulation of survival cells was generated following induction that no longer had the large-scale inversion (108). Thus, genome prophages appear not only to

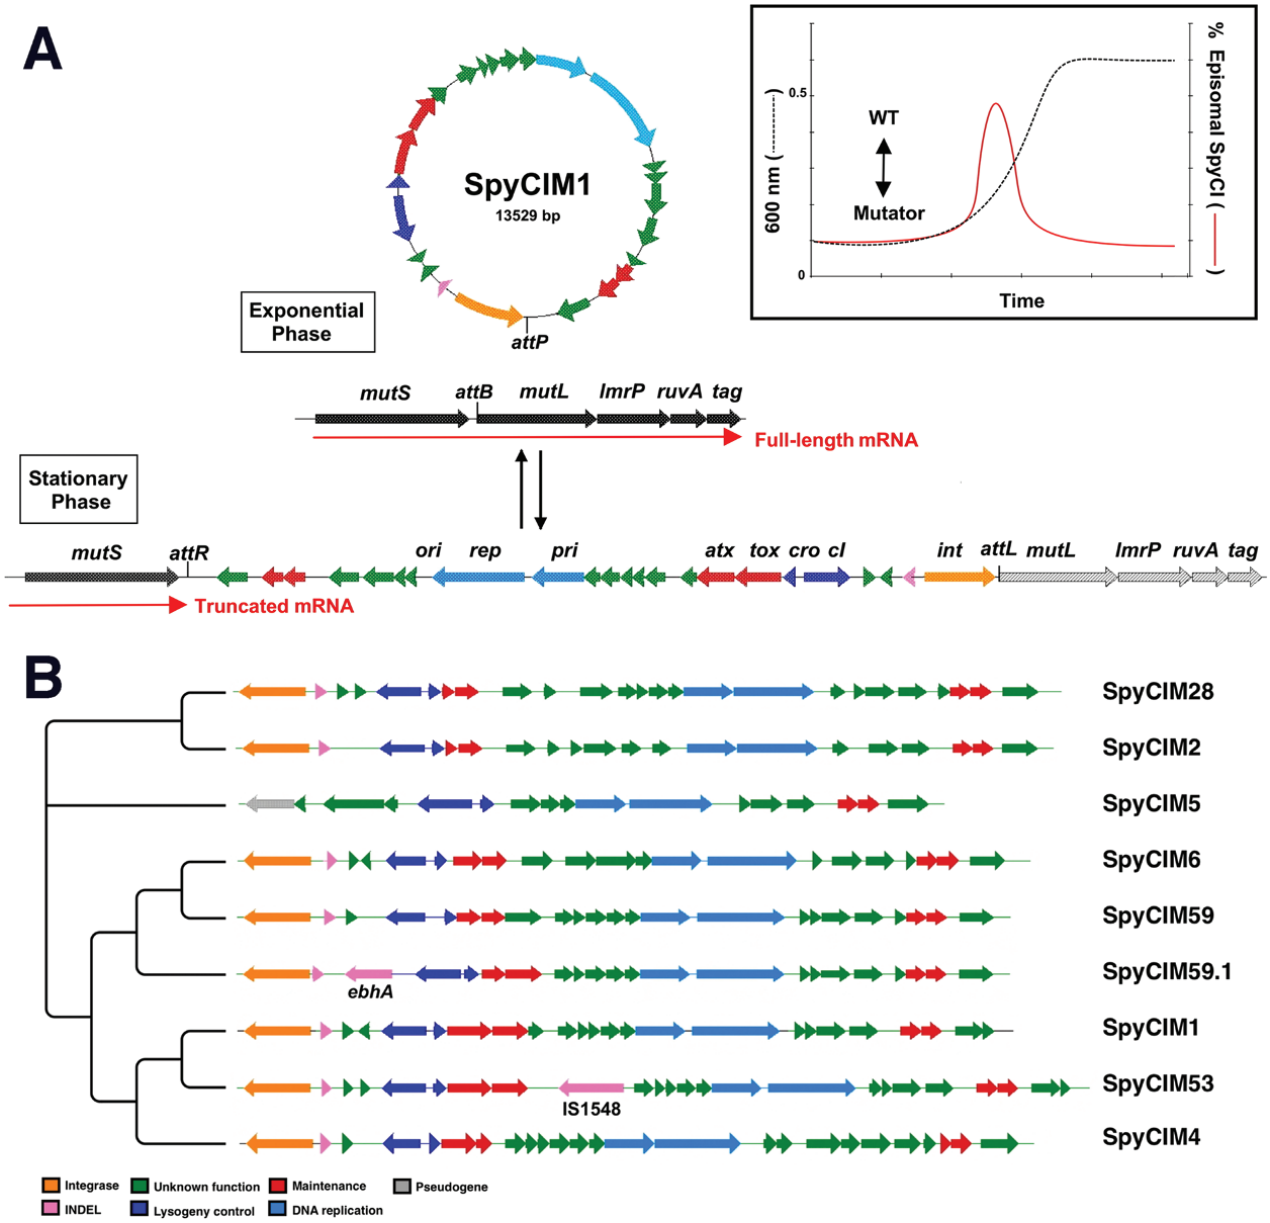

FIGURE 9 (A) SpyCIM1 regulation of the MMR operon through dynamic site-specific excision and integration. The MMR operon of *S. pyogenes* groups the genes encoding DNA MMR (*mutS* and *mutL*), multidrug efflux (*lmrP*), Holliday-junction resolvase (*ruvA*), and base excision repair glycosylase (*tag*). The orientation of this chromosomal region is shown here from the lagging strand to emphasize the MMR operon transcription. During exponential phase, SpyCIM1 excises from the chromosome, circularizes, and replicates as an episome, restoring transcription of the entire DNA MMR operon (WT). Excision and mobilization occur early in logarithmic growth in response to as yet unknown cellular signals (insert; adapted from Scott et al. [53]). As logarithmic growth continues, SpyCIM1 reintegrates into *mutL* at *attB*, and by the time the culture reaches the stationary phase, the integration process has completed, again blocking transcription of the MMR operon. WT, wild-type phenotype associated with unimpeded expression of the MMR operon. Reproduced from *Frontiers in Microbiology* (52) under the Creative Commons Attribution License (CC-BY 4.0). (B) The phylogenetic tree of the SpyCI DNA sequences is presented. The tree was created with TreeGraph 2 (111) using previously analyzed data (52).

improve the fitness of their host cell through the carriage of virulence genes, but also to play a role in genome plasticity.

CONCLUSIONS

The association of *S. pyogenes* with its bacteriophages is a major factor in the biology of this human pathogen, influencing the distribution of virulence genes, the spread of antibiotic resistance, the horizontal transfer of host genes, and the population distribution of cells. These relationships can range from simple predator-prey models to complex symbiotic associations and genome plasticity that promote the evolutionary success of both cell and phage. Further, in prophages the choice of integration site into the bacterial

Downloaded From Vet-eBooks.com

chromosome may alter the streptococcal genotype through either gene inactivation or replacement of normal promoter elements with phage-encoded ones. The similarity that prophages have to pathogenicity islands can hardly be overlooked, and the range of prophage-mediated characteristics that add to host survival or virulence can be easily predicted to increase as new investigations are reported. Genome sequencing has contributed greatly to our understanding of prophage distribution and genetic composition, and this bank of knowledge has been and will be an important foundation for future biological studies of the interactions of *S. pyogenes* and its phages that will be certain to reveal many novel and perhaps surprising relationships.

Molecular Epidemiology, Ecology, and Evolution of Group A Streptococci

DEBRA E. BESSEN, PIERRE R. SMEESTERS AND BERNARD W. BEALL

12

ECOLOGY: HOST TISSUES AND DISEASES

The group A streptococcus (GAS; *Streptococcus pyogenes*) is a free-living organism. Its ecological niche appears to be quite narrow, and its only known biological host of import is humans. There may be occasional or very rare natural infections in non-human primates and other mammals (1, 2).

The primary sites for GAS colonization of the human host involve two tissues: the oropharyngeal mucosal epithelium of the upper respiratory tract (URT) and the superficial layers of the epidermis. GAS have no known environmental reservoir of significance, and transmission is almost exclusively person to person, via either respiratory droplets or direct contact. Thus, the throat and skin of the human host are the primary habitats for GAS. It is at these two tissue sites that GAS undergo successful reproductive growth and transmission of progeny to new hosts (Fig. 1).

Streptococcal pharyngitis and impetigo are superficial, self-limiting infections that usually cause a mild illness that resolves within 2 weeks, even if left untreated. Both are primarily diseases of childhood. Once colonization is established at the URT, the organism can cause a symptomatic pharyngitis, with or without tonsillitis. Symptomatic infection caused by GAS is typically characterized by a copious purulent exudate. Oropharyngeal infection can be cleared via a protective antibody that is produced by the host in response to infection. Alternatively, a "clinically inapparent" infection can arise wherein the infected individual lacks obvious clinical symptoms of illness, yet a specific immune response is mounted and directed to antigens of the infecting organism (3).

Another type of GAS-human interaction that can occur at the URT is asymptomatic carriage, where a vigorous host immune response to many/most GAS antigens is lacking (4). The carrier state can persist for weeks or months, and the organism (presumably) remains capable of transmission to a new host. However, relative to acute pharyngitis, the number of organisms present during carriage may be vastly reduced, and GAS are often in an altered dormant-like state signified by a relative lack of M protein expressed on the cell surface. Intracellular invasion of epithelial cells by GAS may contribute to persistent infection (5). Microcolony and biofilm formation, and the bacterial communities that arise, may also be a key part of the ecology of the GAS carrier state (6).

At the skin, GAS survive and replicate below the dry cornified layer, provoking a strong inflammatory response that gives rise to the purulent lesions of nonbullous impetigo, a form of pyoderma. Recovery of GAS from normal skin can precede impetigo by ~10 days (7, 8). However, it is not entirely clear whether there exists stable GAS colonization and/or a true long-term carrier state at the skin; uncertainty stems from the duration of GAS association with normal human skin in the absence of inflammation (i.e., disease), which may be transient (9). Breaks in the stratum corneum, which can be quite minor and barely noticeable, are a requirement for GAS to establish a firm foothold at this tissue site and cause disease. The scabies mite infests the epidermal layer just below the stratum corneum; scabies can cause intense itching and is a key risk factor in the development of GAS impetigo in many tropical communities (10–12). Also, it is not uncommon for *Staphylococcus aureus* to be a co-pathogen along with GAS in impetiginous skin lesions (13, 14). At least some strains of GAS that cause impetigo can subsequently spread from skin lesions to colonize the URT, peaking at 2 to 3 weeks post-skin infection (7, 8) (Fig. 1).

The relative incidence of GAS disease varies throughout the world in accordance with both season and locale. In the temperate regions of North America and Europe, pharyngitis is highly prevalent during the cold winter months, whereas impetigo thrives during warm, humid weather and is far less prevalent. In many tropical regions, such as the Northern Territory of Australia, GAS impetigo is far more common than pharyngeal infection among the indigenous population, and there are no discrete seasonal peaks in the incidence of disease (10). Climate and the level of hygiene strongly influence the prevalence of impetigo, whereas indoor crowding is a major risk factor for URT infection. These risk factors largely reflect the primary modes of transmission.

Worldwide there are an estimated >616 million cases of GAS pharyngitis per year (15), and >162 million cases of impetigo at any given time (16). In a study conducted ~40 years ago in the United States, for children between the ages of 5 and 7 years, it was estimated that an average of half experience one GAS infection annually (17). During the peak season, asymptomatic carriage rates at the URT range from (very) roughly 15 to 20% or higher; this value depends on the exact cohort (18). Bacteria tend to attain high numbers and densities during purulent infection. Large bacterial

Downloaded From Vet-eBooks.com

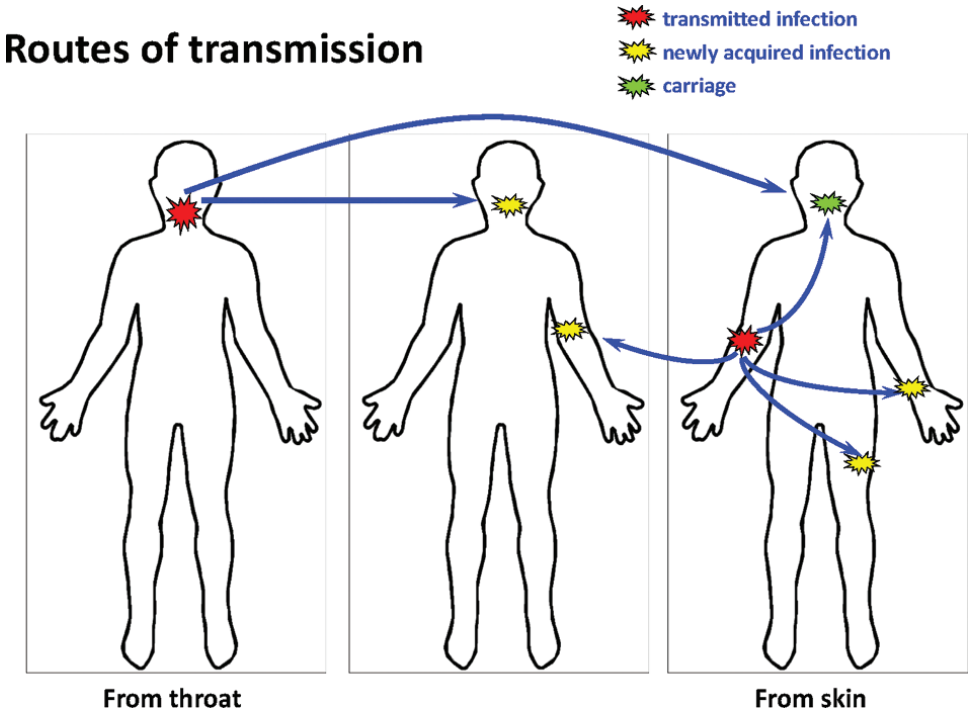

FIGURE 1 Transmission routes for GAS. From the throat, GAS can transmit via the respiratory route to a new host, where it either causes pharyngitis or persists in a quiescent carrier state. In a carrier state, the organism is presumed to be only weakly transmissible. Transmission from the throat to skin is relatively rare. From an impetiginous skin lesion, the organism can be transmitted by direct contact to the slightly damaged skin of a new host or to other damaged skin sites on the same host, causing multiple skin lesions. GAS can also be transmitted from a skin lesion to the throat of the same host, but it is widely assumed to enter a carrier state and is only weakly transmissible. From either the throat or skin, the organism can invade normally sterile deeper tissue, but this is rare relative to superficial infections.

counts yield large infective doses, which in turn can lead to the exposure of several susceptible hosts with the minimum infective dose, thereby augmenting transmission and spread.

A primary reason why GAS is a major public health problem is because of its ability to cause invasive (iGAS) disease and trigger nonsuppurative (i.e., non-pus-forming) sequelae. The latter diseases are of an autoimmune (acute rheumatic fever [ARF]) or immune complex (acute glomerulonephritis) nature. Collectively, the severe GAS diseases are responsible for >500,000 deaths each year (15).

In iGAS disease, bacteria gain access to deep tissue that is normally sterile. Consistent with pharyngitis providing the major GAS reservoir in temperate regions, iGAS disease is also more prevalent in these regions during the winter months (19). Intracellular invasion or paracellular transport of GAS at the URT may facilitate its access to the bloodstream. iGAS infection can be particularly severe in cases of necrotizing fasciitis and toxic shock syndrome. Although iGAS disease is associated with elevated rates of morbidity and mortality, its frequency of occurrence is relatively low. Population-based surveys of iGAS disease over the past 2 decades estimate the annual incidence at ~3 to 4 per 100,000 people per year in the United States and Europe, although more recently, the incidence of iGAS disease in the United States has increased to ~5 per 100,000 people per year (20); worldwide, there are an estimated 663,000 new iGAS cases per year (15). Thus, the overall incidence of iGAS disease is ~1,000-fold lower than the incidence of new pharyngitis and impetigo infections. Invasion of normally sterile tissue is often a result of "bacteremia without focus." When a lack of evidence for a superficial infection is coupled to GAS growth being largely restricted to deep tissue, and the patient is sequestered and nonambulatory, iGAS disease becomes a transmission dead end for the infecting bacterium.

From the ecological perspective of long-term evolution, GAS fitness is largely shaped by adaptations to its primary tissue reservoirs; acquisition of traits that enhance fitness in iGAS disease is probably coincidental. In North America, the composition of the iGAS strain population largely overlaps with the population of GAS strains recovered from superficial (pharyngitis) infections (21), although a few strains appear to have invasive indices at the more extreme high or low ends (22).

Cutaneous wound infections can be considered a mild form of iGAS disease, wherein the histopathology is distinct from nonbullous impetigo. Depending on the study, wound infections are occasionally classified under the broader umbrellas of "pyoderma" or "skin lesions." Ecthyma is a severe form of impetigo with extensive dermis involvement. Impetigo largely afflicts younger children and is mostly prevalent in communities with a warm humid climate (tropics, summer), whereas in contrast, GAS wound infections occur in all age groups and in all geographic regions, including those where URT disease predominates.

Transmission of GAS leading to cutaneous wound infections can occur from one tissue to another site within an individual (e.g., URT → broken skin), through shared skin-penetrating devices (e.g., needles), and possibly by direct

Downloaded From Vet-eBooks.com

person-to-person contact via open wounds. Skin contact may be an important mode of transmission in a recent GAS outbreak among adults that include intravenous drug users (IVDUs) and homeless people in a temperate zone (23, 24).

ECOLOGY: TRANSMISSION

The superficial nature of pharyngitis and impetigo provides GAS with an easy exit from infected hosts and an easy entrance into new hosts. Transmission is strongly influenced by the GAS agent and human host, coupled with both microenvironmental and macroenvironmental factors. The dynamics of both the GAS and human host populations largely dictate the scope of GAS disease outbreaks and epidemics.

Macroenvironment Risk Factors

As discussed above ("Ecology: Host Tissues and Diseases"), the primary environmental risk factors for GAS pharyngitis and impetigo are cold winters and tropical conditions, respectively. Copathogens that may elevate the risk for GAS infection include the scabies mite and *S. aureus* for impetigo and, possibly, undefined infectious agents for pharyngitis.

GAS-Microenvironment Factors

The microenvironments at the throat and skin differ from one another in numerous ways. Also, each tissue undergoes fluctuations in local conditions as a GAS infection evolves. To initiate infection, the GAS organism needs to be reasonably well adapted to the local tissue microenvironment. Distinctions between classic throat and skin strains of GAS (see "Epidemiology: Global Trends" below) are probably rooted, at least in part, in host tissue-specific adaptations. GAS cell surface components implicated in transmission and/or mediating colonization in a new host include the hyaluronic acid capsule and pili, among numerous other extracellular proteins (25–29). Yet the recent emergence and successful spread of *emm*89 iGAS strains is coupled to a loss in capsule (30, 31) (see "Epidemiology: Building Evolutionary Models" below). Conceivably, GAS transmission factors are strain specific.

At the URT, GAS initially encounter saliva and mucus secretions that contain mucins, secretory IgA, digestive enzymes, and antimicrobial peptides. At the broken surface just below the cornified layer of the skin, GAS face the early stages of wound healing: an inflammatory response in the epidermis is characterized by infiltration of low numbers of polymorphonuclear leukocytes and small amounts of plasma containing Igs and complement, plus antimicrobial peptides. As the infection evolves, the bacteria deploy virulence factors that are able to thwart host defenses, allowing GAS to undergo a net increase in growth, with a concomitant increase in infiltration by inflammatory cells leading to the accumulation of a purulent exudate (32).

Competition with normal flora is a key determinant of GAS colonization at the URT. In general terms, competition can be stiffest between highly related organisms. The closest genetic relative of GAS/*S. pyogenes* that is also a common human URT colonizer is *Streptococcus dysgalactiae* subspecies *equisimilis* (SDSE). SDSE usually have cell wall-associated group C or G group carbohydrate and are largely restricted to humans, with >60% genome sequence homology to *S. pyogenes* (33, 34). A few uncommon lineages of SDSE have group A (CHO-A) or group L carbohydrate (thus, the term "GAS" is largely equivalent to "*S. pyogenes*," and in this report, the two terms are completely equivalent unless otherwise noted). Recently, a widely disseminated and long-standing iGAS lineage of SDSE was described that appears to have arisen from a recombination event involving CHO-A biosynthesis genes from *S. pyogenes* (35).

SDSE bacteria are largely commensals of the oropharynx but are capable of causing many of the diseases attributed to *S. pyogenes* (36, 37). Like its close cousin, SDSE expresses capsules composed of hyaluronic acid, cell surface proteins that include M protein and T-antigens, and exotoxins such as streptolysin O; however, SDSE lacks some critical *S. pyogenes* virulence factors, such as the secreted cysteine proteinase SpeB. Besides the potential sharing of human host receptors for adherence to the epithelium, relatively little is known about how these two species—GAS and SDSE—compete for nutrients and other critical resources (38). Signaling between GAS, SDSE, and other streptococcal species has been demonstrated (39), and GAS are susceptible to killing by bacteriocins produced by other streptococcal species (40). Much remains to be uncovered regarding the role of the microbiome in shaping the success of GAS in colonizing and/or causing infection at the URT.

GAS physiology is heavily influenced by the nature and concentration of carbon sources (e.g., glucose), oxygen, and its toxic byproducts, among numerous other factors present in different tissues under shifting conditions (41, 42). Changes in the local microenvironment, coupled with increased bacterial density and nutrient depletion as the organisms reproduce and yield new progeny, impact the transcriptional program of the GAS cell, which in turn directs activation or repression of numerous genes associated with pathogenesis, and presumably transmissibility as well (43).

Acquisition of GAS at the URT does not necessarily lead to an infection, and in the asymptomatic carrier state, the local microenvironment is substantially different from the purulent environs. In the carrier state, virulence factor gene expression and the requirements for adaptation appear to be quite different (e.g., 44, 45).

Human (Host) Factors

In general terms, successful transmission of a pathogen depends on the availability of susceptible hosts, as well as the ratio of susceptible to resistant hosts in the context of the number of person contacts and potential exposures (46). Host genetic susceptibility (or resistance) to superficial GAS infections has not been characterized, and evidence for its existence is largely lacking.

Highly efficacious immunological protection against GAS infection is strain specific (i.e., M type-specific) (47), although a host immune response directed toward numerous other antigenic targets can confer at least partial protection (48, 49). Herd immunity is probably a critical host determinant for circumscribing the degree to which a given GAS strain can successfully transmit and spread within a human population. Thus, the possibility of future immunization with an M type-based vaccine is likely to reshape the composition of the GAS strain population (see "Epidemiology: Strategies for M Protein-Based Vaccines" below).

GAS (Agent) Factors

A key open question is whether GAS engage in a form of evolutionary bet-hedging via transmitting a bolus of organisms with a diverse array of transcriptional profiles, to increase the odds that at least one physiological form will colonize and thrive within an individual host. Alternatively, perhaps there exists a singular transcriptional profile that is

Downloaded From Vet-eBooks.com

deemed optimal for transmission within the wider human host population. Or perhaps a mixture of both strategies is used. Mutations in transcriptional regulatory genes and/or promoter regions may enhance the transmissibility of GAS (see "Evolution: Short Term" below).

GAS exhibit very high diversity in their cell surface proteins, in terms of both the presence or absence of a given protein, and in the sequence heterogeneity among products of the same locus. Several of the heterologous cell surface proteins may impart tissue-specific adaptations (reviewed in reference 50, 51). They also serve as key epidemiological markers (see next section). Genetic changes that lead to alterations in the antigenic composition of the GAS cell surface may aid the organism in escaping herd immunity.

EPIDEMIOLOGY: MOLECULAR MARKERS

The use of serological typing to categorize the pathogens of the *Streptococcus* genus (i.e., cell wall group carbohydrate), as well as the strains within a pathogenic streptococcal species, has a long and deep history. Unlike pneumococci, GAS lack a structurally diverse and immunogenic polysaccharide capsule. Instead, GAS express several cell surface proteins which collectively impart a broad repertoire of antigenic diversity. Underlying the serological phenotype is an extensive history of horizontal gene transfer (HGT) and recombination among the cell surface protein genes, plus accumulated point mutations, that has been shaped (at least in part) by the strong diversifying selection pressures of the host immune response. The antigenic structure of GAS cell surface proteins, and the underlying genotype of both the cell surface protein and core housekeeping genes, is highly complex.

Numerous typing schemes have been used to aid in understanding the epidemiology and underlying organization of the *S. pyogenes* species. A summary of typing (and related) schemes, and their applications and limitations, is provided in Table 1. Each epidemiological molecular marker is discussed in detail below.

M Protein

During the 1920s, work began that aimed at understanding the basis for protective immunity to GAS infection. Antibodies raised to extractable surface antigens, called M proteins, led to opsonophagocytosis of the strain from which the M protein was derived (52). However, antibody directed to the M protein of one organism often failed to confer protection against many other GAS isolates tested. A serological typing scheme arose through the development of antibodies directed to M proteins of different isolates. More than 80 distinct M types were identified, and protective immunity to GAS infection is, in large part, M type specific.

Copurifying with the M type-specific material was M-associated protein (MAP), which has two major antigenic forms (53, 54). The MAP I antigen was largely associated with ARF isolates, and MAP II was highly prevalent among serum opacity factor (SOF)-producing organisms. The MAP antigens were subsequently identified as part of the conserved C repeat region (CRR) of M protein (55), which occupies the COOH-terminal half of the surface-exposed portion of M protein. The CRR has two major antigenic forms known as class I and class II (56). The structure of M protein is depicted in Fig. 2A.

emm types

A nucleotide sequence-based *emm* typing scheme that closely parallels the M serotype scheme was developed ~2 decades ago (57). *emm* typing is based on the extensive nucleotide sequence differences at the 5′ end of the *emm* gene, whereby a unique *emm* type is defined as having <92% nucleotide identity to any other *emm* type, over the sequence corresponding to the first 30 codons of the mature M protein (Fig. 2A). Virtually all contemporary epidemiological studies define GAS isolates according to their *emm* type. Currently, there are ~243 recognized *emm* types (58).

Identification of the *emm* gene is not always obvious, and the problem can be due to paralogous *emm*-like genes mapping immediately upstream (*mrp*) or downstream (*enn*) of *emm* in numerous GAS strains (see next section; Fig. 2B). Confusion about *emm* type assignments has arisen wherein *enn* is directly fused to the 5′ end region of *emm* as the result of DNA excision arising from recombination between the *emm* and *enn* genes.

Among the ~243 *emm* types recognized to date, there are ~1,632 distinct allelic forms of the *emm* type-specific region, known as *emm* subtypes (58). The *emm* subtype alleles are based on sequence differences relative to the typing reference, within a 180-bp segment corresponding to the last 10 codons of the predicted signal peptide coding region and the first 50 codons corresponding to the NH_2-terminus of the mature M protein molecule (59).

emm patterns

Many strains of GAS have *emm*-like genes (*mrp*, *enn*) positioned immediately upstream and/or downstream of *emm* on the chromosome (60–63). Near the 3′ end of each *emm* and *emm*-like gene lies a region that encodes one of four divergent cell wall-spanning domains that can be distinguished by oligonucleotides (60, 64). Using a PCR-based mapping approach, the content of *emm* and *emm*-like genes and their arrangement on the chromosome was determined for GAS isolates of many different *emm* types. The resulting *emm* region maps are referred to as "*emm* patterns"; three major *emm* pattern groupings are recognized (Fig. 2B). M proteins of *emm* pattern E tend to be class II, whereas the *emm* patterns A-C and D groupings largely overlap with the class I CRR (60).

To date, the *emm* pattern genotype has been ascertained for GAS isolates of 170 of the ~243 recognized *emm* types (Table 2). With only two exceptions uncovered thus far (*emm54*, *emm218*), multiple isolates sharing the same *emm* type also share the same *emm* pattern grouping. The majority of *emm* types are represented by *emm* pattern groups D and E, accounting for >75% of the *emm* types analyzed.

emm clades and clusters

An *emm* cluster typing system was recently developed, based on the entire surface-exposed portion of M protein and its capacity to bind six human serum proteins (65). Phylogenetic analysis of >1,000 *emm* genes corresponding to 174 *emm* types reveals 2 main clades (X and Y), and 16 well-supported clusters, accounting for 82% of the *emm* types analyzed. The relationships between *emm* clades, clusters, and patterns for 174 *emm* types are illustrated in Table 3. Nearly all pattern E *emm* types (98%) belong to clade X, whereas 92% of pattern A-C *emm* types are clade Y.

In contrast to patterns A-C and E *emm* types, the pattern D *emm* types are present in both clades X and Y (Table 3) (65). The highly specialized plasminogen-binding *emm* cluster D4 of clade Y represents the largest *emm* pattern D grouping (n = 30 *emm* types). Within clade X, *emm* clusters E5 and E6 constitute a second group of pattern D *emm* types (n = 14); these two clusters include *emm* types of other pattern groups as well. Most of the remaining pattern D *emm*

Downloaded From Vet-eBooks.com

TABLE 1 Epidemiological typing methods for group A streptococci[a]

Scheme	Description of method	Applications	Limitations
M serotyping	Immunoprecipitation, using hyperimmune rabbit antisera	No longer in wide use	
emm typing	Sequencing, yielding >92% nt identity over the first 90 bases encoding the processed (mature) M protein of an *emm* type reference strain	Most commonly used typing method; highly reproducible; low cost; large database at CDC; can be used to infer *emm* clusters and *emm* pattern groups with reasonable accuracy	Based on oligonucleotide primers (via PCR); needs better integration with whole-genome sequencing projects
emm subtyping	Sequencing of 180 nt corresponding to the 10 COOH-terminal codons of the signal sequence and first 50 codons of the mature M protein	Further stratifies *emm* types into unique alleles; performed in parallel with *emm* typing; large database and BLAST server are maintained at the CDC	
emm pattern grouping	PCR-based mapping, based on 3′ ends of *emm* and *emm*-like genes	Assignment of organisms of known *emm* types into groupings that correspond reasonably well to tissue site preferences for superficial infection at the throat and/or skin	Inferences based on *emm* type may occasionally be incorrect; ~30% of *emm* types await *emm* pattern assignment; PCR-based mapping is laborious and limited by design of "universal" oligonucleotides
emm cluster typing	Based on phylogeny and four bioinformatic criteria, related to surface-exposed portion of M proteins; corresponds to binding by several human serum proteins	Used to extend information on *emm* typing; can be easily inferred from *emm* type; binding motifs can be used to infer binding properties of M proteins	Inferences based on *emm* type may occasionally be incorrect; ~29% of *emm* types await *emm* cluster assignment
SOF typing	Inhibition of the serum opacity reaction by hyperimmune rabbit serum	No longer in wide use	
sof typing	Sequencing of ~700 bp region near 5′ end of *sof*	Data can be generated though sequencing of PCR products or whole-genome sequencing	*sof* type assignment needs to undergo standardization; evidence for extensive recombination within the *sof* type region
T serotype	Bacterial cell agglutination, using hyperimmune rabbit antisera	In limited use by specialized laboratories, to supplement *emm* typing	Inconsistent results; labor-intensive; hyperimmune serum is limited and difficult to standardize
FCT region typing	PCR-based mapping; whole genome sequence	Can be used as an initial step in further characterization of pilin genes	Assignment of the FCT region needs to undergo further definition and standardization
FCT gene typing	Sequenced-based		Under development for all pilin subunit and adhesin genes
MLST	Nucleotide sequence of seven (partial) housekeeping genes, from PCR products or whole-genome sequences	Used to define "clones" (i.e., STs) and clonal complexes (i.e., CCs); often coupled with *emm* type; alleles are assigned via simple web-based user queries and curation; database of alleles, STs, and isolates is maintained on PubMLST server (Oxford)	Provides only a small snapshot of the core genome; isolate database is skewed toward unique genotypes (i.e., not population-based)
Whole-genome sequencing	Complete or partial genome assembly	Phylogenetic relationships of closely related organisms via the core genome sequence; investigations of local outbreaks and widespread epidemics; routine surveillance; pipelines for analysis of typing and antibiotic resistance genes	Core genome definition lacks standardization for the diverse range of strains in the species; assembly problems in regions of extensive sequence diversity and/or recombination; bioinformatic analysis can be time-consuming

[a]nt, nucleotide.

types are interspersed throughout clade Y (n = 16). Overall, the *emm* cluster scheme, based on the phylogeny of the entire surface-exposed portion of M protein, is highly consistent with the *emm* pattern scheme that is based on the COOH-terminal peptidoglycan-spanning domain of *emm* and *emm*-like flanking genes.

The *emm* cluster typing system is easy to implement since the *emm* cluster can be inferred from the *emm* type (66–69). Importantly, the *emm* type → *emm* cluster scheme is also highly informative of the functional capacity of the M protein molecule, based on consensus binding motifs for numerous human host plasma proteins (65).

Downloaded From Vet-eBooks.com

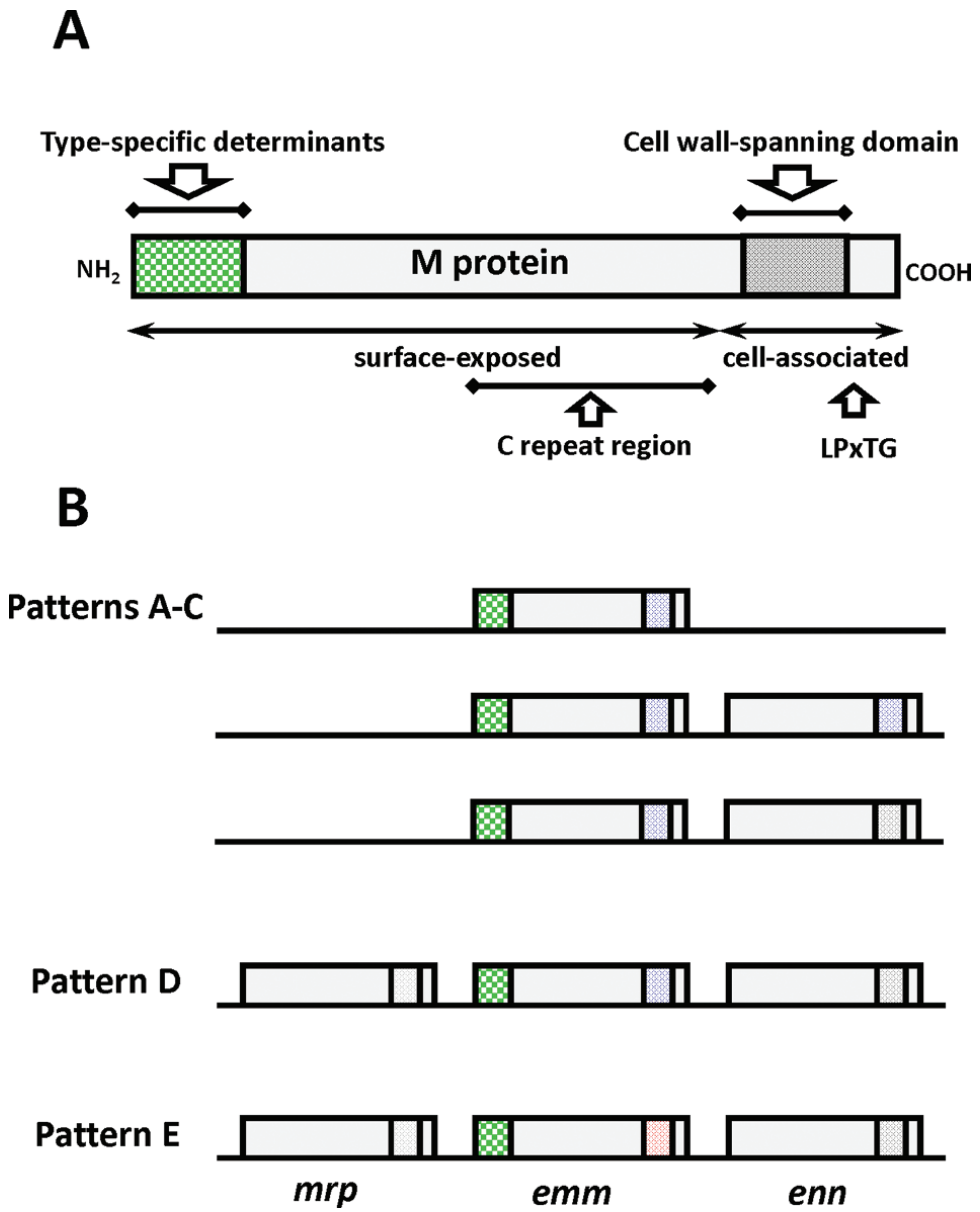

FIGURE 2 M protein structure and *emm* pattern gene arrangements. (A) Key features of M protein are shown, including the type-specific determinants, cell wall-spanning domain, and C repeat region. (B) Chromosomal arrangement of *emm* and the flanking *emm*-like genes (*mrp*, *enn*) gives rise to five *emm* patterns, which form three main groupings (A-C, D, E). Transcription of *emm* and *emm*-like genes is positively regulated by Mga, which is encoded by *mga*, which lies immediately upstream of the *emm* region.

M protein functional domains

As summarized in recent reviews (63, 70), the surface-exposed non-type-specific portion of M proteins (i.e., central region) contains functional domains that bind human host proteins such as IgG (various subclasses), IgA, plasminogen, and fibrinogen. The M type-specific determinants at the NH_2-terminus bind two complement regulators, C4b-binding protein (C4BP) and factor H-like 1.

Binding capacities strongly correlate with *emm* cluster (65). For example, binding of human IgG is mostly restricted to M proteins of *emm* clusters E1 through E6. Similarly, binding of C4BP is limited to M proteins of *emm* clusters E1, E3, E4, and E6. IgA binding is evident only in *emm* clusters E1, E4, and E6 products, whereas fibrinogen binding is restricted to M proteins of clade Y, and plasminogen binding is restricted *emm* cluster D4 (51, 65).

Although much less is known about the M-like proteins Mrp and Enn (Fig. 2B), binding properties shared with M protein have been described (reviewed in reference 63), and in some instances, they may use similar binding motifs. Additional investigation of the structure and functional binding properties of the M-like proteins, and structure of the *mrp* and

Downloaded From Vet-eBooks.com

TABLE 2 Distribution of *emm* types among *emm* pattern groups for 170 *emm* types.

emm pattern group	No. of *emm* types represented	% of total
A–C	35	20.6
D	64	37.6
E	67	39.4
Rearranged (REA)	2	1.2
A–C and D	2	1.2

enn genes, may eventually lead to a higher-resolution typing scheme that includes the entirety of the *emm* chromosomal region.

Serum Opacity Factor

SOF promotes the opacification of serum, wherein the serum opacity reaction can be neutralized by hyperimmune antiserum produced in animals (71). Not all GAS strains produce SOF, but SOF typing was often used as an adjunct for strains that posed challenges for M typing. Of note, SOF producers have a strong association with strains that harbor the MAP II antigen (72). In addition, SOF-producing strains tend to exhibit diminished beta-hemolysis (73).

More recent studies show SOF to be a proteinaceous virulence factor that is either bound to the GAS cell surface or secreted. SOF has an enzymatic domain that interacts with high-density lipoprotein, leading to the opacification of serum, plus a fibronectin-binding domain (74–77). The genes encoding M protein (*emm*) and SOF (*sof*) map ~15 kb apart on the GAS chromosome; as with *emm* and *emm*-like genes, transcription of *sof* is positively regulated by the Mga regulon (78, 79). *sof* types have been defined based on ~600 to 750 bp positioned near the 5′ end of the *sof* gene (80). However, *sof* typing is far less developed than *emm* typing, and attempts to generate a well-supported phylogeny for the *sof* type-specific determinants have largely failed due to extensive intragenic recombination (81).

The relationships between the presence or absence of SOF activity, or the *sof* gene, and the *emm* pattern and *emm* clade as inferred from the *emm* type, are summarized in Table 4. Based on the strong associations between the MAP II material, class II M proteins, and *emm* pattern E (60), it is not surprising that there are strong correlations between *emm* pattern E and the presence of the *sof* gene and/or a positive serum opacification reaction (50, 80, 82, 83). Exceptions include several *sof*-positive strains within *emm* cluster E6 that are assigned to the *emm* pattern D grouping via PCR-based mapping (*emm59*, *emm81*, *emm85*); *emm12* isolates (pattern A-C) have an inactive *sof* gene. Despite the close genome map positions of *sof* and *emm*, a single *emm* type can be found in association with more than one *sof* type and vice versa (80), indicative of HGT of *emm* or *sof* to new genetic backgrounds and intraspecies recombination within the greater *emm* region.

T-Antigens

T-typing is based on agglutination of trypsin-treated GAS cells with hyperimmune rabbit serum (84, 85). The T-typing antisera is produced by immunization with trypsin-treated GAS cells, followed by adsorption of antisera to undigested GAS cells of different T types; ~22 T types have been serologically defined. The T6 antigen gene (*tee6*) was the first one

[b]The SOF product of *sof12* is typically inactive.

cloned (86) and was subsequently mapped to a region of the GAS genome that had been previously characterized as having genes encoding microbial surface components recognizing adhesive matrix molecules that bind fibronectin and collagen (87–89). The acronym FCT (fibronectin-binding, collagen-binding, T-antigen) is widely used to describe this genome region (87). SDSE isolates also express similar T-antigens (90), as do group B streptococci (91, 92).

T-antigens are equivalent to pili. Within the FCT region lie several genes that contribute to the production of pili whose assembly is mediated by sortases (48) (reviewed in references 93–95). Seven FCT region forms are depicted in Fig. 3 (82, 92); the FCT-3 and FCT-4 regions are associated with the vast majority of *emm* types (82). For the most prevalent FCT region forms (i.e., FCT-1, 3, 4, and 5) found among GAS strains of different *emm* types, the pilin backbone (BP) proteins and many of the ancillary pilin (AP) proteins that act as adhesins display extensive sequence heterogeneity (87, 92, 96).

The relationships between T-typing sera and recombinant pilin proteins has been examined (48, 92, 97). In perhaps the most thorough study to date, using 15 T-typing sera, agglutination of trypsin-treated GAS cells corresponds most closely to reactivity with both the BP and AP1 (presumptive adhesin) subunits by immunoblot (92). For a T3/13/B3264 strain (Alab49; FCT-3), the recombinant AP1

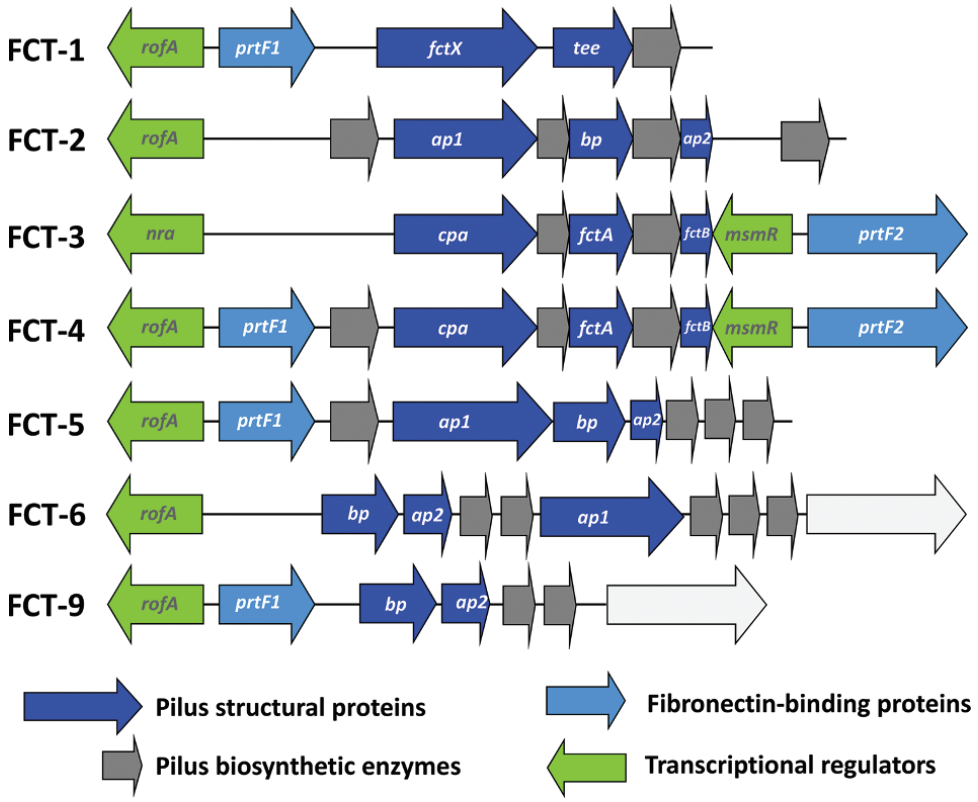

FIGURE 3 Structure of the pilus-encoding FCT region. Seven forms of the FCT region are shown. For pilus structural protein genes: *bp*, *tee*, and *fctA*, backbone pilins; *ap1*, *ap2*, *fctX*, *cpa*, and *fctB*, ancillary pilins. In FCT-2, *ap1*, *bp*, and *ap2* have sequence homology with *cpa*, *fctA*, and *fctB*, respectively, although divergence is high (82). Pilin adhesins include FctX from FCT-1, AP1 from FCT-2, and Cpa from FCT-3 and FCT-4. Pilin subunits that anchor the pilus shaft to the cell wall include AP2 and FctB (249). Fibronectin-binding protein genes include *prtF1* (sometimes designated *sfbI*), *prtF2* (sometimes designated *pfbp*), and possibly others that remain to be classified.

Downloaded From Vet-eBooks.com

subunit (i.e., Cpa) is strongly reactive by immunoblot with each of the anti-T3, anti-T13, and anti-B3264 sera, whereas the BP (i.e., FctA) is bound by anti-T3 sera only (97). However, there is very little amino acid sequence homology between Cpa and FctA, as is also the case for the other adhesin-backbone pilin subunit pairs (82, 98).

That some T-typing sera display immunoreactivity to multiple recombinant pilin proteins seems likely due to incomplete adsorption of the antisera and/or the presence of antigenic epitopes shared among pilin subunits belonging to the variety of GAS strains used for immunization. Possible unmasking of immunological determinants via the trypsin pretreatment used in the cell agglutination assay may further complicate efforts to draw direct connections between T-serotypes and specific pilin protein variant forms. Adding even further complexity to the T-typing scheme are the numerous GAS isolates that agglutinate with multiple T-typing sera, such as T3/13/B3264 or T8/25/Imp19; many other T-serotype combinations (>60 in total) are also observed (83). Overall, the T-typing sera displaying the least cross-reactivity with multiple pilin forms are T2, T4, and T6 (92); these appear to be best represented by the FCT-6, FCT-5, and FCT-1 regions, respectively (Fig. 3), although within these FCT regions lie at least some extensive pilin gene diversity (see, e.g., reference 99 for FCT-1).

T-serotype and M-serotype and/or *emm*-type data for GAS isolates ($n > 20{,}000$) from two large collections (the CDC and the University of Minnesota reference laboratory), recovered in the United States from about the 1980s to the mid-2000s (83), was collated and is summarized in Table 5. There are no strict sampling criteria for this assemblage; it seems reasonable to assume that it largely consists of a combination of isolates causing iGAS disease and strains with high prevalence. In this skewed, non-population-based sample, the dominant T types among *emm* pattern A-C strains are T1, T11 and/or T12, and T3, T13, and/or B3264, reflecting the highly prevalent M/*emm* types M1, M12, and M3, respectively.

T-non-typeable (TNT) GAS probably represent isolates that fail to produce pili; they account for ~9% of total isolates but >20% of *emm* pattern D isolates (Table 5). The relatively large numbers of TNT isolates among pattern D strains may reflect the disproportional presence of *nra* (82); Nra functions as a repressor or activator of pilus gene expression in a strain-dependent manner (88, 100). Nearly 60% of *emm* pattern D isolates are T3, T13, and/or B3264 (Table 5), which appears to be largely represented by the FCT-3 region form (82, 87, 92, 97). The most frequent M/*emm* types among pattern E isolates of this collection are M4 and M28 (83), which largely reflects the dominance of the T4 and/or T28 serotype grouping (Table 5). Several correlations between individual loci within the FCT region and *emm* pattern and/or *emm* type have been noted (50, 82, 92, 101).

Within an *emm* cluster group, there can be a very wide array of T types (based on Table 5; detailed data not shown) (83). For example, the *emm* cluster E3 isolates (13 *emm* types) are found in association with T5, T27, and/or T44 (28%); TNT (16%); T8, T25, and/or Imp19 (11%); T14 (11%); T9 (9%); T4 and/or T28 (9%); T3, T13, and/or B3264 (6%); and T11 and/or T12 (4%), among others. In contrast, cluster D4 isolates (21 *emm* types, all encoding plasminogen-binding M proteins) are far more homogeneous, with 72% associated with T3, T13, and/or B3264 (another 16% are TNT). Although *emm* genes within a cluster are more closely related to each another than to *emm* of other clusters, the extent to which surface pili contribute to the overall antigenic cell surface repertoire appears to vary widely by cluster.

For GAS sharing the same *emm* type, individual isolates often differ in their T-serotype (80, 83). For example, while a substantial majority of M/*emm* type 4 isolates from the Table 5 study are T4, there are other M/*emm4* isolates that have T types T4/28, T8/25/Imp19, T3/13, and TNT (83) (detailed data not shown). M/*emm4* isolates typically have *sof4*, but there are exceptions here as well (80). The unique combinations of M/*emm*, SOF/*sof*, and T types is indicative of HGT of the epidemiological marker genes among GAS.

Unlike M type-specific antibodies, there is no known human host protective effect mediated via T type-specific serum; this may be a consequence of immunoreactivity directed toward trypsin-treated target antigens that are not encountered during natural infection. However, antiserum

raised to recombinant pilin subunits or intact pili can be protective in experimental assays (48, 102). Shortcomings of the T-typing cell agglutination assay include a general lack of good resolution, the time-consuming process, and the requirement for standardized rabbit serum. Because T-typing sera display high levels of immunological cross-reactivity to different recombinant pilin polypeptides, and many GAS isolates agglutinate with multiple T-typing sera, it can be difficult to predict the FCT region genotype form based solely on the T-agglutination pattern.

At present, there is no single widely recognized genotyping scheme for the FCT region form and pilin genes (35, 82, 92, 96), but the need for one seems quite compelling given the importance of the FCT region in strain diversity as well as virulence.

Multilocus Sequence Typing and Core Housekeeping Genes

The first study to examine the population structure of GAS utilized multilocus enzyme electrophoresis (103). Isolates recovered from cases of severe iGAS disease correspond to several distinct lineages as defined by electrophoretic type. The multilocus enzyme electrophoresis approach was replaced by the more standardized multilocus sequence typing (MLST). For GAS, MLST is based on the nucleotide sequences of seven (partial) core housekeeping genes (104). MLST data are maintained at a user-interactive website (www.pubmlst.org/spyogenes) and currently lists 966 distinct sequence types (STs) (105); numerous investigators from throughout the world have generously contributed to this rich data set. Using goeBURST (106), 133 clonal complexes (CC) as defined by single locus variants (SLVs) have been detected. Figure 4 provides a chromosomal map of the relative positions of the core housekeeping genes and the *emm* and FCT regions.

A given pattern A-C *emm* type has a high tendency to be associated with a single ST or CC (104, 107, 108). However, the relationships between *emm* type and ST are not strict, and *emm* types of pattern groups D and E are often found in association with distant STs (see "Lateral Movement of *emm*" below). These data parallel findings on the complex relationships between M/*emm* types, *sof* types, and T types (80, 83) and, taken together, provide supporting evidence for the HGT of *emm* from one genetic background to another.

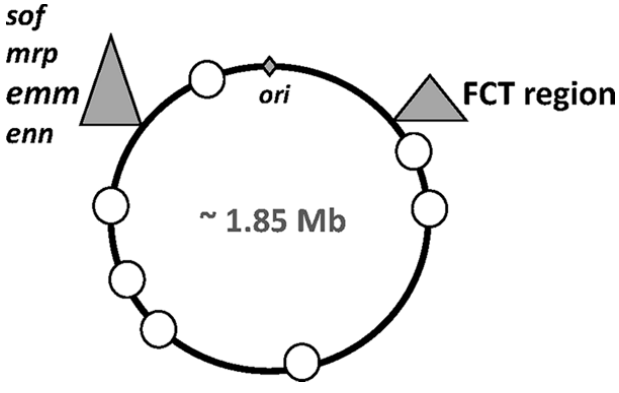

FIGURE 4 Chromosomal map of the epidemiological marker genes of GAS. Open circles represent the seven core housekeeping genes used in MLST (104). The *sof* locus, when present, lies ~15 kb upstream of *emm*. The FCT region, which encodes pilus structural proteins and pilus biosynthetic enzymes plus other adhesins and transcriptional regulators, ranges in size from ~11 to 16 kb. The FCT region lies ~250 to 300 kb from the *emm* region, on the opposite side of the origin of replication (*ori*). GAS genomes range in size from ~1.8 to 1.9 Mb.

Whole-Genome Sequences

The first completely assembled GAS genome was that of an *emm1* isolate (109). In the years that followed, numerous complete GAS genomes were reported for many of the most prevalent *emm* types found in resource-rich nations (updated listings are presented in recent reviews [50, 110]). Via next-generation sequencing technologies, many thousands of genomes of GAS isolates have undergone nucleotide sequence determination (e.g., 24, 30, 111–115). In nearly all studies, core genome sequences are compared for isolates sharing the same *emm* type, and numerous key insights on genetic changes that underlie enhanced transmission and/or virulence have been uncovered. The core genome data can be used to build evolutionary models of outbreaks and epidemics (see "Epidemiology: Building Evolutionary Models" and "Evolution: Short-Term" below).

A core genome MLST has not yet been developed for GAS. Although it is a reasonable concept for some bacterial species, its utility for GAS would probably be rather limited due to the ultrafine resolution this approach would provide for GAS, coupled with the extensive genetic recombination that characterizes this species. Core genome-based phylogenies of GAS of different *emm* types and/or CCs tend to yield lineages with deep branches, indicative of large genetic distances (50, 110, 111, 116).

The use of genome sequence data for surveillance of GAS has begun (35, 117–120). The CDC recently implemented a whole-genome sequence-based typing scheme for population-based iGAS strain surveillance conducted through the Active Bacterial Core program (35). For large-scale strain surveillance, the ability to obtain detailed information on typing and resistance features within a single output, from a single raw data input source, has largely precluded the need for multiple typing protocols and antibiotic susceptibility testing. The GAS typing pipeline automatically restricts an *emm* type to the sequence linked to *emm* consensus primer 1 (121) to improve accurate identification of *emm* and assigns an *emm* subtype (i.e., allele) as well. Partial sequences of BP genes and *sof* are also captured. In addition to *emm* subtype, the *emm*-like genes and MLST alleles and STs are identified, as is *gacI*, which is specific to CHO-A biosynthesis. Among numerous other genes, antimicrobial resistance determinants are also assessed.

A key feature of genome sequence-based active iGAS surveillance is the capacity to detect temporally and geographically related GAS clusters. For GAS isolates that are nearly identical at the single nucleotide polymorphism (SNP) level, the circumstances of where and when the isolates were recovered can be examined to help establish whether there exist disease clusters that may be well suited for an intervention (e.g., health care facilities, vulnerable patient populations such as the homeless, and IVDUs). Thus, next-generation sequencing coupled with an appropriate bioinformatics pipeline can be used as an autodetection tool to help guide public health interventions.

EPIDEMIOLOGY: GLOBAL TRENDS

Infection at the Epithelium of the Throat and Skin

Past studies show that GAS strains bearing certain M types have a strong tendency to cause pharyngitis but not impetigo.

Downloaded From Vet-eBooks.com

TABLE 6 *emm* pattern assignments for GAS recovered in 29 population-based surveys for pharyngitis or impetigo[a]

Disease association	No. of studies	Mean average % pattern A–C	Mean average % pattern D	Mean average % pattern E	Paired t-test[b] (% pattern A–C versus D)	Paired t-test (% pattern A–C versus E)[c]	Paired t-test (% pattern D versus E)
Pharyngitis	23	40.5 ± 19.8	5.8 ± 12.0	53.7 ± 16.0	<0.001	N.S.	n/a
Impetigo	6	9.3 ± 6.7	47.4 ± 8.1	43.4 ± 7.0	<0.001	n/a	N.S.

[a]Based on references 50 and 131. The 29 studies meet the following criteria: (i) isolates are clearly defined for recovery from cases of pharyngitis (or tonsillitis) or impetigo, and (ii) at least 25 isolates can be assigned to an *emm* pattern group based on *emm* type.
[b]Paired t-tests are two-tailed.
[c]N.S., nonsignificant; n/a, not applicable.

Similarly, there are M types often recovered from impetigo skin lesions but rarely from cases of tonsillopharyngitis (8, 122, 123). This observation gave rise to the important concept of classical throat and skin strains that are largely distinct from one another in their epidemiological and disease associations.

There are strong correlations between *emm* pattern groups A-C and D and recovery from cases of pharyngitis versus impetigo, respectively (50, 124, 125). Since the *emm* type is highly predictive of the *emm* pattern group for nearly all *emm* types examined (126, 127), reasonable inferences can be made about *emm* pattern grouping based on knowledge of *emm* types. Such inferences were made on an expanded scale for >5,000 GAS isolates derived from cases of pharyngitis or impetigo in 29 population-based surveillance studies from throughout the world (Table 6). In 23 studies on pharyngitis, *emm* pattern A-C and D isolates constituted a mean average of 41% and 6%, respectively. In six studies of impetigo, the mean average for *emm* pattern A-C and D isolates was reversed, at 9% and 47%. For pharyngitis versus impetigo groups, the difference between the fraction of A-C and D isolates in each surveillance study is highly significant (Table 6). *emm* pattern E isolates account for almost equal fractions of throat and skin infections; the mean average percentage of *emm* pattern E isolates shows no significant difference from pattern A-C isolates at the throat or pattern D isolates at the skin.

Based on the strong clinico-epidemiologic associations, the *emm* pattern A-C strains are designated "throat specialists," whereas the pattern D strains are "skin specialists." As a group, *emm* pattern E strains are considered "generalists." Importantly, the *emm* pattern serves as a useful genotypic marker for the preferred tissue site of infection by GAS (32, 50, 124, 125, 128).

The *emm* cluster typing scheme can also be applied to the 29 population-based surveillance studies on GAS pharyngitis and impetigo (Table 7). Both pharyngitis and impetigo isolates are almost evenly split between clades X and Y, reflected by fractional ratios of percent pharyngitis to percent impetigo approaching 1. However, within clade Y, the distribution of pharyngitis and impetigo isolates are highly skewed among the clusters, with clusters A-C1-5 disproportionately represented by pharyngitis isolates, and clusters D1-5 disproportionately represented by impetigo isolates.

Several predicted binding motifs within M protein strongly correlate with *emm* clusters (65). Based on the 29 population-based surveys, the fractional ratio of pharyngitis to impetigo isolates is highly skewed for the fibrinogen-binding clusters of clade Y (high ratio value, with pharyngitis dominant) and the plasminogen-binding cluster D4 (low ratio value, with impetigo dominant) (51). The differential binding properties for human host proteins, by M proteins in accordance with disease, are potential determinants of tissue tropism. How modulation of the coagulation-fibrinolytic pathways (129) may translate into GAS tissue tropisms is an active line of inquiry.

Invasive Disease

As detailed above ("Ecology: Host Tissues and Diseases"), iGAS disease is extremely rare relative to GAS infection at

the two primary ecological niches. When iGAS disease does occur, it is largely a transmission dead end, with the possible exception of direct contact transmission via open cutaneous wounds among underserved adult populations. Thus, iGAS infections have minimal impact on shaping the long-term evolution of GAS. The occurrence of iGAS disease is strongly affected by host risk factors and to a lesser extent by the genotype of the infecting GAS strain.

In the United States and Europe, most iGAS disease depends on transmission of GAS via a respiratory route (Fig. 1). Whole-genome sequencing of hundreds of GAS isolates has provided important details on genetic changes that enhance transmission and/or invasiveness (see "Evolution: Short-Term" below). The invasive index value provides insight on whether a GAS strain has an inherent ability to better gain access to deep tissue relative to its overall prevalence in the host population (22, 130). The *emm* types associated with iGAS disease have been intensively studied and are well described (e.g., 131–133).

Nonbullous impetigo caused by GAS usually arises in young children in tropical or subtropical climates. GAS can also cause slightly deeper cutaneous infections that are considered "pyoderma," and while they are not considered part of the iGAS disease spectrum, these cutaneous infections are distinct from typical impetigo in terms of patient demographics (i.e., adult, temperate regions) and host risk factors (e.g., IVDU, homeless, military) (23, 24, 134–136). Of interest is the strong association between certain pattern D *emm* types (specifically, *emm59* and *emm81*) and recent infections and outbreaks of deeper cutaneous infections. The *emm59* and *emm81* types are notable for their grouping in cluster E6 and tend to harbor *sof* as well; conceivably, these are "super-specialist" strains containing a hybrid mix of virulence factors that shift the modes of transmission and GAS disease course. Most other GAS-causing skin infection outbreaks among IVDUs are *sof*-positive *emm* pattern E strains (137, 138).

Acute Rheumatic Fever

Acute rheumatic fever (ARF) follows an inadequately treated GAS infection of the URT in a genetically predisposed host by ~3 to 6 weeks and can lead to rheumatic heart disease (RHD) via autoimmune attack of the heart valves (139–143). With >500,000 annual deaths, half attributed to RHD, GAS ranks high among all infectious causes of morbidity and mortality. Recent estimates of the prevalence of RHD are ≥15 to 30 million cases worldwide (15, 144–146); RHD is the leading cause of mortality from acquired heart disease in individuals <50 years old (147) and of all cardiovascular disease in children in resource-poor nations (148). Today, ARF and RHD are largely diseases of poverty, with an occasional resurgence in disease elsewhere (149).

Early epidemiological studies of ARF outbreaks in institutional settings showed that only a subset of GAS strains trigger ARF (11, 55, 140, 150–156). Historically, "rheumatogenic" GAS strains were referred to by their M protein serotypes, with M3, M5, M6, and M18 being highly prevalent. The concept of "nonrheumatogenic" strains is exemplified by the RHD patients of Irvington House during the preantibiotic era, who experienced a GAS outbreak (M type 4) in the absence of recurrent ARF attacks (155). Of ten M types often associated with ARF (M types 1, 3, 5, 6, 14, 18, 19, 24, 27, and 29 [157]), nine are *emm* pattern A-C (one is pattern E); of five relatively common M types that are rarely associated with ARF (M types 2, 4, 12, 22, and 28 [157]), four are *emm* pattern E (one is *emm* pattern A-C) (126, 127).

ARF-associated isolates recovered in Hawaii differ from the classic rheumatogenic *emm* types (158). Atypical *emm* types are also found in tropical Australia, where the prevalence of RHD is among the highest in the world (159). Over time, it has become much less clear which *emm* types are best assigned the "rheumatogenic" label, even though it is widely accepted that not all GAS strains trigger ARF in a genetically susceptible host (150, 155).

The potential role of GAS skin infection in triggering ARF and RHD in certain settings (e.g., noninstitutional, tropical) has been an ongoing debate since the 1960s (160). For example, the indigenous population of Australia suffers from a high incidence of ARF and RHD, yet GAS is far more frequently recovered from impetigo lesions than from the throat. Moreover, the strains recovered from the URT in this host population often belong to the *emm* pattern D skin specialist group or pattern E generalists. The epidemiological co-occurrence of GAS skin infections and RHD supports the idea that impetigo may contribute to this chronic disease. More extensive studies are needed to better understand skin infections and their potential role in ARF and RHD. The possibility that the closely related species SDSE might also trigger episodes of ARF or worsen RHD deserves deeper consideration as well (161, 162).

EPIDEMIOLOGY: DIVERSITY WITHIN HOST COMMUNITIES

Within a human host community over a narrow time frame, numerous GAS strains are in circulation. For the 29 population-based collections of GAS recovered from cases of pharyngitis and impetigo, the number of *emm* types and the Simpsons diversity index was calculated (Table 8). The number of *emm* types for the impetigo collections averaged nearly twice that of the pharyngitis collections ($t < 0.01$, unpaired t-test, 2-tailed). The Simpson's diversity index (D), which incorporates the number of recovered organisms into the calculation, also shows highly significant differences between the impetigo and pharyngitis collections, wherein the impetigo group has a higher mean average D value (a D value of 1 reflects maximal diversity). An analysis that includes all GAS, irrespective of clinical association, also shows fewer numbers of *emm* types accounting for a large proportion of isolates in resource-rich countries, where URT infections tend to predominate (131). The large numbers of circulating *emm* types is likely the consequence of expansive GAS strain migration, even into geographically remote communities (108). The biological basis for the difference in diversity among GAS in host populations experiencing pharyngitis versus impetigo may be tied to the mechanisms for transmission: respiratory droplets versus direct contact. It may be that the respiratory route is more highly efficient, such that a single infected individual can infect many more new hosts (i.e., higher basic reproductive rate), and this in turn leads to dominance by fewer strains, resulting in a lower D value.

EPIDEMIOLOGY: EVOLUTION OF MARKERS (*EMM*)

Although *emm* type diversity within a host community is relatively low for the *emm* pattern A-C throat specialists compared to the pattern D skin specialists (Table 8), there is relatively high diversity among *emm* pattern A-C organisms in terms of the number of *emm* subtypes (i.e., alleles based on the 5′ end of the *emm* gene) that evolved worldwide (Table 9). The average mean number of *emm* subtypes identified for pattern A-C strains is 22.3 subtypes per *emm*

Downloaded From Vet-eBooks.com

TABLE 8 *emm* type diversity within communities for the 29 population-based surveys for pharyngitis and impetigo[a]

Disease association	No. of studies	Mean average no. of *emm* types	Mean average *D* index[b]
Pharyngitis	23	17.4 ± 7.8	0.873 ± 0.065
Impetigo	6	33.8 ± 8.1	0.959 ± 0.012
	Unpaired t-test, 2-tailed	$t = 0.0049$	$t < 0.001$

[b]Simpson's diversity index (*D*) (248) is based on *emm* types.

type, compared to only 4.0 and 6.9 for pattern D and E strains, respectively, based on current data available in the CDC online database (58), which receives numerous deposits from investigators throughout the world.

The >5-fold difference in the number of *emm* subtypes for throat specialists versus skin specialists may be partly due to sampling bias that skews in favor of GAS invasive and pharyngitis isolates in resource-rich nations, such as the highly prevalent *emm1* type (pattern A-C). In addition, the tandem sequence repeats that overlap the *emm* subtype-determining region of *emm5* and *emm6* genes (pattern A-C) are a mutational hotspot due to DNA slipped-strand mispairing (163). However, biological factors such as host immune selection promoting immune escape (164) may also play a role.

Nucleotide sequence alignment of *emm* subtype alleles for each *emm* type-specific region, derived from >500 global GAS isolates ($n = 105$ *emm* types), reveals average ratios of nonsynonymous substitutions per nonsynonymous site (Ka) and synonymous substitutions per synonymous site (Ks) of 4.9, 1.5, and 1.3 for *emm* types of the *emm* pattern A-C, D, and E groups, respectively (107). Thus, diversifying (positive) selection acting on the *emm* type-specific sequence appears to be strongest for *emm* pattern A-C strains.

A likely source of diversifying selection acting on the *emm* type region is the protective host immune response, which can drive immune escape. Conceivably, the immunological pressures at the oropharynx (pattern A-C throat specialists) are more intense than those at the skin (pattern D skin specialists), although an underlying molecular mechanism is

TABLE 9 Relationships between *emm* pattern or cluster and *emm* type and subtype

not presently obvious. Perhaps herd immunity builds up more quickly with a respiratory mode of transmission compared to direct skin contact; as herd immunity builds, the number of susceptible hosts dwindles, leading to more frequent occurrences of immune escape. In further support of a role for herd immunity in shaping the *emm* type content of GAS populations, newly acquired URT infections in older children are skewed toward less common *emm* types, consistent with exposure and protective immunity to the more prevalent *emm* types in early childhood (165).

The collection of M protein types assigned to a single *emm* cluster have high sequence similarity relative to M proteins of other clusters (65). Indeed, an M type-specific region sharing the same cluster as other M types often elicits cross-protective antibodies (see "Epidemiology: Strategies for M Protein-Based Vaccines" below). Ultimately, this cross-protective effect may aid in the design of highly efficacious vaccines that have broad coverage but contain only a limited selection of type-specific epitopes. Whereas 90% of pattern D and E *emm* types belong to 1 of the 16 *emm* clusters, nearly half of pattern A-C *emm* types are standalone and do not cluster with any other *emm* type, highlighting once again a distinct dynamic for the evolution of many pattern A-C *emm* types.

Another possible factor at play in shaping the evolution of *emm* type-specific sequences is functional constraints, such as those imposed by binding C4BP via the type-specific region of numerous M proteins (166–168). Whole GAS organisms that bind C4BP tend to harbor M types associated with *emm* pattern groups D and E (167). Thus, there may be limits to diversification within M proteins that bind C4BP for the GAS strains that utilize this virulence strategy to enhance survival. Also, potentially related to selection pressures acting on GAS is the finding that engineered mutants with *emm* gene deletions have a (near) complete loss in the antiphagocytic effect for pattern A-C strains, whereas the loss is only partial for pattern D and E strains (169).

Overall, the throat specialists are characterized by fewer distinct *emm* types within a human host community but high diversification worldwide within the type-specific region (i.e., more *emm* subtypes). The skin specialists have about twice the number of *emm* types within a community, but diversification within the type-specific region is ~5-fold lower based on the number of *emm* subtypes or Ka/Ks ratios. The *emm* pattern E generalists are most similar to the skin specialists in these values.

The "*emm* type" and "*emm* cluster" definitions are categorical, and the noted differences between throat and skin specialists may partly reflect the placement of the categorical "cutoff" value along a continuum of sequence divergence. Factors that shape the GAS population structure, as defined by *emm* type, likely include the route of transmission, environmental risk factors, the host immune response, tissue-specific host factors, binding functions of M protein, and intrinsic GAS factors that influence mechanisms for genetic change.

EPIDEMIOLOGY: STRATEGIES FOR M PROTEIN-BASED VACCINES

Numerous vaccine strategies for protection against GAS infections were recently reviewed (170–172). Briefly, vaccine strategies can be divided into M protein and non-M protein target antigens, with the latter including streptolysin O, C5a peptidase, CHO-A, pili, and the enzyme arginine deiminase (102, 173–178). However, only the vaccine candidates that incorporate M protein as the target antigen have attained human clinical trial status (179).

M protein vaccines based on the conserved antigens of the CRR (Fig. 2A) have undergone extensive investigation (49, 180–185). Since all M proteins have a CRR, a CRR-based vaccine has the theoretical advantage of providing broad coverage against all GAS strains; several formulations are currently, or will soon be, in clinical trials. Potential drawbacks of a CRR-based vaccine include immune escape. The CRR region of M protein, which includes MAP I/II and the class I/II antigenic epitopes, is not 100% conserved. For example, among 175 *emm* types from a worldwide strain collection, there are 22 alleles of the CRR-based J8 vaccine candidate (65). Importantly, some of the amino acid residues within the CRR of the M protein display signatures of diversifying selection. Immune escape is a possibility for any vaccine target, and current knowledge indicates that it deserves careful consideration for a CRR-based vaccine.

The second category of M protein-based vaccine candidates targets the NH_2-terminal type-specific determinants (179, 186). Pioneering work in the 1940s and 1950s showed that type-specific serum is responsible for protective immunity against the homologous *emm* type (187–190); in contrast, minimal to no protective effects were observed for infection by heterologous GAS types. A 26-valent M type-specific recombinant polypeptide vaccine is the only GAS vaccine to have reached phase II clinical trials, whereupon it was found to be safe and highly immunogenic (179). The "type-specific protection" paradigm of GAS immunity has led to concerns about the potential for low coverage by the multivalent vaccine, especially in tropical settings, where the number of GAS *emm* types can be very high (131, 191–195).

Recent data indicate that cross-protective immunity between closely related *emm* types can induce broader protection via multivalent vaccines than type-specific immunity might otherwise predict. An initial hypothesis on cross-protective immunity was raised following genetic analysis of GAS strains collected in Brazil (196, 197). Cross-protective opsonization by hyperimmune rabbit antiserum generated via immunization with M type-based vaccines was subsequently demonstrated using a 30-valent vaccine (186) and an experimental 4-valent vaccine designed to protect against the 17 *emm* types belonging to *emm* cluster E4 (198).

Superficial skin infection can stimulate a robust antibody response. A recent study of humoral immunity acquired after impetigo infection in Fijian schoolchildren demonstrates that 38% of subjects had a ≥4-fold increase in anti-M-type-specific IgG titers that match the M type of the infecting strain (199). Importantly, cross-protective *emm* cluster-specific immunity was evident for clusters E4, E6, and D4, although the levels of cross-protection were variable depending on both the patient and *emm* cluster. That the cross-reactive immune responses frequently align with *emm* cluster groups holds promise for the design of M type-based vaccines having broad coverage. More data are needed to further solidify the clinical and experimental findings obtained to date; identifying immunoassays to help define correlates of protection (CoPs) is a high-priority goal (200). Serotype replacement may potentially be an issue for GAS following widespread immunization with M type-based vaccines, as is the case for *Streptococcus pneumoniae* and serotype-based capsule vaccines (201, 202).

EPIDEMIOLOGY: BUILDING EVOLUTIONARY MODELS

MLST data can be used to build models of evolutionary descent via eBURST or goeBURST, which are clustering

Downloaded From Vet-eBooks.com

algorithms based on SLVs (and/or double locus variants) among the seven core housekeeping genes (106, 203). The single mismatched allele that defines an SLV pair can arise by either point mutation or homologous recombination, whereby the latter may introduce >1 SNP.

For GAS, the combined total length of the seven housekeeping (partial) alleles is 3,134 bp. However, 3,134 bp represents only a fraction of the GAS core genome; for example, *emm3* type iGAS have a core genome of ~1,645 kb (115), which is ~524-fold longer in sequence than the MLST alleles combined. Based on these values, it can be estimated that an MLST-defined SLV pair of GAS would differ by an average minimum of >500 SNPs within its core genome if genetic change were strictly due to point mutation or intraspecies recombination between very closely related organisms. However, if there was extensive HGT and recombination between more distally related GAS, the number of SNPs that differentiate the SLV pair is expected to be even higher. Given that the core genome of *emm3* type iGAS strains has an estimated 29 to 133 SNPs per isolate (i.e., short-term evolution) (115), the models for evolutionary descent based on the SLVs of MLST using only seven core housekeeping genes may best capture intermediate stages of evolution, which can be quite informative.

MLST data in combination with epidemiological marker genotypes can be compared to whole-genome sequence data. A good example for comparison is the *emm89* strains causing iGAS disease in Europe and the United States, which underwent a marked increase in prevalence during the 2010s (30, 31, 111, 204). Using the ST and GAS isolate data deposited at www.pubmlst.org/spyogenes (105), a goeBURST plot that includes the recent epidemic *emm89* strains is shown in Fig. 5A. The newly emerged epidemic clade of *emm89* corresponds to ST101 (and its descendants). Based on demographic information (i.e., dates of recovery), it seems reasonable to assume that ST407 is ancestral to ST101. Notably, ST407 is recovered in association with two distinct *emm* types: at least one other ST407 GAS isolate in the PubMLST database has *emm78* in place of *emm89*, as do several other SLVs and double locus variants of ST407. Alignment of the 180-bp *emm* subtype regions of *emm78.0* (ST253) and *emm89.0* (ST407, ST101) reveals <60% identity for both nucleotide and amino acid sequences, indicative of substantial divergence (ClustalW; data not shown) and supporting a model wherein *emm78* and/or *emm89* underwent HGT and recombination onto an ST407-related genetic background. Both *emm78* and *emm89* are *emm* pattern E but belong to different *emm* clusters (E1 and E4, respectively).

Examination of the FCT regions of ST407 and ST101 *emm89* type GAS isolates reveals highly divergent Cpa and FctA proteins, corresponding to the AP1 and BP subunits of pili, respectively (Fig. 5B). The distinct Cpa and FctA forms appear to coincide with T serotypes T11 (ST407) and T13 (ST101) (35). The housekeeping gene locus that distinguishes ST407 and ST101 is *yqiL*, which lies adjacent to the FCT region (Fig. 4); *yqiL01* (ST401) differs from *yqiL03* (ST101) by three nucleotide substitutions, highly suggestive of diversification via recombination. In contrast to the eBURST analysis of MLST data, whole-genome sequencing and analysis of the core genomes of *emm89* isolates provides a much higher level of resolution (30, 35, 111, 112). Importantly, several SNPs and indels that distinguish the *emm89* clade 2 → clade 3 transition lead to alteration of virulence factor expression: loss of the hyaluronic acid capsule (Δ*has*A) and transcriptional upregulation of toxin genes encoding Nga and streptolysin O.

The genetic relationships among GAS strains harboring *emm89* and ~20 additional *emm* types were inferred based on ~75,000 SNPs of the core genome (111). The phylogeny shows that the *emm89* isolates of the three clades detailed above, and corresponding to CC407 (ST101, ST407), cluster within the same major lineage; ST142 isolates (double locus variants of ST407; Fig. 5A) also cluster on that same deep branch. However, GAS of other *emm* types, plus *emm89*-ST380 isolates belonging to another CC (204), each cluster along distinct lineages with deep branches (111). ST380 differs from both ST101 and ST407 at all seven housekeeping alleles, indicative of HGT of *emm89* to a distant genetic background.

The MLST data for *emm89* strains captures two different modalities of HGT involving *emm*: replacement of a nascent *emm* by a new *emm* type on the original genetic background (i.e., recipient-new clone pairs, with two *emm* types and one ST) and lateral movement of an *emm* type to a new genetic background (i.e., donor-new clone pairs, with one *emm* type and two STs) (107). Within CC407 (recipient) there is evidence for the former process, involving replacement of *emm78* with *emm89* or vice versa (Fig. 5A). A possible donor of *emm89* to CC407 is *emm89*-ST380 (latter scenario); alternatively, ST380 may have been the recipient of *emm89* from a CC407 donor. Comparisons of completely assembled genomes of possible donor-recipient-new clone pairings may aid in establishing the directionality of horizontal *emm* gene movements.

Based on the connections within CC407, the seven housekeeping genes of MLST appear to recapitulate the more expansive core genome sequence data reasonably well. However, MLST fails to capture SNPs arising in core virulence-related genes that may alter the trajectory of GAS disease in a host population. What MLST may be best tuned to, when combined with typing data on *emm*, pilin genes, and/or *sof*, are HGT events wherein a typing gene is present on distant STs/CCs or multiple typing genes are recovered in association with the same ST/CC (such as divergent CpaFctA in *emm89*-CC407; Fig. 5B). For GAS, MLST relationships can provide an intermediary link between short- and long-term evolution and may help delineate the genetic roots of the emergence of new strains that have unique repertoires of cell surface antigens and their linked virulence functions.

EVOLUTION: MOLECULAR MECHANISMS OF GENETIC CHANGE

Core genes of GAS contain a historical record of numerous homologous recombination events (111, 205–208). Intraspecific gene exchange between GAS strains most likely occurs during cocolonization of the URT or coinfection of impetigo lesions with multiple strains (209). GAS can grow as biofilms or form microcolonies during infection within both tissue niches (210, 211), and the high bacterial density that is attained likely facilitates HGT. There is also ample evolutionary evidence for gene exchange between GAS and other species, such as SDSE (212–218).

A major unresolved puzzle of GAS biology is the molecular mechanisms that govern HGT, leading to the high rates of homologous recombination that is inferred from its evolutionary history. In principle, nonspecific packaging of chromosomal fragments into bacteriophage capsids could provide a vehicle for HGT of bacterial DNA (i.e., generalized transduction). In addition to bacteriophage, GAS are also rich in integrative and conjugative elements (91). The

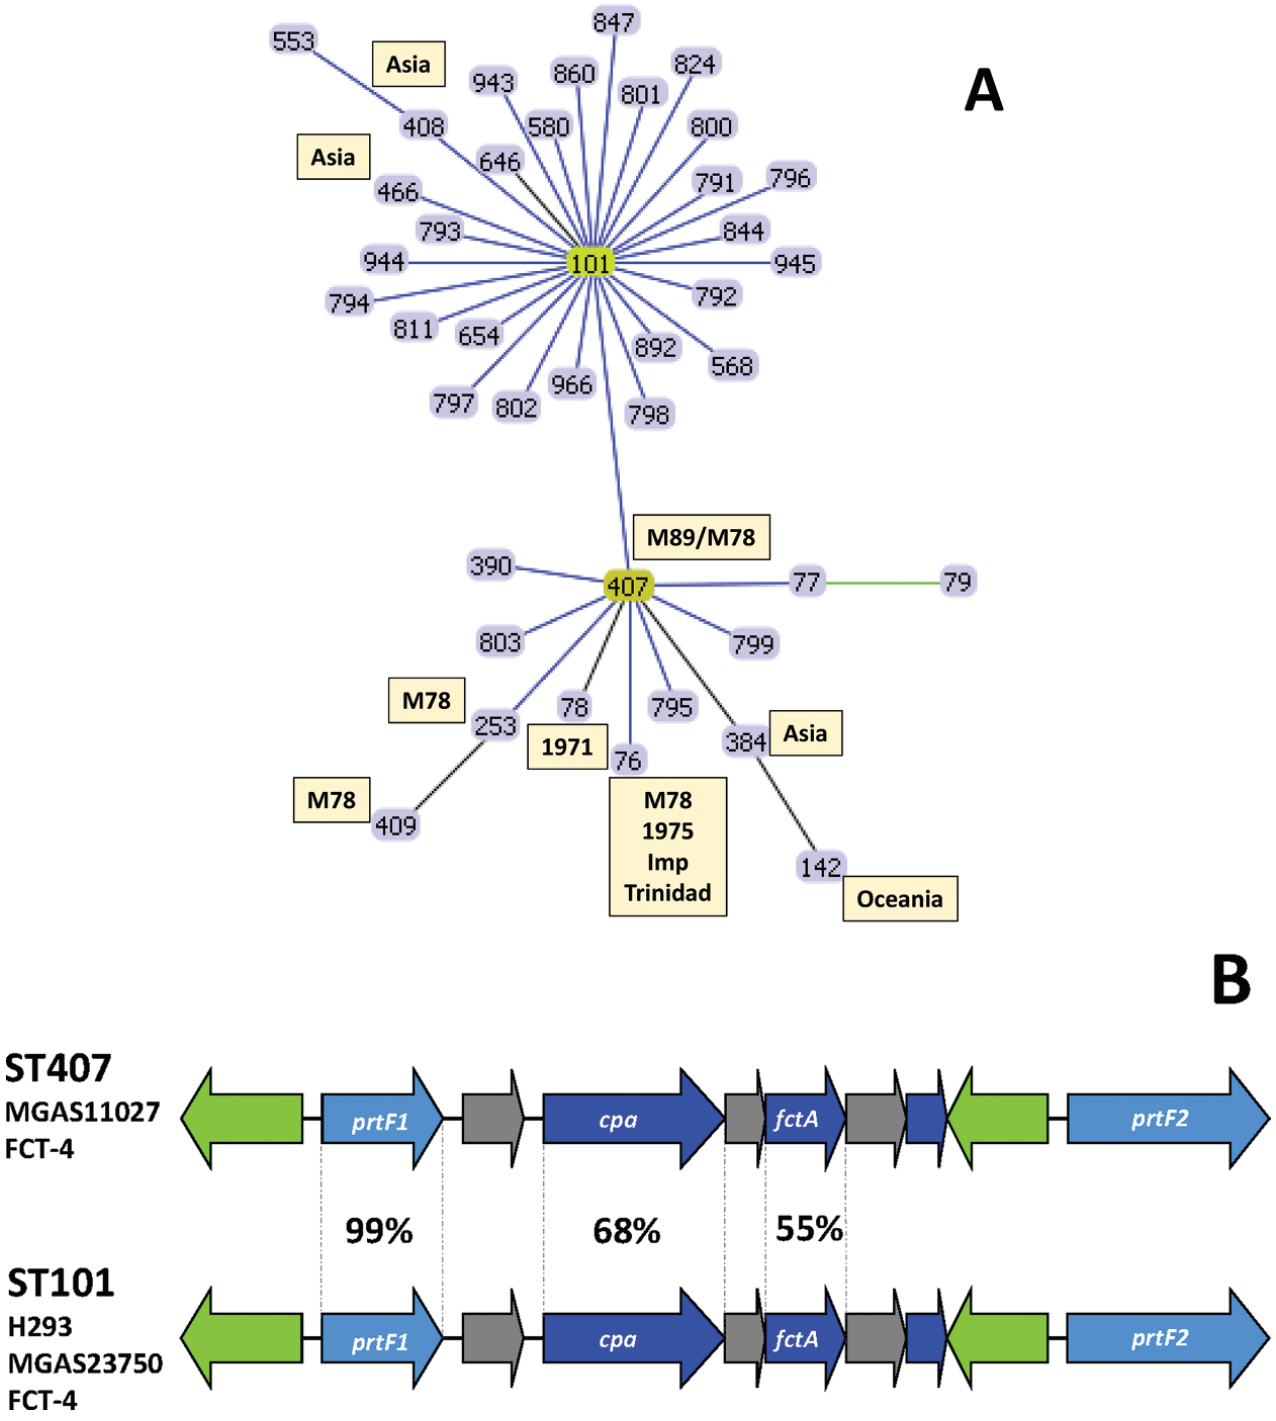

FIGURE 5 Model for evolutionary descent (CC407). (A) goeBURST diagram of CC407, which includes single representatives of 41 STs and is based on data from www.pubmlst.org/spyogenes (105). Unless noted otherwise (orange shaded boxes), all isolates (n = 114) are *emm*89 and were recovered from (i) the 1990s through 2010s, (ii) Europe or North America, and (iii) URT infections or iGAS disease. For evolutionary analysis of *emm*89 (formerly PT4245 [250]) isolates based on the core genome sequence (31, 111), clade 1 strain MGAS11027 is ST407, whereas clade 2 and epidemic clade 3 strains (MGAS23530 and MGAS27061, respectively) are ST101; the epidemic *emm*89 strain H293 from the United Kingdom is also ST101 (30). Note that ST407 corresponds to GAS with either *emm*89 or *emm*78 (105). (B) Amino acid sequence identities among predicted FCT region gene products of ST407 (MGAS11027) and ST101 (H293, MGAS23530) strains (all *emm*89) via ClustalW alignments.

degree to which random DNA fragments may slip through during the conjugative process remains unclear. A conserved RNA uracil methyltransferase (*rum*) gene provides an integration hotspot for both bacteriophage and integrative and conjugative elements in GAS, as well as other related species (219). Natural transformation via high-frequency uptake of naked DNA has not been demonstrated for GAS, although competence gene homologues are present in the GAS

Downloaded From Vet-eBooks.com

genome and (very) low efficiency transformation is detectable in biofilms (220–222). However, GAS secrete numerous DNases that degrade extracellular DNA, which may render the transforming substance unavailable for uptake by a competent cell.

A mutator phenotype that results in an increased mutation rate has been characterized for GAS. This defect in DNA mismatch repair is controlled by excision and reintegration of a streptococcal phage-like chromosomal island (SpyCI) at a site between the *mutS* and *mutL* loci (223) and is present in the genomes of numerous GAS strains (50). SpyCI yields an ~100-fold increase in the rate of spontaneous mutation, to as high as $\sim 10^{-7}$ to 10^{-8} mutations per generation. A possible relationship between the presence of SpyCI and CCs with a relatively low ratio of recombinational to mutational events remains to be explored.

EVOLUTION: LONG TERM

Core Housekeeping Genes

As previously stated, core genome-based phylogenies of GAS of different *emm* types and/or CCs tend to yield lineages with deep branches, indicative of large genetic distances (50, 110, 111, 116). Whole-core genome phylogenies depicted as SplitsTree graphs (neighbor-net analysis) show recombination between GAS of different *emm* types located deep within the network. Furthermore, there is no obvious clustering of the major lineages in accordance with *emm* pattern grouping or by any other recognized parameter.

Numerous methods have been used to assess the relative amount of recombination versus mutation that contributes to genetic change in GAS, based on the seven core housekeeping genes used in MLST (205–208). Together, the findings support the notion that GAS exhibit relatively high levels of recombination which, at least by some measures, is roughly comparable to the levels observed for the pneumococcus.

Using MLST data, the relative amount of recombination versus mutation among the *emm* pattern-defined subgroups of GAS was examined (107, 224). Findings based on several methodologies all point to the same general trend, wherein the pattern A-C throat specialists have the highest tendency to diversify by mutation, and pattern D skin specialists and pattern E generalists have a greater tendency to diversify by recombination. The data on a larger role for mutation, relative to recombination, in genetic diversification among the classical throat strains is consistent with the molecular evolutionary analysis of *emm* subtypes (see "Epidemiology: Evolution of Markers (*emm*)" above; Table 9) (107). Differences among the *emm* pattern-defined groups of GAS in terms of their mechanisms for genetic change underscore different dynamics in shaping their long-term population structures.

GAS strains may encounter ecological separation due to their tissue site preferences for infection (throat versus skin), geographic partitioning (temperate versus tropical) and temporal distances (winter versus summer). Ecological barriers can give rise to allopatric speciation, and therefore, signatures of early stages of speciation within the GAS population may be evident. However, analyses of housekeeping alleles provide strong support for highly fluid HGT and homologous recombination of housekeeping genes among all three *emm* pattern groupings (101, 128, 224). These findings extend to isolates known to be recovered from the URT versus impetigo lesions, regardless of *emm* pattern group (224).

In summary, despite wide spatial-temporal distances between many GAS strains, there is no clear evidence for diminished opportunities for HGT of core housekeeping genes between organisms of the different *emm* pattern groups. Numerous statistical measures all point to a population genetic structure for the *S. pyogenes* species that is highly nonclonal (205–208). Against a background of highly random genetic change in core housekeeping genes, loci that exhibit strong linkage with *emm* pattern genotypes are reasonably good candidates for playing a direct role in the adaptations leading to throat versus skin infection (e.g., 50, 101).

Lateral Movement of *emm*

For the same global set of >500 GAS isolates used to calculate Ka/Ks ratios within the *emm* type-specific region (see "Epidemiology: Evolution of Markers (*emm*)" above), the number of HGT events as a function of *emm* type was measured (107). Movement of *emm* to a distal ST is quantified as recovery of an *emm* type in association with >1 ST differing by ≥5 of the 7 housekeeping alleles; data show an average of 0.17, 0.60, and 0.75 lateral transfer events per *emm* type for the pattern A-C, D, and E groups, respectively. This finding supports the notion that for the classical throat strains, but less so for skin strains or generalists, *emm* type is often a reasonably accurate marker for ST or CC (104, 107, 108). In another measure of HGT and recombination, the number of *emm* types associated with *emm* type-variable STs (i.e., STs recovered in association with >1 *emm* type) was calculated; the number of *emm* type replacements per ST was 0.12, 0.15, and 0.02 for pattern A-C, D, and E isolates, respectively (107). Overall, there were three times as many events captured for HGT of *emm* to a distant ST ($n = 63$) than for replacement of *emm* on the same ST ($n = 21$).

Taken together, these data shed light on GAS strain competition surrounding the narrow time-space wherein the donor, recipient, and newly emerged clone all coexist. Strain competition can be mediated through host/herd immunity (225) and perhaps via other host-pathogen interactions as well. For the throat specialist strains, competition appears to be most intense between strains sharing the same *emm* type, because organisms of the original ST that served as the (presumptive) *emm* donor are rarely recovered. In contrast, for generalists, competition at the level of *emm* type appears to be considerably weaker, as evidenced by the frequent recovery of the same *emm* type in association with multiple distant ST backgrounds. How other cell surface antigens, such as SOF and/or pili, might contribute to the competitive sphere will require study of lateral movements of their genes and alleles within the GAS population.

Full Complement of Epidemiological Markers Considered

How do the host's specific immune defenses perceive the incoming antigenic repertoire present on the GAS cell surface? Except during carriage, the Mga regulon that upregulates the expression of *emm* and *emm*-like genes and *sof* is typically active. The pilus T-antigens appear to be expressed by >90% of the GAS population. The expression/nonexpression of the hyaluronic acid capsule can potentially mask/unmask some or all the GAS cell surface proteins. Setting aside the variance in the transcriptional program, which can have a profound effect on transmission and virulence (see "Evolution: Short Term" below), the collection of epidemiological markers provides a useful construct for defining GAS "strains."

Figure 6 summarizes the relative diversity or presence/absence of each major epidemiological marker in accordance with the *emm* pattern-defined groupings of throat specialists, skin specialists, and generalists. Importantly, *emm* type

Downloaded From Vet-eBooks.com

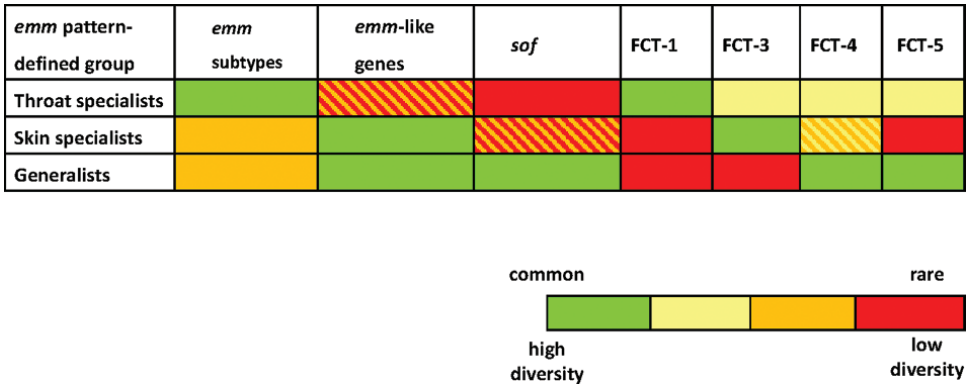

FIGURE 6 Trends in the distribution of epidemiological markers. An overview of the diversity and/or occurrence of epidemiological marker genes among three clinico-epidemiologic phenotype groupings of GAS. The relative distribution of FCT region forms is in accordance with one representative isolate for 94 unique *emm* types, as reported in reference 82; however, given the extensive HGT of *emm* and/or FCT genes to distant genetic backgrounds, the present analysis of the FCT region distribution may be far from complete.

is rarely recovered in association with multiple *emm* pattern groupings (Table 2), thereby allowing reasonably valid inferences to be drawn. The pattern- and cluster-defined *emm* subtype alleles reveal stark differences between the throat specialist, skin specialist, and generalist groupings regarding diversification (Table 9). Major distinctions also lie in the relative distributions of the *sof* locus (Table 4), *emm*-like genes (see Fig. 2B), and FCT region forms (Fig. 3) (82).

Do highly diverse *emm* subtypes compensate for the dearth of *emm*-like genes and *sof* among the throat specialists—and vice versa for the generalists? The diversity among *mrp* and *enn* alleles is modest, but they too have undergone intraspecies HGT (226); selection may be tied to functional binding attributes of the Mrp or Enn proteins (e.g., IgA, IgG) (63, 227–230). The *sof* gene also undergoes rather extensive intraspecies HGT (80); however, *sof* gene movement is nonrandom in that it is largely restricted to the *emm* pattern E generalists (Table 4). Yet the relationships between individual *emm* types and *sof* types are highly varied, with many unique combinations arising via HGT to distant genetic backgrounds (35).

Among the throat specialist group is a wide variety of FCT region forms (Fig. 6) (82). The FCT-1 region is the most prevalent form among representative pattern A-C organisms of unique *emm* types; FCT-1 is characterized by an AP1 adhesin (FctX) and major BP (Tee) that are markedly divergent from the highly variable Cpa and FctA pilins of FCT-3 and FCT-4 (82, 92). Not shown in Fig. 6 is FCT-2, which is (almost) exclusive to the highly prevalent *emm1* organisms; the AP1 and BP pilins of FCT-2 are akin to a distant lineage of Cpa and FctA, respectively (82). Thus, the unusually high success (i.e., fitness) of *emm1* strains may be due, in part, to its antigenically unique pilus structure. Overall, the absence of *sof* and *emm*-like genes among the pattern A-C strain grouping may be compensated for by the antigenic and structural diversity among its pili.

The skin specialist group appears to be the most homogeneous regarding epidemiological marker loci content, largely lacking *sof* but having both *mrp* and *enn*, and an FCT-3 region skewed heavily toward T3/13/B3264 (Table 5); this genotype is coupled to the lowest diversity among *emm* subtypes (Table 9). Also, the skin specialist group is dominated by *emm* cluster D4, encoding the plasminogen-binding M protein (51, 65). However, past lateral movement of *emm* type to distant genetic backgrounds is rather abundant among the skin specialists and is ~2-fold greater than that of *emm* type replacement on the same ST (107) (see "Lateral Movement of *emm*" above); there is also ample HGT of housekeeping alleles. Conceivably, the *emm* pattern D skin specialists represent a more recent subpopulation of GAS (i.e., younger) that has less diversity within any one gene, but the genes themselves are highly recombinatorial. Alternatively, the cell surface protein repertoire of skin specialists may be subject to less intense pressures for diversifying selection, perhaps due to its microenvironment and/or the host immune response at the skin.

The relative lack of pattern D and E *emm* types recovered in association with FCT-1 or FCT-2 regions may be indicative of functional constraints that would otherwise lower fitness, such as inadvertent adherence to a suboptimal tissue via specific host receptors. As a group, the *emm* pattern E generalists display all the *emm* region epidemiological markers and tend to have either the large FCT-4 region or FCT-5 (Fig. 6), both of which harbor the *prtF1* gene that encodes a fibronectin-binding protein (Fig. 3). Pattern E strains are also characterized by relatively high levels of recombination, involving both *emm* and the seven core housekeeping genes of MLST (50, 231, 232). Conceivably, within the generalist grouping are discrete throat or skin specialist strains whose phenotype is masked by the organizational framework (i.e., *emm* pattern group) that is imposed.

Historically GAS "strains" have been defined (primarily) by M serotype and secondarily by T and/or SOF serotype in combination with M type. Over the past 2 decades, *emm* typing has largely replaced GAS serotyping. The multitude of combinations of *emm* type and ST underscores the HGT of *emm* type, which is also consistent with the diverse array of M, T, and SOF serotype combinations observed. Even within a CC, STs are found in association with multiple *emm* types and/or divergent pilin genes (e.g., Fig. 5). Therein lies a conundrum for studying the population biology of GAS: How does one best define "strain?" This may or should be one of the next new challenges to be addressed by the GAS field.

EVOLUTION: SHORT-TERM

The monophyletic grouping of GAS strains in accordance with *emm* type and/or MLST-defined CC readily allows for

Downloaded From Vet-eBooks.com

inference of ancestral-descendent pairs within a branch, especially when coupled to epidemiological collections of strains with known dates of recovery. Whole-genome sequences of hundreds or thousands of GAS isolates sharing the same *emm* type and collected over a narrow spatial-temporal distance have captured epidemic waves of clones that are distinct from presumptive ancestral clones (24, 30, 111, 113–115, 233). An important finding is that within an *emm* type (specifically, *emm1* and *emm3*), iGAS isolates arise from all major lineages occupied by URT isolates and are genetically similar to the circulating pharyngitis strains from which they evolved (114, 234).

Comparative genomics of GAS recovered within a narrow spatial-temporal distance, and in association with a defined bacteria-host ecology (i.e., pharyngitis, asymptomatic carriage, and/or iGAS disease), have revealed high levels of diversifying selection at certain loci, particularly those involved in regulating the phenotypic expression of virulence factors (24, 30, 44, 111, 113–115, 233–240). Affected loci include *has*ABC (hyaluronic acid capsule biosynthesis), *covRS* (two-component system that acts as a global regulator), *rgg/ropB* (standalone response regulator), *mga* (response regulator and activator of *emm* transcription), *lia* (sensor kinase), and *nga-slo* (exotoxins). There are some recurrent themes, wherein downregulation of *emm* enhances URT carriage, downregulation of *speB* enhances iGAS disease, and upregulation of *nga-slo* enhances URT transmission. The contribution of capsule to GAS ecology seems more complex, and perhaps it is GAS strain dependent. In fact, in general terms, all mutations that alter fitness are context dependent and, accordingly, may be strain dependent. In addition to SNPs in critical virulence loci, GAS genomes are profoundly shaped by mobile genetic elements (which are often not included as part of the core genome); bacteriophage and integrative and conjugative elements can harbor critical virulence genes as well (e.g., 114).

EVOLUTION (OR NOT): RESURGENCE OF SCARLET FEVER

Scarlet fever (SF) was a dreaded GAS disease through the early 1900s; it manifests as a URT infection coupled to a pathognomonic scarlatina rash triggered by the action of erythrogenic toxin, which was subsequently characterized as a T-lymphocyte superantigen. The occurrence of SF in the United States and Europe declined mid-century and was largely sporadic in recent decades. However, in 2011 there was an alarming increase in the number of reported cases of SF in Hong Kong and in China soon thereafter (241–243). This upsurge was largely attributed to *emm12* GAS organisms that were resistant to macrolides and tetracycline. Comparative genome sequence analysis with other *emm12* strains revealed a novel prophage harboring the superantigen genes *spe*C and *ssa* (113, 244). However, the Hong Kong SF outbreak was multiclonal in origin.

A resurgence of SF cases also occurred in the United Kingdom, beginning in ~2013 (245). Comparative genomics failed to reveal a single clone or a single gene (e.g., a superantigen gene on a mobile genetic element) associated with those disease cases. As in Asia, the increase in SF incidence was associated with multiple lineages of GAS (246, 247).

Taken together, the recent upsurge in SF appears to be multifactorial and likely includes host-related factors. Numerous GAS lineages are responsible for SF, although resistance to antibiotics may have fueled the spread of some clones. Possible shifts in the content of superantigen genes may collectively have had an effect. The two cohorts—children in Asia and Europe and largely nonrural—possibly had a history of past exposure to a similar set of prevalent *emm* types and strains (131), and their herd immunity may be similar despite the geographic distance. Conceivably, an unknown copathogen may affect host susceptibility to SF and development of the scarlatina rash. Heightened clinician awareness and better reporting and surveillance, and/or changes in clinical practice, can also contribute to a higher disease incidence. The mysterious underpinnings of the recent upsurge in SF cases in Asia and Europe underscore the contributory role of factors other than genetic changes in GAS in shaping the epidemiology of GAS disease.

EVOLUTION AND POPULATION DYNAMICS

A central problem concerning GAS is the difficulty in connecting the evolutionary histories of different *emm* type-defined strains. There are large genetic gaps between extant organisms—but also rampant gene flow. So, what became of the evolutionary intermediates? Was there an extended series of population bottlenecks whereby new clones outcompeted their progenitors? And perhaps each successful new clone bore a new *emm* subtype plus changes in other genes, until a very unique and highly fit organism with a far more divergent *emm* type emerged and gained a strong foothold in the human host population. Perhaps the genetic intermediates went extinct due to low fitness in the context of shifting host-environmental conditions, or perhaps they remain extant, lurking in low numbers in a semiquiescent state and have yet to be sampled.

When did GAS emerge as a human pathogen? Was the GAS progenitor a human commensal? Or was the progenitor an animal pathogen that has yet to be recovered via sampling? Did the new GAS pathogen acquire key genes from a trading partner as a pivotal step in its emergence? What are the genotypes that confer adaptation of GAS to the primary ecological niches of the throat and skin? Are GAS commensals at heart, and should one view their ecology primarily through that lens?

What was the structure of the human population at the time GAS emerged as a human pathogen—highly migratory with intermingling or isolated tribes? What is the minimum host population size necessary to sustain GAS transmission? What becomes of a GAS strain if/when it runs out of susceptible hosts? Does the organism persist in an altered carrier state? Why do there exist ~243 *emm* types? And why are there even far larger numbers of unique combinations of M, SOF, and T antigens? Is the number of unique combinations of cell surface proteins related to characteristics of the human host population? If so, how?

What are the selective pressures shaping the GAS population of today? Is the ability to cause a clinically inapparent infection a more recent adaptation, driven by social behavior in the form of seeking antibiotics when ill, thereby giving the stealth invader a survival advantage? Why did SF recently re-emerge in Asia and the United Kingdom? Why did acute rheumatic fever undergo a renaissance in the United States during the 1980s? How might a future vaccine alter its evolutionary trajectory? A better understanding of the ecology and evolution of GAS, and its population genetic structure, may ultimately lead to interventions that limit its impact on human health.

Surface Structures of Group B *Streptococcus* Important in Human Immunity

LAWRENCE C. PAOLETTI AND DENNIS L. KASPER

13

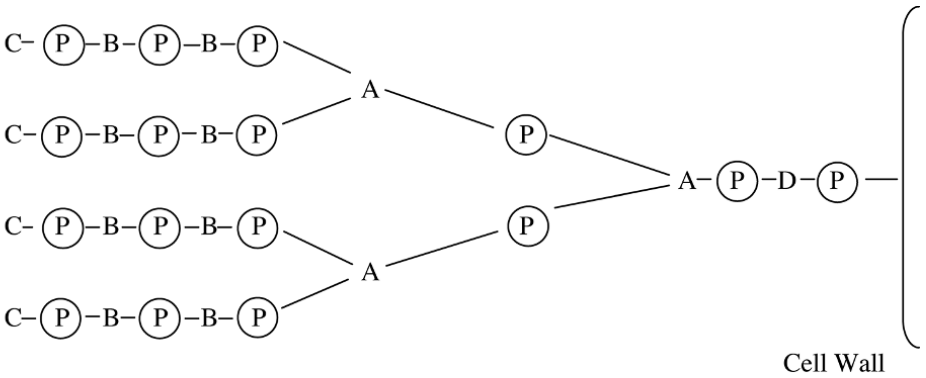
With an uncanny ability to interpret results obtained with a handful of immunologic techniques that would be considered simplistic and insensitive by today's standards, Rebecca Lancefield and her coworkers in the 1930s set the stage for decades of research on *Streptococcus agalactiae*, also known as group B *Streptococcus* (GBS). In contrast to group A *Streptococcus*, which was isolated mainly from humans, the first strains of GBS studied by Lancefield were isolated from cows with mastitis or from "normal milk." At that time, GBS was a well-known cause of bovine mastitis and a concern mainly of the dairy industry and veterinary medicine (1).

The first report of GBS disease in humans appeared in 1938 (2). However, not until the 1960s, when several reports appeared in the clinical literature on the presence of hemolytic GBS among human newborns with sepsis and meningitis, did this pathogen receive serious attention from researchers (3–5). By the 1970s, GBS had eclipsed *Escherichia coli* as the most common bacterial cause of sepsis among newborns, with an incidence of early-onset disease of 2.9 per 1,000 live births and a case fatality rate of 46% (6). Despite variability among surveillance sites, rates of early-onset GBS disease remained high throughout the 1970s and 1980s (7), prompting the Institute of Medicine to declare in 1985 that the prevention of perinatal GBS disease was a national health priority (8).

Today, colonization with GBS—a risk factor for neonatal illness—has been reported in pregnant and nonpregnant adults (including the elderly), not only in the United States (7, 9) but also worldwide (10, 11). Concern about an expanding spectrum of GBS-related disease, in terms of both age and geography, accentuates the need to translate vaccine development efforts against this life-threatening opportunistic pathogen into global vaccine actions (12). This article highlights critical advances in our understanding of the roles of GBS surface antigens—specifically, the group B carbohydrate, the type-specific capsular polysaccharides (CPSs), and proteins—in immunity and of their application as components of experimental vaccines.

CARBOHYDRATE ANTIGENS OF GBS

Group B Carbohydrate



The group B carbohydrate is a cell wall-associated molecule common to all strains and serotypes of GBS. Positioned on the external surface of the cell wall and linked through a phosphodiester bond to the peptidoglycan (13), the group B carbohydrate is composed of rhamnose, galactose, *N*-acetylglucosamine, and glucitol. These sugars form four structurally unique oligosaccharide units (14) linked by phosphodiester bonds to create a complex and highly branched tetraantennary structure (Fig. 1). The terminal position and abundance of rhamnose suggested that this sugar would constitute or be part of an immunodominant epitope; this hypothesis was supported by inhibition studies using a number of derivative oligosaccharides with polyclonal and monoclonal antibodies specific to the group B carbohydrate (15).

Lancefield et al. (16) were the first to demonstrate the inability of antibody to the group B carbohydrate to protect mice from lethal challenge with viable GBS. Indeed, the presence of maternal antibody to the group B carbohydrate was associated with poor neonatal outcome despite good agreement between levels of specific IgG in maternal and cord sera (17). This result confirmed in humans what was already known in animals: that antibodies to the group B carbohydrate were not important to natural immunity.

Still, investigators wondered whether a group B carbohydrate vaccine would be effective in eliciting functional antibody if the carbohydrate's immunogenicity were enhanced. Rainard (18) demonstrated an improved immune response in cows when the group B carbohydrate was coupled to ovalbumin. Antibody induced to this conjugate vaccine was of the immunoglobulin G (IgG) class, was specific for the major sugars of the group B carbohydrate, and was opsonically active against a nonencapsulated GBS strain of bovine origin (18). That high-titered IgG specific for the group B carbohydrate was less active against highly encapsulated GBS strains of human origin was discerned in studies

of a group B carbohydrate-tetanus toxoid conjugate vaccine (19). Adsorption studies using rabbit antisera to this vaccine with GBS strains of human origin that were highly encapsulated or with an isogenic mutant strain that lacked CPS showed CPS interference with specific antibody binding (19); this finding confirmed the inability of group B-specific antibody to access and bind to the group B antigen on highly encapsulated GBS cells. Not surprisingly, antibody to bovine isolates that possess low levels of CPS may be effective in combating GBS disease in the cow, whereas the same antibody would not be effective against more highly encapsulated GBS isolates of human origin. The ability of group B antibody to bind to poorly encapsulated GBS deserves further attention. The expression of CPS by a GBS strain (of human origin) is regulated by the cell's rate of growth (20), whereas the expression of the group B carbohydrate is not influenced by growth rate (21). Since slow growth rates, such as those of microbes colonizing the intestine (a common habitat of GBS), are associated with little capsule production, it might be that antibodies to the group B carbohydrate have a role in limiting colonization with this organism.

Capsular Polysaccharides

With few exceptions, all strains of GBS isolated from humans are encapsulated (Fig. 2, upper left) and can be classified on the basis of serology and CPS structure. Ten distinct GBS serotypes have been identified: Ia, Ib, II, III, IV, V, VI, VII, VIII, and IX. In the past, serotypes Ia, Ib, II, and III were equally prevalent in normal vaginal carriage and early-onset sepsis (i.e., that developing at less than 7 days of age) (9). However, type V is now an important cause of GBS infection (22), and strains of types VI and VIII have become prevalent among Japanese women (23). A pan-European study conducted between 2008 and 2010 showed that GBS serotypes Ia, III, and V together accounted for 88%, 96%, and 67% of strains isolated from neonates with early-onset disease, neonates with late-onset disease, and vaginal-rectal swabs of colonized pregnant women who delivered healthy babies,

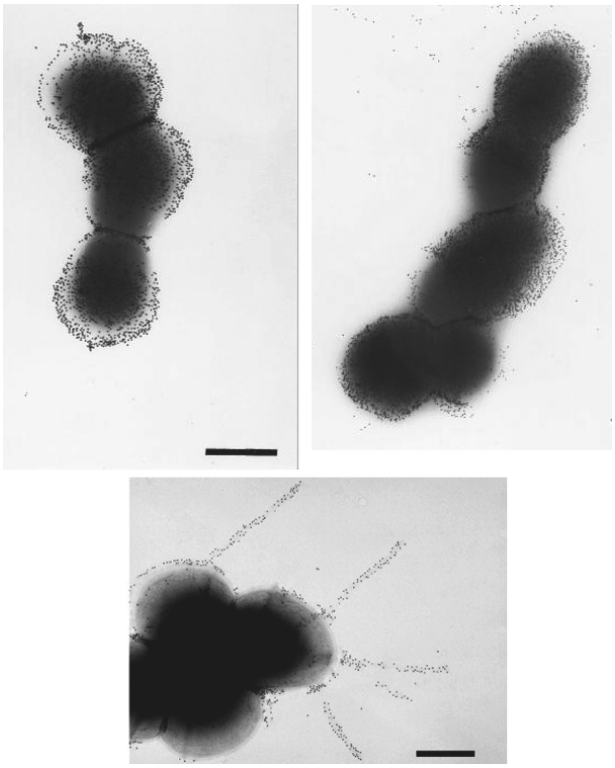

FIGURE 2 Electron micrographs of immunogold-labeled GBS showing surface localization of CPS, a protein antigen, and pili. Bars, 500 nm. (Upper left) CPS of GBS type Ia strain A909 was visualized after incubation with rabbit antiserum to the CPS followed by 20-nm-diameter gold-labeled protein A. (Upper right) The alpha C protein of GBS A909 was visualized after incubation with rabbit antiserum to the purified one-repeat alpha C protein followed by 15-nm-diameter gold-labeled protein A. Both upper images are reproduced from *Infection and Immunity* (163) with permission. (Bottom) Pilus structures of GBS type VIII strain JM9130013 were visualized with immunogold labeling using GBS80 antisera. The bottom image is reproduced with permission from *Science* (121).

respectively (12). These results reaffirm the clinical importance of types Ia and III and demonstrate that type V is an important serotype responsible for neonatal GBS disease in many parts of the world (24).

Remarkably, the serotype-specific polysaccharides of GBS are composed of three or four of only five different sugars: glucose, galactose, *N*-acetylglucosamine, rhamnose, and sialic acid. In marked contrast, other common pathogens such as *Streptococcus pneumoniae* and *Neisseria meningitidis* have different serotype polysaccharide structures that can contain different monosaccharides. The structural chair models in Fig. 3 highlight the heterogeneity among GBS CPSs. Chemical analyses revealed that some of the sialic acid residues were *O*-acetylated (at position C7, C8, or C9) in addition to being *N*-acetylated at C5 (25). Although not exhaustively studied, the percentage of *O*-acetylation on 10 GBS strains tested ranged from ~5 to ~55% (25), a result that should be considered when viewing the structures in Fig. 3. Nuclear magnetic resonance (NMR) proton profiles for 9 of the 10 GBS serotypes can serve as standards that can be evaluated side by side for identification and vaccine quality-control purposes (26).

Types Ia and Ib

Lancefield (27) was the first to notice serologic cross-reactions between strains bearing Ia and Ib antigens, although she did not know what cellular structure contained the differing epitopes. NMR analysis, performed 45 years after Lancefield's observation, showed that the native CPSs of GBS types Ia and Ib are indeed structurally similar, differing only in the linkage of the side chain galactose to *N*-acetylglucosamine (28); the type Ia CPS has a β-(1→4) linkage, and the type Ib CPS has a β-(1→3) linkage in this position. These linkages are critical to the immunospecificity of these CPSs. The repeating unit of Ia and Ib CPSs is a pentasaccharide with a disaccharide backbone and a trisaccharide side chain. Like all GBS CPSs, each possesses an α-(2→3)-linked sialic acid as a terminal side chain saccharide.

Type II

The native type II CPS repeating unit structure is composed of galactose, glucose, *N*-acetylglucosamine, and sialic acid in a 3:2:1:1 molar ratio (29). The repeating-unit structure of this CPS has two side chains—a sialic acid residue and a galactose residue—linked separately to the pentasaccharide backbone.

Type III

The type III CPS has a trisaccharide backbone of glucose, *N*-acetylglucosamine, and galactose and a disaccharide side chain of sialic acid and galactose linked β-(1→4) to the backbone *N*-acetylglucosamine (30). Although sialic acid *per se* is not immunodominant, the negatively charged carboxylate group on this sugar influences the conformation and thus the immunodeterminant epitopes of the entire polymer (31, 32). Removal of the terminal sialic acid from the repeating unit of the type III CPS with mild acid or neuraminidase results in a CPS with structural and immunologic identity to the pneumococcal type 14 CPS (33)—a finding that has enhanced our understanding of the roles of sialic acid in GBS immunity, as discussed further below.

Type IV

The GBS type IV CPS contains galactose, glucose, *N*-acetylglucosamine, and sialic acid in a 2:2:1:1 molar ratio (34). The presence of sialic acid does not appear to be a critical immunodeterminant for type IV CPS as it is for other GBS CPSs (34).

Type V

The repeating-unit structure of serotype V CPS is composed of seven sugars. The CPS has a trisaccharide backbone consisting of glucose, galactose, and glucose as well as two side chains. One side chain consists of glucose linked β-(1→3) to the backbone galactose. The other side chain is a trisaccharide of *N*-acetylglucosamine, galactose, and sialic acid. This side chain is linked β-(1→6) to a backbone glucose and terminates with sialic acid (35).

Type VI

The type VI CPS repeating unit comprises galactose, glucose, and sialic acid in a 2:2:1 molar ratio (36, 37). Type VI was the first GBS CPS described that lacked *N*-acetylglucosamine.

Type VII

The GBS type VII repeating unit contains a trisaccharide backbone and a trisaccharide side chain with a molar ratio of 2:2:1:1 for galactose, glucose, *N*-acetylglucosamine, and sialic acid (38).

Type VIII

The structure of GBS CPS type VIII is the mos unusual and simplest of all GBS serotypes. Like type VI CPS, the type VIII CPS lacks *N*-acetylglucosamine, yet unlike any other GBS CPS, this tetrasaccharide contains rhamnose, a sugar previously associated exclusively with the group B carbohydrate. The type VIII repeating unit contains glucose, galactose, rhamnose, and sialic acid in a 1:1:1:1 molar ratio, with sialic acid as the monosaccharide side chain (39).

Type IX

The most recently identified GBS serotype, type IX (40), contains a capsule with a repeating-unit structure comprising galactose, glucose, *N*-acetylglucosamine, and sialic acid in a 2:1:2:1 ratio. Structurally, the CPS has a trisaccharide backbone and a trisaccharide side chain that terminates with sialic acid (41). It is the only GBS serotype discovered thus far with two *N*-acetylglucosamine residues per hexasaccharide repeating unit.

Sialic Acid as a Structural Feature, a Virulence Factor, and a Site for Protein Coupling

Early studies of GBS capsule structures by Lancefield and Freimer (42) used hot HCl or cold trichloroacetic acid (TCA) (17) extraction methods and resulted in polysaccharide compositional information that was chemically incomplete. In addition, these early extraction techniques yielded only partial information about the antigenicity of the capsules of GBS. These investigators surmised that an acid-labile component contributed to the serologic specificity and negative charge of the CPS antigen. That GBS type-specific CPSs contain sialic acid was cited as a personal communication to Lancefield by Liu in 1972—a discovery verifying that sialic acid indeed "represents the missing antigenic component of the carbohydrate in the TCA antigen" (43). The acidic nature of the TCA extraction procedure resulted in the purification of an incomplete antigen because the α-(2→3) ketosidic linkage between sialic acid and galactose—a bond that is universal among all GBS type-specific CPSs—is acid labile (44).

Subsequent purification techniques avoided acid extraction methods and yielded polysaccharides whose complete structural information was obtainable. For example, structural analysis of GBS type III CPS showed that the acid-extracted or desialylated polysaccharide (core) structure was identical to that of *S. pneumoniae* type 14 CPS (45). This serendipitous connection launched a number of chemical, biochemical, and immunologic studies (46–48) of the fine structural features of this bacterial surface carbohydrate. An early study revealed that carboxylate groups on sialic acid residues form intramolecular hydrogen bonds with the galactose residues in the backbone of the type III CPS (31). Reduction of the carboxylate groups to hydroxymethyl groups of sialic acid destroyed CPS antigenicity with antisera to the native type III CPS, while oxidation of the carboxylate

Downloaded From Vet-eBooks.com

groups with sodium *meta*-periodate to remove carbons 8 and 9 did not affect antigenicity. The finding that GBS CPS retains its antigenicity upon oxidation with sodium periodate became important in the development of a coupling strategy to prepare GBS conjugate vaccines. The requirement for sialic acid to impart antigenicity on GBS CPSs is not universal, however. Whereas the sialic acid residue on type Ia CPS is required for complete antigenicity, the binding of specific antisera to the structurally related type Ib CPS does not depend on sialic acid (49).

Oligosaccharides enzymatically generated from native type III CPS not only defined the pentasaccharide repeating unit but also led to studies that revealed that specific antibody bound in a manner that increases along with the length of the structure (30, 32). NMR analyses and molecular dynamic modeling suggested an extended helix conformational structure of the native, fully sialylated type III CPS (50). In 1999, affinity-binding studies with monoclonal antibodies specific to GBS type III CPS supported earlier findings of a conformational epitope with extended helical segments (51). Almost two decades later, Carboni et al. (using current NMR technology; a new, functionally active, specific rabbit monoclonal antibody; x-ray crystallography; and synthetically and chemically obtained type III oligosaccharides) (52) described a linear, sialic acid-dependent functional epitope "that is fully contained within four consecutive sugars deriving from the PSIII backbone and one branched disaccharide present in this sequence."

Sialic acid is a key regulator of complement deposition on the surface of microbes. Surfaces of activating particles for the alternative complement pathway have little sialic acid (like many nonpathogenic bacteria), whereas nonactivating surfaces are relatively rich in sialic acid (like GBS). Mechanistically, surface-associated sialic acid greatly increases the binding affinity of β-1H for C3b, thereby accelerating intrinsic decay of the C3 convertase, whereas the decreased affinity of β-1H for the surface of an activating particle favors formation of the convertase on bound C3b (53). Therefore, the presence of sialic acid on GBS creates a surface that does not activate the alternative pathway of complement (54). Because the activation of the major particle initiating the alternative complement pathway is inhibited, the host now requires antibodies to activate complement deposition via the classical pathway. Marques et al. (55) reported lower amounts of C3 deposition on GBS organisms that possessed a sialylated rather than a desialylated CPS. In all, these findings suggested a critical role for sialic acid in evading the host's natural immune mechanisms and mechanistically explained a requirement for antibodies to opsonize GBS with C3b and facilitate phagocyte-mediated uptake and killing—i.e., a clear role in GBS virulence.

The role of the complement pathway in the immune response to sialylated antigen (GBS type III CPS) and desialylated antigen (*S. pneumoniae* type 14 CPS) was examined in untreated mice and in mice treated with cobra venom factor to deplete complement (56). Complement depletion did not affect the immune response to the sialylated antigen, but this condition markedly reduced the specific antibody response to desialylated CPS. These results demonstrated the importance of the CPS structure to both complement activation and generation of a specific antibody response (56).

The role of sialic acid as a virulence factor of GBS was confirmed in studies with a transposon mutant of type III strain COH 31r/s that lacked the ability to synthesize sialylated CPS (57). GBS strain COH 31-21 produced an asialo type III CPS that bound to pneumococcal type 14 capsular antisera but not to native type III CPS antisera. This single genetically mediated alteration in capsular structure was found to decrease virulence by 2 orders of magnitude from that of the wild-type parent strain. In fact, the asialo GBS strain was similar in loss of virulence to another transposon mutant, COH 31-15, that completely lacked CPS (57).

Sialic acid is the terminal, or sole, sugar of the side chains of all GBS CPSs (Fig. 3). In addition to its role as a virulence factor, sialic acid has been a convenient site for directed protein coupling in the development of GBS vaccines. Selective periodate oxidation of GBS CPSs removes C9 and creates aldehydes on the capsule's sialic acid at C8 and/or C7, which can serve as binding sites for the ε-amino group on lysine moieties in carrier proteins (the Schiff base reaction). Stable, covalent linkages are formed between the CPS and protein antigens through reductive amination chemistry. While conjugate vaccines prepared with CPSs of GBS types Ia, Ib, II, and III induced in humans the desirable antibody isotype IgG at levels greater than IgM, vaccines prepared with GBS type V did not (58). As discussed further below, the sialic acid moiety had an unexpected key role in the response of the immune system of nonhuman primates and humans to conjugate vaccines prepared with GBS type V CPS.

Genetics of CPS

The transposon mutants described above were the first used to map the genes that are important in GBS CPS expression (59). Since then, complete genomic sequences for the CPS biosynthesis regions of all known serotypes of GBS have been reported (Fig. 4) (41, 60). As in many encapsulated bacteria, genes conserved across diverse capsular serotypes flank genes encoding enzymes unique to a specific capsule serotype. In GBS, a central group of serotype-specific glycosyltransferases and polymerases is flanked on one side (Fig. 4) by genes encoding enzymes that synthesize and activate sialic acid, the terminal sugar on the side chain of all nine serotypes (61, 62). Flanking the other side of the serotype-specific glycosyltransferases (Fig. 4) is a group of genes hypothesized to function in export of the polysaccharide capsule (61). In analyzing the GBS capsular biosynthesis clusters of the different GBS capsular types, Cieslewicz and colleagues found strong evidence for horizontal gene transfer resulting in both intra- and interspecies recombination events (60). While diversity in GBS capsules was thought to be due to immune pressure, the relatively limited number of distinct capsule types might be related to structural elements required for pathogenicity.

The recent emergence of GBS type IX led Berti and coworkers not only to elucidate the chemical CPS structure of this new serotype but also to propose a phylogenetic relationship between it and two other recently identified GBS serotypes, V and VII (41). As shown in Fig. 4, serotype IX is genetically more similar to type V than to type VII, and the differences within the *cps* operon may reflect divergent evolution between serotypes VII and IX (41).

PROTEIN ANTIGENS OF GBS

Milestones in the discovery of GBS protein antigens can be divided into two time periods that reflect advances in molecular and genomic technologies. That surface proteins of GBS are important to immunity was initially recognized in 1975 when Lancefield and coworkers (16) described the cross-serotype protection afforded by rabbit antiserum to protease-sensitive epitopes. This publication led to an appreciation of the diversity of GBS surface proteins and to an increased

awareness of their roles not only in immunity but also in pathogenicity.

The availability of complete genomic sequences for GBS isolates allowed systematic exploration of surface-expressed proteins that may function as protective immunogens (63). Sequences for GBS type III and type V isolates revealed an AT-rich genome with ~2 million nucleotides and ~2,100 open reading frames. As expected, the GBS genome possesses great similarity to those of *Streptococcus pyogenes* and *S. pneumoniae*; the GBS type V genome shares 1,060 of its 2,144 predicted genes with both organisms and 401 genes with one—but not both—of these species. Approximately 650 proteins were predicted to be membrane associated or secreted in the type V genome, including 24 proteins containing an LPXTG motif

(which predicts surface exposure via cell-wall anchoring), 51 lipoproteins, and 177 proteins carrying a signal sequence. Approximately 300 genes were successfully expressed and used to raise antibodies in mice; of these, 139 recognized a predominant band in Western blots and 55 appeared (on the basis of fluorescence-activated cell sorting) to be surface expressed in GBS. In the type III genome, 21 genes encoded LPXTG proteins and, on the basis of characteristic sequences, 36 lipoproteins are also likely to be surface exposed (64, 65).

The combination of genomics and proteomics, along with *in vitro* and *in vivo* functional assays, has revealed a wide range of surface-expressed antigens that may play a role in natural immunity or serve as protective antigens for inclusion in GBS vaccines. Presented in this section and summarized in Table 1 are GBS proteins that have been evaluated as vaccine antigens in animal models of GBS disease.

Alpha C Protein

Wilkinson and Eagon (66) described a protein extract obtained from a serotype Ic strain of GBS. On the basis of this description, Lancefield recognized that the previously designated serotype Ic comprised the Ia CPS and the Ibc protein. In seminal experiments, Lancefield and coworkers demonstrated that antibodies to the protein component protected mice from lethal challenge with either Ia or Ib capsular serotype GBS strains that bore the Ibc proteins (16). Even in their initial work, Wilkinson and Eagon recognized that the protein extract from the Ic GBS strain contained two moieties, one sensitive to digestion with trypsin and the other resistant (66). Bevanger et al. described the trypsin-resistant component as the alpha antigen of the Ibc protein and the trypsin-sensitive component as the beta antigen (67). The term "C proteins" was coined to clarify the distinction between the proteins and the carbohydrate antigens; the presence of the C protein(s) was denoted by the letter following the capsular serotype (e.g., Ia/c) (68). Later work by a number of investigators identified the alpha and beta components as distinct proteins, independently expressed in different strains and encoded by separate genes (69–73). Generally present in strains of serotypes Ia and Ib and frequently present in strains of type II, these antigens are occasionally found in GBS of all serotypes. The trypsin-resistant antigen is now referred to as the alpha C protein (Fig. 2, upper right) and the trypsin-sensitive antigen as the beta C protein. In one survey, these proteins were found in 59% of strains in a collection of 785 clinical isolates from the University of Minnesota (74). All Ib strains expressed C proteins, and 84% expressed both alpha and beta proteins; 91% of Ia strains and 81% of type II strains expressed the alpha C protein. In a similar survey, Bevanger found that 52% of human isolates of GBS expressed the alpha C protein and 25% expressed the beta C protein (75).

Monoclonal antibodies have been used to identify the alpha C protein and to define it as a mouse-protective epitope in GBS (70). In a Western blot analysis, monoclonal

Downloaded From Vet-eBooks.com

antibody reacted with the vast majority of strains of GBS type Ia (all of 14 strains evaluated), type Ib (11 of 15 strains evaluated), and type II (all of 12 strains evaluated). Western blots of surface extracts from GBS strains also demonstrated an unusual phenotypic characteristic of this protein: a pattern of regularly spaced bands with a periodicity of ~8 kDa. Also evident on Western blots was size heterogeneity of the expressed protein from strain to strain, with the size of the largest band varying from <70 kDa to >160 kDa in a panel of 37 isolates. An interesting observation was that the protein sizes did not appear to be randomly distributed but clustered around 100 kDa, with relatively few isolates expressing either a very large or a very small alpha C protein.

The gene encoding the alpha C protein was cloned from the prototype Ia/c strain A909 from the Lancefield collection (76). This gene, *bca*, consists of 3,063 nucleotides and encodes several identifiable regions. A signal sequence with homology to other Gram-positive surface proteins was 56 amino acids long (77). This sequence was followed by an amino-terminal domain of 170 amino acids with a predicted molecular mass of 18.8 kDa. The most striking feature of the gene was a series of nine long tandem repeats that had 246 nucleotides each (encoding 82 amino acids, or 7.9 kDa) and that were identical at the nucleotide level. The repeat region composed >75% of the mature protein, and the correspondence between the size of the repeat region and the distance between the bands on a Western blot suggested that the repeats gave rise to the ladder pattern seen on Western blots. Antibodies to both the repeat region and the amino-terminal domain have been shown to be protective in an animal model and to mediate opsonophagocytic killing *in vitro* (78). The carboxyl terminus showed homology to those of other Gram-positive surface proteins, including an LPXTG domain (identified as a peptidoglycan-binding motif), a hydrophobic membrane-spanning region, and a charged tail thought to be involved in orienting and anchoring the protein to the cell wall (76).

A size discrepancy between the alpha C proteins of GBS isolates from mothers and those from their neonates suggested that a loss of repeats within the protein gene may occur during colonization or infection with GBS (79). This phenomenon was confirmed experimentally in an immune mouse model. While spontaneous deletions within the alpha C protein occur at a low rate ($\sim 10^{-4}$), passage through mice given antiserum to the alpha C protein gave rise to deletion rates approaching 50%. Moreover, the mutants bound poorly to the antiserum and were more poorly opsonized for phagocytic killing than the wild-type strain. *In vitro* experiments showed that purified alpha C proteins containing 9 or 16 repeats bound with high affinity to antibodies to wild-type (9-repeat) alpha C protein, whereas 1- and 2-repeat alpha C proteins bound with lower overall affinity (80). These differences were not due simply to a reduced number of antibody-binding sites but appeared to reflect a conformational dependence of the protein on repeat number. In contrast, antibodies to the one-repeat protein appeared to bind to all of the different constructs with similar overall affinity. Antibodies to the single- or double-repeat proteins showed greater protective efficacy *in vivo* and tended to allow fewer deletion mutants to escape. Further studies demonstrated that immunogenicity in mice was inversely related to repeat number (81): 9- and 16-repeat alpha C proteins evoked lower titers of antibody, particularly to the amino-terminal domain, than did the 1- and 2-repeat variants. These findings suggested that modulation of repeat number may be a mechanism for interaction with and evasion of the host's immune system.

Natural exposure to GBS containing alpha C protein induced functionally active, specific IgG and IgM but only in acute-phase sera from women with invasive GBS disease; colonization with GBS containing alpha C protein did not elicit a systemic immune response (82).

Rib protein

While the alpha C protein is present mainly in GBS strains of types Ia, Ib, and II, a phenotypically similar but immunologically distinct protein, designated Rib, has been discovered in a type III GBS strain (77). This protein, present in 31 of 33 clinical type III isolates studied, showed a laddering phenotype on sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE), resistance to trypsin digestion, and variability in molecular size among clinical isolates. Antiserum to the protein protected between 62 and 90% of mice from challenge with GBS but did not cross-protect the animals against infection by alpha C protein-positive GBS. Amino-terminal sequencing of the protein demonstrated homology to the alpha C protein, with identity in 6 of 12 residues. When cloned and sequenced, the gene encoding this protein showed structural as well as sequence similarity to the alpha C protein (83). Like *bca*, the *rib* gene contains a signal sequence, an amino-terminal region, a series of tandem repeats, and a carboxy-terminal membrane anchor region. Thus, a family of genetically similar, tandem repeat-containing proteins was identified in GBS. Rib has been shown to be identical to the previously recognized protein R4 described below.

Other alpha-like proteins

During the 1980s, the previously obscure GBS serotype V emerged as an important pathogen in the United States. A novel protein identified in many type V strains was phenotypically similar to the alpha C and Rib proteins (84). Antiserum to the purified protein recognized a homologous protein of variable size in 25 of 41 clinical isolates. This antiserum protected 78% of neonatal mice from GBS challenge. Thus, the protein exhibited the characteristic features of this family of proteins: (i) protective efficacy against infection with a homologous GBS strain in a mouse model, (ii) a laddering phenotype on SDS-PAGE with variable molecular size among clinical isolates, and (iii) resistance to trypsin digestion. In addition, this protein displayed amino acid sequence similarity both to the alpha C protein (17 of 18 evaluable residues) and to the Rib protein (5 of 10 residues). Further analysis revealed two more alpha-like genes, *alp2* and *alp3*, found most often in GBS of serotypes V and VIII. These displayed mosaicism, each containing elements of other GBS proteins while preserving the overall structure found in alpha C protein and Rib: an amino-terminal domain, a series of long tandem repeats, and a highly conserved carboxy-terminal domain (85). Alp3 was identical to R28, a protein reported to act as an adhesin in group A streptococci (86). Both proteins contained amino-termini with high degrees of similarity to alpha C protein and Rib protein and repeating units identical to those found in Rib. These findings strongly suggested inter- and intraspecies recombination of genetic material, a phenomenon subsequently noted in the capsular biosynthesis gene cluster.

R proteins

R proteins, also identified by their resistance to trypsin digestion, were initially recognized in *S. pyogenes* by Lancefield and Perlmann (87). Wilkinson (88) identified four immunologically distinct R proteins (R1, R2, R3, and R4) occurring in various combinations in streptococci of groups A, B,

Downloaded From Vet-eBooks.com

and C. Flores and Ferrieri (89) found R proteins of subtypes R1 and R4 in 49 (37%) of 131 GBS clinical isolates. The proteins were present predominantly in type II and III strains. Lindén et al. (90) showed that rabbit antiserum to an affinity-purified R protein from type III GBS protected mice against invasive infection by type II R-positive strains but not against that by type III R-positive strains. The presence of R protein antibodies in human serum correlated with the absence of invasive infection by R protein-expressing GBS strains in human neonates (91).

The R proteins appear to share two important phenotypic characteristics with the members of the tandem repeat-containing family of GBS surface proteins: trypsin resistance and protective capacity. Bevanger et al. (67) isolated a protein from a serotype III strain, designated it an R-associated protein, and found that it was biochemically and immunologically highly similar to both R4 and Rib. Similarly, Lachenauer and Madoff (84) showed that Alp2 from a GBS type V strain was reactive with antiserum to R1. Further characterization of the R proteins will probably reveal that they are members of the same family as the other tandem repeat-containing GBS proteins and that the genes encoding them possess a similar structure. Indeed, Smith and colleagues concluded on the basis of partial amino acid and genetic sequences that Rib was identical to R4 (92).

Beta C Protein

The beta C protein was initially recognized as the trypsin-susceptible component of the C protein (66). Subsequent work has demonstrated its expression on the surface of ~10 to 25% of GBS strains, with predominance in Ib strains (69, 74, 75). Russell-Jones et al. (72) recognized that this antigen was a 130-kDa protein and that it bound specifically to human IgA. This binding occurs via the Fc portion of the IgA heavy chain and is of high affinity, with an affinity constant of $3.5 \times 10^8\ M^{-1}$ (93). The affinity is considerably higher for serum than for secretory IgA. The gene for beta C protein was cloned by several groups (71, 94–96), and antibody to the cloned gene product was demonstrated to have protective capacity against GBS infection in mice (71). Two complete nucleotide sequences for the gene (*bac*) have been published and differ minimally; one is 1,134 amino acids in length (95) and the other, 1,164 amino acids (96). Other than a single amino acid difference, the two sequences differ only in the number of short XPZ repeats found in the carboxy-terminal half of the protein. Both contain consensus Gram-positive signal sequences and carboxy-terminal membrane anchor regions that have extensive homology to other Gram-positive surface proteins (including the GBS tandem-repeating proteins discussed above). Both groups of researchers studying the beta C protein detected IgA-binding capacity in the amino-terminal half of the molecule; however, Jerlström et al. (96) detected IgA binding within two separate non-overlapping subclones, whereas Hedén et al. (95) detected only a single IgA-binding region. Jerlström and colleagues (97) later localized IgA binding to a 73-amino-acid region containing an MLKKIE sequence and found that this sequence was required for IgA binding. These observations suggest that only one IgA-binding region exists (as is the case with other immunoglobulin-binding proteins) and that Jerlström's earlier finding may have resulted from the use of polyclonal IgA, which reacted in an immune fashion with a portion of the protein not involved in IgA binding.

In mice, antibodies elicited to beta C protein appear to be highly protective (71, 98, 99). Immunization of mice with this protein protected their neonatal pups from invasive GBS infection at >90% efficacy, and antibodies facilitated bacterial opsonization for phagocytic killing by polymorphonuclear leukocytes (99). One group has found that antibodies to beta C protein—unlike those to any other GBS antigen—are bactericidal *in vitro*; i.e., they are able to kill GBS in the absence of polymorphonuclear leukocytes (98). Beta C protein has also served as an effective carrier protein in conjugate vaccines. A glycoconjugate containing equal quantities of beta C protein and type III CPS linked by reductive amination was broadly protective against invasive GBS infection in neonatal mice challenged with either type III GBS or a type Ia/c beta-positive strain (100). Rabbit antiserum to the conjugate vaccine was opsonic against multiple strains containing either type III CPS or beta C protein. Similar conjugates with beta C protein have been made with types Ia, II, and III CPSs and have elicited antibody titers comparable to those elicited by CPS-tetanus toxoid (TT) conjugates (101). Lachenauer et al. (102) compared naturally acquired beta C protein-specific IgG levels in mothers colonized with beta C protein-positive GBS to levels in mothers who gave birth to infants who developed invasive illness with beta C protein-positive strains. In contrast to findings with antibody to several type-specific CPSs, no correlation was found between the beta C protein-specific IgG level and protection from invasive disease; however, only a small number of cases were available for study (102). Invasive infection but not colonization with beta C protein-containing GBS resulted in IgM and IgG specific to this trypsin-sensitive surface antigen (103). This finding suggests that this antigen has potential for inducing antibodies in humans if administered in sufficient doses parenterally.

BPS Protein

Erdogan and colleagues described a 105-kDa protein in a GBS strain and initially designated it R5 since it was derived from an R-positive GBS isolate (104). Although initially classified as an R-like protein, it bears no phenotypic relationship to other R proteins and has been renamed BPS protein (group B protective surface protein). In a mouse protection assay, BPS protein elicited antibodies that protected >80% of mice from lethal challenge with a single GBS strain; the survival rate was 20% among controls.

C5a Peptidase (ScpB)

C5a peptidase, a surface localized protease of ~125 kDa present in both group A and group B streptococci, has been shown to inactivate human C5a, an important component of complement-mediated neutrophil chemoattraction (105), but also serves as an anaphylatoxin. In addition, C5a peptidase may play a role in bacterial invasion of epithelial cells and may bind to fibronectin (106, 107). There is evidence that human serum contains antibodies to this protein (108); in group A streptococci, immunization with C5a peptidase elicited antibodies in mice and reduced colonization of the nasopharyx by several group A streptococcal strains (109). While C5a peptidase antibodies do not appear to be opsonic against group A streptococci, there is evidence of opsonic activity against GBS (110) when C5a peptidase is used as a carrier protein. The potential for the use of C5a peptidase in a GBS vaccine is discussed below. Recombinantly expressed C5a peptidase induced opsonically active antibody when delivered intranasally to mice in the presence of cholera toxin or CpG-ODN 1826 adjuvant (111). That recombinant forms of

Downloaded From Vet-eBooks.com

C5a peptidase and Sip (see below) induced mucosal IgA as well as IgG in murine serum and in vaginal tissue suggests that these proteins may have a role in vaccines designed to stem GBS vaginal colonization and thus reduce horizontal transfer of GBS to the newborn.

LrrG Protein

A genetic screen for exported proteins revealed *lrr*G, a gene that is highly conserved among all 17 clinical GBS isolates (representing 9 serotypes) tested (112). This gene encodes a novel leucine-rich repeat (LRR) motif common to bacterial invasins. Recombinant LrrG, shown to function as a GBS adhesin, was highly immunogenic in mice, eliciting antigen-specific IgG1. Active vaccination of inbred mice with recombinant LrrG in the presence of alum protected 10 of 11 mice (91%) from an ordinarily lethal challenge with GBS type III strain 97/0099, whereas only 5 of 12 mice (42%) that received recombinant Rib protein survived (112). These results, in combination with the conserved presence of *lrr*G among almost all GBS serotypes, make LrrG an attractive protein to consider in the quest for a universal GBS vaccine or as a carrier protein for CPS antigens.

SAN_1485

SAN_1485 was one of 43 surface-associated proteins identified by treatment of whole cells of the GBS type III COH1 strain with proteases and subsequent analysis of the recovered peptides by mass spectrometry (113). When administered to female outbred mice, recombinant SAN_1485, which consisted of a 550-amino acid fragment chosen by mass spectrometric analysis of the 1,085-amino acid protein, protected 82% and 87% of pups against challenge with an ordinarily lethal dose of GBS type III strain M781 and COH1, respectively (113).

Sip

This surface-localized protein of ~45 kDa is present in GBS of serotypes Ia, Ib, II, III, V, and VI (114). Immunization of mice with native Sip (surface immunogenic protein) elicited protection against challenge with several GBS serotypes (114). In a neonatal mouse protection assay, Martin and colleagues used recombinantly derived Sip to immunize mouse dams (115). Survival of neonatal pups whose dams had been immunized ranged from 75 to 98% (compared with rates of 0 to 12% among controls) across a broad range of serotypes. Recombinant Sip in combination with rScpB (C5a peptidase, described above) has been tested in mice as a mucosal vaccine (111).

Ornithine Carbamoyltransferase and Phosphoglycerate Kinase

Hughes and colleagues applied proteomics and reverse genetic methods to identify two surface-exposed enzymes of interest from strains of GBS serotypes Ia, Ib, II, III, IV, and V (116). Rabbit antisera to recombinantly expressed GBS ornithine carbamoyltransferase and phosphoglycerate kinase, admixed with GBS type III strain M732, resulted in 46% and 35% survival, respectively, of neonatal mouse pups; in contrast, only 2% of pups that received bacteria and normal rabbit sera survived (116).

BibA and FbsA

Combining genomics with targeted immune responses, ANTIGENome technology identified four conserved proteins on the GBS surface: two hypothetical proteins (Gbs0233 and Gbs1309) and two previously identified proteins (BibA and FbsA) (117). BibA is a well-conserved, cell wall-anchored protein presented as four allelic variants: variant I in type V strain 2603 (V/R) and type II strain 18RS21; variant II in type III strain NEM316 and type Ia strain 515; variant III in type V strain CJB111, type Ib strain H36B, and type Ia strain A909; and variant IV in serotype III strain COH1 (118). Active immunization of female mice with BibA variant I or a BibA variant I N-terminal fragment with Freund's adjuvant protected ~70% of newborn pups from an ordinarily lethal challenge with GBS type II strain 3050 or GBS type III strain D136C (119). Hyperimmune rabbit sera to BibA passively protected mice against challenge with strains of serotype Ia or serotype Ib (117).

FbsA is a GBS fibrinogen receptor protein with repeating units that are each 16 amino acids in length (120). Active vaccination of mice with recombinant FbsA, administered alone or with BibA, did not provide complete (100%) protection against lethal challenge with strains of GBS types Ib, III, or V despite the high degree of human antibody binding to the repeat regions of this protein (117).

Pilus Proteins

The remarkable discovery, through the application of a reverse vaccinology approach, that GBS contained pili (Fig. 2, bottom) (121) subsequently led to studies to determine whether pilus proteins were viable vaccine candidates. Each of three pilus variants encoded by separate pathogenicity islands—PI-1, PI-2a, and PI-2b—consists of five genes (Fig. 5). These well-conserved genes encode for pilus assembly: pilus backbone protein, two ancillary proteins, and two sortase proteins (122). All GBS strains tested harbor one or more of the three pathogenicity islands, a finding that supports the use of pili proteins as vaccine antigens in light of the number of nontypable GBS isolates from invasive disease states (123). In addition, levels of naturally occurring antibody to PI-1 and PI-2a, but not to PI-2b, were found to be lower in mothers of babies with early-onset GBS disease than in controls; GBS from babies with late-onset disease harbored a high frequency of hypervirulent type III of the ST-17 lineage with PI-1 and PI-2b phenotypes (12).

GBS67, GBS80, and GBS104

Again by means of a reverse vaccinology approach, genomes of eight GBS isolates representing serotypes Ia, Ib, II, III, and V were sequenced, and genes encoding for putative surface or secreted proteins were identified by computational analysis (63). Of the 589 proteins identified, 312 were cloned and expressed in *E. coli* and then evaluated as protective immunogens in the mouse maternal immunization-neonatal pup challenge model of GBS disease (Fig. 6). This industrial-scale approach yielded four proteins of great interest, one of which, GBS322, had been identified previously as Sip (see above). When administered to female mice, GBS322 in combination with the other three proteins (GBS67, GBS80, and GBS104) protected 445 (89%) of 498 pups challenged with 12 GBS strains representing six serotypes (Ia, Ib, II, III, V, and VIII); in contrast, only 18% of pups born to unvaccinated dams survived (63).

Evidence is mounting that, of the several GBS pilus proteins identified, GBS80 (also called BP-1 and SAG0645) and GBS67 (also called AP1-2a and SAG1408) are potentially important vaccine components not only because they play a role in attachment of and invasion by GBS *in vitro*

(124) but also because levels of IgG to these proteins were significantly lower in sera from mothers whose babies suffered early-onset GBS disease than in controls (12). Indeed, GBS80 has also been shown to be an effective carrier protein as well as a stand-alone immunogen in mice (125).

GBS VACCINES

CPS Vaccines

Clinical data and experimental observations support an important role for CPS-specific antibodies in the prevention or control of GBS disease. These data include the following: (i) GBS produces type-specific CPSs that are targets of protective immunity (27, 33). (ii) A low level of CPS-specific maternal antibody is a risk factor for disease in infants; conversely, high levels of CPS-specific maternal IgG are associated with protection of neonates (126). (iii) Type-specific antibodies are opsonically active *in vitro* (127) and are protective in animal models of infection (100). (iv) IgG to type-specific CPSs can cross the placenta (128), a critical ability in a maternal vaccine against neonatal GBS disease (6).

Native types Ia, Ib, II, and III CPSs were the first GBS antigens tested as vaccines in adults. The first clinical trial with GBS vaccine enrolled 33 healthy adults to evaluate the safety and immunogenicity of type III CPS extracted by two methods (6). Although both preparations were well tolerated, the EDTA extraction method produced a type III CPS that was more immunogenic than that obtained by TCA extraction. By the 1980s, more than 300 healthy adults, including 40 third-trimester pregnant women, had been safely vaccinated with type III CPS or other GBS CPS vaccines at CPS doses ranging from 10 to 150 μg (128, 129). Although well tolerated, these antigens failed to induce a strong specific antibody response in the target population—i.e., individuals with low levels of preexisting CPS-specific antibody. However, type-specific antibody levels among responders (i.e., mainly those with preexisting specific antibody levels >2 μg/ml) increased sharply 4 weeks after CPS vaccination. High levels of CPS-specific antibody persisted for at least 2 years, and declining levels were restored to their peak upon revaccination with CPS. The class of human antibody among responders to GBS type III CPS (129) and to GBS type II CPS (33) was predominantly IgG. The response to CPS antigens differed with the serotype tested; native type II CPS was the most immunogenic (88% rate of response), and type Ia CPS was the least (40%) (129). GBS CPS vaccines induced antibodies that were active against homologous GBS serotypes in opsonophagocytic assays and were passively protective in animal studies (129). By the late

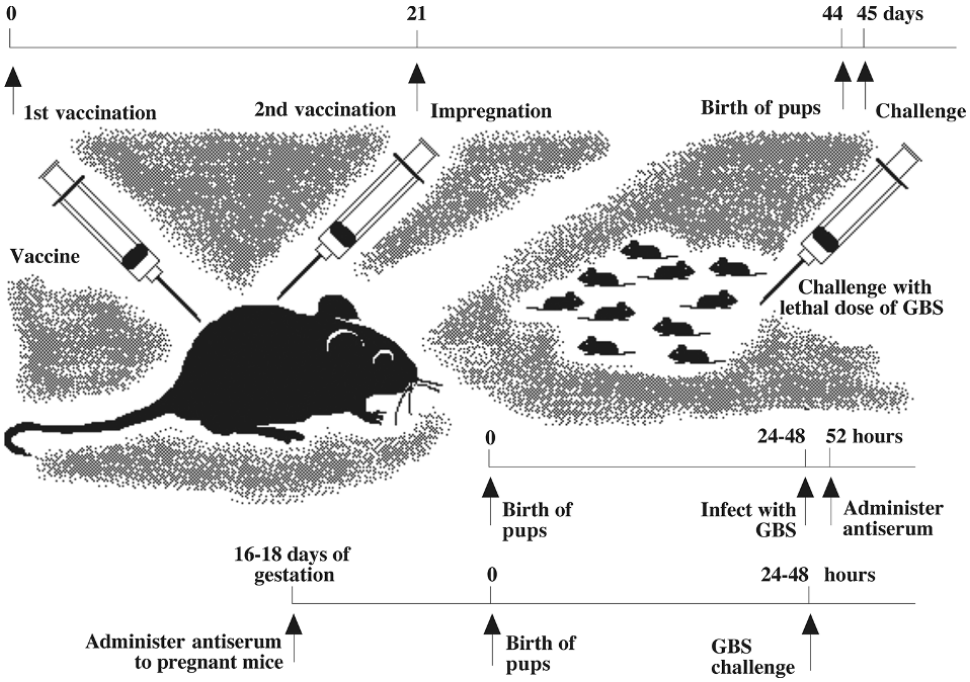

FIGURE 6 Mouse models of GBS disease. The immunogenicity and efficacy of GBS vaccines have been evaluated with the maternal vaccination-neonatal mouse model (top timeline) by actively vaccinating female mice, mating these mice, and subsequently challenging their offspring with GBS. In a passive vaccination-protection model (bottom timeline), newborn pups born to dams that received immune sera during pregnancy are challenged with GBS as a means of measuring the functional capacity of IgG. The therapeutic potential of GBS vaccine-induced antiserum (middle timeline) has been ascertained by inoculating naive pups with GBS 4 h before administration of immune serum. In all three models, pups are infected or challenged with GBS within 24 to 48 h of birth, and survival is assessed 48 h after challenge. Active vaccination of adult mice followed by an intraperitoneal challenge with viable GBS several weeks later has also been used to evaluate vaccines.

1980s, preclinical and clinical results showed that, although the CPS structures were critical vaccine components, they were not sufficiently immunogenic by themselves to be effective GBS vaccines. Researchers then began to focus on the development of GBS CPS vaccines whose immunogenicity was enhanced by methods that preserved their native antigenic structures.

Animal models are useful and often vital in the development of new vaccines. A mouse model of maternal vaccination and neonatal GBS disease (Fig. 6) has been used extensively to evaluate the efficacy of actively administered GBS vaccines or of passively administered type-specific immune sera (130). This model, which focuses primarily on neonatal survival, has been adapted to test the therapeutic potential of human antisera to GBS vaccines (131).

CPS-Protein Conjugate Vaccines

Conjugation technology has yielded an abundance of materials for use as reagents in experimental immunology or as potential vaccines. Without doubt, the clinical success of conjugate vaccines against *Haemophilus influenzae* type b infections spurred interest in adapting this technology to improve the immunogenicity of other poorly immunogenic carbohydrates, including those of GBS.

The first GBS CPS conjugate vaccines were prepared in 1990 by three coupling strategies (Table 2). Native type III CPS was coupled to TT (III-TT) either with adipic acid dihydrazide as a spacer molecule (132) or directly via aldehydes formed on a selected number of sialic acid residues (133). In a different approach, coupling of a type III oligosaccharide of 14 pentasaccharide repeating units to TT with a synthetic 6-C spacer molecule resulted in a single-site attachment of the reducing end of the oligosaccharide (134). The chemical methods used to create these and other bacterial conjugate vaccines have been reviewed in detail by Jennings and Sood (135). Despite differences in coupling chemistries, CPS size, purification methods, and the adjuvant used in the development and administration of these vaccines, all three conjugates were better immunogens in laboratory animals than was uncoupled type III CPS. Moreover, antibodies elicited by these GBS conjugate vaccines were of the IgG class and were functionally active when tested *in vitro* and *in vivo*.

With the coupling chemistry well in hand, progress was then made in developing conjugate vaccines against GBS serotypes other than type III (136, 137). Immunity in mice to multiple GBS serotypes was demonstrated in studies of a mixture of Ia-TT, Ib-TT, II-TT, and III-TT conjugates administered as a single tetravalent vaccine (138). The lack of interference of one serotype with another in the tetravalent vaccine opened the way to the development of a multivalent GBS vaccine for use in humans. However, clinical observations of an increased prevalence of serotype V dictated its inclusion in a multivalent vaccine (139). Preclinical studies of a serotype V-TT conjugate vaccine have paved the way for this innovation (140).

Because protective antibodies to type III GBS CPS appear to recognize a conformational (helical or linear) epitope, all

[l]Recombinant alpha-like protein 3.
[m]Cross-reactive material, a diphtheria mutant toxoid isolated from *Clostridium diphtheriae*.

conjugate vaccines for clinical use were prepared with a coupling method known to preserve both the native repeating-unit structure and the conformation of the CPS (31). This conjugation method (141) is essentially a two-step process: (i) GBS CPS is subjected to mild oxidation with sodium periodate, which creates free aldehyde groups on a limited number of sialic acid residues on the CPS. (ii) The newly created aldehyde groups on the CPS serve as sites for irreversible coupling to free amino groups present on carrier proteins by a process called reductive amination. The end result is a conjugate vaccine that contains CPS covalently linked directly to the protein. A covalent linkage between CPS and the carrier protein was necessary for the formation of efficacious GBS vaccines.

Conjugate vaccines for use in phase 1 and phase 2 clinical trials have been individually prepared by the reductive amination method with GBS CPSs Ia, Ib, II, III, and V. Each CPS was individually coupled to TT, and a second type V conjugate vaccine was prepared with the mutant diphtheria toxoid CRM_{197}. Uncoupled GBS CPS preparations (types Ia, Ib, II, III, and V) were used as control vaccines in these clinical trials.

Clinical trials with III-TT vaccine

The initial clinical trials with the second-generation (i.e., conjugate) GBS vaccines were designed to compare the safety and immunogenicity of conjugated and uncoupled type III CPS and to determine an optimal immunogenic dose (142). Both III-TT (at any CPS dose: 58, 14.5, or 3.6 μg) and III CPS were well tolerated, with minimal reactogenicity reported among the 90 female recipients. The geometric mean concentration (GMC) of III CPS-specific IgG among the 30 recipients of the 58-μg dose (as CPS) of III-TT rose from 0.09 μg/ml before immunization to 4.89 μg/ml 2 weeks thereafter; during this same interval, the GMC of specific IgG among the 30 recipients of III CPS increased from 0.21 μg/ml to only 1.30 μg/ml ($P < 0.05$). The relative immunogenicity of III-TT appeared to be dose dependent, with a peak GMC of type-specific IgG of 2.72 μg/ml in the 14.5-μg group and 1.10 μg/ml in the 3.6-μg group (142). Moreover, antibodies elicited by immunization with III-TT recognized a conformationally dependent epitope of the CPS, promoted *in vitro* opsonophagocytosis and killing of GBS, and were functional *in vivo* in a neonatal mouse protection model (142).

Preliminary results indicate that a III-TT vaccine is also safe and immunogenic when administered to healthy women at 30 to 32 weeks of gestation (143). Maternally derived type III CPS-specific IgG measured in serum from 1- and 2-month-old infants was functionally active *in vitro*.

Clinical trials with Ia-TT and Ib-TT vaccines

The Ia-TT and Ib-TT conjugate vaccines were also well tolerated and were more immunogenic than the respective uncoupled homologous CPSs in nonpregnant, healthy women (144). The GMC of type Ia CPS-specific IgG among recipients of a 60-μg dose (as CPS) of Ia-TT rose from 0.5 μg/ml to a peak of 26.2 μg/ml 8 weeks after vaccination, whereas during the same interval antibody levels among recipients of Ia CPS rose from 0.2 to only 2.4 μg/ml. Levels of type Ia CPS-specific IgG remained high in recipients of the Ia-TT vaccine at 1 and 2 years after vaccination, a result demonstrating the durability of the response. The response to Ia-TT vaccines was dose dependent: 60-μg and 15-μg doses elicited higher antibody levels than did a 3.75-μg dose (144).

Like the other GBS conjugate vaccines, Ib-TT vaccine was safer and more immunogenic than uncoupled homologous CPS (144). The prevaccination GMC of type-specific antibody among recipients of Ib-TT was 0.4 μg/ml, a level that rose to a peak of 14.2 μg/ml 4 weeks after vaccination with a single 63-μg dose (as CPS). In contrast, among recipients of uncoupled type Ib CPS, the prevaccination type-specific antibody GMC of 0.4 μg/ml rose to only 4.4 μg/ml 4 weeks after vaccination. The response to Ib-TT vaccine was dose dependent, with the highest (63-μg) and intermediate (15.75-μg) doses resulting in the greatest magnitude of antibody response (144).

Clinical trials with II-TT vaccine

Coupling of purified GBS type II CPS to TT also resulted in a safe and highly immunogenic vaccine in healthy, nonpregnant adults (145). Responses to the conjugate vaccine were dose dependent, with the lowest CPS dose of 3.6 μg evoking a peak type-specific IgG level of ~15 μg/ml 2 weeks after vaccination. As expected, immune sera were functionally active in an *in vitro* opsonophagocytosis assay against viable type II GBS. Interestingly, high concentrations of type II CPS-specific IgM and IgA were also elicited in a vaccine dose-dependent manner. These antibody isotypes were not elicited in humans who received the other (Ia-TT, Ib-TT, and III-TT) GBS CPS conjugate vaccines, and although one can speculate that the difference may lie in the structural features (described above) of type II CPS, confirmation awaits further experimentation.

Clinical trials with V-TT and V-CRM_{197} vaccines

In response to the emergence of serotype V, conjugates were prepared with purified type V CPS. Two conjugate vaccines—one prepared with GBS type V CPS and coupled to TT, the other coupled to CRM_{197} (Table 2)—were randomly administered to healthy nonpregnant women 18 to 45 years of age (58). Both conjugate vaccines were well tolerated, with no serious adverse reactions reported. Immune responses to V-TT and V- CRM_{197} were similar to those observed for other GBS conjugates, with type-specific IgG reaching peak GMCs of 6.5 to 8.9 μg/ml 2 to 4 weeks after vaccination. No statistical differences were observed between these two preparations.

Because of the increased rate of GBS infection among the elderly, Palazzi and coworkers examined the immune response of a V-TT vaccine in 22 healthy adults 65 to 85 years of age (146). The antibody isotype distribution of V-TT in this age group was similar to that measured in 18- to 45-year-old adults, and GMCs of type V CPS-specific IgG, IgA, and IgM ranged from 2 μg/ml to 3 μg/ml 4 weeks after vaccination; concentrations fell by only ~50% over 1 year. This was the first study that demonstrated the potential of GBS conjugate vaccines to stem disease in the elderly.

In the exploration of a multivalent GBS conjugate vaccine, a dose-ranging study was performed in healthy adults with GBS type V-TT vaccine to determine the amount of antigen that would elicit robust levels of specific IgG (147). While all three V-TT vaccine doses (38.5, 9.6, and 2.4 μg of coupled type V CPS) elicited significantly higher levels of type V CPS-specific IgG than did uncoupled type V CPS, the GMCs of specific IgG elicited by the three doses did not differ statistically—a result that may have been due to the small number of participants. Therefore, a multivalent GBS conjugate vaccine that contains ~2– to 10 μg of coupled type V CPS could lead to optimal immunity to this GBS serotype (147).

Surprisingly, GBS type V conjugate vaccines elicited high GMCs of type V CPS-specific IgM and IgA, a response pattern similar to that measured in recipients of II-TT vaccine (58). Both type II and type V CPSs have two side chains, one of which is composed of a single monosaccharide (Fig. 3). Could this or other CPS structural feature(s) influence the immune response to conjugates prepared with these antigens?

Unlike the well-studied type III CPS, whose structural conformation is influenced by the presence of the side-chain sialic acid (50), the structure of type V CPS is not affected by the presence of this 9-C sugar (148). This key finding led to studies in rhesus macaques with conjugate vaccines prepared with native type V CPS or desialylated type V CPS (dV-TT). Unlike mice, rhesus macaques elicited the same IgM-to-IgG responses to III-TT and V-TT as those measured in healthy humans. A higher IgG-to-IgM ratio observed in rhesus macaques immunized with dV-TT suggested that the terminal side-chain sialic acid impeded critical isotype switching, a result that corroborated structural analyses (148).

Clinical trials with trivalent GBS CPS conjugate vaccines

Clinical trials have progressed to include evaluation of a trivalent (Ia, Ib, III) GBS CPS conjugate vaccine in pregnant women with or without HIV disease (149, 150). For a more complete review of the current status of GBS conjugate vaccines, see Kobayashi et al. (151).

GBS CPS-GBS Protein Conjugate Vaccines (Preclinical)

The drive toward a multivalent GBS vaccine occurred in response to current trends, such as the shift of GBS disease from newborns to elderly adults (152, 153) and the emergence of serotypes such as type IV and type V (154). The findings thus far broaden the target population that would receive a GBS vaccine and strengthen the call for a multivalent vaccine. Toward that goal, vaccines that combine CPSs with various GBS surface-expressed proteins have been generated in an effort to broaden coverage against multiple GBS serotypes. To date, these proof-of-principle vaccines have been evaluated only in laboratory animals.

Conjugate vaccines with ScpB (C5a peptidase)

Conjugate vaccines were prepared by combining a native and a truncated form of ScpB with type III CPS. Both vaccines reduced the severity of pneumonia in mice inoculated intranasally with serotype VI GBS. This result suggests that protective responses independent of GBS serotype could be achieved with ScpB-containing vaccines (106).

Conjugate vaccines with alpha C protein and beta C protein

Beta C protein of GBS (discussed in detail above) has been used both as a carrier for type III CPS and as an immunogen in a conjugate vaccine eliciting protective antibodies to GBS strains of serotype III as well as to non-type III GBS strains that contain this protein (100). Despite this advance, there was little enthusiasm for the use of beta C protein in a GBS vaccine because this protein bound human IgA (97)—a potentially undesirable property for a vaccine antigen. In 2007, Yang and coworkers engineered a recombinant beta C protein (rBCP) that lacked the human IgA binding site ($rBCP^{\Delta IgA}$); this new antigen was reevaluated as a standalone immunogen and as a carrier protein for type III CPS (155). Deletion of the IgA binding site did not negatively alter the antigenicity or the immunogenicity of rBCP, which also served as an effective carrier protein—equal to TT, which had become the gold standard carrier—for GBS type III CPS (155). When administered to female mice, the III-$rBCP^{\Delta IgA}$ vaccine protected offspring from an ordinarily lethal challenge of beta C protein-negative GBS type III strain M781 or beta C protein-positive type Ia strain A909. These results suggest that expanded coverage against GBS disease can be achieved with the use of relevant GBS surface proteins as carrier antigens (155).

Although results in animals vaccinated with III-$rBCP^{\Delta IgA}$ proved that broader coverage could be attained with a relevant carrier protein, a better carrier for GBS CPSs would be the alpha C protein (see above) since it is present on a larger number of GBS serotypes (130). A GBS type III-alpha C protein conjugate vaccine could potentially provide coverage against up to 90% of disease-causing strains of GBS. Conjugate vaccines using both the full-length nine-repeat alpha C protein and a two-repeat alpha C protein as carriers for type III CPS elicited antibodies in female mice that protected neonatal pups against lethal intraperitoneal challenge with either alpha-positive or type III GBS (156).

Building on earlier studies with alpha C protein and rBCP as viable carriers and recognizing the emergence of newer GBS serotypes (e.g., types V and VIII), researchers generated a trivalent GBS conjugate vaccine. The experimental vaccine coupled both recombinant alpha-like protein 3 (rAlp3) and $rBCP^{\Delta IgA}$ to GBS type III CPS; the resulting III-rAlp3-$rBCP^{\Delta IgA}$ vaccine elicited high-titer antigen-specific IgG in mice (157). When given to adult female mice, this vaccine protected offspring from challenge with a GBS type III strain and a beta C protein-bearing GBS type Ia strain but not against an Alp3-containing type V strain or a type VIII strain—this despite the finding that high-titer rabbit sera to Alp3 opsonized and killed the latter strains *in vitro* (157). It is worth noting that rabbit antiserum to Alp3 was also functionally active *in vitro* against six clinical GBS type III isolates, presumably because of cross-reactivity with the Rib protein (157).

GBS Protein Vaccine

A recombinantly expressed fusion protein of the nonimmundominant N-terminal domains of both alpha C protein and Rib (158) showed promise as a vaccine in mice against GBS serotypes containing these surface antigens. This advance led to the first clinical trial in healthy women of a non-CPS-containing GBS protein vaccine (NCT02459262, clinicaltrials.gov).

SUMMARY

The seminal observations by Rebecca Lancefield and coworkers on the role of carbohydrate and protein antigens in GBS immunity have led a generation of researchers not only to a better understanding of these antigens in immunity but also toward the development of effective vaccines. Today, GBS remains a major bacterial cause of disease among neonates and is increasingly common in the adult population, especially among the elderly and those with underlying illnesses (11, 139, 159, 160).

Now, more than 80 years since the first report of GBS infection in humans (2), we have sufficiently unraveled the complexities of the surface structures of this opportunistic pathogen, and we have developed the technologies necessary to produce and formulate effective vaccines against GBS disease (161).

We thank Ying Wang and Francesco Berti for assistance with the chair models of the CPSs, Thomas DiCesare for illustration of the mouse model, and Julie McCoy for editorial assistance. Lawrence C. Madoff coauthored earlier published versions of this chapter.

Most of the GBS research conducted in the authors' laboratories and cited in this review was funded through the National Institute of Allergy and Infectious Diseases of the NIH.

Group B *Streptococcus* (*Streptococcus agalactiae*)

VANESSA N. RAABE AND ANDI L. SHANE

14

INTRODUCTION

Streptococcus agalactiae, also known as group B *Streptococcus* (GBS), was first differentiated from other streptococci by Rebecca Lancefield in the 1930s after it was isolated from milk and cows with bovine mastitis (1). Lancefield described GBS colonization of the vaginal tract of asymptomatic women, but human pathogenicity was not described until 1938 when three reports of fatal postpartum infection were published (2, 3). Invasive GBS disease was rarely identified in humans until the 1960s, when increasing reports of adult and neonatal invasive infections were published (4–7). The incidence of invasive GBS disease continues to increase, and it remains a significant pathogen among both infants and adults.

S. agalactiae has historically been divided into nine serotypes (Ia, Ib, II, III, IV, V, VI, VII, VIII) based on the capsular polysaccharide (8). A tenth serotype (IX) was described in 2007 (9). Among nonpregnant adults in the United States, the most common serotype causing invasive disease is group V (29% in 2005 to 2006), followed by serotypes Ia, II, and III (10). A study from Alberta, Canada, of serotypes associated with invasive GBS disease from 2003 to 2013 demonstrated that the most frequent serotype was III (20%), followed closely by serotypes V (19%), Ia (19%), Ib (13%), and II (11%) (11). The dominant serotypes causing disease vary regionally and differ by invasive and colonizing isolates.

CLINICAL MANIFESTATIONS

The most common syndromes due to invasive GBS disease in adults are bacteremia without a focus and skin/soft tissue infections (10, 12–16). The former often presents with altered mental status, chills, and fevers (8). Bacteremia may also occur secondary to a focal source of infection; polymicrobial bacteremia, most commonly with *Staphylococcus aureus*, may be seen in 26 to 45% of cases (17, 18).

S. agalactiae bacteremia may lead to seeding of the cardiac valves and endocarditis. Vegetations in GBS endocarditis may become extremely large with a high risk of embolization (19, 20). In the 1930s and the 1940s, GBS endocarditis predominantly was associated with acute disease in pregnant and postpartum women, primarily involving the mitral valve (20). Rheumatic heart disease was a common predisposing factor, and embolization of vegetations from valves to the kidneys and spleen was common (20). The epidemiology of GBS endocarditis has evolved over time; a case series beginning in the 1960s described endocarditis affecting men and nonpregnant women, involvement of the aortic and tricuspid valves, and subacute presentations (20). The percentage of GBS infections manifesting as endocarditis is in decline, from 9% in one study conducted in Atlanta in 1982 to 1983 to approximately 3% of GBS infections in the United States in a study from 1990 to 2007 (10, 15). Although cardiac valve abnormalities are a risk factor for GBS endocarditis, cases have been described in structurally normal hearts (21–23). Mortality from GBS endocarditis may be quite high despite medical and surgical interventions, with 41% mortality in one case series of 27 patients from 1984 to 2004 (21).

Skin and soft tissue infections attributed to GBS may manifest as cellulitis, abscesses, foot infection, or decubitus ulcers (24, 25). Diabetes mellitus is a common underlying condition in patients with GBS skin and soft tissue infections (13). Necrotizing fasciitis and pyomyositis attributed to GBS has occasionally been described (18, 25, 26).

Acute and chronic osteomyelitis attributed to GBS has been reported in neonates, children, and adults (27). Infection may arise from direct inoculation from overlying skin/soft tissue infection, skin breakdown such as a decubitus ulcer, or via hematogenous seeding (27). Septic arthritis due to GBS is usually monoarticular, although multiple joints may be involved (28, 29). Any joint may be infected, but commonly affected joints include the knee, ankle, and shoulder (28, 29). Septic arthritis may involve prosthetic joints, with the majority of infections occurring at least 3 months after prosthesis placement; some GBS prosthetic joint infections require prosthesis removal in addition to antimicrobial therapy for successful treatment (30–32).

Group B streptococci, concurrently with other organisms, have been implicated in pneumonia (33). Imaging findings may include unilateral or bilateral lobar infiltrates (33). Dementia, neurological disease, and tracheoesophageal fistulae are associated with GBS pneumonia, likely due to increased risk of aspiration of the organism (34). Colonization of the airway with GBS is infrequent in patients with cystic fibrosis and when it occurs, it does not appear to be associated with worse clinical outcomes (35).

Meningitis is a severe manifestation of invasive GBS disease. It is uncommon in adults but is a common manifestation of late-onset GBS infection in neonates (36). Infants who survive the acute phase of the GBS meningitis infection may have significant cognitive or neurological sequelae; 32 to 44% of infants who survived GBS meningitis have neurodevelopmental impairment, with severe impairment occurring in up to 19% of surviving infants (37, 38).

doi:10.1128/microbiolspec.GPP3-0007-2018

Downloaded From Vet-eBooks.com

Another manifestation of GBS disease includes urinary tract infections. Urinary tract infections may be associated with a variety of GBS serotypes (39). In men, GBS may be associated with prostatitis (34, 40). GBS bacteriuria in women during pregnancy is a risk factor for late gestational maternal colonization with GBS and early-onset neonatal GBS infection (41, 42).

PREGNANT WOMEN

Pregnancy has been associated with a high incidence of invasive GBS disease. In a multistate evaluation from 2007 to 2009, the incidence of invasive disease due to GBS was twice as high in pregnant women (0.04/1,000 woman-years) compared to nonpregnant women (0.02/1,000 woman-years) (43). Although the majority of GBS infections are detected during labor and delivery, women in the postpartum period are also at an increased risk for invasive GBS disease even in the absence of other predisposing conditions (43, 44). Rates of maternal invasive GBS disease in the United States vary by state, with rates ranging from 0.1 per 1,000 deliveries to 0.8 per 1,000 deliveries (45). Worldwide, the incidence of systemic invasive GBS disease in pregnant women is estimated at 0.38 cases per 1,000 pregnancies, with a case fatality rate of 0.2% (44). Serotypes Ia and III account for over half of maternal systemic GBS disease, followed by serotypes V, Ib, and II (44). Systemic maternal GBS disease is associated with increased odds of premature delivery and sepsis in infants (44).

Asymptomatic rectovaginal colonization rates among pregnant women vary widely worldwide (Fig. 1), although the majority of estimates fall between 5 and 30% (46–97). A recent review estimated that 18% of pregnant women worldwide are colonized with GBS, and 98% of isolates were serotypes I to V, although there was regional variability in serotype distribution (98). In this study, colonization rates were highest among pregnant Caribbean women at 35% and lowest among pregnant East Asian women at 11% (98). Estimates of GBS colonization in the United States range from 10 to 30% (94–96). Colonization of GBS may be intermittent throughout pregnancy, although 17 to 28% of women with vaginal or rectal colonization in the first trimester have sustained colonization in the second and third trimesters or at term (99). Women with GBS colonization during pregnancy were recently found to have a 1.21 risk ratio for preterm birth compared to women without GBS colonization, with a higher risk ratio (1.98) observed in women with GBS bacteriuria (100).

Risk factors associated with maternal GBS intrapartum vaginal or rectal colonization include GBS bacteriuria during the current pregnancy and a history of GBS colonization in a previous pregnancy (41, 101, 102). In one study of pregnant women, no significant difference in the composition of the vaginal and rectal flora between GBS-colonized and -noncolonized women was observed (99). Studies examining the role of the composition of the vaginal microbiota in relation to colonization with GBS in nonpregnant women have similarly demonstrated no differences in the α-diversity or carriage of *Lactobacillus* between women with and without GBS colonization (103). The role of probiotic administration in GBS carriage remains unclear. One study of *Lactobacillus rhamnosus* and *Lactobacillus reuteri* administered to 110 women with detectable GBS colonization at 35 to 37 weeks gestation until delivery demonstrated that 43% of women in the probiotic group subsequently had negative GBS screens at delivery, compared to 18% in the placebo group; however, there were no significant differences in fetal outcome (104). However, in another placebo-controlled study of 34 women who received a 21-day course of *L. rhamnosus* and *Lactobacillus fermentum/L. reuteri* probiotics after a positive GBS screen at 36 weeks, no difference in GBS colonization rates after completion of the supplementation and no difference in infant health were observed between the placebo and probiotic recipients (105).

NONPREGNANT ADULTS

Although traditionally thought of as a disease afflicting infants and pregnant women, the incidence of GBS disease is increasing among nonpregnant adults, from 3.6 cases/100,000 people in 1990 to 7.3 cases/100,000 people in 2007,

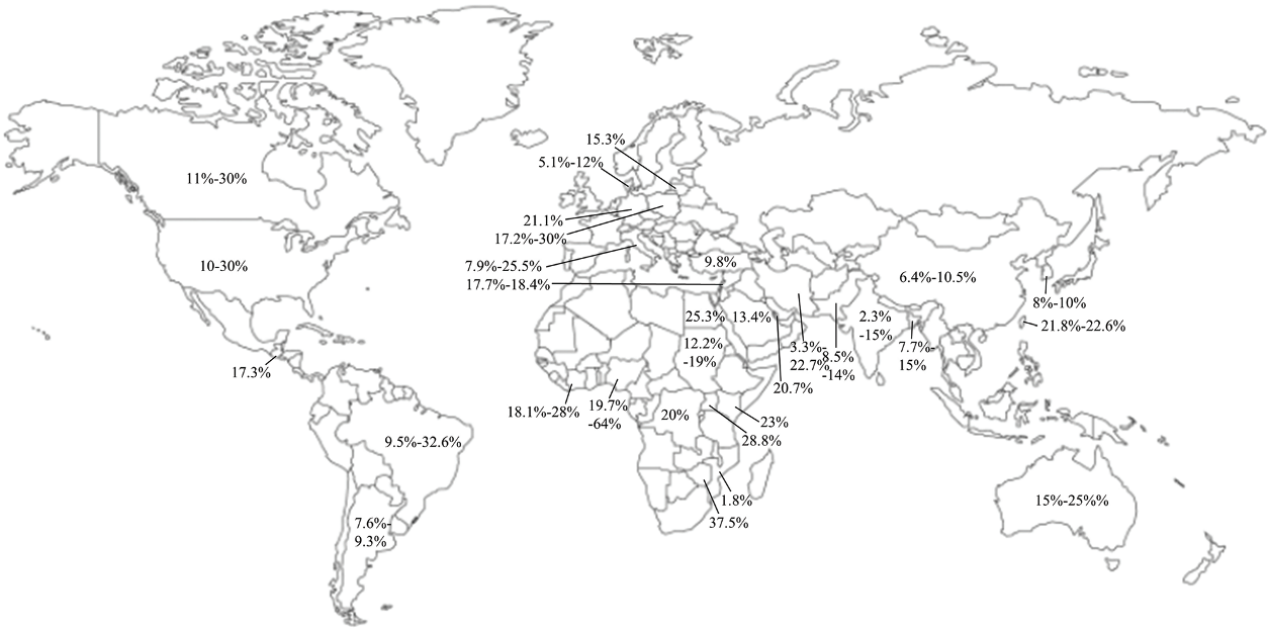

FIGURE 1 *Streptococcus agalactiae* colonization rates in pregnant women.

Downloaded From Vet-eBooks.com

based on surveillance in 10 U.S. states (10). Comorbidities are present in most adults with invasive GBS disease, including heart disease, neurological disorders, kidney disease, liver disease, alcohol abuse, smoking, obesity, malignancy, and immunocompromising conditions (10, 13, 106). Diabetes mellitus is a common comorbidity, particularly among patients with skin/soft tissue infections (10, 13, 106). Higher incidences and mortality rates from GBS disease have been observed among those of black race compared to white race, although the reason for this difference remains unclear (10, 13, 106).

OLDER ADULTS

Higher incidence rates of invasive GBS disease among people age 65 or older compared to the general nonpregnant adult population have been described in the United States (Fig. 2), Canada, the United Kingdom, and multiple European countries (13, 107–111). Annually, invasive GBS affects 25/100,000 adults age 65 and older in the United States (94). The elderly population accounted for approximately 40% of invasive cases reported in the United States in 2015, and they had a higher incidence of deaths (1.08 to 4.73 deaths/100,000 people) compared to the incidence of death in the general population (0.54 deaths/100,000 people) (111). An estimated 12% of elderly long-term care facility residents are colonized with GBS, while an estimated 22% of community-dwelling elderly adults in Houston in one study were colonized with GBS, with 47% carrying serotype V (24, 112). Invasive GBS disease in the elderly commonly presents as bacteremia, urinary tract infection, skin infection, and pneumonia (110, 113). Risk factors for GBS disease in the elderly population include being bedridden and residence in a long-term care facility (107, 110).

NEONATAL DISEASE

GBS is the leading etiology of culture-confirmed neonatal bacterial infection in the United States and results in significant mortality (114). Invasive neonatal GBS disease may be divided into early-onset disease (EOD), occurring at <7 days of life, and late-onset disease (LOD), occurring between 7 and 90 days of life. Serotypes I to V account for 97% of invasive neonatal GBS disease, with serotype III accounting for nearly half (43%) of EOD and 73% of LOD (36). Estimates of the incidence of EOD GBS disease range from 0.7 cases/1,000 live births in 1997 to 0.21 to 0.25 cases/1,000 live births in 2014 and 2015 (Fig. 3) (111, 114–133). Disease due to *S. agalactiae* has been found in 0.58% of neonates with encephalopathy who meet criteria for cooling, a more than 10-fold increase compared to all live full-term infants. These infants have double the risk of fatality compared to those with neonatal encephalopathy without associated GBS disease (134). Worldwide, estimates of EOD cases per 1,000 live births vary from country to country, with incidences of 0.09 in Japan, 0.58 in Panama, 0.76 in Hong Kong, 0 to 1.5 in South Africa, and 2.35 in the Dominican Republic, with a pooled estimate of 0.49 cases per 1,000 live births (36, 135–137). Overall, rates of EOD are highest in Africa and lowest in Asia (36). Worldwide, the pooled incidence of LOD is 0.26 cases per 1,000 live births (36). In the United States, the estimated incidence of LOD is 0.32 cases per 1,000 live births (Fig. 3) (111, 138).

Risk factors for EOD disease include maternal vaginal or rectal GBS colonization, GBS bacteriuria during pregnancy, prolonged labor, prolonged rupture of membranes, low birth weight, prematurity, intrapartum fever, and systemic maternal GBS disease (42, 44, 139). HIV exposure does not appear to be a risk factor for EOD (140). The risk factors for the development of LOD are not as well understood as those for EOD; known risk factors include prematurity and black race (138, 141). While maternal GBS colonization increases the risk of developing LOD, it does not appear to be as strong a risk factor as for EOD (138, 141). Infants exposed to HIV have a 4.43 higher likelihood of developing LOD compared to unexposed infants (140).

EOD is attributed to vertical transmission of GBS from the mother due to either ascending infection from the

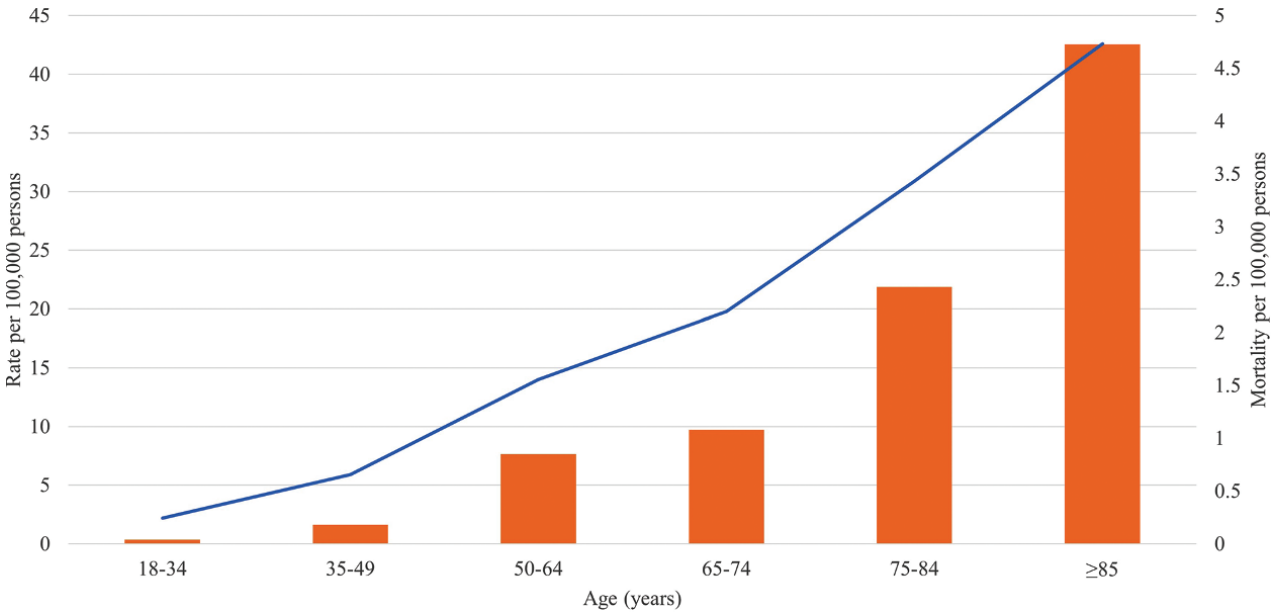

FIGURE 2 Invasive group B *Streptococcus* disease and mortality in nonpregnant adults, United States, 2015. Incidence shown in blue; mortality shown in orange.

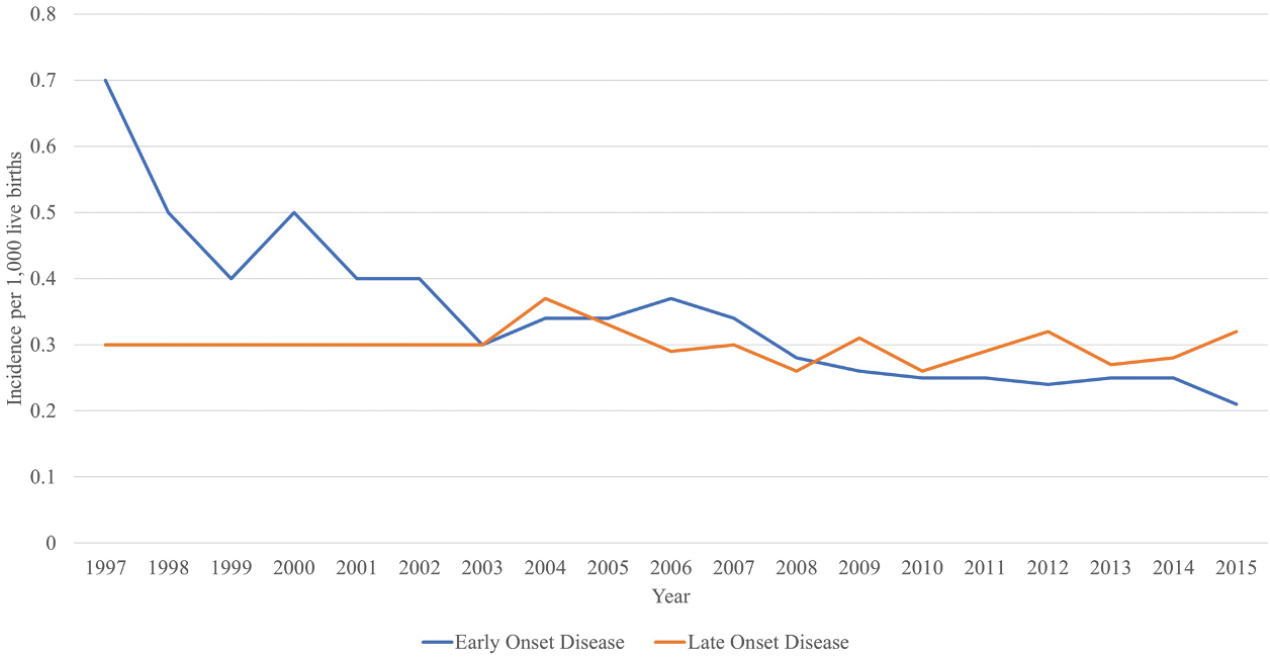

FIGURE 3 Incidence of invasive group B *Streptococcus* disease in neonates, United States, 1997 to 2015.

genital tract or infection obtained during passage through the vaginal canal at delivery; symptom onset may be subtle and may be noted within 24 hours after birth (36, 142). Typical manifestations of EOD include bacteremia and pneumonia, while meningitis, bone and joint, and soft tissue infections are less common (114). LOD is attributed to horizontal acquisition of GBS. Rarely, LOD has been attributed to GBS transmission from human milk among women with GBS mastitis (143). Meningitis is more common in LOD than EOD, although LOD may present as bacteremia, urinary tract infection, bone/joint infection, pneumonia, or soft tissue infections (36, 138, 139).

Neonatal invasive GBS disease overall results in case fatality rates ranging from 1 to 8.4% in full-term infants to 5 to 20% in preterm infants (36, 139). For EOD, mortality rates vary worldwide; in resource-endowed countries the estimated case fatality risk is 5%, but a much higher risk, up to 27%, has been observed in Africa (36). Mortality from EOD in the United States is estimated at 7%, with higher mortality in low-birth-weight and premature infants (114). Worldwide, LOD is estimated to have a case fatality rate of 7% (36). In addition to early- and late-onset invasive disease, *in utero* GBS disease accounts for approximately 1% of stillbirths worldwide and up to 4% of stillbirths in Africa (144).

PREVENTION OF NEONATAL DISEASE

Due to the burden of GBS disease in neonates, preventative measures have been developed to minimize invasive disease. Maternal antibiotic administration to prevent neonatal GBS disease began in 1973 (145). Intrapartum antibiotic prophylaxis reduces EOD among infants born to GBS-colonized women by 86 to 89% (42). In countries without a national policy on intrapartum antibiotic prophylaxis, approximately 1.1% of infants born to GBS-colonized mothers develop EOD due to GBS, whereas in countries with intrapartum antibiotic prophylaxis recommendations, the risk decreases to 0.03% (146). Penicillin or ampicillin administered at least 4 hours prior to delivery is the first-line therapy for intrapartum antibiotic prophylaxis, while cefazolin may be used for penicillin-allergic patients without anaphylaxis, angioedema, respiratory distress, or urticaria (42). In patients with severe penicillin allergy, testing of the GBS isolate for clindamycin susceptibility is recommended with use of intrapartum clindamycin for susceptible isolates and vancomycin for resistant isolates (42). Both risk-based and culture-based models for determining when to administer intrapartum antibiotic prophylaxis are currently in use worldwide and vary by geographic region (147). The United Kingdom does not recommend routine GBS screening cultures for pregnant women and uses risk-based algorithms to guide intrapartum antibiotic prophylaxis, whereas the United States, Canada, Australia, and New Zealand recommend universal screening with GBS cultures (42, 97, 148, 149). Adherence to intrapartum antibiotic prophylaxis guidelines varies widely; estimates of adherence in countries with universal culture-based screening programs range from 20 to 95%, while adherence estimates range from 10 to 50% in countries with risk-based screening programs (147).

Guidelines regarding intrapartum antibiotic prophylaxis for GBS in the United States were first issued in 1996 and have undergone several updates, most recently in 2010. The current 2010 guidelines recommend a screening culture from the vagina and rectum of all pregnant women between 35 and 37 weeks gestation to assess for colonization with GBS and offering intrapartum prophylaxis to all women with positive screening cultures, a history of GBS bacteriuria during the current pregnancy, or a previous infant affected by EOD GBS disease (42). Since the institution of intrapartum antibiotic prophylaxis in the United States, the incidence of invasive early-onset GBS disease has declined from 1.7 cases/1,000 live births in 1993 to 0.76 to 0.77 cases/1,000 live birth in 2005 to 2008 and an estimated 0.21 cases/1,000 live births in 2015 (111, 150, 151). However, while 87% of women in the United States undergo cultures to screen for GBS, only an estimated 36% of women in 2016 received care that was fully

Downloaded From Vet-eBooks.com

compliant with intrapartum antibiotic prophylaxis guidelines; challenges relate to appropriate timing of screening culture collection, appropriateness of intrapartum antibiotic selection, and appropriateness of intrapartum antibiotic dosages and timing (152).

An alternative strategy under development to prevent neonatal and maternal GBS disease is vaccination of mothers in the third trimester against GBS. Lower levels of capsular polysaccharide antibodies in mothers of children with invasive GBS disease compared to mothers of healthy infants have been noted since the 1970s (153, 154). Initial trials of unconjugated GBS polysaccharide vaccines elicited moderate serotype antibody responses (155). More robust antibody responses have been elicited with protein-polysaccharide conjugate vaccines using tetanus toxoid and additional surface protein target vaccines, such as Rib and Alpha C (156–158). Multiple GBS vaccine candidates, including a trivalent protein-polysaccharide conjugate vaccine targeting serotypes Ia, Ib, and III, are currently in development (159). Modeling based on 2015 worldwide disease estimates predicts that a GBS vaccine with 80% efficacy and 90% maternal coverage could prevent 107,000 infant deaths and stillbirths (160).

TREATMENT

S. agalactiae is uniformly regarded to be susceptible *in vitro* to penicillin, although reduced penicillin susceptibility has been detected in isolates from Japan, thought to be secondary to reduced penicillin-binding protein 2× expression (161, 162). However, penicillin G remains the mainstay of treatment for invasive disease. Generally, GBS is susceptible to other beta-lactam antibiotics, including ampicillin; first-, second-, and third-generation cephalosporins; and carbapenems, although the level of activity varies among different agents. In patients who demonstrate an anaphylactic or severe allergy to beta-lactam antimicrobials, alternative therapies include clindamycin, erythromycin, fluoroquinolones, and vancomycin. However, rising levels of GBS resistance to clindamycin, erythromycin, and fluoroquinolones have been noted in a multitude of studies, and these antibiotics should only be used for treatment if penicillin or cephalosporin is not appropriate and susceptibility of the organism has been determined (162–166). Resistance to vancomycin in clinical isolates has been reported (167).

Penicillin G is the first-line treatment for invasive GBS disease in adults (8). The duration of therapy depends on the clinical presentation. Ten days of therapy is generally acceptable for bacteremia, pneumonia, pyelonephritis, and skin/soft tissue infections. Longer durations of treatment are recommended for meningitis (minimum 14 days) and for osteomyelitis, endocarditis, and ventriculitis (minimum 4 weeks) (8). The addition of gentamicin for the initial 2 weeks of therapy is recommended for endocarditis (168).

In neonates with presumptive EOD, empiric therapy with ampicillin combined with an aminoglycoside is the standard of care (139). Once GBS is isolated, penicillin G monotherapy is recommended for treatment of invasive GBS infection in infants. Recommended dosing of penicillin G for infants up to 7 days of age is 250,000 to 450,000 units/kg/day and 450,000 to 500,000 units/kg/day for infants older than 7 days (139). Ten days of appropriate therapy is recommended for uncomplicated bacteremia and 14 days for uncomplicated meningitis, while complicated infections may require a longer duration of antimicrobial therapy. Septic arthritis or osteomyelitis is treated for 3 to 4 weeks, and at least 4 weeks of therapy is recommended for endocarditis or ventriculitis (139).

Genetics and Pathogenicity Factors of Group C and G Streptococci

HORST MALKE

15

The genus *Streptococcus* comprises more than 70 species (some talk of more than 100) classified into eight phylogenetic groups, with Lancefield group C streptococci (GCS) and group G streptococci (GGS) being discovered in four of them, including one unknown group. GCS and GGS carry the immunedeterminant residues *N*-acetylgalactosamine and rhamnose, respectively, on the oligosaccharide side chains of their cell wall carbohydrate antigens. These organisms are distributed in both humans and animals. They are isolated as opportunistic commensals from the skin, nose, throat, vagina, and gastrointestinal tract but may also be associated with clinically important infections of these sites and with hospital outbreaks. Serious diseases caused by human GCS and GGS often resemble those due to their closest genetic relatives, the group A streptococci (GAS, carrying the immunodominant *N*-acetylglucosamine side chains of their cell wall carbohydrate antigens), and include septicemia, pharyngitis, cellulitis, otitis media, septic arthritis, meningitis, infective endocarditis, multiple organ abscesses, necrotizing fasciitis, and toxic shock syndrome (1–11). At one time, the genetic relationships of GCS and GGS strains were complicated and incompletely resolved due to the diversity of species within the serogroups and the uncertainties in assigning species names, particularly to the human-specific strains now classed with the phylogenetic Anginosus group (12). The current classification (Table 1) arrived at by numerous early (13–33) and more recent (34–43) studies relies on habitats, pathogenicity properties, physiological characteristics, and relationships of informational macromolecules, with serological grouping being useful for differentiating infraspecific biotypes. Before the advent of large-scale DNA sequencing and gene cloning technologies, GCS and GGS had rarely been subjected to genetic studies. However, studies of the host range of bacteriophages isolated from GAS, GCS, and GGS, and of their transducing potential, provided evidence for intergroup phage reactions and intergroup transduction between strains belonging to different Lancefield groups, thus amending the original notion of the strict group specificity of streptococcal phage-host interactions and emphasizing the importance of lateral gene transfer for the evolution of GCS and GGS (44, 45). An attempt to elucidate the genetic relationships between GAS, GCS, and GGS based on the nucleotide sequence of selectively neutral housekeeping genes supported events of interspecies gene transfer that predominantly occurred from GAS donors to GCS and GGS recipients (46). In *S. dysgalactiae* subsp. *equisimilis*, recently reviewed studies show that both mobile genetic elements and integrative conjugative elements are involved in horizontal gene transfer, with the latter playing the prominent role in the evolution of this subspecies (47). This applies also to the interspecies transfer of integrative and conjugative elements (ICEs) between *S. salivarius* (Salivarius group) and *S. parasanguinis* (Mitis group; see Table 1), in the case of which components of the mobile subfamily ICE*St3* element were very recently detected in their conjugation modules at high nucleic sequence identities (48). The application of recombinant DNA techniques and phylogenomic studies have advanced our understanding of GCS and GGS in diverse areas, and this article concentrates on the molecular genetics and the structure and function of pathogenetically relevant genes and proteins studied at the molecular level in recent years.

MOLECULAR TAXONOMIC APPROACHES TO THE CLASSIFATION OF GCS AND GGS

Currently, the four GCS and GGS species groups harbor a total of 12 individual species, based on 16S rRNA comparative sequence analysis (Table 1). At least four of them can be subdivided into subspecies, with the possibility of individual isolates within a common phylogenetic group exhibiting a diverse Lancefield group antigen pattern or none at all. The cladogram shown in Fig. 1 resolves the genetic relationships of all 12 species and (i) identifies *S. canis* as the closest relative of *S. pyogenes*, (ii) places *S. massiliensis*, thus far exhibiting an uncertain group assignment, in the Anginosus group, (iii) assigns *S. alactolyticus*, thus far of uncertain grouping as well, close to the *S. equi* clade, and (iv) leaves *S. acidominimus* in the state of unknown grouping and, based on its single-leafed clade, as the species least related to any other species. Of further interest, *S. sanguinis*, not included in Table 1 because it is so far unknown to comprise either group C or G strains (24), turns out not to fall within the Mitis group (Fig. 1), thus confirming that *S. sanguinis* and

[a]Adapted from references 13–43. The order of the group antigens reading across may not correspond to their epidemiological prevalence.
[b]Based on nucleotide BLAST alignments (http://ncbi.nlm.nih.gov) of the specified 16S rRNA sequences relative to that of *S. pyogenes* NZ131 (accession no. NC_011375).

S. parasanguinis are not sister species (14, 22). Current methods for classification of clinically important *Streptococcus* isolates were also explored by determining internal features of their 16S rRNA, with the result of identifying short sequence segments unique to specific species (39). In the above context, such signature sequences were found to be highly conserved in the 16S rRNA genes of *S. dysgalactiae*, *S. equi*, and *S. anginosus* (and *S. pyogenes*), thus rendering identification procedures for them very simple.

Chromosomal DNA-DNA hybridization studies combined with biochemical tests indicate that the Pyogenic streptococci previously named *S. dysgalactiae* and "*S. equisimilis*," together with those belonging to the large-colony-forming GGS and serogroup L strains, exhibit high levels of DNA sequence identity and, on the basis of the commonly accepted species level hybridization (≥70%), constitute a single species, *S. dysgalactiae* (49, 50). Whole-cell protein electrophoresis revealed two subpopulations within this species, leading to differentiation between *S. dysgalactiae* subsp. *equisimilis*, comprising GCS and GGS strains of human origin, and *S. dysgalactiae* subsp. *dysgalactiae*, which harbors animal GCS and serogroup L strains (32). GGS isolated from animals always appear to qualify as *S. canis*. On the grounds of DNA sequence similarity, "*S. zooepidemicus*" is closely related to *S. equi*, warranting a similar subdivision of this species into *S. equi* subsp. *zooepidemicus* and *S. equi* subsp. *equi*, with the latter having evolved as a clonal descendent of the former (51, 52). Recent epidemiological studies have increasingly relied on genotypic classification methods such as restriction endonuclease digestion of total cell DNA followed by conventional (53) or pulsed-field gel electrophoretic analysis of macrorestriction fragment patterns (4, 6, 54), analysis of restriction fragment length polymorphism of rDNA (ribotyping) (27, 28), randomly amplified polymorphic DNA (RAPD) fingerprinting (29, 51, 52), multilocus enzyme electrophoresis (MLEE) (30, 50, 53), and typing based on comparative sequence analyses of the fast-evolving nonfunctional 16S-23S rRNA intergenic spacer region (51, 55, 56). Fluorescent *in situ* hybridization has also been used for the fast identification of GCS associated with necrotizing fasciitis (57). Finally, sequencing an internal fragment of the superoxide dismutase gene has yielded a phylogenetic tree, the topology of which agreed with that obtained from 16S rRNA sequences, rendering this method suitable for species-level identification of various streptococci (26). Taken together, the results obtained corroborate the species classification given in Table 1 and, moreover, testify to the utility of these methods for subspecific typing. For example, RAPD fingerprinting has proved useful in epidemiological investigations designed to delineate new and persistent *S. dysgalactiae* strains that caused intramammary infections in dairy cows (58). Comparison of the discriminatory power of different genomic typing methods revealed that RAPD exceeds MLEE for GGS (and GAS) typing (59) and that pulsed-field gel electrophoresis is even more efficacious than MLEE and RAPD as indicated by its potential to identify 93 distinct types among a total of 41 GAS and 58 GCS or GGS strains, with no types common to strains of different species (54). Although a comprehensive battery of species-specific gene probes for the identification of GCS and GGS has yet to be developed,

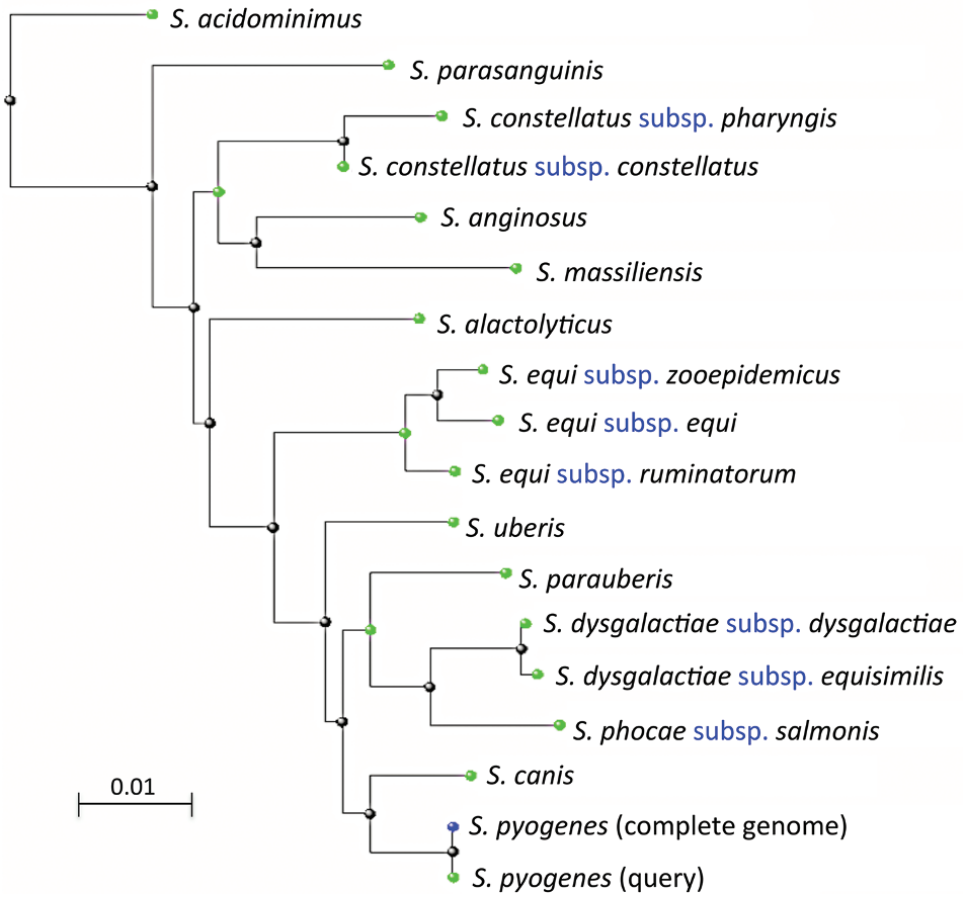

FIGURE 1 Phylogenetic relationships between the GCS and GGS species/subspecies included in Table 1. The cladogram is based on 16S rRNA gene sequences employed in BLAST alignments (http://ncbi.nlm.nih.gov) using the 16S rRNA sequence of *S. pyogenes* NZ131 as a query. The scale bar indicates 0.01 nucleotide substitutions per nucleotide position.

additional attempts to approach this goal have focused on oligonucleotides designed from 16S and 23S rRNA sequences (60). Alternatively, future differential genome analysis applied to GCS and GGS might identify genes that are responsible for species-specific features.

Relying exclusively on serological grouping for identifying GCS and GGS can be misleading, since numerous *S. dysgalactiae* subsp. *equisimilis* strains verified by 16S rRNA sequence analysis turned out to express the Lancefield group A antigen (61–63). Several of these "hybrid strains" were studied more closely and were found to carry the 12-gene *gacA-gacL* linkage group from *S. pyogenes* encoding the Lancefield group A carbohydrate consisting of a polyrhamnose backbone with the immunodominant *N*-acetylglucosamine side chain determined by *gacI* coding for glycosyltransferase (63). Obviously, these strains originate from a recombination event between *S. pyogenes* and a progenitor *S. dysgalactiae* subsp. *equisimilis* strain(s) comprising the entire *gacA-gacL* cluster.

PHYLOGENOMIC FINDINGS IMPLICATING GCS AND GGS

The exponential increase of available streptococcal genomes in recent years coupled with their comparative analysis led to the realization that they constitute dynamic entities undergoing continuous changes. The cladogram in Fig. 1 is concordant with the two latest independently derived phylogenies of the available genome sequences in 2014 for the genus *Streptococcus* when broken down to the clades related to GCS and GGS (37, 42). Both studies relied on, among others, highly revealing gene clustering methods using Markov clustering algorithms, hierarchal clustering, and assigned gene ontology terms to all available genomes (42) or used population structure analysis to investigate the relationships of the genus *Streptococcus* to the phylogenetic species groups (37). Of particular interest are gene gain/loss analyses showing that for most GCS and GGS species groups, their genomes evolve from an initial interval of gene gain (branches preceding those leading to the eight phylogenetic groups) through an interval of gene loss during diversification of the species groups, which ends with final genome expansion as indicated by a positive-gain negative-loss balance for the terminal branches of the present extant species. The exception is *S. uberis* within the Pyogenic group, which shows an overall gene loss at the tip of its branch. This evolutionary streamlining ("reductive evolution") and expansion process (42) is strongly supported by evidence indicating an open *Streptococcus* pan-genome which increases with the number of newly sequenced strains and is characteristic of species striving in multiple habitats open to lateral gene transfer (37, 64). In contrast, the core genome of the genus decreases with increasing genome numbers and finally reaches a plateau accounting for less than a fifth of the average gene content (ca. 2,000 genes [37]).

Downloaded From Vet-eBooks.com

Leaving the genus level and considering the phylogenetic species groups, the corresponding analyses reveal similar trends, although pan-genome sizes are smaller and core genome sizes larger than those at the genus level after new additions. When individual GCS and GGS species are examined, *S. parauberis* of bovine origin and *S. equi* subsp. *ruminatorum* excel at showing a greater gene gain/loss ratio than any other taxon (gain/loss = 6.0 and 3.4, respectively [42]). *S. parauberis* recently isolated as a pathogen from farmed fish (65) showed a considerable amount of gene turnover in this new habitat (gain/loss = 1.3 versus 6.0). It remains to be seen whether intensive aquaculture can account for the restructuring of its genome. Otherwise, in the biggest phylogenetic group, the Pyogenic group, there is little correlation between evolutionary relationships and host species (42). The best examples are the three subspecies of *S. equi*, which have short terminal branch lengths but infect a broad range of hosts. A similar situation is true of the two *S. dysgalactiae* subspecies, suggesting that a combination of reduced intergroup lateral gene transfer and group-specific reductive evolution has shaped the phylogenomic cohesiveness of the phylogenetic groups (42).

Within the phylogenetic groups relevant to GCS and GGS, gene ontology terms, i.e., assessments of the evolution of biochemical characteristics, show differential enrichments in two groups (42). Specifically, in the Mitis group, containing *S. parasanguinis*, genes annotated with the proteolysis term occur in the highest frequency. This reflects the human environments of the group in which proteases have prominent roles in colonization, dental plaque formation, utilization of salivary proteins, interfering with host defenses, or spreading through tissue. The importance of this characteristic is underscored by the observation that it is not subject to extensive reductive evolution. An additional feature found in this group is the enrichment for *N*-acetyltransferases, some of which are responsible for resistance to aminoglycoside antibiotics to which the group is intrinsically resistant. For the second group, the Pyogenic group, most of the enriched terms involve the carbohydrate metabolism, including the phosphoenolpyruvate-dependent sugar phosphotransferase system. This again is due to the wide host and environmental ranges inhabited by this group, as emphasized by the observation that these genes already arose in the branch leading to the phylogenetic group. As could be expected, also enriched in the Pyogenic group is the pathogenesis term, with *S. dysgalactiae* subsp. *equisimilis* and *S. equi* subsp. *equi* sharing 12 genes with each other. Of further interest, the pathogenesis gene ontology term does not occur in the branch leading to the Pyogenic group, suggesting acquisition by lateral gene transfer during evolution of the terminal branches.

In conclusion, evolutionary cohesiveness of the species in the phylogenetic groups generally includes GCS and GGS (42). Population structure analyses of streptococcal strains reveal two distinct evolutionary lineages, which when broken down to GCS and GGS include the Pyogenic group, on one hand, and the Mitis, Anginosus, and Unknown groups, on the other (37). Aside from the central topic of the foregoing considerations, the coccoid morphology of the genus *Streptococcus* contrasts with its molecular dynamics by presenting a "near-dead-end" state in its phylogeny (66, 67). Mapping prokaryotic cell shape onto the phylogenetic tree reveals spherical cells only at the tips of the branches, neither returning to other shapes nor occurring at primordial branches but having a polyphyletic origin. Thus, the coccus has selective value and deserves increased consideration in efforts directed at understanding this multifaceted genus. Investigations into the latter topic will also need to focus on the coordinated regulation of metabolism and virulence as implicated by the omnipresent three metabolite-responsive global CcpA, CodY, and Rex regulators that determine the relationship between streptococci and their hosts (68).

CELL SURFACE-ASSOCIATED PROTEINS

One hallmark of the Gram-positive pathogens is the synthesis of specific cell wall-associated proteins which enable them to interact in various ways with proteins present in the body fluids or extracellular tissue matrix of their mammalian hosts. Such interactions may facilitate colonization, lead to molecular host mimicry, or interfere with various host defenses against invasion.

M and M-Like Proteins

The major bona fide virulence determinant of GAS, M protein, is generally accepted to comprise polymorphic, fibrillar surface-exposed polypeptides that share common structural and functional features, among them a high propensity to form an alpha helix with a periodicity indicative of a coiled-coil structure, the capability of inhibiting phagocytosis by human neutrophils, and the potential to elicit opsonic antibodies that provide type-specific protection. Several studies conducted mainly in the 1980s provided highly suggestive evidence based on serological cross-reactions with typing sera or monoclonal antibodies raised to M protein from GAS, phagocytosis inhibition, and DNA hybridization analysis that M proteins or M-like proteins are also encoded and expressed by GCS and GGS (69). Subsequent cloning and sequence determination of the corresponding genes as well as analysis of immunoreactivity afforded conclusive evidence in support of this notion (47, 70–76). The first M protein gene to be isolated from a human GGS strain, *emmG1*, encodes a product with structural features characteristic of GAS class I M proteins that are epidemiologically associated with rheumatogenic, opacity factor-negative serotypes (76). As expected, structural similarity between MG1 and the GAS class I M proteins was significantly greater in the C-terminal regions (containing the anchor domains and the C and D repeats) than in the N-terminal portions (containing the A and B repeats) of the mature proteins (86 to 94% versus 31 to 35% amino acid identities), an observation consistent with a difference in antigenicity between MG1 and the GAS M types. An *emmG1* probe encoding the variable region of MG1 detected homologous DNA in seven additional M-positive GGS strains but also revealed at least four distinct *emm* alleles harbored by these strains. The essential aspects of these findings were confirmed and expanded by others (31, 63, 77–79) using a greater and epidemiologically unrelated number of GGS isolates that also included strains recovered from animal sources.

It is noteworthy that none of the DNA specimens isolated from GGS strains originating from animals hybridized with appropriate *emm* gene probes from GAS, whereas all DNAs from human GGS strains (large-colony-forming isolates) did (31, 77). Probes designed to differentiate between GAS M class I and class II genes detected only GGS *emm* genes related to GAS M class I genes (31). The complete sequence of an additional GGS *emm* gene (*emmLG593*), together with the sequences of the 5′ ends of 30 additional GGS *emm* genes, revealed six distinct "genetic types" which in paired comparisons shared <95% sequence identity in the *emm* gene region coding for the mature N termini (31). This observation

Downloaded From Vet-eBooks.com

adds further support to the genetic heterogeneity of the M proteins of GGS and, if consistent with future supplementary obsonophagocytotic studies, may be used for the development of GGS M typing schemes for epidemiological purposes. Most interestingly, in the latter studies (31) as well as in those conducted independently by others (78, 79), certain GGS *emm* genes were identified, defined portions of which exhibited exceedingly high levels of sequence identity to the variable regions of well-established GAS class I M protein genes, most notably *emm12* and *emm57*. Inasmuch as the results of total genomic DNA-DNA hybridization, chromosomal restriction endonuclease profiling, and MLEE all indicate that GGS are appreciably divergent from GAS in overall genomic character and, hence, have no recent GAS ancestors, the most likely explanation for the high local homology of certain *emm* genes in the two serogroups is intergroup horizontal genetic exchange followed by homologous recombination events (78, 79). Although several scenarios can be envisaged to suggest possible modes of DNA transfer, the actual transfer mechanisms remain in the dark.

In GCS isolated from horses, several M or M-like proteins have been characterized at the molecular level: SeM (functionally closely related to FgBP) (80) produced by *S. equi* subsp. *equi*, and SzP and SzPSe produced by *S. equi* subsp. *zooepidemicus* (73, 74). SzP and SzPSe are structurally only marginally related to SeM. They are antigenically cross-reactive and are coded by allelic variants of the same hypervariable gene. Functionally, however, all three proteins resemble M proteins of GAS in being capable of inhibiting phagocytosis, eliciting serum opsonic and protective responses, and binding (equine) fibrinogen (74, 80, 81). The complete sequences now available for these proteins are consistent with earlier serological and other observations indicating that the *S. equi* subsp. *equi* proteins are antigenically conserved, whereas those from equine isolates of *S. equi* subsp. *zooepidemicus* exhibit great antigenic variation (52). These observations, together with data derived from comparative MLEE, suggest that *S. equi* subsp. *zooepidemicus* is the ancestral species from which a clone now named *S. equi* subsp. *equi* emanated (51, 52); later, multilocus sequence typing (82) and genome comparisons (83) provided conclusive evidence for this suggestion. Although, unlike the SzP protein family, SeM is highly conserved, sequencing the variable regions from 145 isolates revealed 21 alleles assignable to four phylogenetic clusters (84). This should allow the differentiation of strangle outbreaks. Furthermore, SeM is the stronger opsonizing antigen in small laboratory animals, which together with its proven involvement in pathogenicity (74), has made it the main component of commercial strangles vaccines (8).

Analysis of truncated FgBP/SeM fragments has shown that binding to fibrinogen requires a fairly large stretch of the protein reaching from the vicinity of the N-terminus to about residue 350 of the 534 total amino acids (85). FgBP also uses distinct structural features to bind IgG-Fc (86, 87) and acquires thermal stability owing to an extensive α-helical coiled-coil structure situated in the C-terminal portion of FgPB (88). Of note, in the regions external to the cell wall, the SeM and SzP family proteins share no obvious sequence homology with GAS M proteins (74). However, M antigens closely related to the GAS class I M proteins and to those of the human GGS strains have also been detected on *S. dysgalactiae* subsp. *dysgalactiae* associated with bovine mastitis (75) and GCS isolated from humans (71, 89, 90). It is noteworthy that sequencing the DNA upstream of these M protein genes identified cooriented open reading frames designated *dmgA* (75) and *mgc* (71), respectively, with a high degree of sequence similarity to *mga*, the regulator of *emm* gene expression in GAS. In this connection, the FAI protein found in a GCS isolate from a horse (91) deserves special attention. FAI consists of overlapping functional modules responsible for fibrinogen, IgG, and albumin binding. Its three C repeat copies share 40 to 50% sequence identity with the B repeats of GAS M type 49 and the C repeats of M12 but exhibit no sequence similarity to any portions of SeM or the SzP proteins. Since GAS are usually not distributed in hosts other than humans, it seems doubtful that the strain producing FAI is a genuine horse strain and that the *fai* gene results from intergroup DNA exchange (74).

Given that the virulence mechanisms of *S. canis*, the closest relative of GAS, are incompletely resolved, the M protein of this species, SCM, deserves consideration in this connection. SCM is known to bind mini-plasminogen (mini-PG), the cleavage product of the zymogen PG, with high affinity, thus immobilizing plasmin (PM) onto the cell surface where this protease functions as a major virulence factor by mediating spreading of streptococcal infections. Very recently, SCM turned out to add to the great number of streptococcal proteins that bind to the immunoglobulin G (IgG)-Fc region in a nonimmune fashion (92). The IgG receptor function of SCM involves IgG-Fc from many mammalian sources, including human IgGs. This nonopsonic interaction mediated by the antiphagocytotic action of complement component C1q occurs via a conserved 52-amino acid region in the SCM center, which shows no homology to the IgG-Fc receptor of *S. dysgalactiae* subsp. *equisimilis* (92).

Protein G and Related Ig-Binding Proteins

The most thoroughly studied cell surface protein produced by many human GGS and GCS strains is protein G, which binds the heavy chains of IgG-Fc and Fab with an affinity comparable to that of antigen. Conventional thinking implies a contribution to adherence, inhibition of phagocytosis, and host mimicry in the role that protein G may have in pathogenesis, and evidence in favor of this notion has accumulated in recent years (93). Although the structure of protein G is reminiscent of staphylococcal protein A, the two polypeptides share, except for their C termini, little sequence identity (94–96). The protein G genes (*spg*) of distinct *S. dysgalactiae* strains may differ in their actual nucleotide sequence and size. However, allowing for processes such duplication of internal repeats and recombination and replication slippages involving repeats (94, 97), different *spg* alleles exhibit a very high level of sequence identity, making protein G a unique type among the diverse group of Gram-positive Ig-binding proteins. Compared to protein A, protein G binds not only to human, rabbit, mouse, and guinea pig IgG but also to IgG from cow, horse, sheep, and goat, which protein A does not bind. In addition to showing wider IgG species reactivity, protein G, unlike protein A, also binds human subclass IgG_3. Finally, protein G's reactivity is strictly limited to IgG (protein A also binds IgM.) (95). Because of these properties, protein G has become one of the most versatile tools in immunochemistry. Dissection of the molecule by enzymatic and genetic means followed by functional analysis of defined fragments confirmed early observations indicating that protein G is multifunctional in binding IgG, serum albumin, and α_2-macroglobuline (α_2-M) (85, 95, 98–101). Of particular significance in this context is α_2-M, a component of the innate immune system, which as the major proteinase inhibitor of the plasma, serves as a humoral defense barrier

Downloaded From Vet-eBooks.com

against pathogens in blood and tissues. Thus, as schematically shown in Fig. 2, IgG Fc-binding resides in the C-terminal portion of the protein G molecule and is mediated by two or more repeated domains, whereas the albumin-binding activity is a separate function of repeated domains in the N-terminal half. α_2-M binding resides in the N-terminal tip of the mature protein that lacks repeated sequence elements. Functional remnants of protein G have been retained in the protein G-related α_2-M-binding protein GRAB of GAS (102); however, sequence similarity of GRAB to protein G of GCS and GGS is limited to its N- and C-terminal regions.

The three-dimensional structures of the 56-residue B1 and the 57-residue B2 IgG Fc-binding domains of protein G from GGS strain GX7809 (94) have been determined by nuclear magnetic resonance spectroscopy (103) and X-ray diffraction analysis (104), respectively. The two approaches yielded essentially identical overall structures characterized by a four-stranded β sheet and a helix lying diagonally across the sheet and connecting the outer two β strands, β2 and β3. The IgG-binding interface of this structure is formed by negative charges distributed around the helix and β3 (105). The entire folding motif is very compact and shows high thermal stability owing to extensive hydrogen bonding and tight packing of its buried hydrophobic core. Taking advantage of these properties, the folding thermodynamics and mechanism of the B1 segment have been studied (106) and an M13 phage-B1 domain display system developed to pinpoint primary structure requirements for thermodynamic stability of the B1 domain (107). Interestingly, the IgG-binding domains also bind, in a nonimmune manner, heavy-chain constant-region sequences of the Fab portion of IgG but use disparate parts of their structure to bind the heavy chains of Fc and Fab. The crystal structure of the complex between Fab and the third IgG-binding domain of protein G shows that the outer β2 strand of the molecule aligns in an antiparallel fashion with the last β strand of the constant heavy chain domain of Fab, CH1 (108). In this manner, the β sheet structure is extended into protein G. Because the CH1 domain is highly conserved in the IgG Fab fragments from diverse species, these findings neatly explain the broad specificity of the protein G-IgG interaction. Moreover, provided that backbone-backbone hydrogen bonding between the interacting β strands is preserved, this arrangement allows Fab binding in the presence of considerable primary structure variability.

Fragmentation of human serum albumin located its single protein G-binding site to disulfide loops 6 to 8, with a 5.5-kDa pepsin fragment showing complete inhibition of the interaction between protein G and the full-length albumin (109). The crystal structure for a complex between human serum albumin and the albumin-binding domain (the GA module) of the PAB protein from *Finegoldia magna* (formerly *Peptostreptococcus magnus*) has been solved (110). As a result of an intergeneric sequence transfer event, the GA module exhibits high sequence similarity to the albumin-binding domain of protein G. The human serum albumin/GA complex sheds some light on the amino acid residues involved in conferring broader albumin-binding specificity on protein G than on PAB, which preferentially binds only primate albumins, in accord with the human pathogenic lifestyle of *F. magna* (110).

More recently, IgG-binding proteins have been found that show interesting functional differences from the prototype protein G molecules. The *mag* gene cloned from an *S. dysgalactiae* strain codes for a polypeptide with three discrete domains corresponding to those of the trifunctional protein G (111). However, the albumin-binding spectrum of Mag is broader than that of protein G, including albumins from at least nine mammalian species (112). The *mig* gene isolated from a case of bovine mastitis specifies a protein with binding activity to IgG, which resides in five C-terminal repeats, and to the α_2-M-proteinase complex. The latter activity is located in the N-terminal portion of the Mig protein, which exhibits only weak sequence similarity to the α_2-M-binding domain of the Mag protein. Furthermore, the Mig protein has no albumin-binding activity (113). Finally, the Zag protein, isolated from an *S. dysgalactiae* subsp. *zooepidemicus* strain, shows a molecular architecture that is similar to that of the Mag protein, but its N-terminal α_2-M-binding domain represents a third unique type of this module with little sequence similarity to the corresponding regions of either the Mag or Mig proteins. However, inhibition assays showed that all three proteins compete for the same or overlapping sites in the α_2-M molecule (114). The pathogenetic role of these proteins remains to be further established; however, evidence has been published showing that proteinase-complexed α_2-M bound to animal GCS inhibits phagocytosis *in vitro* (115).

One shortcoming of native protein G with regard to its application as a reagent for purification and detection of antibodies is the low affinity of its multispecific C2 domain for binding to the antibody IgG-Fab fragment (K_d [dissociation constant] ≈ 3 μM), in contrast to the high affinity of C2 for the IgG-Fc region (K_d ≈ 10 nM). To overcome this disadvantage for single-step Fab purification, a phagemid expressing engineered C2, designated protein G-A1, was recently constructed (116). This G-A1 variant possesses eight amino acid substitutions in C2, which greatly improves its human IgG1-Fab isotype affinity (K_d ≈ 25 nM). Rational mutagenesis based on three-dimensional structural evidence led to a series of additional variants showing (i) abolished IgG-Fc but preserved high-affinity Fab binding useful for the separation of the two fragments, (ii) pH-dependent affinity advantageous to antibody fragment purification (1,000-fold change from pH 7 to 4), (iii) enhanced stability in basic conditions useful for regenerating affinity columns, and (iv) specific Fab-antigen affinity enhancement by tethering two protein G-A1 molecules to yield a dimer. Taken together, the engineered protein G variants should prove useful for a multitude of applications.

Fibronectin (FN)-Binding Proteins

Studies published in the early 1980s showed that most GCS and GGS were able to bind FN (117, 118). However, it was

FIGURE 2 Schematic representation of the domain organization of protein G, adapted from reference 102. S, signal sequence; E, α_2-macroglobulin binding; A and B, human serum albumin binding; C, IgG binding; W, cell wall-associated region; M, cell membrane-associated region.

Downloaded From Vet-eBooks.com

not until the early 1990s that surface proteins of GAS, GCS, or GGS that bind to FN were characterized at the molecular level. The primary function of this adhesive matrix protein, extensively studied over the past 3 decades, is to mediate substrate adhesion and migration of eukaryotic cells via integrin receptors that bind to central parts of the molecule containing the arginyl-glycyl-aspartic acid (RGD) sequence motif. Among the best-studied GCS and GGS proteins responsible for FN binding are those encoded by the *S. dysgalactiae* genes *fnbA*, *fnbB* (cloned from the same strain) (119, 120), and *gfbA* (121); the *S. dysgalactiae* subsp. *equisimilis* gene *fnb* (122); and the *S. equi* subsp. *zooepidemicus* gene *fnz* of the animal ZV strain, which also produces the Zag protein (see above) (123). The mature proteins appear to occur in two size classes of about 60 and 120 kDa, but they all consist of C-terminal repetitive domains that are close to the cell wall-spanning regions and mediate binding to the 29-kDa N-terminal segment of FN. Comparison of the C-terminal repeats reveals a consensus sequence consisting of two adjacent glycines surrounded by highly acidic tripeptides that are required for binding activity, as indicated by the inhibitory effect of synthetic peptides that mimic individual repeats and show a high level of cross-reactivity (124, 125).

In addition to these interactions, the sequence motif LAGESGET separating the first and the second repeat of the Fnz protein has been identified as an important part of an FN-binding domain which does not bind the 29-kDa FN fragment (123). The FN-binding proteins F1 and F2 of GAS also have at least two domains, each responsible for binding. The F1 domain N-terminal to the repetitive domain contains the LAGESGET motif (126). The F2 protein, which is homologous to FnbB and Fnb, contains a nonrepeated domain, designated UFBD, which lies upstream of the repeat region and exhibits FN binding independently of the repeat domain (126). UFBD displays a high degree of sequence similarity to FnbB and Fnb regions N-terminal to their repetitive domains, strongly suggesting that FN-binding proteins generally use multiple domains for ligand binding (127, 128). This also includes Fnz (129) and FnbA, in which a previously unidentified region, Au, upstream of the repeats is capable of independent FN binding (130). Interestingly, a monoclonal antibody raised to FnbA enhances, rather than inhibits, FN binding to protein fragments or synthetic peptides containing Au and recognizes only the Au-fibrinogen complex (130). Circular dichroism analysis suggested that the ligand-binding site containing Au has little secondary structure but on binding FN is induced to form a predominantly β sheet structure that is seen by the antibody (131). The infected host might respond to such ligand-induced conformational changes with antibodies directed against the complex, thus stabilizing, rather than blocking, tissue adherence of the pathogen (130). That FN-binding proteins do contribute to adherence is shown, e.g., by the correlation between the presence of the *gfbA* gene (present in 36% of GGS strains tested) and the ability of such cells to adhere to human skin fibroblasts, as well as by the transformability of a nonadherent strain to the adherence phenotype upon introduction of *gfbA* (121). There is also evidence that GCS and GGS, like their GAS relatives, are capable of invading nonphagocytic host cells (99, 132, 133), a potential that is dependent on FN-binding proteins. A model for the internalization process based on structural studies implies that the originally disordered primary C-terminal FN-binding repeats form an extended tandem β-zipper upon binding to the string of F1 modules contained in the N-terminal 29-kDa FN domain. The binding of multiple FN molecules results in integrin clustering on the host cell membrane and subsequent endocytosis of the streptococcal cells (134).

Apart from the microbial surface components recognizing adhesive matrix molecules characterized above, a novel FN-binding protein, Sfs, displaying partial sequence similarity to collagen, was identified in many strains of *S. equi* subsp. *equi* and subsp. *zooepidemicus* (135). Sfs, which also has a counterpart in GAS, binds to the 30- to 40-kDa collagen-binding domain of FN and, accordingly, inhibits the binding of collagen to FN. Furthermore, the N-terminal fragment of protein Fnz from *S. equi* subsp. *zooepidemicus* binds to murine cells, collagen, and FN, suggesting that this protein is involved in the control of complex adhesive processes in infected tissues that express the αVβ3 integrin (136). The *fnz* gene suffered a one-nucleotide deletion in the middle of the coding sequence, giving rise to a frameshift creating the truncated but still functional *fne* gene encoding the N-terminal half of Fnz that binds to collagen. Interestingly, both Fne and Sfs are secreted into the growth medium due to the lack of a cell wall-anchoring motif, rendering their direct involvement in streptococcal adherence to host cells doubtful. However, both proteins interfere with the binding of collagen/gelatin to FN, reiterating their possible mediation of matrix assembly and cell migration processes (137, 138). Regarding Fne, its crystal structure provides surprising evidence for similarity to the *S. pyogenes* SF370 Spy0125 pilus adhesin and binding of the Fne C-terminus to the collagen/gelatin domain through the β-zipper extension mechanism mentioned above (138). Given the importance of the mutual interaction of FN and collagen in the extracellular matrix for the normal development and properties of many tissues, the above findings significantly add to our understanding the GCS and GGS surface proteins' potential for adherence to epithelial host cells and their invasion, enabling spreading of the pathogen into deeper tissue.

Plasmin(ogen)-Binding Proteins

Under this heading, the focus is on GCS and GGS strains that, in interaction with their specific hosts, recruit plasmin(ogen) on their cell surface. Species that carry such nonactivating PG-binding proteins mainly, but not exclusively, include *S. canis* and *S. dysgalactiae* subsp. *equisimilis*. Essentially, these proteins fall into two groups: (i) M-(like) proteins and (ii) so-called moonlighting proteins synthesized in the cytoplasm and transported to the cell surface (139). Although early studies provided evidence for the presence of plasmin(ogen) on the cell surface, the nature of the receptor proteins responsible for binding remained largely unknown (140–142). Sequence information is available, however, for two related M-like proteins from human GCS and GGS strains capable of binding PG to distinct sites of these proteins (141). Moreover, the GGS protein showed partial sequence identity to the PG-binding M-like protein from GAS termed PAM (141), hinting at the possibility that M-like proteins might be responsible for PG binding. Plasminogen binding and activation is also a common property of bovine mastitis-associated group C strains, with features indicating species specificity regarding the origin of the plasma proteins (142). Subsequent studies reviewed in references 139 and 143 provided ample evidence and specific details of the involvement of M-like proteins as the receptor molecules for plasmin(ogen) binding. They are linked to the streptococcal cell wall via a typical LPxTG motif and, in the case of *S. canis* and *S. dysgalactiae* subsp. *equisimilis*, exploit kringle 5 of mini-PG as their binding site. The two species differ,

Downloaded From Vet-eBooks.com

however, in the mode of PG activation: while the former uses host-derived urokinase and tissue-type PG activator, the latter expresses streptokinase (SK) to generate plasmin (PM). Surface-bound PG protects against phagocytosis and promotes adherence to endothelial cells, while PM is involved in the degradation of the extracellular matrix facilitating bacterial invasion.

The surprising discovery in GAS that the glycolytic enzyme glyceraldehyde-3-phosphate dehydrogenase (GAPDH), which possesses none of the hallmarks of Gram-positive cell surface proteins, can be localized to the cell wall to function as a major binding protein for a variety of mammalian proteins, including PM (144, 145), prompted the isolation and functional analysis of the corresponding gene (*gap*C) in the human group C strain H46A (146). In this strain, *gap*C is an essential gene which occurs in a single copy and is abundantly transcribed. Its product shares 95% sequence identity with *S. pyogenes* GAPDH. Moreover, the number and position of lysine residues shown to be involved in plasmin(ogen) binding (144, 146) are identical in the two proteins. The binding parameters for human PG and PM of purified GapC protein were determined by real-time biospecific interaction analysis, with results indicating that the protein binds PM and PG with about 10-fold different affinities (K_d values, 25 nM and 220 nM, respectively). Thus, the zymogen and active enzyme appear to possess low-affinity binding sites for the *gap*C gene product, a result that is at variance with that ascribed to GAS GAPDH, whose PM-binding activity was reported to be 3 orders of magnitude higher (147). On reexamination, the GAS strain involved turned out to display other PM-binding substances on the surface in addition to GAPDH (148). A candidate substance could be the glycolytic enzyme α-enolase, which was subsequently identified as a novel ubiquitous streptococcal surface protein with strong plasmin(ogen)-binding capacity (149). Given the 2-μM concentration of PG in plasma, even the high K_d value for the association of this protein with GapC would suggest that, in the vasculature, the great majority of the *S. equisimilis* H46A PG-binding sites are occupied, even if GapC is the only PG-binding protein. An SK-negative mutant of H46A, isolated to eliminate endogenous PG-activating capacity, has been shown to bind PG as indicated by the generation of cell-surface-associated PM activity following exposure to exogenous PG activators (150).

A novel aspect characterizing the interaction of plasmin(ogen) with surface GAPDHs relates to the finding that limited prior treatment with PM greatly increases the subsequent PG-binding capacity of these proteins (146). Presumably, the underlying mechanism involves the exposure of new PG-binding sites on GAPDH by PM, which preferentially catalyzes the hydrolysis of α-amino-substituted lysine (and arginine) esters. In the infected host, streptococci capable of transporting GAPDH (and α-enolase) to the cell wall and secreting SK would thus appear to have evolved a remarkable system to generate and amplify cell-surface protease activity. Host PG bound with low affinity can be converted to the active enzyme directly on the cell surface. The cell-bound PM may generate additional PG-binding sites on GAPDH to start new cycles of PG binding and activation, resulting in amplification of the tissue-invasive potential of the pathogen. Although there exist strains producing proteins unrelated to GAPDH that display high-affinity plasmin (ogen)-binding sites (141), the special role of GAPDH (and possibly α-enolase) is due to its general occurrence on the surface of the pyogenic streptococci (145, 149). A major challenge to what is presently understood of the PG-binding and -activating capacity of pathogenic streptococci relates to the identification of possible factors involved in the modulation of cell surface protease activity that may be necessary to avoid destructive proteolysis of surface structures important for colonization and invasion. It is interesting to note that a screen designed to identify *Escherichia coli* genes expressed preferentially by natural isolates when incubated in nutrient-poor aquatic medium identified a streptococcal *gap*C homolog (85% sequence homology), suggesting acquisition of the gene by horizontal transfer from a Gram-positive organism and possible involvement in the preparation of cells for the colonization of a new host (151).

Targeting Alginate

The exopolysaccharide alginate, a copolymer of D-mannuronic acid and α-L-guluronic acid, is produced by mucoid strains of *Pseudomonas aeruginosa* that are the functionally predominant pathogens in the polymicrobial biofilm associated with devastating chronic pulmonary infections in cystic fibrosis (CF) patients (152). The oral commensal GCS species *S. parasanguinis* and *S. anginosus* have recently been found to be able to become numerically dominant in the biofilm, thus specifically modulating the behavior of *Pseudomonas* in clinically interesting ways (153, 154). In a similar vein, a recent study implicated the biofilm matrix rather than *P. aeruginosa* in the anti-inflammatory response in CF patients, thus directing attention to the possible role of the induction of the innate immunity system in CF (155).

Within a 6-hour dual-species biofilm formed by the mucoid *P. aeruginosa* strain FRD1 and the oral commensal *S. parasanguinis* strain FW213, strain FRD1 promoted the number of FW213 colony-forming units (CFU) by more than 10-fold compared to the single FW213 biofilm (153). Similarly, FRD1 promoted the planktonic cell growth of FW213. In the presence of alginate lyase, which destroys the copolymer by cleaving its β-1,4 linkage, FRD1 was unable to promote the FW213 biofilm. Moreover, FRD1 mutants defective for alginate biosynthesis did not enhance the FW213 biofilm. The importance of alginate in the dual-species biofilm was further supported by immunofluorescence microscopy and confocal laser scanning microscopy, showing that the streptococcal cells are colocalized with alginate, thus exploiting the latter as a biofilm matrix component. In the search for the biofilm-related factors that determine the streptococcal interaction with alginate, sortase A was found by mutational analysis to be responsible for promoting not only the mono-species but also the dual species FW213 biofilm. Since sortase A was previously known to anchor the fimbria-associated BapA1 and Fap1 adhesins to the cell surface of oral streptococci, further mutational analyses showed that BapA1 is required for enhanced biofilm formation by *S. parasanguinis* in the presence of alginate. Finally, these results obtained *in vitro* were expanded by employing the *Drosophila melanogaster in vivo* model in combination with the available set of mutants, showing that the wild-type alginate producer FRD1 promotes *S. parasanguinis* colonization *in vivo* and that, under these conditions, either BapA1 or Fap1 suffice to enhance *S. parasanguinis* colonization (153).

The interaction between the mucoid alginate overproducing CF-associated *P. aeruginosa* strain DWW2 and the oral commensal *S. anginosus* strain 3a stands in striking contrast to the dual-species FRD1-FW213 interaction reviewed above (154). To mimic the atmospheric microenvironments relevant to the CF airway, the responses of DWW2 and 3a to biofilm mono- and coculture were investigated in normoxic, hypercapnic, and anoxic conditions, with the focus put on

Downloaded From Vet-eBooks.com

numerical developments of CFU, the measurement of pyocyanin expression by DWW2, the influence of strain 3a on the reversion of DWW2 to a nonmucoidal phenotype, and the virulence *in vivo* of the two species using the *Galleria mellonella* infection model. The results obtained revealed that (i) in agreement with the study reviewed above (153), the streptococcal CFU increased in number in coculture, (ii) the streptococcus was instrumental in furthering the reversion of the DWW2 mucoid phenotype to the nonmucoid variant, exhibiting increased pyocyanin expression, and (iii) the nonmucoid, high-pyocyanin-expressing phenotype of DWW2 was highly virulent *in vivo*, causing 10% larval survival after 24 h incubation in mono-infection and 0% survival for coinfection (154).

The contrast evident in the results of the above studies (153, 154) lies in the different effects the two streptococcal species may have on CF pathogenesis. Whereas *S. parasanguinis* appears to interfere in a favorable fashion with the pathogenic effects of *P. aeruginosa* by restricting its potential for biofilm formation, *S. anginosus* behaves in a detrimental way from a clinical point of view by increasing pyocyanin production that impairs a wide range of cellular components and pathways. To resolve the conflict presented by the two streptococcal species, it should therefore be interesting to investigate the effect of *S. parasanguinis* on pyocyanin expression by *P. aeruginosa* FRD1.

Complement Fragment C5a Peptidase

Complement fragment C5a functions as a chemotaxin that mediates phagocyte recruitment to the site of infection. GAS and human GGS have been found to produce a highly specific cell-wall-anchored serine endopeptidase that cleaves C5a in the polymorphonuclear leucocyte-binding site, thereby limiting the activity of this chemotactic signal. In Southern hybridization experiments, probes specific for the GAS C5a peptidase gene, *scpA*, detected homologous *scpG* sequences in all human GGS strains tested (6, 156) but failed to detect the gene in GGS isolated from animals (156). As far as GCS strains are concerned, the latter observation should be expanded by more recent evidence showing that the ScpZ protein of an *S. equi* subsp. *zooepidemicus* strain, C55138, originally isolated from a pig with septicemia, shares sequence identity, particularly at the highly conserved enzymatically active site, with ScpA (157). The *scpA* and *scpG* genes appear to be very similar, and their products cross-react serologically (156). However, the *scpG* and *scpC* genes in GGS and GCS, respectively, show different linkage relationships from *scpA* because, in either serogroup, they are not located 3′-adjacent to *emm* or *emm*-like genes as is the case for *scpA* in the *mga* regulon of GAS (71, 79, 156) (see also Fig. 3). Whether *scpG*/C are members of the *mgc* regulon (71) is an open question; loss of synteny of the component genes of the *mga* regulon in GGS/GCS may be taken to indicate recent acquisition of individual genes by horizontal gene transfer. In fact, in *S. agalactiae*, *scpB* is localized on a composite transposon flanked by insertion sequences, thus highlighting the possibility of lateral transfer involved in the shuffling of *scp* genes (158).

CYTOPLASMIC MEMBRANE-ASSOCIATED ENZYMES

Hyaluronan Synthase

The hyaluronan (hyaluronic acid) capsule of the Pyogenic streptococci has an important role in resistance to phagocytosis and in virulence (8, 159). In GAS, the three genes required for hyaluronan synthesis, *hasA*, *hasB*, and *hasC*, constitute an operon (160). For efficient hyaluronan export, an ATP-binding cassette transporter system is required, the genes of which are located in opposite orientation adjacent to the *has* operon (161). A *hasA* homolog encoding hyaluronan synthase, which catalyzes the alternate addition of UDP-acetylglucosamine and UDP-glucuronic acid to form the capsule polymer, has been cloned from *S. equi* subsp. *equisimilis* (162). The GCS enzyme (seHAS) sequence is 72% identical to that of its homolog from GAS (spHAS), and accordingly, the two proteins cross-react serologically. Both proteins are processive enzymes, and the size distributions of the hyaluronan chains they synthesize are similar. However, seHAS shows a 2-fold faster chain elongation rate than spHAS, making it the most active hyaluronan synthase described thus far (162). Furthermore, the membrane topology of seHAS is likely to be identical to that experimentally deduced for spHAS. This enzyme exhibits four membrane-spanning domains and two membrane-associated domains, with the termini of the protein and several central regions situated intracellularly (163). The hyaluronan synthases seHAS and spHAS were overexpressed as His_6-tagged membrane proteins in *E. coli*, purified to homogeneity, and extensively characterized kinetically. They represent lipid-dependent enzymes, the activity of which is strongly stimulated by cardiolipin and phosphatidylserine (164–166). In contrast, sulfhydryl-modifying reagents and the lipid-soluble 4-methylumbelliferone proved to be inhibitors of seHAS activity (167, 168). Despite suggestions to the contrary (169), no phosphoryl modification of streptococcal HAS has been detected (167). Although the 6.2-kb restriction fragment from the encapsulated GCS strain that served to clone *hasA* (162) is potentially large enough to also accommodate *hasB* and *hasC* (160), definitive proof for the existence and functioning of this operon in GCS or GGS has not been reported.

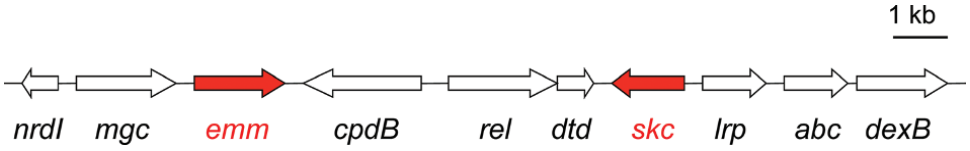

FIGURE 3 Organization of the streptokinase-M protein gene region in the *S. dysgalactiae* subsp. *equisimilis* H46A chromosome based on references 71 and 183. Arrows represent the genes and their orientation: *nrdI*, ribonucleotide reductase; *mgc*, multigene regulator of GCS; *emm*, M protein; *cpdB*, 2′,3′-cyclic nucleotide 2′-phosphodiesterase, *rel*, bifunctional (p)ppGppase and (p)ppGpp synthetase; *dtd*, D-tyrosyl-tRNA^{Tyr} deacylase; *skc*, streptokinase; *lrp*, leucine-rich protein, now recognized as a transcriptional regulator of the PucR family featuring a C-terminal helix-turn-helix domain; *abc*, ATP binding cassette transporter; *dexB*, α-glucosidase.

Downloaded From Vet-eBooks.com

Operon organization of the three genes required for capsule synthesis cannot be taken for granted, as evidenced by *S. uberis*, in which *has*C is essential for capsule production but is not situated 3′-adjacent to *hasAB* (64).

Cytoplasmic Membrane Lipoprotein Acid Phosphatase

Attempts to elucidate the linkage relationships of the *S. dysgalactiae* subsp. *equisimilis* H46A *gap*C gene (see above) resulted in the discovery of a novel streptococcal gene 3′-adjacent to, and cooriented with, *gap*C (170). This gene, designated *lpp*C, codes for a 32.4-kDa membrane lipoprotein as indicated by the presence of a lipoprotein-specific signal sequence cleavage and lipidation site (VTG↓C), by globomycin sensitivity of signal sequence processing, and by tight association of the protein with the streptococcal cytoplasmic membrane or the outer membrane of *E. coli* when heterologously expressed in this organism. Southern, Northern, and Western analyses revealed that *lpp*C has homologs in GAS and is transcribed independently of *gap*C as monocistronic 0.9-kb mRNA from a σ^{70}-like consensus promoter (170). Later, lipoproteins cross-reacting serologically with LppC were also detected in disparate strains of two *S. equi* subspecies (171). Currently, database searching shows that LppC homologs are generally distributed in the genus *Streptococcus*, including the known phylogenetic groups harboring GCS and GGS that exhibit 65% (*S. anginosus*) to 93% (*S. canis*) sequence identity to LppC. Moreover, disparate pathogenic genera showing significant sequence identity to LppC include, among others, *Haemophilus*, *Staphylococcus*, *Helicobacter*, *Gemella*, *Sneathia*, *Chlamydia*, *Peptoanaerobacter*, and *Flavobacterium*. Among those, of particular interest is the *hel* gene of *H. influenzae*, which encodes the major outer membrane antigen *e* (P4), exhibiting 58% sequence similarity to LppC.

Biochemical, serological, and genetic evidence has been provided to show that LppC represents a novel class of Gram-positive lipoproteins in functioning as an acid phosphatase (172), now assigned to class C acid phosphatases, which fall into the DDDD superfamily of phosphohydrolases (173). Their enzymatic activity was found in the *Haemophilus e* (P4) antigen as well and led to a re-evaluation of its primary role as an outer membrane protein (173, 174). In a search of a physiological role for LppC, various physiological substrates were tested at an optimum pH of 5.0, and efficient phosphohydrolase activity was found to be restricted to all of the 15-nucleoside and 2′-deoxynucleoside 3′- and 5′-monophosphates examined (175). In contrast, 22 additional mono- or multiphosphorylated *in vivo* substrates tested were not detectably hydrolyzed, among them phosphates involved in signal transduction pathways necessary for oxidative burst activation in neutrophils. In the presence of p-nitrophenyl phosphate and suitable acceptors with free hydroxyl groups, the enzyme also showed transphosphorylating activity, explaining the failure of hydrolyzable phosphomonoesters to support the growth of strain H46A in chemically defined medium lacking free inorganic orthophosphate (P_i); i.e., possible P_i deficiencies cannot be complemented by the hydrolysis of such substrates. Rather, LppC-catalyzed transphosphorylation of *in vivo* acceptors yet to be identified may occur simultaneously, thus constituting a sink that renders growth-sustaining quantities of free P_i unavailable. Growth studies in modified chemically defined medium also showed that strain H46A is capable of *de novo* purine synthesis but depends on salvage pathways for pyrimidine acquisition. However, while UMP could compensate for U deficiency in both the wild type and an *lpp*C mutant, CMP utilization specifically required the functional *lpp*C gene (175).

Although the studies reviewed above provide considerable insight into the physiological role LppC may have in interaction with its hosts, it remains to be investigated whether this protein is additionally involved in specific pathogenetic processes, which might be suggested by its general association with disparate pathogens. Given that its homolog *e* P4 is highly immunogenic, that anti-P4 antibodies exhibit bactericidal activity, and that P4 reduces colonization of *H. influenzae* in mice (176), LppC deserves to be considered a vaccine candidate as well.

PerR-Regulated Iron Efflux Mediated by PmtA

S. pyogenes homeostatically copes *in vivo* with metal sequestration as well as metal overload poisoning by its host. Very recently, the cytoplasmic membrane-associated ATPase PmtA (PerR-regulated metal transporter A) was found by genetic, biochemical, and bacterial growth analyses to act as an iron [Fe(II)] efflux system that is part of the oxidative stress response (177). The broad peroxide-responsive transcription regulator PerR from *S. pyogenes*, which functions to sense and modulate the response of GAS to oxidative stress, is also expressed in *S. uberis*, *S. equi*, and *S. dysgalactiae*, with amino acid sequence identities amounting to 88%, 92%, and 94%, respectively. Regarding PmtA, current databank analyses reveal sequence identity to the *S. pyogenes* protein in *S. phocae* (76%), *S. parauberis* (77%), *S. uberis* (79%), *S. canis* (92%), and *S. dysgalactiae* (94%). Thus, the PerR-PmtA iron efflux system as described in *S. pyogenes* (177) is highly likely also operative in GCS and GGS.

EXTRACELLULAR PROTEINS

Streptokinase

The first SK gene (*skc*) to be cloned (178) and sequenced (179) originates from the most potent and commercially exploited producer of this PG activator, the human *S. dysgalactiae* subsp. *equisimilis* strain H46A. Later, an SK gene (*skg*) from a human GGS strain was also characterized (180), and the two encoded proteins were found to share 98% sequence identity. To date, SK alleles belong to those streptococcal genes that have most frequently been sequenced from diverse strains, and research in this area has appreciably expanded our knowledge of this important streptococcal gene and its product in various areas. Part of this work has been reviewed previously (181, 182); here, I focus on recent studies conducted to elucidate the expression control, structure-function relationships, and aspects of adaptive evolution of SK.

Expression control of the SK gene

Because gene regulation is influenced by the spatial association of genes on the chromosome, it is appropriate to point out that the SK genes show homology of synteny in the genomes of GAS and of human GCS and GGS (71, 183, 184), and numerous subsequent studies based on nucleotide sequence analyses confirmed these early results. Conservation of linkage appears also to be true of an equine group C SK gene that hybridizes with *skc* (184) but encodes an SK that preferentially activates horse PG and antigenically differs from the proteins produced by human strains (185). *skc*, *skg*, and *ska*, collectively designated *skn*, are transcribed as 1.3-kb monocistronic mRNA from a highly conserved chromosomal region in which they are interspersed among unrelated genes transcribed in the opposite direction (Fig. 3).

Downloaded From Vet-eBooks.com

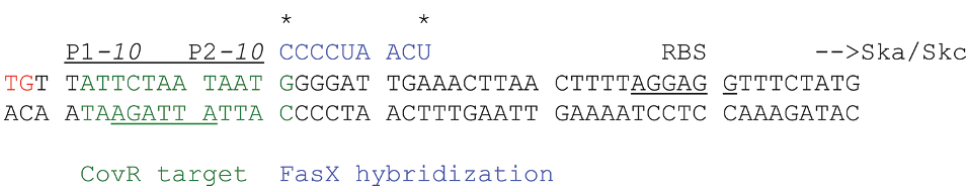

FIGURE 4 Primary structural features of the 5′-untranslated region 47 nucleotides upstream of the *ska/skc* ATG translational start codon. Additionally indicated are the -10 regions of the tandem P1 and P2 promoters (underlined), including (in red) the TG nucleotide extension of P1, the target sequence of CovR (in green) with the consensus binding site underlined, the FasX hybridization site (in blue), the two major transcription initiation sites (stars), and the mRNA ribosome binding sequence (RBS, underlined). These features are based on references 188, 190, 196, and 199.

Transcription is terminated by a hypersymmetrical intrinsic terminator with bidirectional activity shared by the oppositely oriented *skn* and *rel-dtd* transcription units (186, 187). S1 nuclease mapping has identified the core promoter P1 with an extended -10 region that directs transcription initiation predominantly at a G located 32 bases upstream of the *skc* translational start site (188). A second core promoter, P2, with a -10 region immediately 3′-adjacent to that of P1, but distinctly less potent then P1, directs transcription initiation predominantly at an A 24 bases upstream of the Skc start site (Fig. 4). Circular permutation analysis combined with determination of the activity of nested deletions in the DNA upstream of the -35 region identified an intrinsic DNA bending locus that has a pivotal role in *skn* expression (182, 189). Deletions covering the bending locus greatly decrease the core promoter strength in strain H46A but not in *E. coli* (182, 190), consistent with the observation in the latter species that promoters with a TG motif 1 bp upstream of the -10 region, as realized for P1 (Fig. 4), function activator independently, even in the absence of a recognizable -35 region. Region 2.5 of *E. coli* RNA polymerase sigma factor RpoD, i.e., sigma^{70}, implicated in contacting the TG motif (191), is completely conserved in all streptococcal homologs of RpoD (sigma^{42}), including representative strains from three phylogenetic groups of GCS and GGS. In particular, their 2.5 regions do carry the amino acid residues H455 and E458, which are responsible for recognition of the TG extension (Fig. 5).

Nevertheless, as shown by the above findings, the streptococcal system is much more stringent with respect to supplementary structural requirements for full *skn* promoter activity and displays strain-specific *skn* expression levels. Thus, using reporter gene constructs in allele swap experiments between GCS and GAS strains revealed that the host genetic background dictates *skn* expression, suggesting the existence of trans-acting factor(s) with strain-specific activity that modulate *skn* expression. Evidence for the action of such factors was provided after the discovery in GAS of two independent two-component signal transduction systems, *covRS* (192) and *fasCAX* (193), which regulate *skn* expression negatively and positively, respectively (194, 195). Thus, assessing the apparent SK activity of streptococcal strains requires the dissection of the opposing activities of the *cov* and *fas* systems. Specifically, sequence analysis showed that "wild-type" H46A is actually a derepressed mutant for Skc (and streptolysin S) synthesis, carrying a K102amber mutation in *covR* (194). The high-affinity binding site (CB-4; ATTCTAATAATG) of CovR from *S. pyogenes* overlaps the two -10 regions of *ska* (196) and is completely identical to the corresponding *skc* region specified above for P1and P2 (Fig. 4). In general, knowledge of the FasA response regulator is less advanced than that of CovR. The bootstrapped phylogenetic tree published previously (197) places FasA in a widely distributed family of streptococcal response regulators (the FasA-BlpR-ComE family) that is involved in behavioral processes, such as quorum sensing, and that uses the C-terminal LytTR domain for DNA binding (195, 198). The FasA proteins, which are distributed predominantly among the Pyogenic streptococci, form a well-supported cluster within this protein family. Underscoring their distinct position, the *fasX* gene, encoding a nontranslated small regulatory RNA functioning as the terminal effector of the *fasCAX* operon (193, 194), has no homologs in the *comE* and *blpR* clusters. FasX uses its internal 9-ribonucleotide CCCCUAACU sequence to bind 32 nucleotides upstream of the *ska/skc* AUG start codon to the 5′-untranslated region of *ska/skc* mRNA covering the two major transcription initiation sites, thus increasing transcript stability posttranscriptionally (188, 199). Given that, as specified above, the corresponding *skc* mRNA exhibits exactly the same sequence conditions, this mechanism for enhancing SK activity functions beyond reasonable doubt also in GCS. To facilitate comprehension, Fig. 4 illustrates that the binding site of CovR and the hy-

FIGURE 5 Sequence comparison of *E. coli* and *S. pyogenes* σ factors between region 2.4 and the start of region 3. Identical and similar amino acids are marked by asterisks and dots, respectively. The residues identified in *E. coli* (191) as contacting the TG extension of the -10 P1 promoter hexamer are highlighted in red.

Downloaded From Vet-eBooks.com

bridization site of FasX share a 1-base overlap; however, because the two opposing regulators target different molecules, i.e., DNA and mRNA, respectively, direct competition between them for binding to the 5′-untranslated *ska*/*skc* regions can be ruled out.

Structure-function relationships of SK

SK produced by *S. dysgalactiae* subsp. *equisimilis* strain H46A was predominantly used in the many structural studies reported in the literature. This protein has at least three functions in the process of PG activation: (i) high-affinity plasminogen binding to form a 1:1 stoichiometric PG:SK complex, (ii) interacting with PG to structure the active site, i.e., forming the virgin enzyme with amidolytic activity (conformational activation; i.e., PG*:SK formation), and (iii) binding and processing of substrate PG molecules, resulting in cleavage of the activating R561-V562 peptide bond to generate the active enzyme, plasmin (PM) (200, 201). Solution structural studies have presented evidence that the 414-amino acid mature SK is an elongated globular molecule that consists of three independent folding domains of roughly equal sizes (202, 203, and references therein). The crystal structure of SK complexed with microplasmin (μPM, i.e., PG residues 542 to 791, containing the catalytic site) illustrates these domains denoted α (residues 1 to 150), β (151 to 287), and γ (288 to 414), interconnected by flexible strands (204). Each of these domains contacts μPM, with the β domain having the fewest interactions and exhibiting the highest degree of residue polymorphism (205). In contrast, the SK termini appear to be unstructured and mobile, explaining early findings showing that SK muteins lacking up to 15 N-terminal or 41 C-terminal residues or that truncated SKs fused to foreign proteins continue to activate PG, albeit with diminished activity (202, 203, 206–208, 263, 264). Studies of binding interactions between SK and PG domains using surface plasmon resonance (209) showed that the β domain, in addition to contacting the PG catalytic domain, interacts with PG kringle 5. Based on these studies, the mechanistic steps involved in PG activation include (i) binding of all SK domains to the PG catalytic domain, (ii) cooperation of the α and γ domains to induce PG*:SK formation, and (iii) recognition of substrate PG by PG*:SK through interactions mediated by the α domain. A unified hypothesis for the mechanism of coupling between conformational and proteolytic PG activation based on parabolic time-course assays implies that PG*:SK initially binds PG in the substrate mode to form a ternary PG*:SK:PG complex, from which free PM is produced. SK affinity for PM is much higher than that for PG, so the catalytic PM:SK complex in the substrate mode readily activates remaining free PG at concentrations of PG>>SK. This ultimately results in full conversion of free PG to PM (200, 201, 210). Taken together, the studies summarized above suggest that, except for the very ends of the polypeptide chain, most of the SK sequence is essential for efficient functionality. Nevertheless, attempts were made preferentially in two fields to improve the therapeutic potential of SK as a cost-effective thrombolytic agent. First, to reduce its immunogenicity, known antigenic epitopes were targeted by directed mutagenesis experiments which, for example, identified an S138K substitution that, after transfer to therapeutic SK, led to a loss of anti-SK antibody binding without detrimentally affecting PG activation activity of the mutein (211). Second, in experiments aimed at increasing the *in vivo* half-life of SK, which is susceptible to cleavage by PM, a K59E mutant was identified to exhibit the desired effect while maintaining PG activation activity (212). Additionally, to reduce the host PG activation activity of SK and hence hinder the acquisition of PM activity on the streptococcal cell surface to counteract invasive processes, SK interaction, particularly between its α-domain and PG, could be a promising target for engineering successful variant SK molecules (213). Finally, taking the gene fusion approach to construct and express hybrid *skc* genes extended at their 5′-ends by DNA segments encoding the fibrin-binding kringle domains of PG led to bifunctional hybrid SKs, the genetic design of which needs to be optimized for ultimately improving the therapeutic potential of SK (207).

Adaptive evolution of SK alleles

It has been known for a long time that SKs exploited by streptococci to infect mammals show species-specific activity, a phenomenon likely due to PG features specific to their respective hosts. More recent studies based on knowledge gained about the mechanism of PG activation have provided molecular insights into this phenomenon (214). Thus, SKs produced by different human streptococcal strains show a strong conservation of amino acid residues that contact sites in the loop residues of human μPm. On the other hand, such residues lack conservation among SKs from animal streptococci that activate the corresponding animal PGs. Conversely, different animal PGs show greater sequence diversity from human μPm in loops that contact SKs produced by human-pathogenic streptococcal strains. Streptococci may thus evolve to produce SKs that match their evolving target PGs, whereas PGs evolve to escape from such interactions. Such coevolutionary patterns in PG activation would thus appear to be advantageous for both sides and make SK a determinant of host species specificity for streptococcal infections (214). In fact, a transgenic mouse line expressing human PG exhibited significantly increased mortality upon infection with GAS (215).

A study designed to uncover molecular evolutionary mechanisms underlying tissue-specific streptococcal infections analyzed the sequences of *skn* genes in skin-tropic strains known to bind host PG via the PAM protein and to depend on both types of genes for virulence at the skin (216). Exploiting the well-known fact that the β domain of SK shows the highest level of sequence heterogeneity, a tight association was found between the presence of PAM and a well-supported subcluster 2b *ska* allele. This observation indicated coinheritance of the corresponding genotypes maintained by coselective pressure due to epistasis rather than a physical genetic linkage of the *ska* and PAM-encoding *emm* loci. Interestingly, in contrast to the β domain-encoding region of the *ska* alleles, the *skn* alleles from GCS and GGS, including the *S. dysgalactiae* subsp. *equisimilis* strain H46A, show a high degree of sequence homogeneity and are most closely related to subcluster 2a alleles of *ska*. This subcluster is predominantly associated with throat-tropic GAS strains, apparently consistent with the lifestyle of GCS and GGS which primarily inhabit the upper respiratory tract. More specifically, the *S. pyogenes* SF370 *ska* allele is much more strongly related to the *skc* alleles than to the subcluster cluster 1 or 2b *ska* alleles, suggestive of relatively recent interspecific gene transfer from GCS or GGS. Although it remains an open question whether subcluster 2a *skn* alleles facilitate colonization of the throat, this finding suggests that an *skn* allele from GCS or GGS was transferred from either group to GAS, where it both stayed as a subcluster 2a allele and evolved into a subcluster 2b allele. Lateral transfer in the opposite direction seems to be less likely because the housekeeping genes of GCS and GGS strains carrying a subcluster 2a allele show great heterogeneity (216).

Downloaded From Vet-eBooks.com

Aside from the above considerations, a review focusing on the polymorphism of the SK alleles, including those from GCS and GGS, links this feature with strains associated with acute poststreptococcal glomerulonephritis (205). The basic observation relates to a stretch of about 70 amino acid residues in the SK β-domain in which sequence identity drops to below 50% when the proteins from nephritogenic and nonnephritogenic strains are compared. The sequences unique to the former may be considered the nephrotropic domain with which their SKs, after *in situ* PG activation in the glomerular structures, trigger the complement cascade of proteolytic processes leading to poststreptococcal glomerulonephritis (217, 218).

Streptolysins and Streptodornase

Based on the well-known observation that a positive antistreptolysin O test is not specific for recent GAS disease, successful attempts were made to clone and sequence the streptolysin O (*slo*) genes of GCS (*S. dysgalactiae* subsp. *equisimilis*) and GGS (*S. canis*) (219). The *slo* gene proved to be highly conserved in the three serogroups, with the sequence identity of the protein exceeding 98%. Moreover, in recent comparative studies involving invasive and noninvasive *S. dysgalactiae* subsp. *equisimilis* isolates, *in vivo* evidence was provided that implicated Slo, next to Skc, as a primary virulence factor responsible for necrotizing soft tissue infections (220). Expectedly, the *slo* gene was not detected in two subspecies of *S. equi* (219, 221). However, a streptolysin S-like activity has been characterized in *S. equi* subsp. *equi* and shown to be subject to transposon inactivation at a single locus (221). Conclusive evidence was provided later, showing that the production of this important cytotoxin is encoded in the same nine-gene *sag* operon that was characterized in GAS and *S. dysgalactiae* subsp. *equisimilis* (human GGS) associated with severe necrotizing soft tissue infections (222). Interestingly, a *sag* operon homolog was also detected in all examined strains from the Anginosus group, which in contrast to the strains in the Pyogenic group, exhibited two functional tandem *sagA* genes (*sagA1* and *sagA2*), the primary structures of which are highly conserved (223). Compared to an *S. anginosus* reference strain, *sag* operon sequence identities against the corresponding genes of other streptococcal *sag* operons range from 53 to 75%. The origin of the twin *sagA* genes, which are specific for *S. anginosus*, remains unclear; two possibilities have been suggested: gene duplication in a one-*sagA* gene operon with subsequent (relatively rare) mutations in *sagA2* or, alternatively, previous loss of *sagA2* from a *sag* operon originally carrying two *sagA* genes (223).

Four classes of streptodornases/DNases (A to D) have been described to be produced by the genus *Streptococcus* (224–226). Among them, DNase B appears to be the most common and best characterized. These enzymes, often occurring in multiple forms in the same strains, exhibit different pH ranges for optimal activity and most frequently are phage-encoded. The streptodornase gene *sdc* first cloned from *S. dysgalactiae* subsp. *equisimilis* strain H46A (227) encodes an enzyme exhibiting only 48% overall sequence identity to the *sdaD* gene later isolated from a GAS strain (228). However, sequence identity is much higher (>80%) in the two conserved domains shared by GAS and GCS strains (225).

Although suggestive evidence for the involvement of these enzymes in pathogenetic processes has existed for a long time, conclusive evidence produced more recently in three animal models of infection implicated them in GAS disease progression by enhancing evasion of the innate immune response (229).

CAMP Factor

CAMP (not to be confused with cAMP) refers to a pore-forming cytolysin originally found in *S. agalactiae* (GBS) that acts synergistically with the β-toxin (sphingomyelinase C) of *Staphylococcus aureus* generating a cohemolytic reaction on sheep and bovine erythrocytes previously hydrolyzed by sphingomyelinase (230, 231). In clinical tests, it was long used to differentiate GBS from GAS. However, genome sequencing of GAS strain SF370 revealed a functional secretory CAMP protein (Cfa) exhibiting 59.9% amino acid identity to the equally sized GBS protein (232). Previously, CAMP factor genes were also found in *S. uberis* and *S. canis* with residue identities to the GBS protein amounting to 63% and 67%, respectively (233). Among GCS/GGS, current knowledge restricts the elaboration of the CAMP factor to the above two species, with unclear roles of the protein in pathogenesis. However, after intravenous injection in rabbits, partially purified CAMP protein from GBS (Cfb) was lethal, and intraperitoneal injection together with a sublethal dose of GBS cells led to septicemia and death in mice. In addition, Cfb is capable of binding the Fc sites of immunoglobulins (231). However, compared to the wild type in *in vitro* and *in vivo* assays, deletion of the *cfb* gene in GBS did not cause any changes of the virulence properties of the mutant (234). Possibly resolving this conflicting situation, it has been shown that the expression of β-hemolysin (CylE) and Cfb is intricately coregulated by CovR and the serine/threonine kinase Stk1 in a CovR-dependent manner: CovR represses *cylE* but activates *cfb*; Stk1 alleviates CovR repression of *cylE* as well as activation of *cfb* by phosphorylation of CovR; thus, Stk1 positively regulates *cylE* and negatively regulates *cfb*, and collectively, CovR and Stk1 may fine-tune gene expression in GBS in a beneficial manner for niche adaptation (235). Regarding GCS/GGS, it seems appropriate to point out that both CovR and Stk1 are also elaborated by *S. dysgalactiae* subsp. *equisimilis* and *S. uberis*, making it worthwhile to explore their comparative and functional relationships in these species as well.

Pyrogenic Exotoxins

Pyrogenic exotoxins (Spe) are not only potent superantigenic host T cell mitogens but have also been shown to play a role in the manifestation of acute streptococcal infections (236). GAS are known to produce at least 11 types of superantigens. Although the first reports of such infections involving non-GAS isolates appeared in the 1990s, it was not until the early 2000s that *speA*, *speC*, and *speG* as characterized before in GAS were also detected in human GCS and GGS (237, 238). Similarly, *S. equi* subsp. *equi* strains were found that harbored *speH*, *speI*, *speL*, and *speM* genes (13, 239). While *speH* and *speI* were consistently seen in all isolates, they were absent from *S. equi* subsp. *zooepidemicus* (13). Moreover, these two genes were linked, like their orthologs in GAS, to a bacteriophage genome, strongly suggesting that intergeneric phage-mediated transfer is responsible for their spread. However, more recently, three novel superantigen genes (*szeF*, *szeN*, and *szeP*) were identified in *S. equi* subsp. *zooepidemicus* (240), with their encoded proteins sharing 59%, 49%, and 34% sequence identity with SpeH, SpeM, and SpeL, respectively, previously seen in *S. equi* subsp. *equi* (13, 239). Among numerous *S. equi* subsp. *zooepidemicus* strains screened, about half (7 out of 15) associated with human diseases produced at least one of the novel antigens in question, with *szeN* and *szeP* being located next to a prophage remnant. Overall, these data strongly suggest that veterinary as well as human diseases caused by GCS and GGS

are afflicted by both intra- and intergeneric exchange of superantigen genes (240).

Although it is not known to represent superantigens, attention may be directed under the above heading to *S. parasanguinis*, which produces members of the LXG polymorphic toxin family, the C-terminal domain of which functions as a lipid phosphatase that degrades lipid II essential for cell wall biosynthesis in this Firmicute species. In a polymicrobial environment, this antibacterial toxin mediates cell contact-dependent interspecies antagonism, thus shaping the composition of such bacterial communities (241).

THE STRINGENT AND RELAXED RESPONSES OF *S. DYSGALACTIAE* SUBSP. *EQUISIMILIS*

Like their closest phylogenetic relatives, GAS, GCS, and GGS are polyauxotrophic, and shortage of an amino acid instantly limits the availability of the corresponding aminoacyl-tRNA. Thus, these organisms have evolved a stimulus response network that involves peptidases, proteinases, and peptide and amino acid transport systems for generating the free amino acids necessary for growth and a dynamic response to the protein-rich environment of their hosts (242).

Sequence analysis of *S. dysgalactiae* subsp. *equisimilis* chromosomal DNA 3′-adjacent to the *skc* gene (183) led to the unexpected discovery of the 739-codon *rel* gene (Fig. 3), the first homolog from a Gram-positive organism of the paralogous *E. coli relA* and *spoT* genes to be cloned, sequenced, and functionally characterized in some detail (243–245). In *E. coli*, these genes are involved in the metabolism of guanosine 5′,3′-polyphosphates [(p)ppGpp] which accumulate in response to starvation for amino acids or glucose exhaustion (246, 247). The accumulated (p)ppGpp mediates a broad pleiotropic response marked by a rapid shutdown of stable RNA (rRNA and tRNA) synthesis (the stringent response) and, concomitantly, by affecting the synthesis of about half of the cellular proteins. The crystal structures of *E. coli* RNA polymerase holoenzyme with (p)ppGpp revealed that both nucleotides bind to a site at the interface between the β′ and ω subunits of RNA polymerase holoenzyme (248).

As revealed by *in vivo* complementation experiments with appropriate *E. coli* mutants and verified by *in vitro* enzyme activity assays, the *rel* gene of *S. dysgalactiae* subsp. *equisimilis*, designated rel_{Seq} here, encodes strong (p)ppGpp 3′-pyrophosphohydrolase activity [(p)ppGppase] and weaker ribosome-independent (p)ppGpp synthetic activity resulting from its ATP:GTP 3′-pyrophosphoryltransferase capacity (243). Homologs of Rel_{Seq} are present in all known GCS and GGS phylogenetic groups, with sequence identities ranging from 91 to 98% in the Pyogenic group and amounting to about 78% in the Anginosus and Mitis groups. *In vivo*, the net effect of the opposing Rel_{Seq} activities favors (p)ppGpp degradation, resulting in the failure of rel_{Seq} to complement the absence of *relA* and, hence, resulting in its functional likening to *spoT*. Structural support for this inference provided the detection of immunological cross-reactivity of Rel_{Seq} with polyclonal antibodies to SpoT but not RelA and, vice versa, of SpoT but not RelA with antibodies to Rel_{Seq}. However, despite these clear observations, disruption of the chromosomal rel_{Seq} gene at codon 216 by insertion mutagenesis abolished the (p)ppGpp accumulation response following amino acid starvation of wild-type *S. dysgalactiae* subsp. *equisimilis*, a phenotype characteristic of *E. coli relA* but not *spoT* mutants. Further functional characterization of rel_{Seq} showed that amino acid deprivation of *S. dysgalactiae* subsp. *equisimilis* triggers a rel_{Seq}-dependent stringent response characterized by rapid (p)ppGpp accumulation at the expense of GTP and abrupt cessation of net RNA accumulation in the wild type but not in the insertion mutant, which displays a relaxed response (244). Thus, one of the most interesting results of this work is the finding that the Rel_{Seq} protein is bifunctional and shows activities that reside separately in the paralogous SpoT and RelA proteins from *E. coli*. This establishes an important variation of the *E. coli* paradigm for regulating (p)ppGpp levels and presumably the expression of genes controlled by the second-messenger properties of (p)ppGpp. In fact, Rel_{Seq} has proved to be of seminal importance to the subsequent establishment of the RelA/SpoT homolog (Rsh) superfamily of bifunctional [(p)ppGpp] synthetases and hydrolases and their distribution and function across all living organisms (249).

Cloning and expression of defined rel_{Seq} fragments followed by catalytic activity assays of the purified protein fragments revealed that the two enzymatic activities reside in the N-terminal half-protein (residues 1 to 385) and that the removal of the C-terminal half-protein has reciprocal regulatory effects on the opposing activities of the N-terminal domain (245). Further dissection of the bifunctional N-terminal domain by a nested deletion analysis revealed nonoverlapping minimal fragments of residues 1 to 198 and 211 to 347 for full hydrolytic and synthetic activities, respectively (250). The 2.1-Å crystal structure of Rel_{Seq}1-385, the first X-ray structure to be reported for an enzyme involved in the metabolism of (p)ppGpp (251), fully explains the solution biochemical studies in trapping the enzyme in two distinct conformations that typify the opposing (p)ppGpp hydrolase-OFF/synthetase-ON and hydrolase-ON/synthetase-OFF states (Fig. 6A to C). The individual active sites are located >30 Å apart (Fig. 6D) and, being mutually exclusive, demonstrate how reciprocal regulation of the two opposing activities can prevent futile cycling in the metabolism of (p)ppGpp. The conclusions derived from the crystal structure are fully supported by extensive point mutagenesis (Fig. 6C) and enzyme inhibition experiments (251). Concomitant with prevention of wasteful macromolecular synthesis by a rapid shutdown

for panel A. The disordered synthetase site (downregulated) is illustrated as dashed lines with a red arrow. (C) Primary and secondary structure of Rel_{Seq}1-385. The secondary structure is color-coded as in panels A and B. Unique secondary structure assignments for panel A are placed immediately below the corresponding assignments for panel B. Residues absolutely conserved throughout the mono- and bifunctional RelA and SpoT homologs are underlaid with blue boxes. Residues conserved in SpoT and the bifunctional enzymes but mutated in the hydrolase-incompetent RelA homologs are underlaid with red boxes. Upright and inverted black triangles above the sequence indicate residues which when substituted experimentally by missense mutations lead to defective hydrolase and synthetase activities, respectively. Reproduced from reference 251, with permission. (D) Semitransparent surface rendering of the bifunctional N-terminal half of Rel_{Seq}1-385 based on its 2.1-Å X-ray structure (251). The hydrolysis site (underlaid in green) binding the ppGpp analog ppG2′-3′p (stick rendering) is separated by the central 3-helix bundle and about 30 Å away from the synthesis site (underlaid in red) binding GDP (stick rendering). of futile RNA synthesis following the failure of aminoacyl-tRNA pools to keep up with the demands of protein synthesis, the functional significance of the streptococcal stringent factor consists of strongly supporting cell survival under nutritional stress conditions. After overnight incubation in a chemically defined medium deprived of isoleucine plus valine, the survival fractions of mutants that failed to elicit stringency were 3 orders of magnitude lower than those of the wild type ($N/N_0 \approx 10^{-5}$ versus $\approx 10^{-2}$) (252). The short half-lives of 20 and 60 seconds for pppGpp and ppGpp, respectively, ensure quick recovery from the stasis-like survival state when the nutritional conditions improve (244). Expanding the knowledge of the (p)ppGpp metabolism in the genus *Streptococcus*, the *rel* gene from GAS was included in genetic studies showing that, apart from its primary function of stable RNA synthesis inhibition, (p)ppGpp also negatively affects the transcription of important groups of genes encoding regulators, virulence factors, metabolic enzyme genes, and genes for transport systems (253). Of pivotal interest is the strong negative stringent control of the streptococcal gene, collectively referred to as rsh_{Str}, itself: exposure to isoleucine plus valine starvation results in a 40-fold increase of truncated rsh_{Str} expression in an isogenic rsh_{Str} insertion mutant strain relative to the rsh_{Str} wild type. Such a high degree of negative autoregulation may be indicative of a gene with broad connectivity to sustain cellular homeostasis.

Of further interest and also implicating GCS and GGS are transcriptional analyses of wild type, rsh_{Str}, and *codY* mutant strains exposed to branched-chain amino acid starvation. These experiments showed that in addition to the stringent response, streptococci are capable of mounting an rsh_{Str}-independent response to amino acid deprivation that involves transcriptional modulation of a wide array of housekeeping genes as well as accessory and dedicated virulence genes. For example, among the genes responding with elevated transcript levels to starvation conditions are those encoding aminoacyl-tRNA synthetases, oligopeptide permease, two-component regulators (*cov* and *fas*), and members of the streptolysin S operon. Based on these observations, a regulatory network with feedback mechanisms has been proposed that counteracts the stringent response by the action of the branched-chain amino acid-activated pleiotropic transcriptional repressor CodY. This network links the levels of key rate-limiting enzymes to virulence gene expression and enables streptococci in a dynamic way to take advantage of protein-rich host environments (252, 254).

CONCLUSIONS AND PROSPECTS

It is apparent from the preceding account that molecular biological investigations into GCS and GGS during the past decade have proceeded to generate new information about the lifestyles of these organisms, whether presenting themselves as commensals or opportunistic pathogens causing readily controllable as well as life-threatening invasive infections (255). Molecular taxonomic approaches have solved classification problems, and phylogenomic studies revealed the relationships of GCS and GGS to the phylogenetic species groups of the genus *Streptococcus*. Complete genomic sequences are now available for all species in the Pyogenic group, including *S. phocae* (35), and for most species in the Anginosus and Mitis groups. Through faster, more practical, and less unwieldy techniques for comparative genome characterization in this field, the genomes of GCS and GGS will more comprehensively be shown to be in constant flux, largely determined by intraspecific and interspecific lateral gene transfer.

Concerning virulence gene expression, small noncoding RNAs with regulatory functions at the posttranscriptional level in response to environmental signals have also been detected in GCS and GGS, including *S. dysgalactiae* subsp. *equisimilis*, *S. uberis*, and *S. equi* (256), with FasX involved in SK regulation belonging to those studied best (193) (see also Fig. 4). In GAS, the number of small RNAs considered

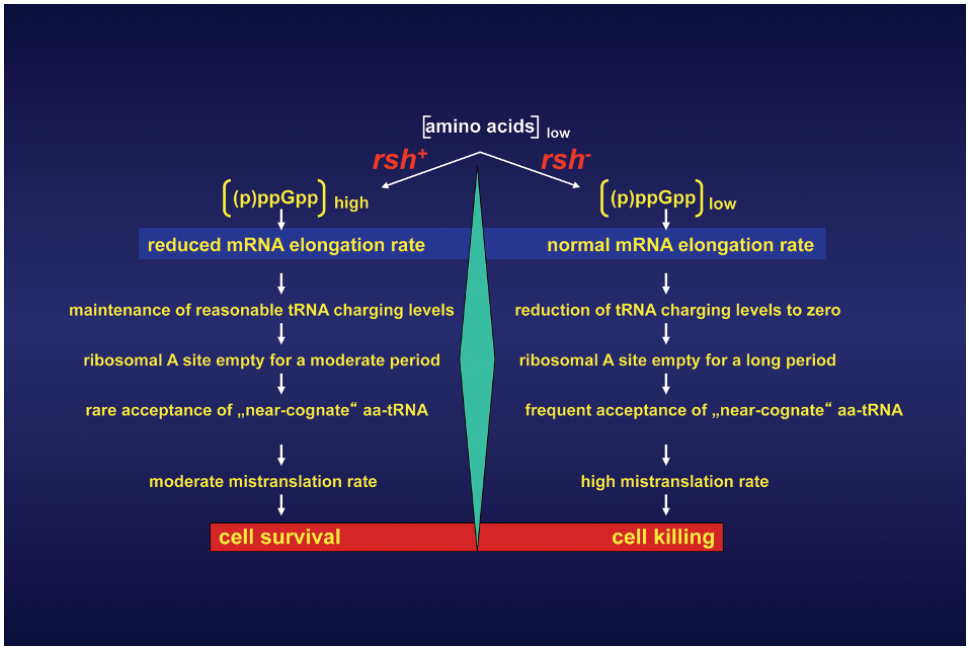

FIGURE 7 Hypothetical metabolic mechanisms explaining differential bacterial survival rates under stringent and relaxed conditions based on data reviewed in reference 246 and references therein.

Downloaded From Vet-eBooks.com

candidates for this important gene-regulatory mechanism has been found by a genome-wide analysis to amount to about 75 (257).

On the level of translated proteins with potential pathogenetic significance, this account addresses six cell-surface-associated proteins, three membrane-associated proteins, six extracellular proteins/protein groups, and one intracellular protein. How future basic research and translational medicine might proceed on the basis of current knowledge has been suggested above at the corresponding positions whenever possible. The following considerations single out, from a perspective point of view, the stringent response with its potential for supporting bacterial cell survival under nutritional stress conditions (252, 254, 258). Figure 7 attempts to present a hypothetical mechanism for this potential which covers both the areas of pathogen persistence and treatment approaches. Regarding the former, the stasis-like carrier state requiring survival functions may characterize cells that not only adhere to host cells but also succeed in invading them. However, (p)ppGpp accumulation in these conditions still awaits experimental support, at least as far as the genus *Streptococcus* is concerned (259). Regarding the latter, the now available structural knowledge of the streptococcal stringent factor (251) makes this enzyme a viable target for the design of antibacterial agents. In fact, replacing the 5′- and 3′-pyrophosphate moieties (p-O-p) in ppGpp with nonhydrolyzable bisphosphonate groups (p-C-p) which inhibit the stringent response by competing with GDP/GTP-Rsh binding inhibits ppGpp accumulation with high activity at small concentrations (260). Furthermore, a 2′-desoxyguanosine analog of ppGpp named relacin, in which the 5′- and 3′-pyrophosphate moieties are replaced by glycyl-glycine dipeptides linked to the ring sugar by a carbamate bridge inhibits the stringent response *in vitro* and *in vivo*, thus greatly decreasing cell viability (261). In Gram-positive bacteria, relacin strongly interferes with sporulation and inhibits biofilm formation. Given the ubiquitous occurrence of Rsh proteins in the bacterial kingdom and the absence of homologs in Mammalia, relacin might be a viable candidate for therapeutic application. A lingering issue in this context is whether or not the extracellular and intracellular asymptomatic carrier states feature the stringent response as a prerequisite for relacin to work. Alongside knowledge regarding the structure of Rsh_{Str}, the high-resolution structure of the entire 70S ribosome/RelA/deacyl-tRNA complex from *E. coli* revealed interesting conformational rearrangements of RelA during targeting of the 30S-ribosomal deacetyl-tRNA site. The resolved dynamics at near-atomic resolution may lead to further progress in translational medicine by therapeutic targeting of the stringent response (262).

Pathogenicity Factors in Group C and G Streptococci

CLAIRE E. TURNER, LAURA BUBBA AND ANDROULLA EFSTRATIOU

16

INTRODUCTION

The pyogenic streptococci of Lancefield groups C and G were initially recognized as a cause of animal infections long before they were even considered as agents of human disease, even though they are widely distributed in animals and humans. They comprise a heterogeneous complex of streptococcal species that act as causative agents of a spectrum of diseases ranging from mild pharyngitis to skin infection to life-threatening systemic infections associated with high mortality rates. In this article we provide an overview of the various group C and group G streptococcal species, the diseases they cause, and the major pathogenicity factors that contribute to their virulence (Table 1).

TAXONOMY AND IDENTIFICATION

Taxonomic classification of group C streptococci (GCS) and group G streptococci (GGS) has always proven to be a complex issue. However, extensive taxonomic studies over the past few years have distinguished most of the veterinary pathogens belonging to Lancefield groups C and G from the human pathogens. Previously, GCS and GGS were divided into the following species: *Streptococcus dysgalactiae* subsp. *equisimilis* (only GCS, human pathogen), *Streptococcus dysgalactiae* subsp. *dysgalactiae* (GCS, animal pathogen), *Streptococcus equi* (animal GCS), *Streptococcus zooepidemicus* (animal and human GCS), *Streptococcus canis* (animal GGS), the *Streptococcus anginosus* group, and *Streptococcus phocae* (1). GCS and GGS of human origin are now considered to constitute a single subspecies, *S. dysgalactiae* subsp. *equisimilis*. Therefore, the current taxonomy characterizes the species as follows: *S. dysgalactiae* is divided into the subspecies *S. dysgalactiae* subsp. *equisimilis* and *S. dysgalactiae* subsp. *dysgalactiae* (hereafter referred to in this article as *S. equisimilis* and *S. dysgalactiae*). *S. equi* is divided into the subspecies *S. equi* subsp. *equi*, *S. equi* subsp. *zooepidemicus*, and *S. equi* subsp. *ruminatorum* (hereafter referred to as *S. equi*, *S. zooepidemicus*, *and S. ruminatorum*). However, it has been suggested that *S. equi* may simply be regarded as a subclone of *S. zooepidemicus* (2). On the basis of genetic evidence, *S. dysgalactiae*, *S. equi*, and *S. canis* are more closely related to each other than to the *S. anginosus* group and constitute species with the "large-colony" colony phenotype. *S. phocae* is a new species expressing the group C antigen thus far only isolated from seals (3, 4). Some of these species may also contain strains which express the Lancefield group A or group F antigens (Table 2).

HUMAN DISEASE AND DIAGNOSIS

GCS and GGS can cause a wide range of diseases from mild to severe, among both human and animal populations. GCS and GGS generally colonize the human respiratory, gastrointestinal, and genitourinary tracts, with an estimated <4% asymptomatic pharyngeal carriage rate in adults (5–7). Human invasive infections caused by GCS and GGS have been associated with underlying conditions, such as diabetes, cardiovascular diseases, and chronic skin conditions (8–10). While *S. dysgalactiae* is considered an animal pathogen, *S. equisimilis* is almost exclusively a human pathogen, with increasing prevalence and overlaps in clinical manifestations with group A *Streptococcus* (GAS). *S. equisimilis* infections include acute pharyngitis, pneumonia, endocarditis, cellulitis, peritonitis, septic arthritis, bacteremia, and toxic shock syndrome (11–23). Like GAS, *S. equisimilis* has also been linked to the poststreptococcal sequelae rheumatic heart disease, and in high endemic areas of rheumatic fever, carriage rates of GCS/GGS have been found to be higher than those of GAS (24, 25).

Infections with *S. zooepidemicus* and *S. canis*, normally considered zoonotic species, have also been reported in humans (26–29), including severe infective endocarditis (30).

Generally, person to person transmission of GCS/GGS occurs via respiratory droplets or skin contacts, but other zoonotic vehicles of transmission such as unpasteurized milk products are also possible (26, 27, 31).

S. dysgalactiae predominantly resides in domestic animals such as cattle, sheep, cats, and dogs that are either healthy carriers of the bacterium or go on to develop diseases such as pneumonia, arthritis, septicemia, and abscesses, particularly bovine mastitis. *S. equi*, a pathogen primarily restricted to horses and donkeys, causes strangles, which is a highly contagious disease characterized by purulent discharges from the respiratory tract and the development of abscesses (32). This organism is not considered to be part of the normal flora, because of its close association with disease. In contrast, *S. zooepidemicus* is an opportunistic commensal that colonizes mucosal surfaces and causes rhinopharyngitis, pneumonia (33), endometritis, neonatal septicemia, and wound infections in horses (34) as well as disease in other domestic

S. equi* subsp. *zooepidemicus	Animals, humans	C
S. phocae	Animals (seal)	C
***S. anginosus* group**	Humans	A, C, F, G

[a]From reference 1.

animals such as cattle, sheep, pigs, and chickens. Although uncommon, *S. zooepidemicus* is also responsible for a range of zoonotic infections in humans (26, 27).

The small-colony phenotype of group C and G streptococci is expressed by the *S. anginosus* group, formerly known as *Streptococcus milleri*. The group contains three species, *S. anginosus*, *Streptococcus constellatus*, and *Streptococcus intermedius* (1), and forms a distinct subclade by phylogenomic analysis (35).

Strains belonging to the *S. anginosus* group express group antigens F, C, A, and G or no antigen. These strains are also likely to be non-beta-hemolytic. Members of these species are recognized as common commensal organisms of the human oral cavity, gastrointestinal tract, and genitourinary tract. They are also associated with abscess formation in the mouth and other body sites (36, 37) as well as pharyngitis (38) and endocarditis (39, 40). It has also been reported that *S. anginosus*, along with *Streptococcus mitis* and *Treponema denticola*, can be isolated from esophageal cancer tissue and by initiating inflammation in the cancerous tissue has a role in the development or progression of these cancers (41, 42).

Several assays are available to detect, classify, and genetically describe GCS and GGS. Routine microbiological diagnosis follows the same guidelines that are in use for the identification of the other beta-hemolytic streptococci (43). The beta-hemolytic streptococci isolates are divided into large and small colonies forming groups based on the growth on sheep blood agar: the large-colony-forming group is "pyogenic." The small-colony-forming species make up the anginosus group and are not referred to as GCS or GGS, even though they may cross-react with C or G sera. Lancefield agglutination tests are still used to group beta-hemolytic streptococci into the Lancefield groups. Fermentation tests are used to classify GCS as *S. equisimilis* or *S. zooepidemicus* and are based on a spectrum of biochemical tests which are now available commercially (44). More recently, matrix-assisted laser desorption ionization–time of flight mass spectrometry has been described as a rapid alternative for the identification of streptococci (45). In addition, multilocus sequence analysis of seven housekeeping genes (46) and other sequence-based assays are performed to analyze the streptococcal phylogenies. In particular, sequencing of the *emm* gene, which encodes the hyper-variable surface protein M, and 16s rRNA genes is undertaken for phylogenetic analysis of these streptococci based on sequence similarities (47, 48).

Next-generation sequencing is increasingly being used for genetic characterization, phylogenetic analyses, virulence and pathogenicity profiles, and antibiotic resistance analyses (22, 49). *S. equisimilis* and *Streptococcus pyogenes* (or GAS) share a high genetic similarity (~72%) and similar virulence genes, suggesting a common evolutionary origin and genetic exchange (22, 25, 50).

MECHANISMS FOR ADHERENCE

S. equisimilis causes a spectrum of disease in humans similar to that caused by *S. pyogenes*, and molecular studies have demonstrated virulence determinants that are almost identical. Putative virulence determinants of *S. equisimilis* include adhesins, toxins, and factors that are essential for dissemination in human tissues and for interference with the host immune responses.

Adhesion of microorganisms to host tissues represents a critical phase in the development of infection. It is therefore unsurprising that microorganisms have evolved dedicated mechanisms for attachment and adherence to extracellular matrix components of the host (51, 52). Of these components, the high-molecular-weight glycoprotein fibronectin appears to be the major attachment target of Gram-positive cocci, including GGS and GCS. Fibronectin itself is responsible for substrate adhesion of eukaryotic cells via specific cell surface factors of the integrin family. It also specifically interacts with other matrix components, such as collagen, fibrin, and sulfated glycosaminoglycans, demonstrating that this molecule fulfills multifunctional roles within the extracellular network (53). Being present in the extracellular matrix of most tissues, as well as in plasma and other body fluids in its soluble form, fibronectin represents an exquisite target for bacteria to exploit the cell attachment properties of this molecule by linking the pathogen to specific target cells. Epithelial cells of the human upper respiratory tract are bathed in secretions containing fibronectin in its soluble form. Once bound to the bacterial surface, it enables the pathogen to attach and subsequently colonize the primary site of infection.

Fibronectin binding proteins (FBPs) were first identified in *Staphylococcus aureus* and *S. pyogenes* (54), and approximately 11 have been defined in *S. pyogenes*, highlighting their importance for this pathogen (55). Binding by these bacteria to eukaryotic cells via fibronectin is also an important preliminary event prior to the invasion of these cells (56–58). The FBPs from streptococci and staphylococci share a common architecture, with a putative signal sequence at the N terminus and a wall- and membrane-spanning region. The major fibronectin binding domains are located within the C-terminal part of the proteins and are composed of 3 to 5 repetitive units that consist of 35 to 37 amino acid residues and bind to the 29-kDa N-terminal fragment of fibronectin. Further binding studies of PrtF/SfbI from *S. pyogenes* and FnBPA in *S. aureus* also indicate the presence of a secondary fibronectin binding site upstream of the repeat regions (54).

The first FBPs to be identified in group C and G streptococci were FnbA and FnbB from *S. dysgalactiae* (59). FnbA can opacify serum and bind fibrinogen, like the serum opacity factor of *S. pyogenes* (60). Both FnbA and FnbB bind fibronectin through C-terminal repeat regions (51).

Three FBPs have been defined in *S. zooepidemicus*: FNZ, FNZ2, and SFS. Although the modular organization of FNZ, an *S. zooepidemicus* FBP, is similar to those from other species, homology at the amino acid level is weak (61). Fibronectin

Downloaded From Vet-eBooks.com

binding is mediated through a repeat region and a second upstream region containing the amino acid motif LAGESGET. This motif is also present in the secondary binding domain of SfbI (62), where it acts independently of the repeat region in binding to fibronectin (63). This domain is also present in GfbA, the homologue of SfbI in *S. dysgalactiae* (64). *fne* is the homologous gene to *fnz* in *S. equi* (65). However, FNE is unique in that a single nucleotide deletion in the *fne* gene has resulted in the truncation of the protein, so with the loss of the cell-wall binding motif, it is secreted into the surrounding environment. The truncated FNE also lacks the classic fibronectin binding repeats found in the C-terminal region of FNZ but is able to bind fibronectin through the amino-half domain, also found in FNZ. Consequently, fibronectin binding at the bacterial surface is much lower for *S. equi* than *S. zooepidemicus*, although both have an additional cell wall-anchored FBP: FNEB and FNZ2 (66). FNE also binds to collagen, and the protein affects the interstitial fluid pressure *in vivo* (67). The molecular structure of the interaction between FNE and fibronectin has been reported (68). FNZ2 also has both collagen and fibronectin binding properties (69). SFS of both *S. equi* and *S. zooepidemicus* strains contains a signal peptide but no cell wall binding motifs or traditional fibronectin binding motifs. SFS inhibits binding between fibronectin and collagen. If SFS were to bind fibronectin attached to the bacterial surface through FNEB/FNZ/FNZ2, this might inhibit binding of fibronectin to collagen, which could have several physiological consequences (70). The molecular interaction between SFS and fibronectin has been reported (71).

Some of the FBPs and collagen binding proteins identified in *S. pyogenes* are chromosomally located within the fibronectin and collagen binding proteins and T antigen encoding (FCT) locus. There are at least nine types of FCT regions in *S. pyogenes* that vary by gene content and order, but within this region are the genes required to make the pili. The pilus has been shown to contribute to the formation of biofilm and mediate adherence to host cells (72–75). Whole-genome sequence analysis of group C and G streptococci has also identified potential FCT regions. One putative pilin locus, FimI, exists within the genome of *S. equi* strain 4047 (76). Although no pili structures have been identified for *S. equi*, the proteins of FimI are expressed during growth and have the potential to affect adherence *in vivo* (77). The gene encoding the collagen binding protein CNE of *S. equi* (78) is present in this FimI locus. A homologous locus was also found in *S. zooepidemicus* isolates, as well as an additional one or two potential pili loci (76, 79). Two FCT regions were also found in *S. equisimilis*, which share high levels of genetic identity to FCT regions from different *S. pyogenes* genotypes, suggesting multiple horizontal gene transfer events (22, 80).

An alternative way for group C and G streptococci to adhere to host cells is via binding to other extracellular matrix molecules, including fibrinogen, vitronectin, laminin, collagen, and plasminogen (81, 82). The M-protein-like fibrinogen binding protein of G streptococci (FOG) can act as an adhesin by binding collagen IV (83) and has been shown to also bind collagen I fibrils in dermis *in vivo* (84).

Vitronectin is a multifunctional serum protein that affects the humoral immune system by binding to and inhibiting the complement membrane attack complex (85) and is also a major matrix-associated adhesive glycoprotein that regulates blood coagulation. The ability of group C and G streptococci specifically to interact with vitronectin (86) and mediate the adherence to both epithelial and endothelial cells (87, 88) was demonstrated some time ago. However, a specific vitronectin binding protein has never been identified in streptococci.

ANTIPHAGOCYTIC FACTORS

A major requirement of pathogenic streptococci is to be able to resist phagocytosis. The streptococcal M protein, first identified and characterized in *S. pyogenes*, is the major antiphagocytic factor (89). It is a multidomain surface-exposed molecule that forms a coiled-coil secondary structure with significant irregularities that in the B-repeat region are essential for the fibrinogen binding properties (90). Binding of complement factors, fibrinogen, and inhibition of C3b deposition on the bacterial surface are mechanisms by which the M-protein can inhibit opsonization of the organism by the alternative complement pathway, thus evading the host's nonspecific immune defense mechanism.

Several M-like proteins have been identified in group C and G streptococci. Protein MG1, the first group G streptococcal M-like protein characterized on the molecular level (91), exhibits typical structural and biological features of M proteins, such as coiled-coil structure and the ability to generate type-specific opsonizing antibodies. Protein MG1 shares highly homologous sequences with the C-terminal repeat region of class I M proteins, which are frequently associated with rheumatic fever. M proteins of GGS are also responsible for conferring resistance to phagocytosis (92).

In human strains of GGS, FOG is critical for bacterial pathogenesis through its antiphagocytic action of binding fibrinogen (93). It also has the ability to bind IgG subclasses IgG1 and IgG2, although FOG-bound IgG1 can trigger the complement cascade through C1/C1q activation. It is unclear whether this is detrimental to the bacteria, because FOG remains protective against phagocytosis (94).

The antiphagocytic protein SeM (FgBP) appears to be the predominant M-like protein on the surface of *S. equi*, capable of binding fibrinogen and IgG4 and IgG7 subclasses (95–97). SeM confers resistance to phagocytosis, but this also requires the presence of the hyaluronic acid capsule (98). Like the M protein of *S. pyogenes*, SeM is variable at the N-terminal region, suggesting selective pressure (99). Interestingly, this does not appear to be the case for two other M-like proteins expressed by *S. equi*: Se18.9 and SzPSe (99). The antiphagocytic protein Se18.9 is commonly found in strains of *S. equi*, but rarely in strains of *S. zooepidemicus* (76), and acts by binding to fibrinogen and the complement regulatory protein, factor H (100). SzP proteins are also antiphagocytic and are expressed by both *S. equi* and *S. zooepidemicus*. Whole-genome sequence analysis of *S. zooepidemicus* strain H70 identified a potential M-protein homologue in SzM that resembles SeM in its secondary structure, which consists of a predicted C-terminal coiled-coil (76, 101). The N-terminal of SeM is unique to *S. equi* and binds fibrinogen (97, 102). SzM can also bind fibrinogen but cannot bind IgG (103). The M protein of *S. canis* specifically binds the Fc region of IgG in a nonopsonic manner (104).

DemA is an *S. dysgalactiae* protein with homology to FgBP identified by screening of a phagemid expression library (105). The mature DemA protein is 54 kDa in size, contains a signal sequence and a cell wall binding domain, and is predicted to have a coiled-coil secondary structure. DemA shows greatest homology to the FgBP at the C-terminal end in a region that does not participate in fibrinogen binding. The amino acid motif VSKDLADKL present with the repeat units of both DemA and FgBP suggests that the sequence may have an important biological function. DemA is able to bind

Downloaded From Vet-eBooks.com

IgG from various animal sources, reminiscent of type IIa Ig-binding proteins of *S. pyogenes* in a domain distinct from the fibrinogen binding domain. Nucleotide sequencing of the *dem*A locus identified an open reading frame upstream of *dem*A that is homologous to *mga*, a positive regulator of M-protein expression in *S. pyogenes* (105).

C5a peptidase of *S. pyogenes* (ScpA) is well known to specifically cleave and inactivate the chemoattractant C5a, but it has also recently been shown to cleave the complement factor C3 and the chemoattractant C3a (106), expanding its impact on immune evasion. ScpA has also been identified as an adhesion factor enabling bacteria to adhere to endothelial and epithelial cells (106). Homologues of ScpA have been identified in group B streptococci (ScpB) and group C and G streptococci isolated from humans but not from GGS from animals (107, 108). Both *S. equi* and *S. zooepidemicus* also carry homologous C5a peptidase genes (*scpE* and *scpZ*, respectively). However, the C5a peptidase gene in *S. equi* is reported to be a pseudogene (76). Unlike in *S. pyogenes*, where *scpA* is located in the *mga* regulon that includes the *emm*-gene, the *scp* genes of group B, C, and G streptococci are associated with a transposon, suggesting that lateral genes transfer between these species (107, 109).

The *S. pyogenes* cell wall envelope proteinase, SpyCEP, is another protease that contributes to the prevention of phagocytosis through the specific cleavage of interleukin-8 and other chemokines to prevent the activation and migration of neutrophils (110, 111). Similar enzymes have been identified in *S. equi* (SeCEP) and *S. zooepidemicus* (SzoCEP) which share 98% identity to each other and 59% identity to SpyCEP (108). SeCEP has been shown to cleave both human and equine IL-8, and vaccination with a recombinant portion of SpyCEP prevented bacterial dissemination in a murine model of *S. equi* invasive infection, suggesting an important contribution to disease (112).

IMMUNOGLOBULIN BINDING AND INACTIVATING PROTEINS

Streptococcal protein G is a surface molecule associated with the majority of group C and G streptococcal isolates of human origin. Protein G interactions with immunoglobulins and other host proteins have been the subject of detailed reviews (113–115). Protein G is defined as a type III IgG Fc receptor and interacts with a wide species range of immunoglobulins, as well as human serum albumin, kininogen, and α_2-macroglobulin. Protein G exhibits a modular structure in which the binding sites for IgG are located in the C-terminal repeat region (114–116). The central A/B-repeat region constitutes the binding domain for serum albumin, and the N-terminal E region is responsible for interacting with the native form of α_2-macroglobulin (82). In contrast to human pathogenic strains of GGS that exclusively bind to the native (slow) form of α_2-macroglobulin via protein G, animal-derived isolates of bovine and equine origin bind the proteinase-complexed (fast) form of the molecule. The B1 domain of protein G involved in immunoglobulin binding consists of an α-helix and four β-strand sheets. This domain has been used as a model structure in numerous biochemical studies examining protein folding, protein interaction, and synthetic protein design (117–119).

Two protein G-related proteins, MIG and MAG, from two mastitis-causing *S. dysgalactiae* strains (120) and MAG (121, 122) and ZAG (123) from *S. zooepidemicus* have been characterized on the molecular level. Like protein G, MAG and ZAG exhibit serum albumin and type III Fc receptor activity, whereas the protein MIG lacks albumin-binding activity. However, MAG is able to bind to immunoglobulins from a greater number of animal sources than protein G. MAG, ZAG, and MIG also bind to the fast form of α_2-macroglobulin. The α_2-macroglobulin binding region in MIG is not homologous to those of protein G, MAG, ZAG, and GRAB. In phagocytosis assays a MIG isogenic mutant strain of *S. dysgalactiae* was not as resistant to opsonization by bovine neutrophils as the parental strain (124). MIG has also been shown to bind to bovine immunoglobulin A (125) and can inhibit bacterial internalization into host cells (126).

As well as IgG binding proteins, group C and G streptococci can express variants of the *S. pyogenes* IdeS and EndoS, which are IgG-degrading enzymes. While IdeS cleaves the hinge region of IgG (127), EndoS removes core IgG glycans (128). Both *S. equi* and *S. zooepidemicus* express two forms of IgG-endopeptidases, IdeE/IdeE2 and IdeZ/IdeZ2, respectively, that are capable of cleaving IgG from several mammalian species (129, 130), although IdeE2/IdeZ2 cleave horse IgG with greater efficiency than IdeE/IdeZ (130). EndoS homologues have also been identified in *S. equi* (EndoSe) and *S. zooepidemicus* (EndoSz), and they share 86 to 89% sequence identity to each other and 70% identity to EndoS of *S. pyogenes* (131). EndoSd has also been found in *S. equisimilis* with IgG hydrolyzing activity (132), and IdeP was identified in the group C *S. phocae* subsp. *phocae* that affects marine animals, although its function has not been confirmed (133).

ENZYMES AND TOXINS

After colonization, adherence, and evasion of host immune responses, the dissemination of pathogenic streptococci in tissues is regarded to be an important step for the onset and development of an invasive disease. One of the factors involved in this process is streptokinase, a protein found in groups C, G, and A streptococci (134). The formation of a streptokinase/plasminogen complex results in the exposure of the plasminogen active site, which then catalyzes the conversion of other plasminogen molecules into plasmin (135). Plasmin is a key serine protease in the fibrinolytic system that is able to break down tissue barriers, thereby enabling the dissemination of streptococci. M proteins coordinately interact with the secreted streptokinase by binding either fibrinogen (136) or plasminogen (137). A high level of variation exists within the streptokinase gene, *ska*, and alleles of *ska* have been associated with tissue tropisms and differing levels of plasminogen activation (138). There is some overlap of alleles between human strains of group C and G streptococci and GAS (139). Streptokinases have been isolated from both human and animal group C and G isolates and have specificity for the plasminogens of their respective hosts (140). Thus, streptokinases from human group A, C, and G streptococci isolates have greater homology to each other than to animal isolates of group C and G streptococci. A study by Caballero et al. (58) found the amino acid homology between streptokinases from human and animal *S. equisimilis* isolates to be only 35%. Homology between the streptokinase from *S. equisimilis* of equine and porcine origins was only 21%. The ability of streptokinases to cleave plasminogen from specific species may therefore be a critical factor in determining the host range of individual streptococcal strains (141). Invasive human strains of *S. equisimilis* have been found to express higher levels of streptokinase, and this can drive virulence in a murine model of invasive necrotizing

Downloaded From Vet-eBooks.com

fasciitis, suggesting an important role for streptokinase in disease (142, 143).

Streptolysin O (SLO) is the prototype of a family of thiol-activated cytolysins produced by the genus *Streptococcus* and by other Gram-positive bacteria, including *Bacillus*, *Clostridium*, and *Listeria* species (144). The genes coding for SLO of group C and G streptococci (*S. dysgalactiae*) are almost identical to that of *S. pyogenes* (145). SLO homologues have not been described in *S. equi*. SLO is able to disrupt the cytoplasmic membrane of several eukaryotic cell types that include erythrocytes, leukocytes, macrophages, platelets, and epithelial cells. Separate from its pore-forming activity, SLO also acts to translocate NADase into host cells (146), which contributes to cytotoxicity by depleting energy stores. Other functions of these two streptococcal toxins include limiting neutrophil responsiveness and potentiating bacterial survival, replication, and persistence inside keratinocytes, epithelial cells, and macrophages, which may protect GAS from the immune response and antimicrobial therapy (147–151).

Streptolysin S (SLS) is another cytolysin secreted by groups A, C, and G streptococci, including the animal-pathogenic *S. equi* species (152). SLS belongs to a distinct group of hemolytic toxins that are characterized by their resistance to oxidation and sensitivity to trypan blue. SLS activity results in damage to membranes of various cell types as well as subcellular organelles (153). In contrast to the 57-kDa SLO, SLS is a small, 57-amino acid protein. The gene encoding SLS, *sag*A, is part of a locus containing nine open reading frames which contain significant homology with genes from bacteriocin loci (154, 155). In *S. equisimilis*, SLS expression is under the control of both the *covRS* and *fas*CAX two-component regulatory systems, which in *S. pyogenes* have been shown to be involved in the regulation of multiple virulence factors (156). In a mouse infection model, *S. equisimilis* expressing SLS proliferates and induces necrotic lesions at the site of infection, whereas SLS-negative strains do not, suggesting that SLS is an important factor in the development of necrotizing fasciitis (154).

Streptococcal pyogenic toxins (spes) are superantigen genes capable of cross-linking the major histocompatibility complex class II on antigen-presenting cells to the T cell receptor, leading to proliferation of T cells and substantial release of inflammatory cytokines. Eleven superantigen genes have been identified in *S. pyogenes*, and they are thought to drive the development of scarlet fever and toxic shock syndrome, the latter contributing to high mortality rates following necrotizing fasciitis. Recent work has also identified a role for superantigens in upper respiratory tract infection (157). Homologues of the GAS superantigens have been identified in group C and G streptococci (158). The most commonly found superantigen in *S. equisimilis* is *spe*G (*spegg* or *spe*G^{dys}) (159, 160), and genomic analysis indicates that *S. pyogenes* and *S. equisimilis spe*G genes are orthologues that are direct descendants from a common ancestor gene (161). The gene for *spe*G can also be found in *S. canis* (158). The role of *S. equisimilis spe*G in humans is unclear because the presence of this gene does not correlate with disease severity and it does not confer mitogenic activity toward human mononuclear cells, although it can stimulate bovine T cells (160, 162, 163). The streptococcal superantigens *spe*A, *spe*C, *speJ*, *speK*, *speH*, *speL*, *spe*M, and *ssa* are found infrequently in *S. equisimilis* and other human group C and G streptococci (160, 164–166).

Homologues of *S. pyogenes* superantigens *speH* and *speI* can be carried by strains of *S. equi* (167), and homologues of *speK* and *speL* can be carried by both *S. equi* and *S. zooepidemicus*, although because of confusion with the nomenclature, *speK* homologues were originally termed *speL*$_{se}$/*seeL*/*szeL*, and *speL* homologues were termed *speM*$_{se}$/*seem*/*sze*M (160, 167–169). Three additional superantigen genes, termed *szeN*, *szeP*, and *szeF*, have been identified in *S. zooepidemicus* only and are capable of stimulating equine peripheral blood mononuclear cells (170). *S. dysgalactiae*-derived mitogen shows homology to *spe*M of *S. pyogenes* and can stimulate human mononuclear cells (160, 171). The majority of the superantigens found in *S. pyogenes* and group C and G streptococci are associated with prophages which may drive the lateral transfer of these virulence factors between streptococcal species (76, 172, 173).

CONCLUSIONS

Many recent studies have highlighted the increasing number of systemic infections caused by *S. equisimilis*, particularly among immunocompromised individuals and specific populations, and this therefore suggests that this species will gain even more clinical importance in the future. High nucleotide similarities among virulence genes and their association with mobile genetic elements support the hypothesis of extensive horizontal gene transfer events between streptococcal species of the pyogenic group. A better understanding of the mechanisms of pathogenesis will hopefully be revealed by whole-genome sequencing, and this may result in more effective clinical strategies for the pyogenic group of streptococci in generally.

This chapter is dedicated to the memory of Gursharan Singh Chhatwal, an inspiring "streptococcologist" who leaves us with wonderful memories of Lancefield 2002 held in Goa, India, and many others.

Infections Caused by Group C and G Streptococcus (*Streptococcus dysgalactiae* subsp. *equisimilis* and Others): Epidemiological and Clinical Aspects

GIO J. BARACCO

17

Conrary to the homogeneity typical of streptococci belonging to Lancefield groups A (*S. pyogenes*) and B (*S. agalactiae*), groups C and G streptococci (GCGS) represent a variety of species that are widely variable in regard to biochemical reactions, hemolytic characteristics, predilection for host species, and clinical illnesses produced in humans and animals. These organisms are found as commensals in the throat, skin, and occasionally the female genitourinary tract, and their epidemiologic patterns and clinical manifestations reflect this distribution.

HISTORY AND TAXONOMY

The classification of GCGS is complex and has been continuously evolving over the past few decades. Most human infections with GCGS are caused either by members of the *S. anginosus* group (SAG) (*S. anginosus*, *S. constellatus*, and *S. intermedius*, also formerly known as the *S. milleri* group), which form small colonies (<5 mm), can be alpha-, beta-, or nonhemolytic, and may also express Lancefield group F (most common) or group A (rare) antigens or no group antigen at all, or by *Streptococcus dysgalactiae* subspecies *equisimilis* (SDSE), which forms large colonies (>5 mm) that resemble those of *S. pyogenes* when cultivated on sheep blood agar plates and is typically beta-hemolytic. SDSE and SAG may express either group C or G antigens. Certain uncommon strains of SDSE may also express Lancefield group L or group A antigens (1–3). In addition, *S. dysgalactiae* subsp. *dysgalactiae* (SDSD), *S. equi* subsp. *equi*, and *S. equi* subsp. *zooepidemicus* express group C antigens, while *S. canis* strains are group G (4).

While well known to veterinarians as a cause of bovine mastitis, *S. dysgalactiae* (from the Greek for "bad milk") was dropped from the Approved List of Bacterial Names in 1980 (5). It is unclear whether this was an oversight or if there was a more concrete reason such as the absence of a reference strain, but in 1983 Garvie sought to correct this error and published an article that included a detailed microbiological description and a reference strain (6). In 1996 Vandamme proposed distinguishing two subspecies of *S. dysgalactiae* based on their host of origin, with animal isolates designated as *S. dysgalactiae* subsp. *dysgalactiae* and human isolates receiving the name *S. dysgalactiae* subspecies *equisimilis* (4). Vieira et al. agreed with the separation into two subspecies but suggested that the distinction be based on the type of hemolysis produced, designating nonhemolytic and alpha-hemolytic GCGS strains as SDSD and beta-hemolytic strains as SDSE (7). This is the currently accepted taxonomic classification, although it has continued to be challenged (8). In 2001 it was proposed that SDSD and SDSE be recognized as distinct species based on clinical and epidemiological grounds, but the motion was rejected by the International Committee on Systematic Bacteriology because taxonomic evidence did not support it (9). Multiple reports of exceptions to the Vieira subdivision have been published, and some authors have found it to be very inaccurate when assessed by DNA fingerprinting (10). It is possible that some of these discrepancies can be explained by continued evolution of the species through horizontal transfer of genes from other beta-hemolytic streptococci, especially *S. pyogenes*, to SDSE (10, 11). In the absence of widespread availability of genomic identification, many clinical laboratories continue to designate animal strains as SDSD and human strains as SDSE or continue to report these bacteria using the Lancefield classification.

In this article we will, to the extent possible, focus on the species-based nomenclature of streptococci. However, many of the studies reviewed, particularly those in the older literature, employed the Lancefield classification, making it impossible to know the causative species.

EPIDEMIOLOGY

The SAG members are normal commensals in the oral cavity. All three species, but especially *S. intermedius*, have been found in gingival crevices, dental plaque, dental root canals, and the naso- and oropharynx. *S. anginosus* isolates are also commonly isolated from urogenital and gastrointestinal sources (1, 12).

SDSE is a common commensal of humans (13). It is thought that the horizontal transfer of virulence factors such as fibronectin-binding protein, M protein, and bacteriocin-like inhibitory substance activity from human streptococci to animal strains of *S. dysgalactiae* enabled them to colonize humans (14). Some studies have suggested that pharyngeal colonization with SDSE may be protective against infection

doi:10.1128/microbiolspec.GPP3-0016-2018

Downloaded From Vet-eBooks.com

with other pathogens, since its presence has been found to have an inverse correlation with the incidence of pharyngitis (15). On the other hand, invasive infections caused by SDSE have been emerging in many parts of the world (16). SDSE is responsible for over 80% of invasive infections caused by beta-hemolytic streptococci of groups other than A and B (2). The incidence of bacteremia caused by SDSE has increased 2- to 3-fold and approaches that of *S. pyogenes* in many countries. In Finland, the incidence of group G streptococcal bacteremia increased from 1.8 cases/100,000 population in 1995 to 4.3 cases/100,000 population in 2004 (17). In Norway, the incidence of invasive GCGS infections increased from 1.4/100,000 inhabitants in 1999 to 6.3/100,000 in 2013 (18). The increased virulence of SDSE seems to be related to clonal expansion of a few clades carrying specific virulence factors, such as *cbp*, *fbp*, *spe*G, *sic*G, *gfb*A, and *bca* (19, 20). Most SDSE strains express a functional homolog of the potent *S. pyogenes* beta-hemolysin/cytolysin streptolysin S that contributes to the pathogenesis of necrotizing soft tissue infection (21). SDSE strains also express M proteins that share structural and functional properties with *S. pyogenes* M proteins (22, 23). Similar to invasive GAS infections, a high percentage of patients with invasive SDSE infections have comorbid illnesses, including diabetes mellitus, malignancies, immunosuppression, intravenous drug use, and breakdown of the skin (1, 16, 24).

Transmission of SDSE, when it occurs, is likely to be from person to person, and most cases are sporadic in nature, rather than associated with common source outbreaks. When outbreaks do occur, they are generally associated with close personal contact or perhaps with environmental contamination. By contrast, *S. equi* subsp. *zooepidemicus* is generally associated with exposure to animals or to common source outbreaks, especially consumption of contaminated dairy products.

ANIMAL INFECTIONS

SDSD is a major cause of mastitis in cows and dromedary camels and various infections in lambs (25–27). *S. equi* subsp. *equi* is occasionally found in the upper respiratory tract of normal horses and is the causative agent of equine strangles. This acute, contagious, and deadly respiratory disease has led to explosive epidemics in horse stables and has serious potential economic consequences for horse fanciers (28). *S. equi* subsp. *zooepidemicus* is a cause of infection in a variety of animal species, including horses, cows, dogs, rabbits, llamas, alpacas, guinea pigs, and swine (25, 26, 29–33).

HUMAN INFECTIONS

The SAG is usually classified, and described, with the "viridans" group of streptococci. These species are characterized for their disposition to form abscesses in various organs, including lung, pleural space, brain, oral and abdominal cavities, skin and soft tissues, and the genitourinary tract with or without associated bacteremia (34–36). Although less common than other viridans streptococci, *S. anginosus* may also cause endocarditis (12, 37, 38). Many invasive SAG strains, however, belong to serogroups other than C or G or are nongroupable (34, 39).

This review will focus on the more common infections caused by SDSE, as well as on the few reported human cases caused by *S. equi* subsp. *zooepidemicus*, *S. equi* subsp. *equi*, and *S. canis*. Strains of these streptococci have been associated with infections of many body sites (14, 26, 40–45).

Pharyngitis and Acute Glomerulonephritis

The role of SDSE in sporadic cases of pharyngitis remains somewhat controversial. Although occasionally isolated from patients with pharyngitis, streptococci of this species are also often cultured from the throats of healthy individuals (12). Marchello and Ebell conducted a meta-analysis of the prevalence of group C streptococci in patients with sore throat. They found a prevalence of 6.1%. However, the absence of a healthy control group did not allow the authors to conclude whether these bacteria were the actual pathogens (46). Several clinical and laboratory-based studies have looked at the clinical manifestations of patients with pharyngitis in whom SDSE was isolated. In general, signs and symptoms of patients with pharyngitis in whom SDSE is isolated are indistinguishable from those in whom *S. pyogenes* is found (47, 48). Turner et al. (49) studied students reporting to a college health service with acute pharyngitis and compared them with controls without infectious problems. Group C streptococci were cultured at a higher rate from students with pharyngitis than from the control group. Patients with positive cultures for group C streptococci were more likely to have features suggestive of a bacterial infection, such as exudative tonsillitis and anterior cervical lymphadenopathy, than were those with negative cultures. Furthermore, these group C strains resisted phagocytosis in human blood and contained genomic DNA encoding an M protein similar in structure to that of group A streptococci, providing further evidence of possible human virulence (50). In a later study, the same group of authors described 265 students with exudative pharyngitis and compared them with 75 patients with rhinovirus infection and 162 students with noninfectious problems. SDSE was isolated significantly more frequently from patients with exudative pharyngitis than from either control group (51). Twenty-two cases of pharyngitis from which group C streptococci were isolated occurred during the fall of 1974 in a school for boys with learning disabilities. Although it is likely in this epidemiologic setting that the infecting strains were SDSE, they were unfortunately not speciated (52). On the more severe side of the spectrum, SDSE has rarely been reported as the cause of severe and even necrotizing tonsillitis (53, 54).

Streptococci expressing group G antigen have clearly been linked to outbreaks of pharyngitis. Many of those outbreaks were related to a common source, usually a food product. In one such outbreak during a single week in 1968, 176 students at a college were evaluated for pharyngitis. The attack rate in the student body was 31%. Signs and symptoms were similar to those characteristic of group A streptococcal pharyngitis, suggesting an etiologic role for the organism. Epidemiologic investigation linked the outbreak to contaminated egg salad (55). In another common source outbreak, 72 people who attended a convention developed pharyngitis, with group G streptococci isolated from most who had cultures performed. All the patients had consumed chicken salad prepared by a single cook whose throat culture was positive for the organism (56). Another epidemic of group G streptococcal pharyngitis involving 68 students occurred over a 1-week period at a North Carolina college. Because no common food source could be identified, the author concluded that the mode of spread was most likely person to person. The very sharp epidemic curve and brief duration of the outbreak suggest, however, that contamination of a common food vehicle is more likely. In support of this conclusion are the facts that all students interviewed had eaten in the campus cafeteria in the week preceding illness and that one student with a positive culture was a food

Downloaded From Vet-eBooks.com

handler (57). A community-wide outbreak of group G streptococcal pharyngitis, unrelated to any common source, was documented among private pediatric patients in the winter and spring of 1986 to 1987 in Connecticut (58).

Epidemics and clusters of pharyngitis cases due to *S. equi* subsp. *zooepidemicus* are typically related to a common source, usually consumption of unpasteurized dairy products. A remarkable feature of such outbreaks is their association with poststreptococcal acute glomerulonephritis. From December 1997 to July 1998, 253 cases of acute glomerulonephritis due to *S. equi* subsp. *zooepidemicus* occurred in Nova Serrana, Brazil, among people who had consumed locally produced unpasteurized cheese. Ten patients required dialysis and three died (59). A follow-up report 2 years later of 134 of these patients showed that five of them required continuing dialysis. Of the 69 patients from that cohort who could be found and reevaluated, 42% had hypertension, and there was a high proportion of patients (up to 30%) with persistent renal function abnormalities (60). Duca et al. described 85 patients with pharyngitis due to *S. equi* subsp. *zooepidemicus* following the ingestion of improperly pasteurized milk, 87% of which were adults. Approximately one-third of the patients developed acute glomerulonephritis, generally in the second or third week of illness (61). In a smaller outbreak, five members of a family developed an upper respiratory infection related to *S. equi* subsp. *zooepidemicus* after consuming unpasteurized milk (62). Three of the five family members subsequently developed poststreptococcal glomerulonephritis, which was confirmed in one case by renal biopsy.

Infections of Skin and Soft Tissue

SDSE is a frequent cause of skin and soft tissue infections, and the skin is often the portal of entry for serious invasive disease and bacteremia. These infections can manifest as pyoderma, cellulitis, erysipelas, surgical wound infections, abscesses, necrotizing soft tissue infections, and pyomyositis (63–67). In some series, GCGS have been isolated with as much or greater frequency than *S. pyogenes* in patients with cellulitis and erysipelas (68, 69). Infection caused by these organisms may complicate ulcers associated with diabetes mellitus, immobility, or venous and lymphatic compromise of any cause (14). Recurrent cellulitis may occur, for example, in the limb that underwent saphenous venectomy of patients who have experienced coronary artery bypass grafting or in the extremities of individuals who have had axillary, pelvic, or femoral node dissection for cancer (70). Severe skin and soft tissue infections caused by SDSE include cases of necrotizing fasciitis, Fournier's gangrene, and necrotizing myositis (67, 71). Bruun et al. described a series of 70 cases of necrotizing fasciitis, 9 of which were caused by SDSE. The in-hospital case fatality rate of patients with SDSE was 33%, compared to 11% for those caused by *S. pyogenes* (67). These infections typically occur in patients who are older and have underlying comorbid conditions, such as malignancy, cardiovascular disease, alcoholism, and diabetes mellitus (44, 72). Injectable-drug users seem to be at increased risk for cellulitis and skin abscesses caused by SDSE, and the skin is the usual source of bacteremia in such patients (64). Burn patients are also at risk for skin and skin graft infections with SDSE; such individuals accounted for 8% of cutaneous group G streptococci infections in one series (63, 73).

There are numerous reports of streptococcal toxic shock syndrome (STSS) in patients with severe infections caused by SDSE (74–83). Sachse et al. studied 24 pathogenic isolates of SDSE and found a gene encoding the streptococcal pyrogenic exotoxin G (speG^{dys}), demonstrating that this species has the potential to produce superantigen-like proteins. They failed, however, to show the presence of genes related to the superantigens SPEA, SPEC, SPEZ (SMEZ), SPEH, and SPEI (84). Another study, however, demonstrated that some strains of SDSE do carry the bacteriophage-associated genes *spe*A, *spe*C, *spe*M, *ssa*, or *sme*Z identical to their counterparts in *S. pyogenes*. This suggests that these genes may be transferred from one species to the other, conferring enhanced pathogenicity (85).

In contrast to SDSE, the rare cases of skin and soft tissue infection due to *S. equi* subsp. *zooepidemicus* and *S. equi* subsp. *equi* usually involve exposure to animals. One case of cellulitis with bacteremia due to *S. equi* subsp. *zooepidemicus* was reported in a renal transplant patient who was exposed to horses at a show (86); a case of severe facial cellulitis due to *S. equi* subsp. *equi* was reported in another man who also had equine exposure (87), and a case of necrotizing myositis was reported in a previously healthy Norwegian farmer with two asymptomatic Shetland ponies in his stable (88). Two cases of streptococcal toxic shock syndrome caused by *S. equi* subsp. *zooepidemicus* have also been described (74, 89).

Joint and Bone Infections

While not common, SDSE is a known etiology of infectious arthritis, in both native and prosthetic joints (90–92). A group of reference hospitals in France published their experience with streptococcal bone and joint infections. They found SDSE to be present in 12% of cases and *S. anginosus* in 11%. These species were second only to *S. agalactiae* in frequency. In this series, the isolation of SDSE was associated with an unfavorable clinical outcome (93).

González Terán et al. reviewed 24 patients with group C streptococcal arthritis, two from their experience and the other 22 from the literature. Twelve (50%) cases were caused by SDSE, three by *S. equi* subsp. *zooepidemicus*, and the other nine were not speciated. Nine of the patients had polyarticular involvement. One-third (eight patients) had a preexisting arthropathy, including rheumatoid arthritis, gout, seronegative arthropathy, osteoarthritis, and others. Four of the patients were immunosuppressed, two had HIV infection, and two were on chemotherapy. Only two patients, one infected with *S. equi* subsp. *zooepidemicus*, and the other with SDSE, had a history of animal exposure (horses in both cases) (94).

Numerous cases of infectious arthritis due to group G streptococci have been reported. Serious medical illnesses and previous joint disease were common features in these patients. In five cases of group G streptococcal infectious arthritis from the UCLA hospital system, all patients had prior joint disease and two had infected prostheses (95). In a series of seven patients, only one patient had no underlying systemic or rheumatologic illness. The remaining six patients all had prior trauma, surgery, or inflammation of the affected joint, and four of the six patients also had underlying medical conditions, including diabetes mellitus, alcoholism, and cardiovascular disease (96). In another review of 50 previously reported cases of group G streptococcal arthritis, more than one-third of patients had chronic joint disease, while just under half of the patients had one of four underlying conditions: malignancy, alcoholism, diabetes mellitus, or injectable-drug use (97). Osteomyelitis has also been described with GCGS, but it is reported less frequently than infectious arthritis. In these cases, there is also often a significant underlying disease (44, 63).

Downloaded From Vet-eBooks.com

Maternal and Neonatal Infections

Although SDSE can be found as part of the normal female genitourinary flora, its presence in clinical specimens often indicates infection. There have been at least two published outbreaks of puerperal fever caused by SDSE. In the first, 33 confirmed cases in England were caused by a single strain of SDSE. Clinical features included fever and signs of perineal infection. Sources of infection were postulated by the authors to be environmental, because the organism was cultured from toilet seats and bath plug holes. However, the organism was also cultured from the throats of many of the nursing staff (98). In the second outbreak, which occurred 4 years later in England, seven women developed puerperal fever caused by SDSE (99). Interestingly, the isolates shared the same M serotype with the strain responsible for the first outbreak. Though the microorganism was not isolated from the environment, it was speculated that transmission may have occurred through use of a common toilet seat. These epidemiologic and microbiologic data suggesting transmission by fomites must be interpreted with caution. The role of environmental contamination versus health care-related person-to-person transmission in such outbreaks remains to be determined.

Neonatal group C streptococcal infection is rare. In one reported case, meningitis due to SDSE developed in an infant whose mother was being treated for chorioamnionitis at the time of delivery (100). In another case, a preterm infant developed meningitis due to SDSD; the source of infection was not determined, because the mother was not ill and the organism could not be cultured from her (101).

Although clinical infection is rare, colonization of neonates with group G streptococci seems to be a common finding. In one study, cultures were taken from the nose and umbilicus of more than 3,000 neonates over a 1-year period at a New York hospital. The monthly incidence of positive cultures for group G streptococci ranged from 41 to 76%. Seven cases of neonatal sepsis due to these organisms were diagnosed over the same time period. Five of the seven cases occurred in the setting of complications of pregnancy or childbirth (102). In a larger review, which included this series, premature or prolonged rupture of the amniotic membranes was the most common risk factor associated with group G streptococcal infection (103).

Bacteremia, Endocarditis, and Other Serious Invasive Diseases

SDSE, *S. equi* subsp. *zooepidemicus*, and other streptococci with either group C or G antigen have been reported with increasing frequency to cause bacteremia, most commonly secondary to skin and soft tissue infection (16, 24, 42, 104). Many patients affected by these organisms (up to 70% in some series) have serious underlying diseases, especially malignancy, cardiovascular disease, diabetes mellitus, immunosuppression, and alcohol or injectable-drug use (40, 41, 44, 45, 105).

Bacteremia due to SDSE may be primary in approximately 20% of cases or secondary to a focal site of infection, most often from the skin or soft tissues. Auckenthaler et al. reviewed 38 patients who were bacteremic with group G streptococci at the Mayo Clinic-affiliated hospitals, representing 0.25% of all patients with positive blood cultures over a 10-year period. Seventy percent of the patients acquired the infection in the community, and the skin was the portal of entry in approximately three-quarters of the patients. Most of the hospital-acquired bacteremias involved a postoperative wound or a transcutaneous procedure. The patients tended to be older, with most being in the sixth to eighth decades. Many patients had venous insufficiency, lymphedema, or another cause of chronic lower extremity edema (40). Carmeli et al. reported 10 cases of group C streptococcal bacteremia in Israel and reviewed several other case series. In this review, some patients had primary bacteremia, but most cases were secondary to pharyngitis, epiglottitis, pericarditis, pneumonia, skin and soft tissue infection, endocarditis, or an infected aneurysm (41). In a review from Boston University, 29 patients with group G streptococcal bacteremia were identified over a 3-year period. The median age of the affected patients was 68 years, and one-half had a skin infection as the primary source of the bacteremia (45). In another series, six cases of bacteremia were reported in injectable-drug users. The portal of entry for these patients was the skin. All of the infected patients had injected drugs for at least 10 years (64).

Some studies have noted a high rate of relapsing or recurring bacteremias caused specifically by organisms carrying the group G antigen. A series of 84 cases of group G SDSE in Israel included 6 patients (7%) who developed recurrent bacteremia, ranging from two to four episodes per patient. Two of the six patients had SDSE with the same *emm* type (*emm stG*840.0) isolated from their subsequent bacteremias, and the other four had different isolates in each incident (42). Another series, in Singapore, reported a rate of recurrent bacteremia of 5.8% (106). This finding suggests that, although group G streptococci contain M proteins, infections with these organisms may not induce solid protective immunity (22). This assumption is supported by studies in a murine model of group G streptococcal cellulitis (107).

Bacteremia caused by *S. equi* subsp. *zooepidemicus* is generally associated with animal contact and tends to occur in outbreaks associated with exposure to animals or animal products. In 1999, Bradley et al. (108) reviewed 88 cases of bacteremia caused by group C streptococci reported in the literature. Of these patients, 21 reported exposure to animals or animal products and, as expected, most of these had bacteremia due to *S. equi* subsp. *zooepidemicus*. Ten patients had consumed unpasteurized milk, four patients were farmers, one was a butcher, and several had other contact with animals. In the same series, 24 patients with definite or probable endocarditis were described. Of these, five cases were due to *S. equi* subsp. *zooepidemicus*, four were due to SDSE, and the remainder were unspecified. Animal exposure was noted only in patients with infection due to *S. equi* subsp. *zooepidemicus* or unspeciated organisms. Underlying cardiac disease was seen in 60% of the patients for whom adequate information was available. Edwards et al. described an outbreak of 11 cases of bacteremia due to *S. equi* subsp. *zooepidemicus* in West Yorkshire. Presentations included primary septicemia, endocarditis, infected aneurysm, and meningitis. All 11 patients had consumed unpasteurized milk from the same source (43). Yuen et al. (109) reported 11 cases of *S. equi* subsp. *zooepidemicus* bacteremia with sepsis over a 4-year period in Hong Kong. The patients had a variety of presenting syndromes, and 55% had a serious underlying illness. None of the patients reported exposure to animals or animal products. After further investigation, it was believed that the infections were acquired from ingestion of undercooked pork. Furthermore, condemned septicemic pigs were found to be infected with *S. equi* subsp. *zooepidemicus* strains whose DNA fingerprints were identical to the human isolates. More recently, a fatal *S. equi* subsp. *zooepidemicus* bacteremic infection was reported associated with equine exposure (110).

Endocarditis due to GCGS is also an emerging disease. Like bacteremia from other sources, endocarditis tends to occur in older patients with serious underlying conditions and carries a high risk of severe disease, embolic events, metastatic infections, and death (111, 112). Clinical manifestations are similar to those seen with *S. pyogenes* endocarditis. Oppegaard et al. (113) reported a series of nine cases of definite endocarditis caused by SDSE in Norway between 1999 and 2013. The median age was 64 years, and all but two had underlying comorbid conditions. In general, the patients were acutely and severely ill. The median time of illness to admission was 1 day. Mitral and aortic valves were affected with similar frequency. Four of the nine patients had embolic events, and seven had cardiac complications. Valve replacement was needed in three of the nine patients. Mortality at 30 days was 22%. In a literature review of 40 cases of group G streptococcal endocarditis, the average age was 56 years and the overall mortality was 36%. Underlying disease was present in about one-half of the patients; six patients had a malignancy, six were diabetic, four were alcoholics, and three were injectable-drug users. Also, one-half of the patients had known preexisting valvular disease, with mitral regurgitation being the most common abnormality. Three cases occurred in patients with prosthetic valves (114). In a series of seven cases not included in the above review, the average age of the patients was 72 years, and only one patient was younger than 60 (115). Underlying medical conditions and/or preexisting valvular disease were noted in most cases.

Some patients with SDSE and *S. equi* subsp. *zooepidemicus* bacteremia develop multifocal metastatic infections, including meningitis, peritoneal abscesses, pericarditis, and pneumonia (116–120).

TREATMENT

SDSE and the other large-colony group C and G streptococci are typically susceptible to penicillin, which is considered the drug of choice to treat infections caused by these organisms. Their range of MICs to penicillin G is between 0.03 and 0.06 μg/ml (121). Besides beta-lactams, glycopeptides, daptomycin, and linezolid are also consistently active *in vitro* (122).

Lam and Bayer found that bacterial killing by penicillin is impaired when high concentrations of organisms (>10^8 colony-forming units/ml) are found (123). This phenomenon is well described for *S. pyogenes*, which downregulates the production of penicillin-binding proteins during its stationary phase of growth, resulting in a paucity of targets for penicillin (the "Eagle effect") (124). Another observation has been that in certain patients with endocarditis or septic arthritis, but also in some patients with pharyngitis, there is a poor or delayed response to therapy (125). The reason for this suboptimal response is unclear, and it may be from a combination of microbiological and host factors. The addition of gentamicin to a cell wall active antibiotic has been shown to be synergistic *in vitro*, and some have suggested its use in certain patients with severe and invasive SDSE infections, provided there is no contraindication to use an aminoglycoside antimicrobial agent (126, 127). However, there are no definitive clinical data to support that recommendation at this time. Recently, a penicillin-resistant strain was isolated from the blood of three epidemiologically linked patients in Denmark. The four isolates had a penicillin MIC of 0.5 to 2 mg/liter, belonged to a single clone, and had mutations in multiple penicillin-binding proteins (PBPs), including PBP2x mutations similar to those found in *Streptococcus pneumoniae* and *S. agalactiae*, and mutations in PBP1a and PBP1b (128).

Susceptibility to tetracyclines, macrolides, clindamycin, and fluoroquinolones is variable and cannot be assumed without proper testing (123, 129, 130). Megged (131) reported resistance rates of 38.8% and 27.8% to erythromycin and clindamycin, respectively, in Israel. Mechanisms of resistance are varied, with strains expressing constitutive macrolides-lincosamides-streptogramin B (MLS_B), inducible MLS_B, and M phenotypes. Another study, also from Israel, found resistance to clindamycin, erythromycin, azithromycin, and tetracycline in 11.1%, 18.2%, 21.2%, and 49.5% of SDSE, respectively (132). Similar high rates of resistance have been found in such distant geographical locations as Taiwan, Austria, and Brazil (133–136). Investigators in Portugal reviewed a collection of 314 human isolates of SDSE and found a levofloxacin resistance rate of 12%. Resistance was found in multiple *emm* types and genetic lineages and was associated with mutations in both *gyrA* and *parC*. The data also showed evidence of recombination between SDSE and *S. pyogenes*, but not between SDSE and SDSD (137).

The Cell Wall of *Streptococcus pneumoniae*

WALDEMAR VOLLMER, ORIETTA MASSIDDA AND ALEXANDER TOMASZ

18

INTRODUCTION

Since the last revision of this article (2006), a number of important publications have appeared in the literature, the inclusion of which made it necessary to limit the topics of this article to information that has bearing on the biochemical and genetic aspects of covalently linked components of the pneumococcal cell wall. Information on proteins noncovalently attached to the cell wall, cell walls and phase variation (Jing Li and Jing-Ren Zhang, in press), and inflammatory activity of cell walls (Allister J. Loughran, Carlos J. Orihuela and Elaine I. Tuomanen, in press) are reviewed separately.

Historically, studies of the pneumococcal cell wall were motivated by such unique features as the presence of choline in the teichoic acids and the pleiomorphic changes that accompany removal or alteration of choline residues and by structural changes in peptidoglycan that are associated with penicillin resistance. Most recent contributions to the field include immunofluorescence (1–7) or fluorescent tagged (8, 9) microscopic localization of cell wall synthetic enzymes at sites of wall synthesis, identification of genetic determinants and enzymes that are involved with the chemical modification of peptidoglycan precursors and peptidoglycan itself, the synthesis of teichoic acid precursors and the assembly of lipoteichoic acid (LTA) and wall teichoic acid (WTA), and the mechanisms and regulation of the cell wall machinery at the central growth zone.

FUNCTIONAL ANATOMY OF THE PNEUMOCOCCAL CELL WALL

The overwhelming majority of natural isolates of pneumococci are wrapped on their outermost surface by one or another of the more than 90 chemically different capsular polysaccharides that this bacterial species is capable of synthesizing (10). Under these diverse structures lies the cell wall, which as far as the resolution of currently used analytical techniques can tell, is much more uniform in its chemistry: it is composed of a peptidoglycan covalently linked to chains of an unusually complex teichoic acid (11–13) which contain as structural components phosphoryl choline residues (14, 15). The phosphoryl choline residues play multiple roles in the physiology and virulence of the pneumococcus (see below). The two polymers, peptidoglycan and teichoic acid, make up the bulk of the cell wall in roughly equal (milligram to milligram) proportions (16). In most but not all cases, chains of the capsular polysaccharide are attached by covalent bonds to the underlying peptidoglycan (17) (Fig. 1).

In electron microscopic thin sections (18) prepared by the method of Kellenberger (osmium tetroxide and glutaraldehyde fixation followed by uranyl acetate and lead citrate staining), the cell wall of *Streptococcus pneumoniae* strain R36A appears as a band of uniform width composed of two electron-dense lines (30 to 40 nm each) enclosing a wider low-density layer (60 to 80 nm). The distribution of teichoic acid chains appears to be uniform within this wall layer (19), and this is presumably also true for the peptidoglycan. Some anatomically differentiated areas may be identified through electron microscopy: (i) The equatorial areas where cell wall growth becomes centripetal (formation of septum or cross wall) represent the "growth zones" of the entire wall. (ii) In dividing cells, a circumferential thickening ("hump") of the cell wall appears at the place of the incipient septa. (iii) Parallel to, or perhaps just prior to the beginning of, the formation of septum, the hump appears to be split at the center, and the two halves begin to move on the cell surface symmetrically to the left and to the right of the ingrowing septum coupled to the growth and eventual division of the cell into two daughter cells. Due to the conservative mode of replication of the pneumococcal cell wall (see below), these two half-humps are morphological age markers: they divide the cell wall of each pneumococcal cell into two hemispheres which differ in age by one cell generation. The functional correlates of these morphological changes began to be identified by the use of immunofluorescence microscopy, which allowed the localization of the various pneumococcal high-molecular-weight penicillin-binding proteins (PBPs) and the FtsZ-ring to equatorial and septal areas of the bacteria in various stages of cell division (2–4, 7). A special role of two hydrolases, the carboxypeptidase PBP3 (1, 20) and the endopeptidase PcsB (21–23), in these processes was also proposed. (iv) The final stage of cell division, the separation of daughter cells, may be inhibited in pneumococci by several means resulting in the formation of long chains of bacteria. Under these conditions, one can observe by electron microscopy a thin bridge of cell wall material connecting

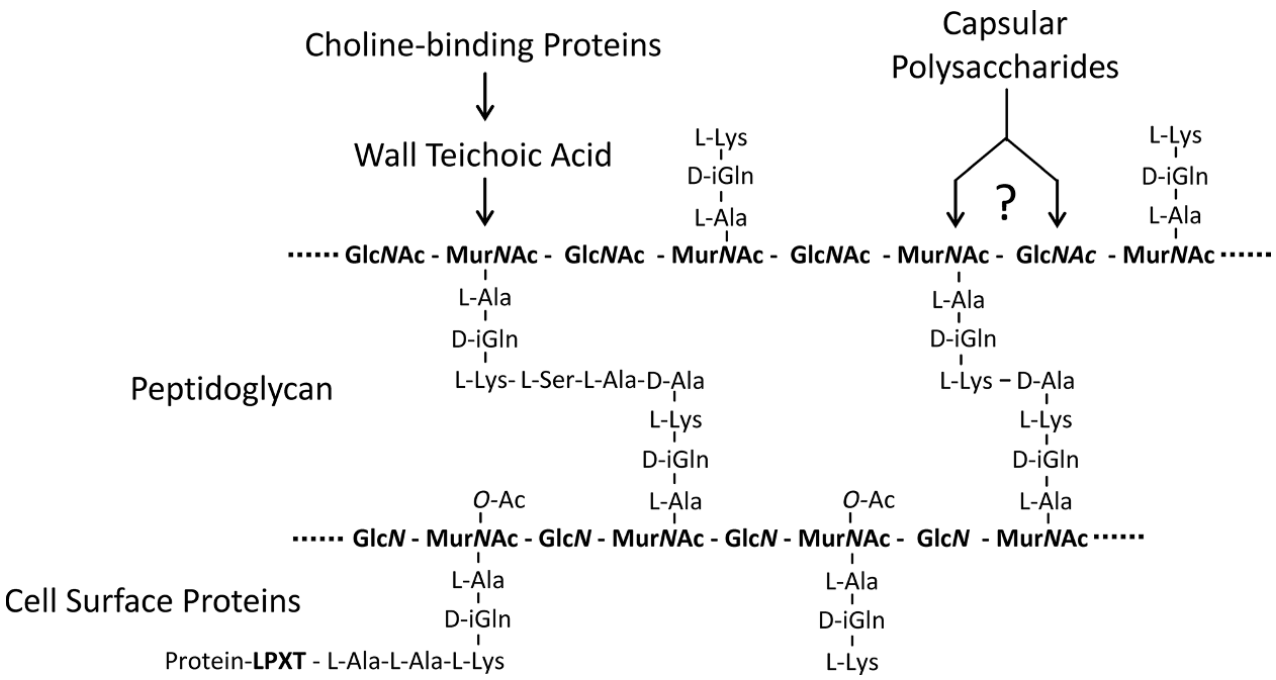

FIGURE 1 Diagram of the cell wall complex of pneumococci. Some of the MurNAc and GlcNAc residues in the glycan chains of peptidoglycan are modified by *O*-acetylation or *N*-deacetylation, respectively. Direct and indirect peptide cross-links are shown. Capsular polysaccharides have been assumed to be connected to MurNAc residues in peptidoglycan, but recent work showed that they might be connected to GlcNAc residues. Surface proteins are covalently linked to peptides in peptidoglycan; choline-binding proteins attach noncovalently to phosphoryl choline residues in WTA.

neighboring cells to one another. The hydrolase, LytB (an endo-β-1,4-*N*-acetylglucosaminidase), has been identified as an enzyme essential for the terminal separation of daughter cells at the end of cell division (24, 25).

STRUCTURE OF PEPTIDOGLYCAN

Purified cell walls of the nonencapsulated strain R6St (streptomycin-resistant) of *S. pneumoniae* were hydrolyzed by the pneumococcal amidase (*N*-acetylmuramic acid L-alanine amidase; the product of the *lytA* gene) under conditions in which this enzyme can quantitatively release the peptide units of cell wall muropeptides. A method that uses muramidase digestion of the pneumococcal cell wall or peptidoglycan followed by high-performance liquid chromatography (HPLC) separation of muropeptides, through an adaptation of the method of Glauner and Schwarz, has been described (26, 27).

In the amidase method, the family of peptides was separated by HPLC and size fractionation and determination of amino acid composition and NH_2 termini. Partial sequencing of the peptides generated by HPLC and analysis using time-of-flight mass spectrometry has allowed the identification of a surprisingly large number of monomeric, dimeric, and trimeric peptides (28) showing a diversity comparable to that seen among the muropeptide species identified in *Escherichia coli*. In the structural assignments, it was assumed that the amino acids within the stem peptides had the usual alternating sequence of L- and D-amino acids beginning with L-alanine in position 1, followed by a D-isoglutamine and then by L-lysine. The carboxyterminus in the stem peptide is occupied by two consecutive D-alanine residues; however, such muropeptides with intact pentapeptide residue are rare in pneumococci cultivated under normal growth conditions. Extension of this analytical technique to cell walls of clinical isolates from a large variety of isolation sites and dates and expressing a variety of different capsules has led to the proposition that the cell wall muropeptide composition of *S. pneumoniae* grown in the commonly used semisynthetic medium and harvested in the late exponential phase is constant and characteristic of the species. The most abundant monomer of the pneumococcal peptidoglycan was a tripeptide, and the most frequent dimer was a directly cross-linked tri-tetrapeptide. Interestingly, the representation of carboxyterminal alanine was extremely rare, suggesting the presence of powerful DD- and LD-carboxypeptidases. These enzymes, PBP3 and LdcB, will be discussed below.

An interesting feature of the peptide network was the presence of both directly and indirectly cross-linked components. In the latter, alanyl-serine or alanyl-alanine dipeptides formed the cross-link. In terms of cross-linking mode, the pneumococcal cell wall may be classified as either A1 (directly cross-linked) or A3 (cross-linked via an interpeptide bridge), depending on which dimer one chooses. A massive distortion of peptidoglycan composition in the direction of preponderance of indirectly cross-linked components was demonstrated in several penicillin-resistant clinical isolates (29).

The amidase also releases the glycan chains, which in *S. pneumoniae* harbor two modifications: *N*-deacetylation of some of the GlcNAc residues, resulting in glucosamine, and *O*-acetylation at some of the MurNAc residues. The latter modification is acid labile and lost during the removal of WTA to purify peptidoglycan, and therefore the glycan chains released by the amidase carry glucosamine residues, the percentage of which depends on the strain and growth conditions. The isolated glycan chains can be chemically reacetylated and analyzed by HPLC with or without partial digestion by muramidase. This analysis revealed that glycan chains of less than 25 disaccharide units are virtually absent

Downloaded From Vet-eBooks.com

in pneumococcal peptidoglycan (27), in sharp contrast to that of staphylococci or *E. coli*, in which short glycan chains prevail (30, 31). That pneumococcal peptidoglycan contains relatively long glycan chains was confirmed by size exclusion chromatography (32).

The muramidase method in combination with mass spectrometry allowed detection of ~50 different muropeptides (27). It confirmed the above-mentioned peptide composition and quantified the abundance of modifications in un-cross-linked (monomeric) and cross-linked (dimers, trimers) structures, allowing predictions about the activities of cell wall enzymes. For example, nonamidated D-glutamate residues at position 2 were significantly less abundant in cross-linked muropeptides, suggesting that enzymes performing cross-linking reactions (the PBPs) require the presence of the amidated D-glutamate residue at position 2 (27, 33). The analysis also revealed the presence of cross-linked muropeptides (mainly trimers) that lacked GlcNAc or the GlcNAc-MurNAc disaccharide at one of the peptides, indicating *N*-acetylglucosaminidase and amidase activities, presumably those of LytB and LytA, respectively. Muropeptide analysis has recently been used to study different aspects of pneumococcal cell wall physiology (34–36).

PEPTIDOGLYCAN BIOSYNTHESIS AND REMODELING

Pneumococci contain the essential genes of the general biochemical pathway of peptidoglycan synthesis and cell morphogenesis that were studied extensively in other model species such as *E. coli* and *Bacillus subtilis* (37, 38). Many of the peptidoglycan precursor genes and cell division proteins cluster in three chromosomal regions, instead of one single cluster present in *E. coli* and *B. subtilis*, consistent with the hypothesis that the ovococcal-shaped pneumococci require less coregulation of cell wall and division genes than rod-shaped species (39). In this section we will focus on covalent modifications in the peptidoglycan that are important for the physiology or lifestyle of pneumococci.

Modifications of the Peptidoglycan Precursor

Many Gram-positive species amidate the D-isoglutamate residue at the α-carboxylic group by transfer of an amido group from L-glutamine to the cytosolic precursors UDP-MurNAc-pentapeptide or the bactoprenol-linked precursors lipid I and lipid II. This amidation reaction is catalyzed by a complex of two proteins, MurT and GatD, which were originally identified in *Staphylococcus aureus* (40). MurT and GatD are essential in both *S. aureus* and *S. pneumoniae* (40, 41), consistent with the observation that amidation of the lipid II precursor is required for efficient cross-linking in an *in vitro* assay for peptidoglycan synthesis with purified PBPs (33). Hence, MurT and GatD seem to be essential because they provide a modification needed for the essential peptide cross-linking reaction.

The presence of a branch consisting of 2 to 7 L-amino acids added to the ε-amino group of L-lysine at position 3 of the stem peptide is another widespread modification in Gram-positive bacteria whereby the sequence of the branch varies between species. Virtually all *S. aureus* strains have a pentaglycine branch, but the peptidoglycan is less homogeneous in *S. pneumoniae*, in which strains can significantly differ in the amount of three types of peptides: with no branch, with an L-Ala-L-Ala branch, or with an L-Ser-L-Ala branch (42).

The branch is added to the lipid II precursor by the ligases MurM and MurN. The *in vivo* substrate of MurM is lipid II, and the enzyme catalyzes the addition of a serine or alanine residue (depending on the particular *mur*M allele) to the free amino group of lysine in the stem peptide in a reaction in which the amino acid donor is presumed to be an amino acyl-tRNA (43). This reaction is followed by the MurM catalyzed addition of an alanine to complete the dipeptide branch (see Fig. 2). Although the peptide branches synthesized by MurM and MurN are not essential for pneumococcal growth, they are required in various strains to express high levels of β-lactam resistance. A more detailed description of the connection between the *murMN* operon and β-lactam resistance is provided in "The *murMN* Operon," below.

Penicillin-Binding Proteins

S. pneumoniae has six PBPs, of which three, PBP1a, PBP1b, and PBP2a, are class A bi-functional glycosyltransferase-transpeptidases capable of polymerizing the precursor lipid II to form the glycan chains and performing peptide cross-linking reactions. None of these bi-functional enzymes are essential, but double mutants lacking *pbp1a* and *pbp2a* are not viable (44), and *in vitro* experiments with the purified proteins showed that both require amidated lipid II substrate for efficient transpeptidase activity (33).

S. pneumoniae also has two essential class B monofunctional transpeptidases, PBP2x and PBP2b, involved with septal and peripheral peptidoglycan synthesis, respectively (7, 45). Consistent with their roles, cells depleted of PBP2x become elongated, and cells depleted of PBP2b are shorter. PBP2x has two C-terminal PASTA (PBP and serine/threonine kinase-associated) domains which are required to localize the protein at midcell (46). Genetic evidence points to an important role of branched peptide substrates for these PBPs. The remaining PBP, PBP3, is not a synthase but is a carboxypeptidase for trimming of pentapeptides to tetrapeptides (see below).

Trimming of the peptides by carboxypeptidases

Newly synthesized peptidoglycan contains abundant pentapeptides with a D-alanyl-D-alanine terminus, but these are trimmed in two steps to tripeptides which prevail in the mature pneumococcal peptidoglycan. The DD-carboxypeptidase PBP3 produces tetrapeptides (47), which are the substrate for the LD-carboxypeptidase LdcB (or DacB) to produce the tripeptides. The wall peptide composition in a PBP3-defective mutant (48) and in the laboratory strain R36A growing in the presence of subinhibitory concentrations of clavulanic acid, a selective inhibitor of PBP3 in this bacterium (49), showed accumulation of peptide species that retained carboxyterminal D-alanine residues. Pneumococci grown in the presence of clavulanate also showed abnormal physiological properties: premature induction of stationary phase autolysis, hypersensitivity to lysozyme, and reduced MIC values for deoxycholate and penicillin.

The *ldcB* gene was identified in a search for hypothetical peptidoglycan hydrolase genes, and a deletion mutant has defects in cell shape and septation (50), as has a *dac*A mutant lacking PBP3 (1). However, only *dacB* mutants were significantly attenuated in an intranasal mouse infection model and showed increased uptake by professional macrophages and reduced adherence to lung epithelial cells (51). The *dacB* mutant is rich in tetrapeptides (50, 52), but it is not known why the presence of tetrapeptides instead of tripeptides has these drastic effects on the physiology and pathogenicity of pneumococci. The crystal structure of LdcB shows a catalytic domain with a fold characteristic for the LAS family of Zn-dependent peptidases (51, 52).

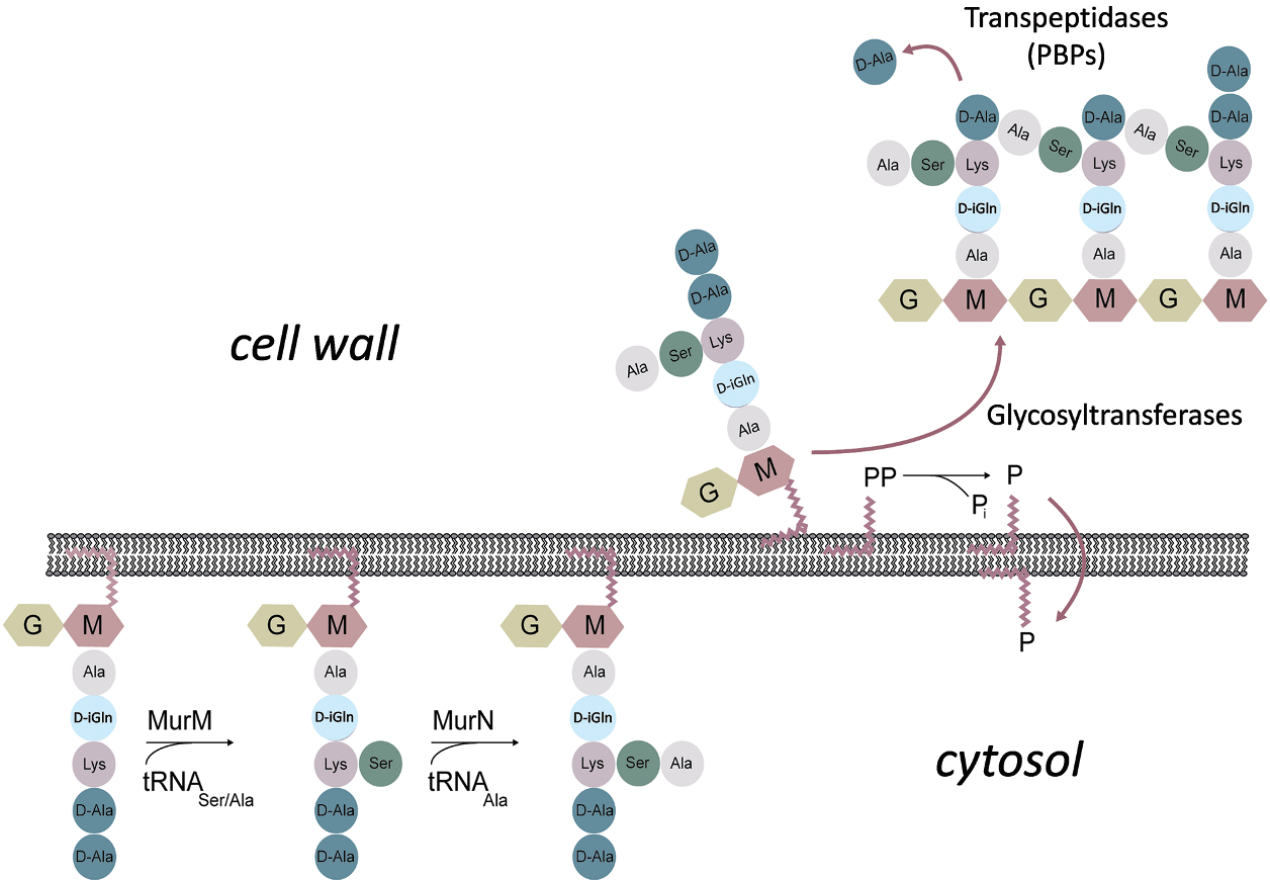

FIGURE 2 Role of MurM and MurN in cell wall branching. The substrate of the MurM- and MurN-catalyzed branching reaction is lipid II, which is composed of *N*-acetylated disaccharide units of glucosamine (hexagon with G) and muramic acid (hexagon with M) with the pentapeptide attached to the M residues. Lipid II is anchored on the plasma membrane through the carrier lipid bactoprenyl phosphate (zig-zag line). Attachment of the completed precursor to the preexisting cell wall occurs on the outer surface of the plasma membrane by the activity of glycosyltransferases and transpeptidases. Reproduced with permission from reference 82.

The Putative Lytic Transglycosylase MltG

The *mltG* (*spd_1346*) gene was recently linked to peripheral peptidoglycan synthesis based on the observation that its inactivation suppresses the requirement for PBP2b, MreCD, RodA, and RodZ, i.e., genes that are all part of the pneumococcal elongation machinery (53). MltG has a YceG-family domain that likely acts as an endolytic transglycosylase since the known MltG endolytic transglycosylase homologue from *E. coli* can replace MltG function in *S. pneumoniae*. A model has been proposed according to which MltG removes nascent glycan strands, produced by PBP1a, from their membrane anchor to facilitate their incorporation into the old cell wall by RodA and PBP2b (53). However, direct biochemical proof of a lytic transglycosylase activity of MltG has yet to be presented, and the lytic transglycosylase products, 1,6-anhydro-*N*-acetylmuramic acid termini in glycan chains and turnover products, have yet to be detected.

Peptidoglycan Hydrolases Involved in Septum Remodeling and Cleavage

Several peptidoglycan hydrolases are important for pneumococcal growth and morphology. The extracellular protein PcsB localizes to the cell division site, where it is required for proper septum formation and cleavage (54). The *pcsB* gene is the only essential gene under the control of the WalRK cell wall stress regulon, and the depletion of *pcsB* results in growth arrest and severe morphological defects. The active site of PcsB resides near the C-terminus and belongs to the CHAP (for cysteine, histidine-dependent amidohydrolase/peptidase) family of peptidoglycan endopeptidases, but such an activity could only be observed for purified PcsB when tested in an in-gel zymogram assay. In the cell, PcsB requires activation by the essential membrane-bound ABC transporter-type FtsEX complex (54, 55). The crystal structure of PcsB shows an inactive homodimer in which the V-shaped coiled-coil domain of each monomer inserts into the active site groove of the other, explaining why this dimer form is inactive (23). It was suggested that FtsEX utilizes ATP hydrolysis to induce conformational changes in the PcsB dimer to unlock this mutual inhibition. However, the precise roles of FtsEX and PcsB in septum formation and cleavage have yet to be established.

LytB is a secreted endo-β-*N*-acetylglucosaminidase with a choline-binding domain consisting of 14 to 18 imperfect repeats, which direct the enzyme to the septum and cell pole regions, followed by an SH3b peptidoglycan-binding domain, a small carbohydrate-binding domain with unknown function, and a C-terminal catalytic domain (56). LytB functions at the final stages of the division process to separate the daughter cells. Mutants lacking LytB grow in deeply constricted chains of unseparated cells (57). Purified LytB is able to disperse chains of cells of a *lytB* mutant. LytB cleaves

Downloaded From Vet-eBooks.com

at sites with fully acetylated GlcNAc residues and has preference for monomeric peptides, suggesting a substrate-assisted catalytic mechanism (25).

Apart from their role in cleavage of the septum and autolysis, peptidoglycan hydrolases do not seem to be very active during pneumococcal growth in the laboratory. There is a minimum of peptidoglycan turnover at the hemispherical regions, with the old peptidoglycan remaining virtually inert during growth (58, 59).

Peptidoglycan *N*-Acetylglucosamine Deacetylase PgdA

An unusually high proportion of hexosamine units in the glycan strands of the pneumococcal cell wall are not *N*-acetylated, explaining the resistance of this peptidoglycan to the hydrolytic action of lysozyme, a muramidase that cleaves in the glycan backbone. A gene, *pgdA*, was identified as encoding for the peptidoglycan *N*-acetylglucosamine deacetylase A with amino acid sequence similarity to fungal chitin deacetylases and rhizobial NodB chitooligosaccharide deacetylases (60). PgdA is a metal-dependent enzyme belonging to the family 4 carbohydrate esterases. Its crystal structure shows a His-His-Asp catalytic triad in its active site (61, 62). Pneumococci in which *pgdA* was inactivated produced fully *N*-acetylated glycan and became hypersensitive to exogenous lysozyme in the stationary phase of growth. The *pgdA* gene may contribute to pneumococcal virulence by providing protection against host lysozyme. A pneumococcal strain expressing capsular type II with inactivated *pgdA* showed reduced virulence in the mouse model of intraperitoneal infection (63).

Peptidoglycan *O*-Acetyltransferase

Many bacteria modify the C6-OH group of MurNAc residues in their peptidoglycan by an *O*-acetyl group, and this modification has been implicated in the regulation of autolysins and resistance to lysozyme (64). The pneumococcal *adr* gene encoding the *O*-acetyltransferase has been initially identified in a mariner mutagenesis screen for increased sensitivity to penicillin in the background of the resistant strain Pen6 (65). *Adr* mutant cells also show higher sensitivity to lysozyme, and Adr shares sequence homology with the peptidoglycan *O*-acetyltransferase OatA of *S. aureus* (66). Muropeptide analysis by HPLC and mass spectrometry showed that the *adr* mutant lacked muropeptides with *O*-acetylated MurNAc residues, suggesting that Adr is the pneumococcal peptidoglycan *O*-acetyltransferase. Recent work showed that peptidoglycan *O*-acetylation by Adr occurs at midcell and that this modification protects the cell wall from cleavage by the autolysin LytA (67).

Sortase A-Dependent Covalent Attachment of Proteins to the Pneumococcal Cell Wall

Most virulence-related pneumococcal proteins studied so far were shown to be attached to the cell surface through the choline residues of teichoic acids, and pneumococci have been described as a paradigm for the display of virulence proteins through specific but noncovalent associations with the cell surface (68). Such choline-binding proteins include PspA, PsaA, the enzyme phosphoryl choline esterase (69, 70), and LytA, in which a 20-amino-acid repeat was shown to recognize choline residues in wall or membrane teichoic acids (71). The observations described in this report demonstrate that the mechanism of surface display of proteins does not depend on the choline-binding paradigm alone; pneumococci also use covalent anchoring for some surface proteins. Data available from the genome of *S. pneumoniae* strain R6 (72) indicate that there are at least 23 proteins carrying the LPXTG motif, and 15 of these have this recognition sequence at the C terminus, as expected for proteins that are processed by a typical sortase.

Inactivation of sortase gene *srtA* in *S. pneumoniae* strain R6 caused the release of beta-galactosidase and neuraminidase A (NanA) from the cell wall into the surrounding medium. Both of these surface proteins contain the LPXTG motif in the C-terminal domain. Complementation with plasmid-borne *srtA* reversed protein release. Deletion of *mur*M, a gene involved in the branching of pneumococcal peptidoglycan, also caused partial release of beta-galactosidase, suggesting preferential attachment of the protein to branched muropeptides in the cell wall. Inactivation of *srtA* caused decreased adherence to human pharyngeal cells *in vitro* but had no effect on the virulence of a capsular type III strain of *S. pneumoniae* in the mouse intraperitoneal model. These observations suggest that similar to other Gram-positive bacteria, sortase-dependent display of proteins occurs in *S. pneumoniae* and that some of these proteins may be involved in colonization of the human host (73).

PEPTIDOGLYCAN COMPOSITION AND PENICILLIN RESISTANCE

The first series of highly penicillin-resistant clinical isolates examined using the HPLC method were from South Africa. It was in these isolates that the mechanism of resistance, namely, reduction in the antibiotic "affinity" of PBPs, was identified for the first time (74). It was also in genetic crosses with these isolates used as DNA donors that the stepwise nature of penicillin resistance (i.e., the sequential reduction in the penicillin affinity of several high-molecular-weight PBPs in parallel with the gradually increasing penicillin MIC value) was recognized (74).

Analysis of the penicillin-resistant South African clinical isolates revealed that they produced cell walls of a radically different composition from the one seen in the penicillin-susceptible and nonencapsulated laboratory isolate (75). When the HPLC analysis was extended to the walls of several penicillin-susceptible clinical isolates and several resistant strains (all but one from South Africa), the striking shift toward indirectly cross-linked wall peptide composition in the resistant isolates was fully confirmed. A link between resistance to penicillin and abnormal wall composition was also suggested by the analysis of genetic crosses: a shift toward the distorted wall composition of the resistant DNA donor was observed in genetic transformants above a certain MIC value. It was suggested that the anomalous wall peptide composition reflected the altered substrate preference of the penicillin-resistant PBPs, a shift from the linear to the branched wall peptide precursors (75).

THE *murMN* OPERON

A considerable clarification concerning determinants of cell wall structure and its relationship to penicillin resistance was obtained by the identification of the *murMN* operon, which encodes enzymes involved in the synthesis of branched structured muropeptides in the pneumococcal peptidoglycan (42). The same determinants were also described independently and named *fib* by another group (76). The *murMN* operon shows homology to the *femXAB* genes of *S. aureus*, which are involved with the addition of the pentaglycine

Downloaded From Vet-eBooks.com

branches to the epsilon amino group of lysine residues in the staphylococcal peptidoglycan (77).

Inactivation of the *mur*M operon or inactivation of the *mur*M gene alone did not interfere with growth of the bacteria but caused the production of a peptidoglycan composed exclusively of linear muropeptides. Another consequence of inactivation was the complete loss of the penicillin-resistant phenotype. Examination of a large number of *S. pneumoniae* clinical isolates representing different genetic lineages has identified several distinct *mur*M alleles carried by penicillin-resistant strains which also showed different and unique muropeptide composition in their peptidoglycan (78). Analysis of the *mur*M alleles from penicillin-resistant isolates showed that they differed from one another and from the *mur*M carried by penicillin-susceptible strains in regions of considerable sequence diversity that were distributed as heterologous "patches" along the *mur*M gene sequence. Different *mur*M alleles from several penicillin-resistant *S. pneumoniae* strains, each with a characteristic branched peptide composition, were introduced on a plasmid into a common penicillin-susceptible laboratory strain. All transformants remained penicillin susceptible, but their cell wall composition changed in directions which corresponded to the muropeptide pattern of the strain from which the *mur*M allele was derived. This observation suggests that the muropeptide composition of *S. pneumoniae* is determined by the particular *mur*M carried by the strain (43, 78) (Fig. 3A and B; Table 1).

The relationship between *mur*M alleles and the penicillin-resistant phenotype is less clear. In genetic transformation of high-level penicillin resistance, it was shown that successful expression of the resistant phenotype required that the transformants received not only the particular mosaic *pbp* genes of the DNA donor but also the *mur*M allele carried by the donor strain (79). However, in other experiments the linkage between penicillin resistance and abnormal wall composition was lost in transformation experiments in which

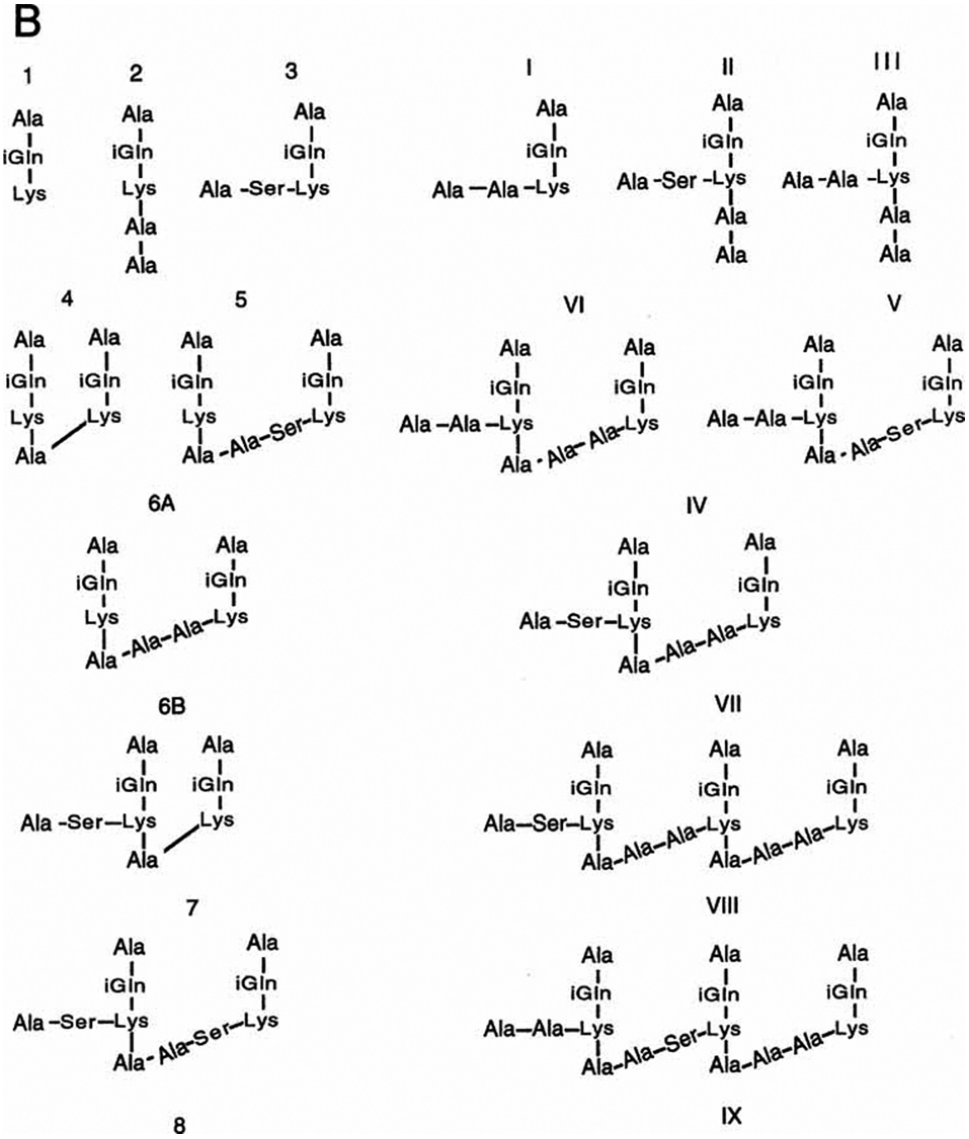

FIGURE 3 *(continued)*

the first round of transformation was followed by a second backcross (80). Interestingly, in this particular experiment the penicillin-resistant secondary transformants began to show "fitness" defects: defective growth and premature autolysis in antibiotic-free medium, similar to the defective physiology observed in laboratory isolates of penicillin-resistant pneumococci (81).

Genetic analysis and molecular modeling of the *mur*M protein has identified amino acid residues that appear to be critical for the specificity of this protein and also pinpointed domains which interact with the aminoacyl tRNA and the bactoprenyl-linked substrate of the *mur*M catalyzed reaction (82).

STRUCTURE OF WTA AND LTA

The Pneumococcal C-Polysaccharide and F-Antigen

In 1930, long before LTAs and teichoic acids were discovered and defined, Tillet and coworkers (83) described pneumococcal teichoic acid as pneumococcal C-polysaccharide by. Thirteen years later, in 1943, Goebel and his colleagues isolated pneumococcal LTA and named it lipocarbohydrate or pneumococcal F-antigen owing to its fatty acid content and immunological properties (84). In these early studies, a structural relationship between C-polysaccharide and lipocarbohydrate was suggested, and in contrast to the various strain-specific capsular polysaccharides, lipocarbohydrate and C-polysaccharide were considered pneumococcal common antigens. This was confirmed by serological methods which showed that all 90 known capsular types of *S. pneumoniae* possess C-polysaccharide and F-antigen (19). The two polymers differ immunologically, because Forssman antigenicity is associated with the LTA (85, 86). As shown by immunoelectron microscopy, C-polysaccharide is uniformly distributed on both the inside and outside of the cell walls, and LTA is located on the surface of the cytoplasmic membrane (12).

Choline, the surface signature of pneumococci, was identified as a component of teichoic acid and LTA (14, 15). The complex structures of WTA and LTA could not be unraveled

before modern analytical techniques became available (87). In 1980, Jennings and coworkers published the first complete structure of pneumococcal teichoic acid (11). The structure of pneumococcal LTA was clarified in 1992 (85) and revised in 2013 (88), and subsequent reinvestigation of the WTA, isolated from the same strain from which the LTA had been isolated, revealed that both polymers possess identical chain structures (13, 82). The linkage structure of WTA to peptidoglycan was recently established (13), and all genes required for teichoic acid synthesis were predicted by sequence comparisons (89).

Structure of Teichoic Acid TA and LTA

The chains of LTA and teichoic acid contain 4 to 8 identical pseudo-pentasaccharide repeating units which consist of the rare positively charged amino sugar 2-acetamido-4-amino-2,4,6-trideoxy-D-galactose (AATGal), D-glucose, ribitol 5-phosphate, two *N*-acetyl-D-galactosaminyl (GalNAc) residues, and one or two phosphocholine residues. Hydroxyl groups of ribitol can be substituted by D-alanine. The repeats are joined together by an α-1,4 glycosidic linkage between AATGal and a GalNAc residue of the adjacent repeat. The functionally important phosphocholine residues are phosphodiester-linked to O6 of the *N*-acetyl-D-galactosaminyl residues. The number of phosphocholine residues per repeat is strain specific: in LTA and WTA of strain R6, the majority of repeats carry two phosphocholine residues, whereas most of the repeats in strain Rx1 are substituted with one (Fig. 4). Moreover, the terminal repeating unit of both WTA and LTA can occur with or without the phosphocholine substitution at both GalNAc residues. The chain of LTA is β-1,3 glycosidically linked via the AATGal residue to O3 α-D-Glcp (1–3)-diacylglycerol (Fig. 4).

Microheterogeneity of LTA became apparent by hydrophobic interaction chromatography and mass spectrometry analysis (85, 88). The chain of LTA may vary in length between four and eight repeats, with the range differing from sample to sample. On SDS-polyacrylamide gel electrophoresis, LTA yields a ladder-like pattern of up to six bands, each differing from the next by one repeat. Species with one phosphocholine per repeat are distinguished from species with two by higher mobility of the individual bands.

In addition to the unusual complexity of the chemical structure of teichoic acid, pneumococci are also unique because their WTA and LTA possess identical repeat and chain structures, whereas in other Gram-positive bacteria, WTAs and LTAs are structurally and biosynthetically distinct entities. In LTA and WTA, the AATGal residues are of conformational importance because the positively charged amino groups interact electrostatically or by hydrogen bonding with the negatively charged phosphate groups on the adjacent glucosyl residues (87, 90).

Pneumococcal WTA chains have been isolated with or without attached peptidoglycan fragments and were shown to contain four to eight repeating units (13, 27). WTA is linked to the peptidoglycan by a phosphodiester bond to O6 of some of the MurNAc-residues, which is demonstrated by the release of MurN-6-P on HCl hydrolysis of cell walls (91) and of muropeptides. It is estimated that, dependent on the

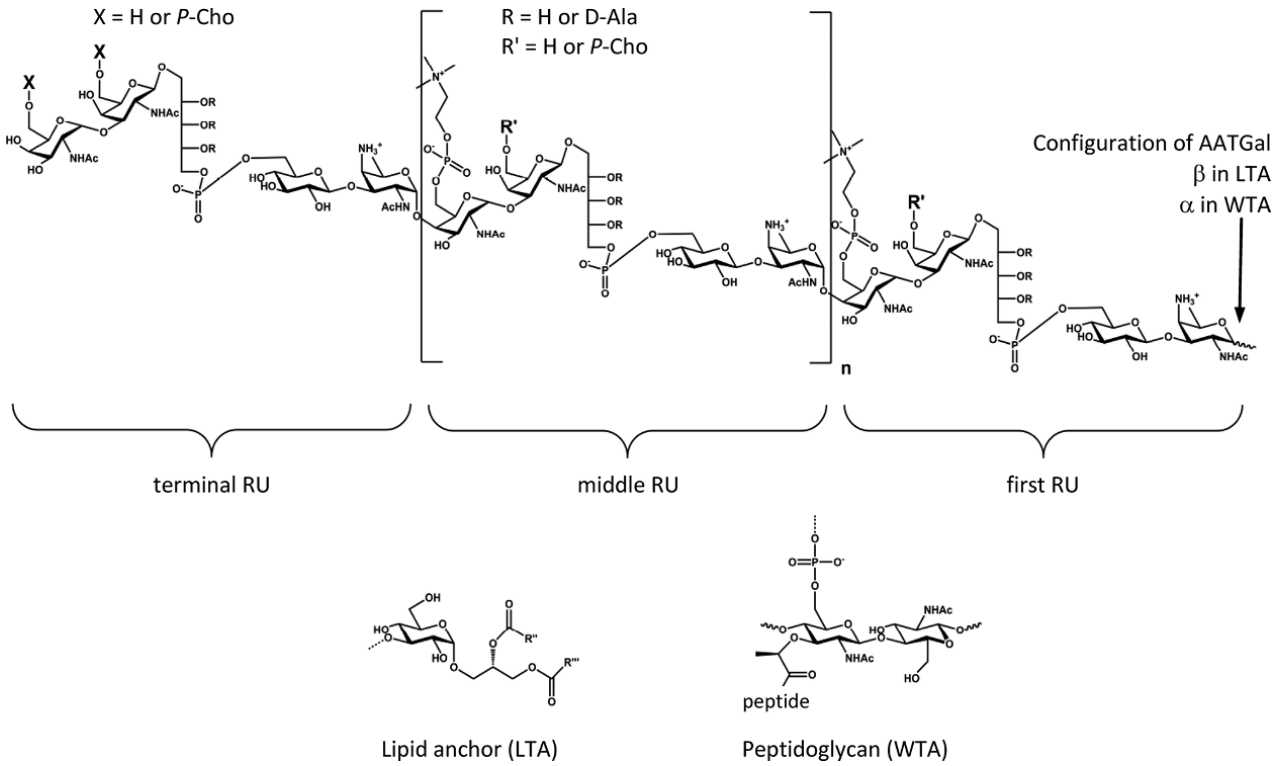

FIGURE 4 Structure of the pneumococcal LTA and WTA. Both types of teichoic acid have identical chains (top) which carry phosphoryl choline and D-alanine residues. In LTA the teichoic acid chains are β-glycosidically linked from AATGal to the lipid anchor (bottom left). In WTA the linkage occurs via an α-linkage from AATGal to MurNAc-phosphate in peptidoglycan. The figure was kindly provided by Nicolas Gisch (Research Centre Borstel, Germany). RU, repeating unit.

particular strain, between 15 and 30% of the muramic acid residues carry WTA chains (16, 92). In other Gram-positive bacteria, connecting the WTA chain and muramic acid by a phosphodiester bond typically has a linkage unit containing glycerophosphate or *N*-acetylmannosamine, but these components could not be detected either in the hydrolysate of pneumococcal cell walls or in WTA-containing muropeptides. Since no other sugar was found either, an acid-degradable sugar like AATGal was suggested as a component of the linkage unit (87). Indeed, peptidoglycan chains with attached WTA could be isolated, showing that the AATGal residue of the first repeating unit has an α-configuration and is directly linked to MurNAc 6-phosphate (13).

SYNTHESIS OF TEICHOIC ACIDS AND MODIFICATIONS

Although only few enzymes of the pneumococcal teichoic acid pathway have been biochemically studied, the complete pathway was deduced from bioinformatics analysis (89). Many teichoic acid genes cluster in three genomic regions, called lic1, lic2, and lic3. The lic1 region contains genes encoding components for the uptake of choline (LicB), the choline kinase LicA, and the cytidyltransferase LicC, which produces CDP-choline. In addition, the lic1 region encodes for TarI and TarJ, which synthesize CDP-ribitol (93). The adjacent lic2 region contains the *tacF* gene, encoding the putative teichoic acid flippase, and the *licD1/licD2* genes, encoding phosphotransferases for decoration of the teichoic acid subunits with phosphoryl choline residues. The lic3 region locates elsewhere on the chromosome and was identified by the presence of a gene, called *licD3*, with sequence similarity to *licD1* and *licD2*, which is surrounded by four other putative teichoic acid genes. LicD3 is most likely the phosphotransferase for the transfer of ribitol phosphate during synthesis of the repeating unit, which involves eight additional enzymes that synthesize the repeating unit linked to the carrier lipid bactoprenol phosphate. Presumably, Spr1222 polymerizes the teichoic acid precursors to the nascent chains, which are still linked to the carrier lipid, before these are flipped across the cytoplasmic membrane by TacF. Interestingly, TacF is specific for choline-loaded teichoic acid precursor chains, ensuring that the mature teichoic acids contain phosphoryl choline residues (94).

After reaching the outer leaflet of the cytoplasmic membrane the teichoic acid chains are transferred to either peptidoglycan to become WTA or to the glycolipid to form the LTA. The transfer to peptidoglycan is catalyzed by members of the LCP (LytR-CpsA-Psr) family of proteins, which have been identified as phosphotransferases involved in cell wall assembly in Gram-positive bacteria (95). The three LCP proteins of *S. pneumoniae* appear to have semiredundant roles in the attachment of capsular polysaccharides and WTA to C6-OH of MurNAc residues in peptidoglycan (96). However, strain D39 and strains with serotypes 8 and 31 link the capsule polymer via a 1,6-glycosidic bond to GlcNAc residues of the peptidoglycan. Such linkage is inconsistent with catalysis by LCP enzymes, indicating that the nature of the capsule attachment enzyme is still elusive (97). In the case of LTA, it is the membrane protein TacL that transfers the teichoic acid precursor chains onto the glycolipid anchor. Interestingly, mutants lacking *tacL* grow normally under laboratory conditions but show attenuated virulence in mouse models of acute and/or systemic infections by *S. pneumoniae* (13).

Downloaded From Vet-eBooks.com

Pneumococci contain a *dlt* operon, the products of which are responsible for the decoration of LTA and WTA repeating units with D-alanine residues, which are attached via an ester linkage to OH groups in ribitol (98). This modification introduces positive charges to teichoic acids and thus increases resistance to cationic antimicrobial peptides. While *S. pneumoniae* strain D39 modifies its teichoic acids by alanylation, this modification is not present in the laboratory strain R6 or in strain TIGR4 due to mutations in the *dlt* operon rendering it nonfunctional.

Phosphoryl Choline Esterase Enzymatic Removal of Phosphoryl Choline Residues from the Pneumococcal Cell Wall

The *pce* gene encoding for a teichoic acid phosphoryl choline esterase (Pce), an enzyme capable of removing phosphorylcholine residues from the cell WTA and LTA, was identified independently by two research groups (69, 70). Pce carries an N-terminal signal sequence and contains a C-terminal choline-binding domain with 10 homologous repeating units similar to those found in other pneumococcal surface proteins. The catalytic (phosphorylcholine esterase) activity is localized on the N-terminal part of the protein. The mature protein was overexpressed in *E. coli* and purified in a one-step procedure by choline-affinity chromatography. The product of the enzymatic digestion of ^{3}H-choline-labelled cell walls was shown to be phosphorylcholine. Inactivation of the *pce* gene in *S. pneumoniae* strains by insertion-duplication mutagenesis caused a unique change in colony morphology and a striking increase in the virulence of a capsular type III strain in the intraperitoneal mouse model. Pce may be a regulatory element involved with the interaction of *S. pneumoniae* with its human host. Sequence comparison indicates that Pce, the protein originally identified through its unique enzymatic activity (99), is identical to choline-binding protein E (CbpE), described by Masure and colleagues as a protein implicated in the attachment of pneumococci to nasopharyngeal cells (100). The crystal structure of Pce shows a catalytic site with two zinc ions and an elongated binding domain recognizing the phosphocholine residues of teichoic acid (101).

MULTIPLE FUNCTIONS OF CELL WALL CHOLINE RESIDUES

Nutritional Requirement for Choline

Choline is an essential growth factor for all natural isolates of pneumococci which have to import this nutrient from the growth medium (102). Choline may be replaced by other amino alcohols such as ethanolamine, which can incorporate into LTA and teichoic acid at the same positions as phosphocholine, but it cannot replace phosphocholine functionally. Ethanolamine-grown cells show a number of striking abnormalities, including inhibition of cell separation (growth in long chains), inhibition of DNA uptake in genetic transformation, lack of autolysis during treatment with penicillin and other wall inhibitors and detergents (103), production of an "immature" (enzymatically inactive) form of the autolytic enzyme LytA (104), and production of a cell wall that cannot absorb LytA (105), and is completely resistant to the hydrolytic action of LytA (106). However, the requirement of LytA for built-in phosphocholine residues is no longer seen when solubilized cell wall polymers are degraded to muropeptides (12) or when the teichoic acid is removed from peptidoglycan (48). These observations may be interpreted to indicate that teichoic acid prevents the access of autolysin to its cell wall substrate and that this effect is overcome by binding of the enzyme to the phosphocholine residues.

There are several proteins in pneumococci—including LytA, LytB, and LytC—that specifically recognize and bind to phosphocholine residues. These proteins contain distinct domains which are responsible for their specific biological activities, whereas the choline-binding domains are homologous and contain 6 to 10 choline-recognizing repeats of ~20 amino acids each. The structure of crystallized LytA and LytC and their interaction with choline residues in the cell wall have been described (107, 108).

Choline-Independent Strains

A choline-independent strain, R6Cho^{-}, was recovered from a heterologous cross with DNA from *Streptococcus oralis* (48). *S. oralis* also incorporates phosphocholine into its cell wall teichoic acid but, unlike pneumococci, has no nutritional requirement for choline. Other choline-independent strains, for example, JY2190 and R6Chi, are mutants generated by serial passage of strains in chemically defined medium containing decreasing concentrations of ethanolamine with each passage (94, 109). None of these strains had acquired the capability to synthesize choline or ethanolamine, because phosphorylated amino alcohols could not be detected in TA and LTA. In spite of the absence of phosphocholine, there was no alteration either in the structure of LTA and teichoic acid or in cell wall composition, including the stem peptide profile. Only the phosphate content of cell walls was reduced, consistent with the absence of phosphocholine. *In vivo*, the lack of active autolysins became apparent by impaired cell separation at the end of cell division and by resistance against stationary phase and penicillin-induced lysis. Due to the absence of choline from LTA, PspA was lost into the surrounding medium, whereas in spite of choline-free teichoic acid, the amidase was retained on the cells. Both choline-independent strains retained the capacity to incorporate choline into teichoic acids: when grown in the presence of choline, PspA was retained, cells separated normally and became penicillin sensitive, and phosphocholine was discovered on LTA and teichoic acid.

In the case of strain R6Chi and related strains, the lack of a nutritional requirement for choline was explained by the loss of specificity of the teichoic acid flippase TacF for choline-loaded teichoic acid precursor chains (94). R6Chi contains a single point mutation in the *tacF* gene, rendering the cells choline independent. When growing in the presence of choline, R6Chi still incorporated phosphocholine into its teichoic acids, suggesting that the mutated TacF can transport choline-loaded and -unloaded teichoic acid precursor chains. The presence of the *tacF* mutation also allowed for the deletion of otherwise essential choline utilization genes *licABC*, producing a strain that did not incorporate choline into its cell wall even when growing in the presence of exogenous choline. An encapsulated version of this mutant was used to demonstrate the crucial role of cell wall choline residues in immune evasion (110)

CELL GROWTH REGULATION DURING THE CELL CYCLE

Growth Zone and Cell Wall Segregation

Similar to other streptococci, pneumococci incorporate new cell wall units into the preexisting wall material at a single growth zone located at the cell equator (midcell). Both

Downloaded From Vet-eBooks.com

peptidoglycan and teichoic acids units and also capsular polysaccharide (111) enter the pneumococcal surface at this growth zone, which could be visualized by exploiting the unique selectivity of a pneumococcal enzyme, the peptidoglycan hydrolase LytA, for choline-containing segments of the cell wall (58). Pneumococci require choline for growth, and the design of this experiment was based on the observation that the choline component of the WTA can be replaced by structural analogues such as ethanolamine. Pneumococci grown in ethanolamine-containing medium show several striking abnormalities: unlike the choline-grown bacteria, pneumococci utilizing ethanolamine grow in long chains and are completely resistant to the cell wall-degrading activity of LytA (103). Upon addition of trace amounts of radiolabeled choline to a culture grown on ethanolamine, the bacteria immediately shifted to the utilization of choline so that the nascent wall units that began to incorporate into the cell surface contained choline residues in the teichoic acid component of the nascent cell wall and produced regions that were susceptible to hydrolysis by exogenous LytA enzyme added to the medium. It was possible to show by electron microscopy that under these conditions the LytA enzyme performed an enzymatic "microsurgery" on the bacteria: it has selectively removed a thin equatorially located band of cell wall, thus identifying the anatomical site of wall incorporation and growth zone (58).

Another abnormality of the ethanolamine-grown pneumococci, the complete inhibition of cell separation, has allowed the design of experiments to test the mode of inheritance of pneumococcal cell walls. Pneumococci labeled in their wall by titrated choline were shifted to an ethanolamine-containing medium in which the bacteria continued to grow in the form of chains of cells, i.e., "linear clones" in which the distribution of radioactively labeled bacteria could be followed (by autoradiography) as a function of cell generations in the ethanolamine-containing medium. Since the teichoic acid choline does not exhibit turnover during growth, the localization of radioactively labeled cells within the chains of bacteria could provide clues as to the mode of wall segregation. The finding was that the radioactive label remained in large clusters in association with cells that were located either at the tips or at the center of chains. The results demonstrate the conservation of large hemispherical segments of the cell wall which are passed on intact to daughter cells during cell division (112).

Novel methods such as staining nascent peptidoglycan with fluorescent vancomycin (113), incorporating fluorescent D-amino acids (114), and superresolution microscopy (32) confirmed that pneumococci incorporate new cell wall units into the preexisting wall material at a single growth zone located at midcell.

Cell Wall Growth and Cell Division Complexes

The mode of growth and cell wall segregation described above suggests that *S. pneumoniae*, similar to the model rods *E. coli* and *B. subtilis*, grows by alternating cycles of peripheral (side wall) and septal peptidoglycan synthesis, which may overlap for part of the cell cycle in the former (32). Consistent with this, the *S. pneumoniae* chromosome was found to encode proteins that are part of the elongation machinery (elongasome), such as MreC, MreD, MltG, RodZ, RodA, PBP2b, PBP1a, and CozE and others that are part of cell division machinery (divisome), such as FtsZ, FtsA, ZapA, ZapB, EzrA, FtsE, FtsX, FtsK, FtsL, FtsB(DivIC), FtsQ (DivIC), SepF, GpsB, DivIVA, FtsW, PBP1a, PBP2x, PcsB, and LytB, as well as proteins that have a regulatory role in these processes (4, 39, 53, 115–118).

Nevertheless, the characteristic ovococcal shape of pneumococci suggests that there must be major differences in the cell wall growth mechanism compared to those of the rods. One central difference is that pneumococci, despite conservation of all the other components of the elongation complex, lack the rod-shape determinant MreB, i.e., the actin-like protein that in rod-shaped model bacteria provides the dynamic cytoskeletal scaffold to maintain the rod shape (119). The second difference is that, despite previous reports (2), both components of the elongasome and divisome show a clear septal localization, with no substantial variation in timing of recruitment, although they may show differences in localization profile. The latter is best reflected by the specific midcell localization of peptidoglycan synthases PBP2b and PBP2x, which are involved with peripheral and septal cell wall growth, respectively (7). Importantly, these differences from rods have led to the proposal that in *S. pneumoniae* and other oval-shaped cocci, the elongation and septal machineries coexist in a single, intimately interconnected and tightly regulated complex, or supercomplex (Fig. 5) rather than in two separated ones (39, 115). Subsequent studies supported this model and provided insights into the coordination and regulation of the complex during the cell cycle (120–123).

Information regarding gene essentiality among *S. pneumoniae* proteins involved in cell growth and division is available thanks to both global and dedicated studies. However, it was not possible to assess directly the effect of inactivation of these genes until genetic systems allowing the generation of merodiploids and conditional lethal mutants became available. Moreover, recent work employing a clustered regularly interspaced short palindromic repeat interference method (41) provides an additional powerful tool to confirm results obtained with other methods and identify and characterize new essential genes.

Genes encoding pneumococcal elongasome proteins were found to be essential in *S. pneumoniae* strain D39 (53, 123, 124). However, some of these genes were not essential in strain R6, a laboratory derivative of D39, and similar strains (53, 122–124). Presumably, these laboratory strains contain preexisting suppressor mutations that could compensate for the loss of otherwise essential genes. Interestingly, inactivation of *mreC*, *mreD*, *mltG*, and *rodZ* in *S. pneumoniae* D39 is directly suppressed by mutations that inactivate *pbp1a* function or upon *pbp1a* deletion (53, 124). Strain R6 contains an allelic variant of PBP1a (T124A D388E), the functional importance of which has yet to be determined. In agreement, allele swapping experiments showed that the *pbp1a* allele from R6 was sufficient to compensate for *mreCD* loss in the R6 genetic background but less so in the D39 background, suggesting that other mutations present in R6 must be involved in the strong suppression of *mreCD* essentiality (124). This result is also supported by the fact that *pbp2a*, which shows a synthetic lethal relationship with *pbp1a*, can be readily inactivated in strain R6 (44).

A previously uncharacterized gene, *spd_0768* (*spr0777* in R6), encoding the membrane protein named CozE (for coordinator of zonal elongation) was identified in a Tn-seq screen for genes dispensable in D39 with inactivated *pbp1a* (118). Inactivation of *cozE* or *mreCD* in the presence of PBP1a resulted in an aberrant relocalization of PBP1a and peptidoglycan synthesis from midcell to the whole cell periphery, and cells became increasingly spherical before they lysed. Similar to *mreCD*, *cozE* is dispensable in the R6 genetic background. CozE interacts directly with MreCD and PBP1a.

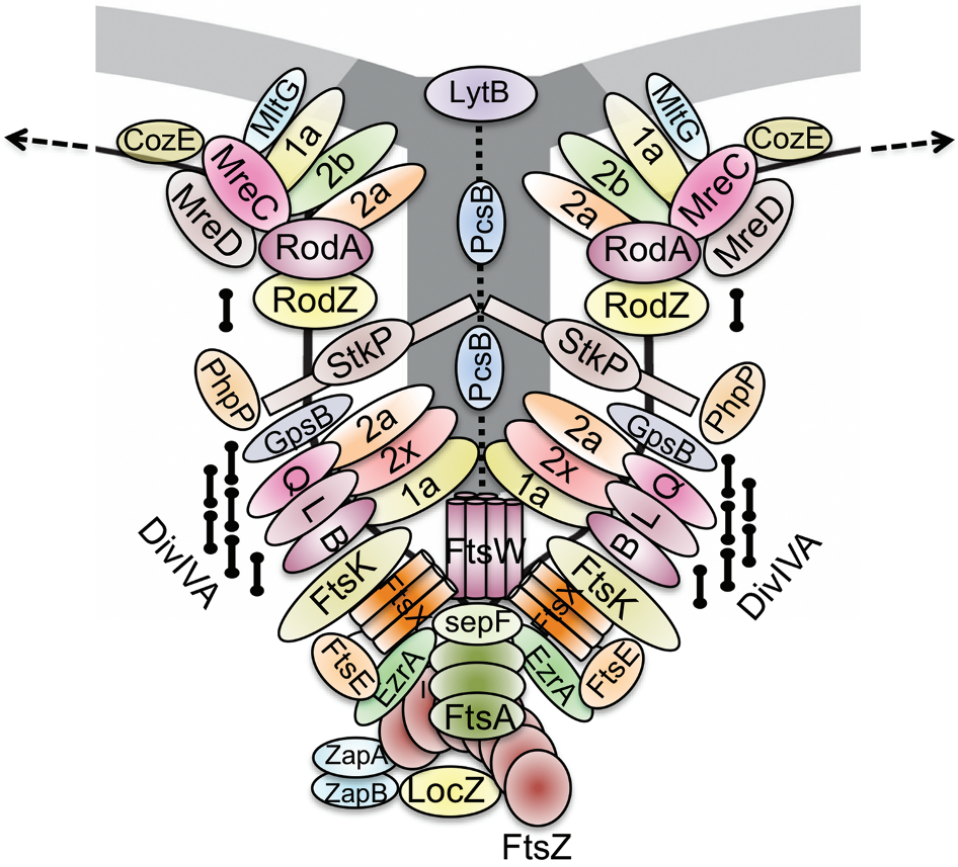

FIGURE 5 Cartoon of a cell wall growth and division complex at midcell showing elongation and cell division proteins and the peptidoglycan hydrolases PcsB and LytB, which cleave the septum for pole formation and cell separation.

Together, the results were interpreted as CozE being part of a coordination mechanism, critical for proper zonal cell wall synthesis, by connecting PBP1a with the other components of the elongation machinery via direct interactions (118).

With the exception of *pcsB* and *gpsB*, which showed strain-dependent essentiality, inactivation of cell division genes was more consistent between strains. Of these, *ftsZ*, *ftsA*, *ezrA*, *ftsEX*, *ftsL*, *ftsB* (*divIC*), and *pbp2x* were demonstrated to be essential in different commonly used genetic backgrounds (7, 45, 46, 54, 121, 125).

As in other bacteria, in *S. pneumoniae*, cell division starts with the localization of the tubulin-like FtsZ and the actin-like FtsA cell division proteins (126) that assemble at midcell to form the Z-ring required for the recruitment of the other components to complete cytokinesis.

Photoactivated localization microscopy showed that as in other bacteria, the Z-ring in *S. pneumoniae* displayed a patchy structure rather than forming a homogenous ring, providing important insight into its *in vivo* organization (127). Following the fluorescent tagged-FtsZ localization and the Z-ring diameter, it was observed that FtsZ molecules assemble at midcell at the beginning of the cell cycle to form a single patchy ring, which thickens and then disassembles during constriction, while new Z-rings assemble at the future division sites (or new equators) of the newborn cells. Notably, unconstricted double Z-rings, suggesting short-lived intermediates, were observed in a small percentage of cells at midcell but not at the future division site (127).

Once the Z-ring is formed, the later pneumococcal cell division proteins localize to midcell, and a few to midcell and cell poles, in exponentially growing pneumococcal cells. A hierarchical order of recruitment to the septum has not been determined, and it may not even be a linear sequence of events, although colocalization studies based on fluorescence microscopy suggest that divisome assembly occurs in at least two steps. In the absence of MreB, it is still unknown how elongation components are targeted to midcell and how lateral and septal growth are coordinated. FtsZ is believed to be the best candidate to act as a scaffold to coordinate both side-wall and septal synthesis (127), although this role has not been experimentally verified, and the effect on *S. pneumoniae* cells of depletion of essential proteins involved in the initial steps of cell division were not available until recently.

A recent study characterized conditional lethal mutants for the cell division protein FtsA, providing insights about how integration of the elongation and septation machineries at a single mid-cell location in *S. pneumoniae* may result in a distinct cell growth pattern characteristic of oval-shaped cocci. Unexpectedly, the complete depletion of FtsA in the pneumococcus resulted in cell ballooning and, ultimately, lysis, in sharp contrast to the cell filamentation phenotype observed in rods (121). FtsZ rings and peptidoglycan synthesis delocalized upon FtsA inactivation, suggesting that the cells could neither elongate nor divide. In contrast, inactivation of genes encoding other cell division components, such as GpsB (5) and SepF (128), which in *B. subtilis* are

Downloaded From Vet-eBooks.com

synthetically lethal with *ftsA* (129, 130), resulted in enlarged and elongated cells, with multiple FtsZ rings but not cell ballooning or lysis. Consistent with these results, and in contrast to the model rods where FtsA localizes after FtsZ, in *S. pneumoniae*, FtsZ and FtsA are targeted to midcell at the earliest stages of the process, and both form a ring that remains colocalized throughout the cell cycle, while GpsB and SepF are recruited later, after the Z-ring is assembled (121).

Taken together, these observations led to the hypothesis that in oval-shaped cocci, the actin-like FtsA, and not FtsZ, could play a major role in coordinating peripheral and septal peptidoglycan synthesis, likely carrying out a role similar to the actin-like MreB in preseptal synthesis in *E. coli*. However, since FtsA is needed to tether FtsZ to the membrane (131) and FtsZ may be required for FtsA to be targeted to the septum, additional work is necessary to distinguish any direct role for FtsA in coordinating both modes of peptidoglycan synthesis from that of FtsZ.

While the elucidation of the mechanisms that in *S. pneumoniae* control the intimate coordination between the two peptidoglycan biosynthetic machineries still awaits further study, new insights came from an unanticipated source, the screening for mutations that bypass the need for PBP2b. This approach identified the membrane-bound, likely endolytic transglycosylase, MltG (see above), which is involved in cell elongation (53). More recently, the inactivation of two other genes, *spd_0675* and *spd_1849* (*spr0683* and *spr1851* in R6), was shown to remove the requirement for PBP2b, MreCD, RodA, RodZ, and GpsB in *S. pneumoniae* D39 (123). The corresponding proteins, named KhpA and KhpB, form an RNA-binding complex which regulates cell division posttranscriptionally. Inactivation of *khpA* or *khpB* resulted in cells with a significant reduction in cell volume, but they overall maintained a normal aspect ratio while inducing a strong increase in the expression of the WalRK cell wall stress regulon and modulating the level of FtsA through a posttranscriptional mechanism. Indeed, overproduction of FtsA was found necessary and sufficient to compensate for the loss of PBP2b, MreC, MreD, and RodA but not GpsB, indicating that KhpAB must also regulate other genes in addition to *ftsA* (123).

Two independent studies also identified Spr1851/Spd_1849, either as a novel substrate for phosphorylation by the Ser/Thr protein kinase, StkP, in the laboratory strain *S. pneumoniae* Rx1 (132) or as a suppressor of *pbp2b* in the R704 derivative of laboratory strain R6 (133) and named it Jag (for Jag-domain protein) or EloR (for elongasome-regulating protein), respectively. Jag was found to be phosphorylated at least at T89 (132). Experiments with null or phosphoablative (T89A) alleles of *eloR* in the R704 strain revealed that both *pbp2b* and *rodA* could be deleted, while its phosphomimetic form (T89D or T89E) could only be tolerated in strains that acquired suppressor mutations in *mreC* and *rodZ* (133). In contrast, no phenotype was observed in either KhpB phosphoablative or phosphomimetic derivatives in *S. pneumoniae* D39, indicating that T89~P phosphorylation of KhpB is not necessary for its function in the progenitor strain background (123). Despite discrepancies between strains, these studies highlight the crucial yet complex role of StkP in the regulation of the pneumococcal cell cycle.

Regulators of Cell Wall Growth and Division and Role of Phosphorylation

Similar to other Gram-positive bacteria, *S. pneumoniae* possesses, in addition to histidine kinases of two-component systems, a conserved signaling system consisting of a Ser/Thr protein kinase, StkP, and a cognate PP2C-type phosphatase, PhpP (134, 135). StkP belongs to the subfamily of eukaryotic-type Ser/Thr kinases, ESTKs, and consists of a cytoplasmic kinase domain, a transmembrane region, and a C-terminal part outside the cell made up of four PASTA domains, similar to the two PASTA domains in PBP2x (136).

StkP acts as a dimer and forms a signaling pair with PhpP (137, 138). Several StkP substrates playing a role in cell wall metabolism and cell division were identified to be phosphorylated *in vivo* in a global study of the pneumococcal phosphoproteome (139). However, only some of them have been confirmed to be specifically phosphorylated by StkP *in vitro* and/or *in vivo*. These include the phosphoglucosamine mutase GlmM, the peptidoglycan precursor biosynthesis enzyme MurC, the cell division proteins DivIVA (135, 140–144), the recently discovered substrates MapZ/LocZ (145, 146), and Jag/EloR/KhpB (123, 132, 133, 147). Although StkP is not essential in *S. pneumoniae*, the multiple phenotypes of an *stkP* mutant suggested that it was involved in the regulation of cell growth and cell division (140, 141), virulence, competence (134), and stress resistance (148). It was later shown that both StkP and its cognate PhpP localize to the division site with active peptidoglycan synthesis and that the PASTA domains of StkP were required for its septal localization, indicating that they bind to newly synthesized and still un-cross-linked peptidoglycan chains *in vivo*. Inactivation of *stkP*, or overproduction of PhpP, resulted in elongated cells with multiple and often unconstricted division rings, perturbed in cell wall synthesis. In contrast, *S. pneumoniae* cells overproducing StkP, or lacking functional PhpP, were significantly smaller and rounder (132, 143). These data indicate that StkP and PhpP play an important role in coordinating cell wall synthesis during growth and division to achieve and maintain the characteristic ovococcal shape. StkP was proposed to act as a molecular switch that, through phosphorylation of key division substrates, signals the shift from peripheral to septal cell wall synthesis (143).

A parallel study of the role of StkP in pneumococcal cell division partially confirmed these results and proposed diverse functions for the different StkP domains in the R6-derived strain R800 (142). In this strain, deletion of the *stkP* gene or expression of a truncated protein lacking the kinase domain (StkP-PASTA-TMH) resulted in round and chaining cells rather than in elongated cells, while the elongated morphology was only observed in mutants expressing a truncated protein lacking the PASTA domains (StkP-KD-TMH) or the catalytically inactivated StkP(K42M) (142), in agreement with what was already reported for the *S. pneumoniae* mutant StkP(K42R) and other *stkP* mutants lacking the PASTA domains obtained in different genetic backgrounds (140, 141, 143). The round and chaining phenotype, connected with the *stkP* deletion or truncation (142), was not observed in other studies and was interpreted to be likely due to differences in genetic background, growth conditions, or suppressor mutations in specific *stkP* null strains (39). To date, the molecular mechanisms of StkP's regulatory function on its substrates is still unclear, although recent studies have reported some advances in this direction.

In 2014, Fleurie et al. reported that the DivIVA paralog, GpsB, a putative component of the pneumococcal cell elongation and cell division complex, was required for proper localization and activation of StkP in the *S. pneumoniae* R6 derivative strain R800 (120). R800 cells deleted for *gpsB* were viable but displayed an elongated and twisted-towel phenotype, more severe than that previously reported for *S. pneu-*

Downloaded From Vet-eBooks.com

moniae D39 cells depleted of *gpsB*, where this gene is essential (5). Both FtsZ and peptidoglycan synthesis were shown to have a helical pattern of localization in Δ*gpsB* R800 cells, in which phosphorylation of all StkP substrates, including itself, was abolished, consistent with the StkP delocalization observed. The R800 Δ*divIVA* phenotype, instead, was consistent with the Δ*divIVA* phenotype previously reported for *S. pneumoniae* Rx1 strain (3); however, its characteristic rounder and chainy morphology was reinterpreted as a major defect in cell elongation (120) rather than a defect in septum closure and pole maturation as originally proposed (3). In addition, *divIVA* inactivation was found to suppress the elongated phenotype of Δ*gpsB* cells. Together, these observations formed the basis for a model in which DivIVA (required for cell elongation) and GpsB (required for cell division) constituted the mechanism for the molecular switch to coordinate peripheral and septal peptidoglycan synthesis, connecting them to the Z-ring through the cell division protein EzrA: GpsB and DivIVA did not interact directly with FtsZ, but both interacted directly with EzrA, which in turn interacted with FtsZ (120). In this model, GpsB, which has been shown to be phosphorylated in *Streptococcus agalactiae* (149) and *B. subtilis* (150) but not in *S. pneumoniae*, would be needed for StkP localization at midcell and for consequent phosphorylation of itself and its substrates, in particular DivIVA, to activate septum closure. The elongated phenotype of the *S. pneumoniae* R800 cells expressing the phosphoablative DivIVA allele T201A, the only amino acid residue of the protein shown to be phosphorylated (142), further supported this interplay between GpsB, DivIVA, and StkP.

In 2016, Straume et al. reported that *S. pneumoniae* R6 depleted for PBP2b, which grows as long chains of characteristic lentil-shaped cells, has an altered stem peptide composition and is hypersensitive to the peptidoglycan hydrolase CbpD, which is produced during competence (45). They developed a genetic screen to identify genes that, when inactivated, would display a PBP2b-like CbpD-dependent lytic phenotype, encoding proteins functionally related to PBP2b (151). Four out of the twenty proteins tested, RodA, DivIVA, Spr0777 (later identified as Spd_0768/CozE), and MreD (but not of MreC), showed a PBP2b-like competence-induced autolytic response and consequently belong to the cell elongation complex (45). Intriguingly, this study revealed that the *mreD* mutant differed from the expected morphology observed in other studies for *mreD* mutants in the same or similar genetic backgrounds (39, 118, 124), highlighting once more the difficulties in understanding individual effects of gene inactivation in *S. pneumoniae*.

The CbpD-dependent lysis data were then correlated with protein-protein interactions between the identified proteins using the bacterial two-hybrid analysis system (152). PBP2b interacted with RodA, confirming that these proteins have a close functional relationship also in *S. pneumoniae*. Other interactions detected were between DivIVA and PBP2b, between DivIVA and Spr0777(CozE), and the known DivIVA self-interaction (3, 151).

Taken together, these data were interpreted as DivIVA being part of, and required for, proper localization of the pneumococcal elongasome, likely recruited by its interacting partner CozE, supported by the observations that truncations determining the loss of DivIVA localization were also associated with the loss of the elongasome function (151). However, direct experimental proof for the lack of localization of DivIVA in the absence of CozE or known components of the elongasome in the absence of DivIVA, is presently missing. Moreover, Δ*divIVA* cells showed a significantly smaller increase in the amount of branched stem peptide incorporated in the peptidoglycan with respect to that of cells depleted for PBP2b, RodA, or CozE (151). Because DivIVA is dispensable and shows a similar phenotype in all *S. pneumoniae* genetic backgrounds, while other members of the elongation complex are not, a deeper understanding of the localization profile and time of arrival at midcell of the different cell cycle proteins would be needed to reveal their precise functions. The regulatory function in cell wall biosynthesis of its paralog, GpsB, appears to become more clear. Similar to DivIVA, GpsB is also found in Gram-positive bacteria and contains a conserved N-terminal domain, which recognizes the negative membrane curvature at the nascent division septum (130, 153–155).

The *gpsB* gene is essential in *S. pneumoniae* strain D39 but not in its laboratory derivatives, strains R6 and R800 (5, 120). The recent work of Rued et al. (122) showed that GpsB was not strictly required for StkP localization or peptidoglycan synthesis at division septa. GpsB depletion resulted in elongated cells with multiple Z-rings, but no helical localization of FtsZ in twisted-towels cells was observed. However, D39 cells depleted for GpsB showed decreased StkP-mediated phosphorylation that could be suppressed by functional inactivation (mutation or deletion) of its cognate PhpP phosphatase, which also relieved the cells from the need of GpsB. A similar suppressor mutation inactivating PhpP was detected in Δ*gpsB* mutants obtained in the other, commonly used, D39 laboratory derivative, Rx1 (122). Importantly, GpsB forms a complex with EzrA, MreC, StkP, PBP2a, and PBP2x and directly interacts with some of these proteins. Moreover, functional relationships were identified, based on synthetic lethality with Δ*pbp1a* or Δ*pbp2a*, with PBP2a and with PBP2x, in which transpeptidase activity was prevented from localizing at the center of division septa in the absence of GpsB (122). A previous study reported that, although PBP2x is not an obvious StkP substrate, the two proteins formed a complex in the *S. pneumoniae* membrane, and the PASTA domains of StkP interacted directly with the extracellular region of PBP2x, likely allowing correct localization of both proteins at the division site (6).

Taken together, these results highlight a key role for GpsB in regulating the peripheral and septal synthesis through the regulation of PBP activities during the cell cycle, in agreement with what is observed for other Gram-positive bacteria (156, 157). A revised model for GpsB function would then be that, on one hand, GpsB activates PBP2a and StkP-PBP2x to close the septal ring, but on the other hand, it negatively regulates peripheral elongation by inhibiting the activity of PBP2b and MreC (122).

While these aspects of the function of GpsB are relatively well understood, the role of phosphorylation in GpsB function is not. The recent studies of GpsB (120, 122) both agreed that inactivation of GpsB reduces StkP-mediated phosphorylation and, consequently, that GpsB is important for optimal phosphorylation. However, because GpsB does not appear to be a substrate of StkP, the functional relationship between the two proteins remains unclear. Hence, whether StkP phosphorylates DivIVA as part of a molecular switch that together with GpsB and StkP controls peripheral versus septal peptidoglycan synthesis remains controversial. In contrast with what was reported for the *S. pneumoniae* R800 strain (120), Δ*divIVA* mutations were not found to be epistatic to Δ*gpsB* mutations in strains D39 and its derivatives R6 and Rx1 (122), and Δ*divIVA* cells did not show any detectable morphological phenotype when producing the

Downloaded From Vet-eBooks.com

phosphoablative DivIVA T201A allele (122, 151), which is also different from what was observed in the *S. pneumoniae* R800 strain (120, 142).

Division Site Selection (MapZ/LocZ) and Origin of Replication

Until recently, no mechanisms for targeting FtsZ and the division complex to the nascent septum were identified, and no counterparts of the widespread or specific systems described in other bacteria, were found to be present in *S. pneumoniae*. Rod-shaped model species use the Min system and nucleoid occlusion to prevent asymmetric cell division and/or prevent the septum from constricting over unsegregated chromosomes, but in contrast to the striking conservation of the proteins that constitute the cell elongation and division complexes, the proteins involved are poorly conserved (reviewed in 158–160).

It came as a surprise when two independent studies reported the characterization of a previously unknown substrate of StkP, annotated as Spr0334 (SPD_0342 in D39), and showed that a specific system for correctly identifying the midcell did indeed exist also in *S. pneumoniae* (145, 146). The protein was named MapZ (for midcell-anchored protein Z) (145) or LocZ (for localizing at the midcell of Z) (146) and was shown to be a membrane protein consisting of a cytoplasmic domain and two extracellular domains separated by a highly entropic serine-rich region. MapZ/LocZ has a rather narrow phylogenetic distribution, being present only in streptococci, enterococci, and lactococci.

Consistent with its proposed function, MapZ/LocZ was found to localize as a ring at midcell at the very early stages of cell division and before FtsZ (145) or FtsZ/FtsA (146). After the equatorial rings of new daughter cells assemble into septal rings, MapZ/LocZ splits into two rings that move away with the so-called wall bands or equatorial rings until they reach the equators of the newly forming daughter cells, marking the future division sites (145, 146).

The gene encoding MapZ/LocZ was found to be dispensable in four genetic backgrounds, R800 (145), D39, R6, and Rx1 (146), and its deletion resulted in misshapen cells often showing misplaced septa (145, 146). Moreover, in the absence of MapZ/LocZ, FtsZ (and FtsA) rings formed but were not localized and/or correctly oriented with respect to the longitudinal axis of the cells. A direct interaction between the MapZ cytoplasmic domain and FtsZ was detected, and MapZ alleles lacking the N-terminal domain were unable to promote correct FtsZ placement (145). Finally, both studies identified that MapZ/LocZ was phosphorylated by StkP at Thr67 and Thr78 and that both phosphomimetic (T67-78E) and phosphoablative (T67-78A) allelic variants localized to midcell, although the phenotypes of the strains differed completely, ranging from severe defects in cell shape and viability with aberrant FtsZ structures and reduced numbers of Z-ring per cell (145) to no evident morphological defects and a wild-type morphology (146).

Thus, although the overall conclusions of the MapZ/LocZ studies agreed on the protein function, the two works differed in important details: (i) the growth and morphological defects are significantly more severe in the R800 background than in the others; (ii) in R800 there is a third MapZ ring forming at midcell after the initial ring splits into two and moves apart from the cell center, but this was not seen for LocZ in other strains; (iii) the relocalization of MapZ at the midcell (third ring) requires that the central FtsZ ring splits into two rings that eventually reach the MapZ rings at the equators, whereas in the other strains, FtsZ disassembles from midcell to assemble *ex novo*, guided by LocZ, at the future division sites, as the FtsZ ring at midcell constricts progressively (145). While these issues need to be clarified, further analysis of MapZ, using both a genetic and a structural approach, demonstrated the importance of the second extracellular domain, which shows a marked flexibility at acid pH, while demonstrating that the first extracellular domain is likely a molecular scaffold or pedestal, required to mark the division site (161).

A more recent study indicated that MapZ/LocZ is not involved in division site selection but, rather, in the selection of the correct division plane and that the replication status and the position of the chromosome have, instead, a crucial impact on spatial regulation of cell division. In particular, the position of the chromosome origin of replication precedes MapZ/LocZ at midcell and promotes the use of the correct division site (162). These conclusions were based on the reasoning that Δ*mapZ*/Δ*locZ* mutants are not elongated but, rather, are shorter and with only minor changes in cell morphology with respect to wild-type cells. Advanced fluorescent microscopy and image analysis showed that FtsZ localization is not affected in cells lacking MapZ, suggesting that it would not be critical for accurate timing of the Z-ring assembly at midcell (162). The localization profile of MapZ/LocZ during the cell cycle was consistent with previous reports; however, two and not three MapZ-rings were observed, in line with what was previously observed for *S. pneumoniae* D39 and related derivatives (146) and not for *S. pneumoniae* R800 (145).

The reported mislocalization of FtsZ in Δ*mapZ*/Δ*locZ* cells was attributed to the FtsZ fusion protein used in the previous studies to detect FtsZ localization in the null mutants (145, 146). This consideration applies only to the MapZ study, where a GFP-FtsZ fusion used was the only source of FtsZ in the cell (145), but not to the LocZ study, where the CFP-FtsZ fusion was ectopically produced, in addition to native FtsZ (146). Nevertheless, the Δ*mapZ*/Δ*locZ* phenotype was reinterpreted in a new light and suggested that MapZ/LocZ could function in cell wall remodeling rather than in site selection, similar to peptidoglycan hydrolases and class C PBPs (162). However, this intriguing hypothesis awaits experimental validation.

In conclusion, the study of the cell cycle of *S. pneumoniae* has benefited greatly from work on other organisms, in particular, the model rods with which the pneumococcus has many similarities as well as many marked differences. The gap in knowledge between *S. pneumoniae* and the model organisms is rapidly closing, and it will be interesting to see how further works develop. Regulation of the cell cycle through phosphorylation is a relatively new and active area of research (163) that will likely provide new insights on how *S. pneumoniae* succeeded to manage peripheral and septal growth that emanates from a single insertion site located at the cell center or midcell.

Streptococcus pneumoniae Capsular Polysaccharide

JAMES C. PATON AND CLAUDIA TRAPPETTI

19

BACKGROUND

The presence of what is now recognized as the polysaccharide capsule on the surface of *Streptococcus pneumoniae* was noted by Pasteur in the first published description of the organism in 1880, and since that time it has been the direct or indirect focus of intensive investigation [reviewed by Austrian (1, 2)]. Studies during the first three decades of the 20th century demonstrated the existence of multiple capsular serotypes of *S. pneumoniae* and the fact that antibodies to the capsule conferred type-specific protection against challenge in laboratory animals. The capsular material itself was isolated by Dochez and Avery in 1917 (3), but the fact that it was immunogenic led them to believe that this "soluble substance of the pneumococcus" was proteinaceous in nature. It was not until 1925 that Avery and colleagues (4, 5) demonstrated that the pneumococcal capsule consisted of polysaccharide, the first nonprotein antigen to be recognized.

The capsule forms the outermost layer of encapsulated strains of *S. pneumoniae*. It can be up to approximately 400 nm thick, accounting for more than half of the pneumococcal volume (6), and for the vast majority of cases is covalently attached to the outer surface of the cell wall peptidoglycan (7). A total of 98 structurally and serologically distinct capsular polysaccharide (CPS) types have been recognized to date (8), and the chemical structures of the repeat units for approximately 70% of these have been determined (9). The simplest CPS types are linear polymers with repeat units comprising two or more monosaccharides. The more complicated structural types are branched polysaccharides with repeat unit backbones composed of one to six monosaccharides plus additional side chains. Two nomenclature systems for CPS serotypes have been developed, but the Danish system, which combines antigenically cross-reacting types into groups, is now preferred to the American system, which lists serotypes in chronological order of discovery. Examples of some of these structures are shown in Fig. 1.

The polysaccharide capsule has long been considered to be a *sine qua non* of pneumococcal virulence (2). The vast majority of fresh clinical isolates of *S. pneumoniae* are encapsulated, and spontaneous nonencapsulated derivatives of such strains are almost completely avirulent. Indeed, as early as 1931, Avery and Dubos (10) demonstrated that enzymic depolymerization of the CPS of a type 3 pneumococcus increased its 50% lethal dose more than 10^5-fold. Similar virulence defects were later reported for type 2 and 3 pneumococci with defined mutations in genes essential for CPS synthesis (11–14). However, notwithstanding the critical importance of the capsule for invasive disease, "nontypable" *S. pneumoniae* strains have been associated with outbreaks of conjunctivitis and have been isolated from the nasopharynx and middle ear. While some of these isolates may produce novel CPS serotypes that do not react with existing typing sera, most have genetic defects in the *cps* locus, which encodes CPS biosynthesis, or lack the *cps* locus altogether (8, 15, 16).

The clear morphological distinction between encapsulated (smooth) and nonencapsulated (rough) pneumococci, as well as the massive difference in systemic virulence, facilitated early studies of the phenomenon of capsular transformation. This was first demonstrated by Griffith (17), who found that a proportion of mice injected with a mixture of live rough and killed smooth pneumococci died. Smooth pneumococci expressing the same capsular serotype as the killed smooth strain were isolated from the blood of these mice. The transformation reaction was subsequently performed *in vitro* and led to the seminal discovery that the transforming principle, the carrier of genetic information, was in fact DNA (18).

ROLE IN PATHOGENESIS

The pneumococcal capsule is undoubtedly the most important defense against the host immune system and contributes to pathogenesis in multiple ways. The majority of CPS serotypes are highly charged at physiological pH, and this is thought to promote nasopharyngeal colonization by repelling sialic acid-rich mucopolysaccharides, thereby avoiding entrapment of *S. pneumoniae* in nasal mucus and facilitating access and attachment to the surface of epithelial cells (19). CPS inhibits both the classic and alternative complement pathways by limiting binding of immunoglobulins, complement components, and C-reactive protein to deeper bacterial surface structures. It reduces opsonization with C3b/iC3b and physically impairs interactions between bound C3b/iC3b or Fc regions of immunoglobulins with cognate receptors on phagocytic cells (20, 21). The CPS may also contribute to pathogenesis by inhibiting entrapment of pneumococci in neutrophil extracellular traps (22) and by impeding recognition of Toll-like receptor ligands on the bacterial surface, thereby impairing MyD88-mediated antibacterial defense (23).

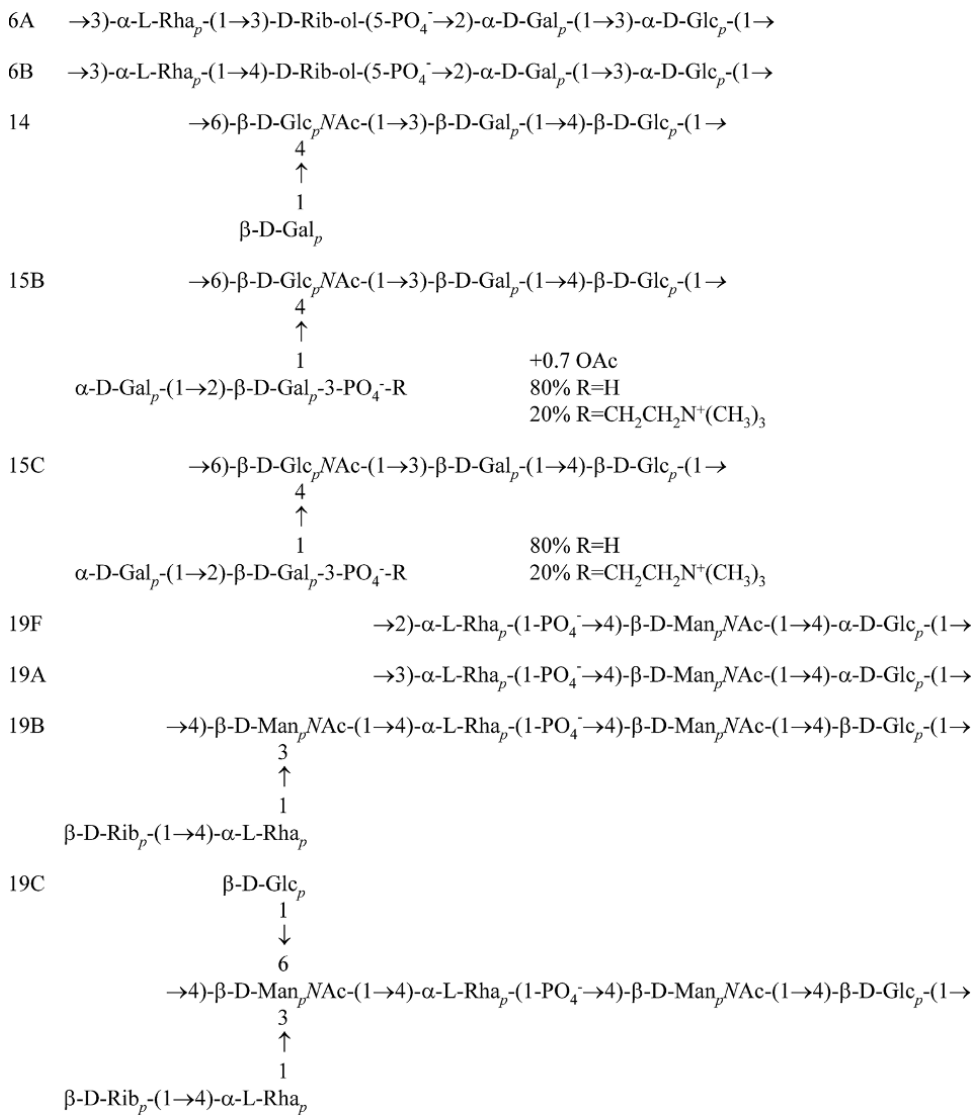

FIGURE 1 Comparison of the CPS biological repeat unit structures of *S. pneumoniae* serotypes 6A, 6B, 14, 15B, 15C 19F, 19A, 19B, and 19C. These are based on published chemical repeat unit structures (9), adjusting for the fact that Glc is the first sugar of the biological repeat unit.

Analysis of a series of mutants producing different amounts of CPS has demonstrated that within a given strain and serotype, the virulence of *S. pneumoniae* is directly related to capsular thickness (24). However, CPS serotypes differ in the efficacy with which they inhibit opsonophagocytosis *in vitro* and in their ability to elicit a humoral immune response (25), which largely correlates with differences between pneumococcal serotypes in their capacity to cause invasive disease (2). Otherwise isogenic pneumococci expressing different CPS serotypes exhibit marked differences in virulence for mice (26, 27), competitiveness in a nasopharyngeal carriage model (28), and efficiency of host-host transmission (29). Capsule-switch mutants expressing CPS serotypes associated with higher rates of invasive disease in humans also bound higher amounts of the alternative complement pathway inhibitor factor H *in vitro* (30). The difference in virulence between pneumococcal serotypes is clearly a function of the biological properties of the CPS itself and is not simply related to the thickness of capsule. For example, type 3 and type 37 pneumococci both produce very thick capsules, but only the former is of high virulence for humans or laboratory animals (2).

CPS-BASED VACCINES

In the immune host, binding of specific antibody to the CPS results in opsonization and rapid clearance of the invading pneumococci. For this reason, a polyvalent pneumococcal CPS vaccine was licensed in the late 1970s. The vaccine provides serotype-specific protection, and the current formulation contains CPS purified from 23 of the 98 recognized serotypes. However, the distribution of *S. pneumoniae* serotypes varies both temporally and geographically. The current vaccine covers approximately 85 to 90% of disease-causing serotypes in the United States and Europe, but in parts of Asia, coverage is <60% (31). Furthermore, serotype prevalence data are scanty for many developing countries, so vaccine coverage is uncertain. The CPS vaccine is protective in healthy adults (against invasive infections caused by those serotypes included in the formulation), but the efficacy is

Downloaded From Vet-eBooks.com

much lower in other groups at high risk of pneumococcal infection, such as the elderly; patients with underlying pulmonary, cardiac, or renal disease; and immunocompromised patients. Efficacy is poorest in young children, for whom the CPS vaccine has little or no demonstrable clinical benefit. Polysaccharides are T-cell-independent antigens and thus are poorly immunogenic in young children. This is particularly so for the five pneumococcal CPS types that were the most common causes of invasive disease in children (32). Poor immunogenicity of polysaccharide antigens can be overcome by conjugation to protein carriers, which converts them into T-cell-dependent antigens, resulting in immunoglobulin class switching, affinity maturation, and memory. A highly efficacious 7-valent pneumococcal PS-protein conjugate vaccine (PCV) was licensed in 2000, followed more recently by 10- and 13-valent formulations (9). These PCVs elicit strong, boostable antibody responses to the included serotypes and provide robust, albeit still strictly serotype-dependent, protection. An unexpected benefit of the high levels of serotype-specific immunoglobulin G generated by PCVs has been reduced acquisition of carriage among immunized children that has lowered overall rates of transmission, thereby protecting unimmunized populations against the included serotypes ("herd immunity") (33, 34). However, the clinical benefit of PCVs is being offset by significant increases in both carriage and disease caused by nonvaccine serotypes (35, 36). These occupy the nasopharyngeal niche vacated by the vaccine types as a direct result of immune pressure from widespread use of PCVs (37, 38). Serotype replacement can result from two distinct scenarios. The first of these is by unmasking of strains belonging to nonvaccine serotypes already being carried in the population at low frequency. Elimination of more competitive serotypes covered by the PCV then allows the numbers of the nonvaccine strains to increase in the nasopharynx, increasing the likelihood of both transmission to others in the community and progression to localized or invasive disease. Alternatively, highly competitive strains whose CPS is included in the PCV may acquire the genes encoding synthesis of a nonvaccine serotype CPS by natural transformation with donor DNA from a nonvaccine strain simultaneously present in the nasopharynx. Such "capsule switching" is discussed in more detail later in this chapter. Regardless of the underlying mechanism, widespread use of PCVs is undoubtedly altering the serotype distribution of pneumococcal carriage and disease, which will necessitate ongoing surveillance with a view to periodic adjustment of PCV formulations.

CPS BIOSYNTHESIS GENES

The frequency of transformation of pneumococci from one CPS type to another observed during the classic studies of Griffith, Avery, and others suggested that at least those genes encoding the serotype-specific components of the CPS biosynthetic machinery were closely linked on the chromosome. Additional genetic and biochemical studies by Austrian, Bernheimer, and colleagues (39, 40) demonstrated that during transformation, CPS biosynthesis genes are transferred as a cassette. Advances in gene cloning and DNA sequencing technology in the 1990s resulted in publication of annotated sequences of the complete genetic loci encoding CPS biosynthesis for several *S. pneumoniae* serotypes and functional characterization of some of the genes therein (41–59). Further advances in high-throughput DNA sequencing enabled publication of annotated sequences for the remainder of the known serotypes by the mid 2000s (60). These studies have provided a sound basis for understanding how the pneumococcus acquired the capacity to synthesize such a vast array of CPS serotypes.

The type 3 locus (designated *cps3* [61] or *cap3* [62]) and the type 19F locus (designated *cps19f* [41]) were the first to be completely sequenced and were shown to be located at the same position in the chromosome, between *dexB* and *aliA* (41–44). The *cps* loci from all other serotypes except type 37 have also been localized to the same position on the chromosome. Type 37 has a cryptic copy of the type 33F *cps* locus located between *dexB* and *aliA*; it contains many deletions and point mutations and is not involved in type 37 CPS production. Instead, type 37 CPS biosynthesis is directed by one gene, *tts*, located elsewhere on the chromosome (54). The mechanism of CPS biosynthesis that occurs in type 37 is similar to that in type 3, and this mechanism is distinct from that in all other serotypes analyzed to date, as described below.

CPS Biosynthesis in Types 3 and 37

Type 3 CPS has a simple disaccharide repeat unit comprising glucose (Glc) and glucuronic acid (GlcA). The *cps3*/*cap3* locus contains only three intact genes, which are transcribed as a single unit (42, 43). The first gene (*cps3D* or *cap3A*) encodes the UDP-Glc dehydrogenase required for the synthesis of UDP-GlcA (63). The second gene (*cps3S* or *cap3B*) encodes the type 3 synthase, a processive β-glycosyltransferase that links the alternating Glc and GlcA moieties via distinct glycosidic bonds (41, 42, 64). There is a significant degree of amino acid sequence similarity between Cps3S/Cap3B and other bacterial polysaccharide synthases, including HasA, which synthesizes the hyaluronic acid capsule of group A streptococci (65). These synthases have a common predicted architecture, with four transmembrane domains and a large central cytoplasmic domain. This latter region is believed to contain two distinct catalytic sites capable of forming the two different glycosidic linkages (66). The final complete gene in the *cps3*/*cap3* locus (*cps3U* or *cap3C*) encodes a Glc-1-phosphate uridylyltransferase. However, Cps3U/Cap3C is not essential for CPS biosynthesis in type 3 pneumococci, because inactivation of the gene has no effect on CPS production (42). This enzyme is also encoded by the *galU* gene, which is located elsewhere in the chromosome, and its product (UDP-Glc) is required for CPS biosynthesis in all pneumococci, regardless of serotype (67).

Type 37 CPS is a branched polysaccharide with a linear backbone of Glc with a monosaccharide Glc side chain, and a single gene, *tts*, is responsible for its biosynthesis. Tts is a processive β-glucosyltransferase, which has sequence similarities to a group of plant and bacterial cellulose synthases, especially to the highly conserved motifs thought to be critical for catalysis and/or binding of UDP-Glc (54). The presence of the Cps3S/Cap3B and Tts synthases is sufficient for type 3 and type 37 CPS production, respectively. However, the expression of type 3 CPS also relies on the capacity of the cell to synthesize UDP-GlcA, which is a substrate for Cps3S/Cap3B (68, 69). CPS synthesized by processive transferases does not need a dedicated export system, because the C-terminal hydrophobic domains of these proteins have been predicted to form a pore in the membrane through which the growing polysaccharide chain is extruded as it is synthesized (66).

CPS Biosynthesis in Other Pneumococcal Serotypes

The CPS structures for most other serotypes are more complex than types 3 and 37, with an oligosaccharide repeat

Downloaded From Vet-eBooks.com

unit consisting of at least three sugars (9). These repeat units may also contain phosphodiester linkages, pyruvate, glycerol, phosphoryl choline, and/or ribitol. In some serotypes one or more sugars may also be acetylated (9). The respective *cps* loci are also much more complex than those of types 3 and 37, which reflects their more elaborate biosynthetic mechanism. The loci vary from approximately 13 to 30 kb in length and consist of from 10 to more than 20 genes that appear to be arranged as a single transcriptional unit (60). Functions for many of the gene products have been determined experimentally, with the remainder assigned on the basis of amino acid sequence similarities with known proteins and with reference to the structure of their CPS repeat unit. The genes in each *cps* locus are arranged in a common block-wise fashion, as shown for a selection of serotypes in Fig. 2. The first four genes (*cpsABCD* [also referred to as *wzg*, *wzh*, *wzd*, and *wze*, respectively (70)]) comprise the 5′ portion of each *cps* locus; their products have all been implicated in the regulation of CPS production and are discussed later. The central portion of each *cps* locus encodes the glycosyltransferases responsible for assembly of oligosaccharide repeat units, the repeat unit transporter (Wzx), and the polysaccharide polymerase (Wzy). The 3′ regions of the various *cps* loci encode enzymes for synthesis of those activated monosaccharide precursors required for CPS synthesis which are not ubiquitous in *S. pneumoniae*, acetyl transferases and sugar modifying enzymes (60).

Biosynthesis of CPS in these serotypes occurs by a Wzx/Wzy-dependent polymerization pathway, analogous to group 1 CPS biosynthesis in *Escherichia coli* and O-antigen assembly in Gram-negative bacteria (71). The initial step involves transfer of a sugar-1-phosphate moiety to a lipid carrier (undecaprenyl-phosphate) on the cytoplasmic face of the cell membrane. In serotypes containing Glc, this step is carried out by the Glc-1-phosphate (Glc-1-P) transferase CpsE/WchA (60, 72). For those serotypes that lack Glc, the first sugar is linked to the lipid carrier by a *cps* locus transferase of the WciI, WcjG, or WcjH homology groups (60), except for serotype 1, where the function is provided by the glycosyltransferase that initiates teichoic acid biosynthesis

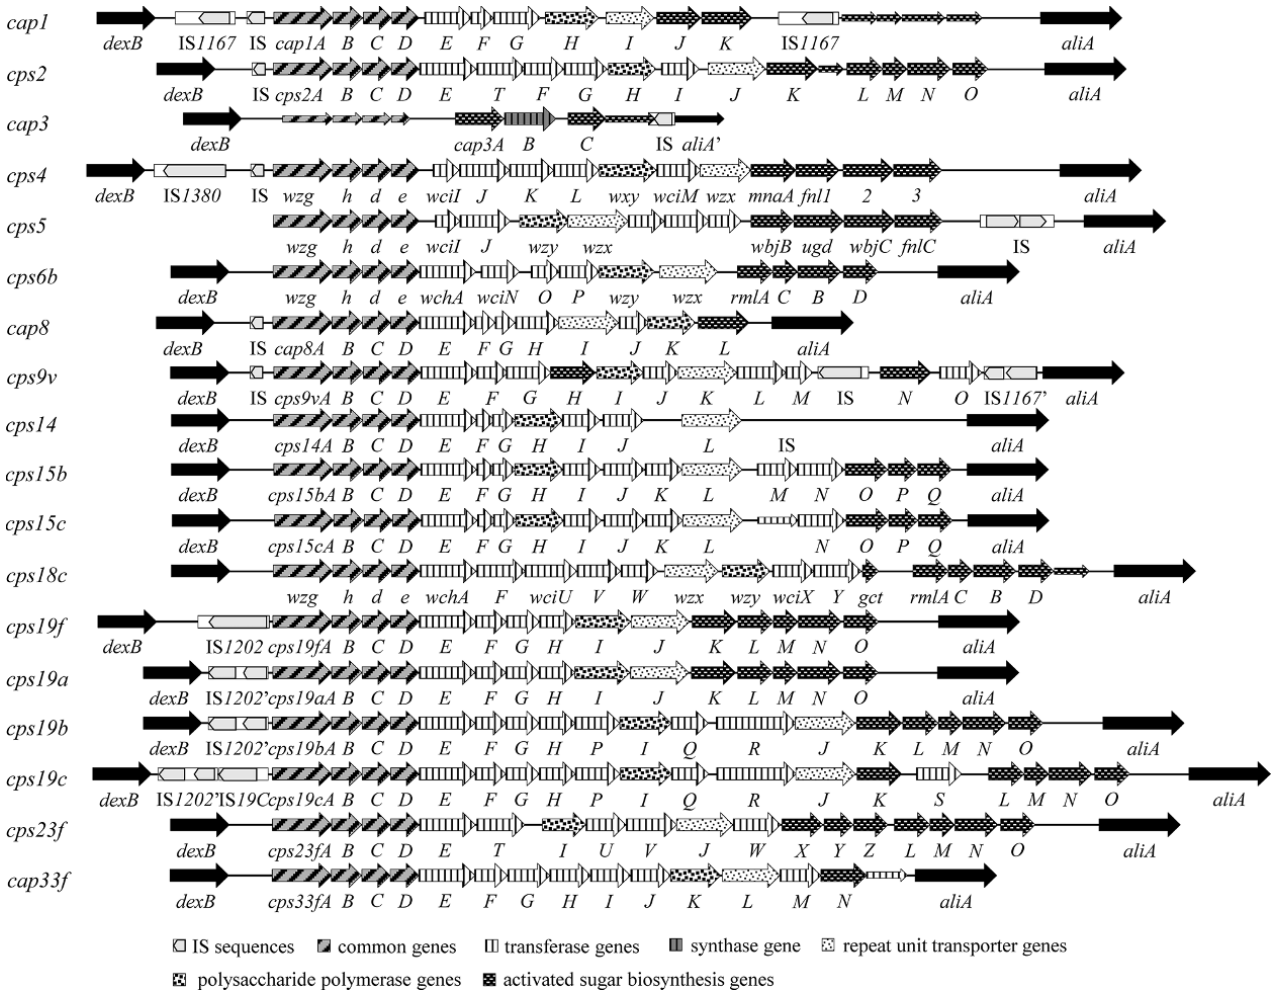

FIGURE 2 Organization of the *cps* loci from selected *S. pneumoniae* serotypes. Gene and locus designations are as published. Open reading frames (ORFs) within the DNA sequence are indicated by large boxed arrows. Highly conserved ORFs, or those encoding proteins belonging to a particular functional group, are identified as shown in the legend at the bottom of the figure. Assignment of an ORF to a given function-related group is based on the published information for each locus as well as on additional database comparisons for some of the ORFs. The short boxed arrows represent cryptic ORFs not required for CPS biosynthesis in the respective serotype.

Downloaded From Vet-eBooks.com

(9). These glycosyltransferases are membrane-associated, which facilitates interaction with the lipid carrier (41). Other glycosyltransferases then catalyze the sequential transfer of the other component monosaccharide precursors (synthesized in the cytoplasm by the activated monosaccharide synthesis genes) to form the polysaccharide repeat unit. These lipid-linked repeat units are then translocated from the cytoplasmic to the extracellular side of the cell membrane by the repeat unit transporter ("flippase") Wzx and polymerized in a block-wise fashion by the polysaccharide polymerase Wzy, extending the polysaccharide at the reducing terminus. The final step involves direct covalent linkage of the reducing end sugar (usually Glc) to the GlcNAc residue of the cell wall peptidoglycan via a 1,6 glycosidic bond (73). There is uncertainty regarding which enzyme is responsible for this linkage. CpsA, a LytR-CpsA-Psr protein family member, has been proposed to play a role (74), but CpsA deletion mutants are not defective in CPS attachment (75). A recent proposal is that Wzy may be a bifunctional glycosyltransferase capable of recognizing both peptidoglycan and CPS as acceptor substrates, thereby catalyzing both polymerization of CPS and its linkage to the cell wall (73).

COMPARISON OF *CPS* LOCI FROM DIFFERENT SEROTYPES

The common genomic location and block-wise arrangement of genes in the *cps* loci (see Fig. 2 for examples) has provided insights into the mechanism of generation of capsular diversity. The first five genes, *cpsABCD* and *cpsE/wchA*, are highly conserved in most *cps* loci, except in serotypes that do not contain Glc in their CPS. These serotypes contain *cpsABCD* but not *cpsE/wchA*, which encodes the initiating Glc-1-P transferase (48, 51, 60, 72). The *cpsCDE* genes exist as two distinct classes, suggesting that all pneumococcal serotypes have evolved from two distinct ancestral *cps* types (51, 60). Within one class, the genes share greater than 95% sequence identity but share only 70% identity with those from the other class. Some serotypes, such as type 4, contain a hybrid *cps* locus, where recombination between a class I and a class II locus has occurred. Additionally, the type 3 and type 37 *cps* loci, which do not require the *cpsA-E* gene products for CPS biosynthesis, still retain defective copies of these class I and class II sequences, respectively, suggesting that they also have a common ancestry with other pneumococci of the same class.

The central part of the *cps* locus is serotype-specific, because it encodes glycosyltransferases which exhibit a high degree of substrate specificity and form distinct glycosidic linkages. Accordingly, serotypes only have transferases in common if they have identical glycosidic linkages between identical sugar moieties in their CPS. For example, closely related glycosyltransferases present in the *cps* loci of types 19F, 9N, and 9V are predicted to join Man*N*Ac via a β(1→4) linkage to Glc (44). This central region also encodes the repeat unit transporter/flippase Wzx and the polysaccharide polymerase Wzy. Closely related polymerase and transporter genes only occur between serotypes with near-identical repeat unit backbones, such as types 19F and 19A, types 19B and 19C, and types 14, 15B, and 15C (51, 52, 59). Recognition of the specificity of these genes laid the foundation for definitive determination of serotype by multiplex PCR rather than by classical serological methods (76), and this has been further facilitated by the availability of sequence data for all CPS serotypes.

Activated monosaccharide synthesis genes, located at the 3′ end of the *cps* locus, are more widely distributed among different *S. pneumoniae* serotypes than genes encoding specific glycosyltransferases. Even so, there is substantial deviation among functional homologues. For example, the genes encoding UDP-Glc dehydrogenases from serotypes 1, 2, and 3 exhibit 60 to 90% amino acid sequence identity to each other. Also, the type 19F and type 4 genes encoding UDP-*N*-acetylglucosamine-2-epimerases are only 66% identical. However, the four genes encoding synthesis of dTDP-rhamnose from Glc-1-P have been shown to be closely related with greater than 95% amino acid sequence identity in all serotypes tested that contain rhamnose in their CPS (44). Interestingly, defective copies of these genes have also been identified at the 3′ end of *cps* loci from serotypes not containing rhamnose in their CPS, such as type 1. Their presence suggests that the ancestor of type 1 pneumococci may have been a serotype containing rhamnose (48).

COMPARISON OF *CPS* LOCI FROM CLOSELY RELATED SEROTYPES

Comparison of *cps* loci of serotypes within group 19 enabled one of the earliest reconciliations of genetics with CPS structure. Serogroup 19 comprises serotypes 19F, 19A, 19B, and 19C, and the structures of their CPS repeat units are shown in Fig. 1. Types 19F and 19A have an identical trisaccharide repeat unit and differ only in the nature of the glycosidic linkage formed during polymerization. Both of these types are important causes of human disease, particularly in young children. Types 19B and 19C are only occasionally associated with human disease; they have more complicated CPS repeat units than types 19F and 19A but differ from each other only by one additional Glc side chain in type 19C. The *cps* loci of all four members of group 19 are closely related (41, 44, 45, 52). Thirteen genes (*cps19A-H* and *K-O*) are conserved in all four serogroup members. Nearly all of the common genes from types 19F, 19B, and 19C are >95% identical to each other, whereas those from the type 19A *cps* locus are more divergent. Although the 19A and 19F loci are identical in terms of the number and arrangement of the genes present, sequence homology between individual *cps19a* and *cps19f* genes varies from 70 to 99% (at both the DNA and the deduced amino acid sequence levels). This sequence divergence is surprising given that only an alteration in *cps19fI/wzy*, such that an α (1→3) rather than an α (1→2) linkage is formed during polymerization of the repeat units, is required to change a type 19F pneumococcus into type 19A (52). This suggests either that the type 19F and 19A loci diverged in the distant evolutionary past or that their component genes originated from different sources.

The type 19B and 19C *cps* loci are nearly identical and contain five genes between *cps19H* and *cps19K* unrelated to the genes in the type 19F and 19A *cps* loci (Fig. 2). These genes encode a repeat unit transporter and a polysaccharide polymerase that are specific for type 19B and 19C CPS, as well as two additional putative glycosyltransferases and an unknown protein that might possibly be involved in synthesis of an activated ribose precursor. These five genes encode all of the functions required to convert a type 19F pneumococcus to type 19B (45). The type 19C *cps* locus differs from the type 19B locus only in the insertion of a putative glucosyltransferase gene (*cps19cS*) between *cps19cK* and *cps19cL* (Fig. 2). The presence of this gene accounts for the additional Glc side chain in the otherwise identical repeat unit structures (Fig. 1).

The structures of the type 6A and 6B CPS repeat units differ only in the linkage between the rhamnose and ribitol moieties (Fig. 1), and as expected, the type 6A and 6B *cps* loci

Downloaded From Vet-eBooks.com

are very closely related (57, 60). The sequences for the genes encoding the rhamnosyltransferase differ only by a few bases and result in very few amino acid changes. However, these changes are clearly sufficient to alter the serotype-determining linkage. Genetic relationships of *cps* loci within serogroups 9, 12, and 15 and other closely related serotypes have been discussed by Bentley et al. (60).

CAPSULAR TRANSFORMATION *IN VIVO*

There is growing evidence that the phenomenon of capsular transformation first observed by Griffith (17) is a common event *in vivo*, even before the widespread introduction of PCVs which provide additional immune selection. Indeed, the *cps* locus has recently been identified as an evolutionary hot spot with elevated rates of recombination and substitution (77). Even before the advent of high-throughput genome sequencing, the application of molecular typing techniques resulted in the detection of otherwise genetically indistinguishable pneumococci expressing different capsular types. This was particularly evident in clonal groups that are resistant to multiple antibiotics. Indeed, derivatives of a highly successful, multiply resistant type 23F clone (which originated in Spain) expressing types 3, 9N, 14, 19A, and 19F capsules were isolated well before the introduction of PCVs (27, 78–80). Examination of sequence polymorphisms in the conserved regions of the *cps* loci for the parental multiresistant type 23F strain and eight otherwise identical type 19F clinical isolates indicated that in each case, the 5′ recombination occurred upstream of *dexB*. In six of the eight type 19F strains, the 3′ crossover point was downstream of *aliA*. However, in the other two, a recombination crossover point between the introduced type 19F sequences and the type 23F chromosome was identified; this was in *cpsM* in one strain and *cpsN* in the other (81). Thus, capsule switching involves the exchange of very large DNA fragments, ranging from at least 15 kb to over 22.5 kb. The existence of multiple crossover points as well as additional minor polymorphisms within the type 19F-derived *cps* genes also indicated that the eight multiply resistant type 19F strains that were studied arose as a consequence of a minimum of four independent transformation events involving different type 19F donors. It therefore appears that these capsule switching events may be relatively common among pneumococci in nature (81). Multiple serotypes of *S. pneumoniae* are frequently carried concurrently in the human nasopharynx (2), providing ample opportunity for exchange of DNA between types. In addition to enhancing the spread of drug resistance among diverse capsular types, these exchanges provide a mechanism for evasion of serotype-specific host immune defenses, such as those resulting from immunization with PCVs, which provide cover against a limited range of serotypes.

Complete or partial insertion sequences have been located adjacent to many of the *cps* loci, and in some serotypes, the locus is flanked at both the 5′ and 3′ ends by such elements. The *cps*-flanking regions appear to be common targets for insertion elements, and this has led to the suggestion that they may play a role in horizontal transfer of *cps* genes (47, 48). There are precedents for this in other bacteria; the *H. influenzae* type b capsule genes, for example, are located on a 17-kb compound transposon (82). However, the identification of crossover points within the *cps* loci of the type 19F derivatives of the multiresistant type 23F *S. pneumoniae* clone referred to above confirms that at least in these cases, capsular exchange occurred as a consequence of homologous recombination rather than by transposition. Nevertheless, Muñoz et al. (48) demonstrated that IS*1167* sequences flanking the *cap1* locus could direct ectopic integration of these genes into copies of IS*1167* located elsewhere in the pneumococcal chromosome, resulting in genetically binary strains.

The contribution of the CPS itself to *in vivo* recombination is somewhat paradoxical. On one hand, dense genomic sampling of carriage isolates in a refugee camp indicated that the highest frequencies of donation and receipt of recombined DNA fragments occurred in nonencapsulated lineages of *S. pneumoniae*, consistent with the capsule acting as a physical barrier to DNA exchange (83). On the other hand, among encapsulated lineages, recombination was positively associated with serotypes expressing larger capsules and extended nasopharyngeal carriage duration (84). The nasopharyngeal environment is particularly conducive to genetic exchange because not only are multiple *S. pneumoniae* strains carried simultaneously, colocalizing donors and recipients, but transformation frequency itself is enhanced in nasopharyngeal biofilms wherein competence genes are upregulated and capsule thickness is reduced (85). However, the complexity and diversity of pneumococcal *cps* loci can be only partially explained by genetic recombination within the *S. pneumoniae* species. Recent studies have demonstrated the presence of intact *cps* loci genes in a wide range of commensal streptococci. The degree of sequence homology indicates that many pneumococcal CPS serotypes have evolved by import of *cps* fragments from commensal *Streptococcus* species, resulting in a mosaic of genes of different origins (86). Such interspecies recombination is now recognized as having an important role in the evolution of pneumococcal *cps* loci and the emergence of new CPS serotypes (77).

REGULATION OF CPS PRODUCTION

Colonization of the nasopharyngeal mucosa is an essential first step in the pathogenesis of pneumococcal disease and involves direct interaction between pneumococcal adhesins and specific receptors on host epithelial cells. In some cases, asymptomatic carriage progresses to invasive disease, and although the events involved are not fully understood, it is clearly a watershed in the bacteria-host relationship. This transition involves a major switch in the expression of important virulence determinants as the pneumococcus adapts to the altered microenvironment (87, 88). Maximal expression of capsule is clearly important for systemic virulence, but the degree of exposure of other important pneumococcal surface structures, such as phosphoryl choline moieties on cell wall teichoic acid and various surface proteins involved in adherence to host cells, may also be influenced by capsular thickness. Nonencapsulated pneumococci exhibit higher adherence to, and invasion of, human respiratory epithelial cells *in vitro* than otherwise isogenic derivatives expressing either type 3 or type 19F capsules (89). Thus, the very feature (encapsulation) that is most important for systemic virulence of *S. pneumoniae* could be disadvantageous during the colonization or cellular invasion phase. Thus, regulation of CPS production is crucial for survival of the pneumococcus in different host environments.

Role of *cpsABCD*

As mentioned previously, the first four genes of the *cps* locus, *cpsABCD* (*wzg*, *wzh*, *wzd*, and *wze*) are common to all pneumococcal serotypes, except types 3 and 37, and deletion of any one of these genes has been shown to affect the level of CPS expression (90). Homologues of *cpsB-D* are found in most Gram-positive capsule loci, but *cps*A homologues have only been identified in the *cps* loci of other members of

Downloaded From Vet-eBooks.com

the genus *Streptococcus*. Interestingly, although CpsA resembles a *Bacillus subtilis* transcriptional attenuator, its homologue in group B streptococci appears to function as a transcriptional enhancer (91). To date, *cpsA* has not been shown to affect *cps* transcription in *S. pneumoniae*. Type 19F and type 2 mutants in which the *cpsA* gene had been deleted produced reduced levels of CPS (approximately two-thirds that of the respective wild-type strains) (14, 90, 92). However, there were no obvious differences in the amounts of CpsB and CpsD proteins detected by Western blotting in any of the strains (90, 93). Nor is there convincing evidence that pneumococcal CpsA catalyzes the linkage of CPS to peptidoglycan, as discussed above. Thus, the precise function of CpsA in pneumococcal CPS biosynthesis or regulation remains uncertain.

CpsB, CpsC, and CpsD collectively constitute a phosphorelay system implicated in modulation of CPS production at a posttranscriptional level. CpsC and CpsD belong to the PCP2b family of polysaccharide copolymerases and were predicted to function together in polymerization and export of CPS in a fashion similar to PCP2a proteins, such as Wzc and ExoP, in the production of CPS and exopolysaccharide in Gram-negative bacteria (41, 71, 94, 95). CpsD has similarities to the C-terminal domain of PCP2a proteins and is an autophosphorylating protein-tyrosine kinase (90, 95). These kinases contain Walker A and B ATP-binding motifs and a tyrosine-rich region at the C-terminus which becomes phosphorylated at multiple tyrosine residues, initially via the ATP-binding domain and also via transphosphorylation which occurs independently of the ATP-binding domain (11, 90, 92). In *S. pneumoniae*, the tyrosine-rich region of CpsD is arranged as an ordered (YGX) motif varying from two to four repeats in different serotypes, with four being the most prevalent. CpsC is a membrane protein with two membrane-spanning hydrophobic domains; the N and C termini are located in the cytoplasm, while the central portion is exposed on the external side of the cell membrane. It has similarities to PCP1/Wzz proteins associated with polymerization of O-antigen in Gram-negative bacteria and to the N-terminal domain of PCP2a proteins (95). CpsC is required for initial CpsD tyrosine-autophosphorylation but is not required for transphosphorylation between CpsD proteins (90). CpsB has been identified as a manganese-dependent phosphotyrosine-protein phosphatase belonging to the PHP (polymerase and histidinol phosphatase) family of phosphoesterases and is required to dephosphorylate CpsD (96). CpsB is also thought to be able to bind CpsD and prevent transphosphorylation between CpsD proteins (11).

Although CpsB, CpsC, and CpsD clearly have a role in modulation of CPS production, the precise manner in which this is achieved remains uncertain, and the situation has been complicated by phenotypic differences between mutants constructed in different strain backgrounds. Indeed, CpsD phosphorylation has been reported to have opposite effects on total CPS production in some studies (90, 93). The capacity of CpsD to cycle between the phosphorylated and dephosphorylated state may facilitate interactions with the polymerization machinery that modulate CPS chain length and cell wall ligation (14, 75, 90, 92, 93). Regardless of its actual role, loss of CPS regulation via phosphorylation of tyrosine in CpsD affects the ability of *S. pneumoniae* to translocate from the lungs into the bloodstream in a murine intranasal challenge model (14). Interestingly, CpsD phosphorylation has been reported to be suppressed by high oxygen concentrations via modulation of CpsB phosphatase activity, which may imply a role in the adjustment of CPS expression between host sites that differ in oxygen availability (97, 98).

Recent advances in cell imaging technologies have provided novel insights into the collective function of the CpsBCD phosphorelay system. CpsC and CpsD have been shown to localize to the division septum in growing pneumococcal cells, and this depends on a functional ATP binding domain in CpsD. In the absence of either CpsC or CpsD, CPS was still produced and linked to the cell surface, but it was absent from the division septum, suggesting that the two proteins are spatial regulators of CPS synthesis (99). Further studies showed that the cytoplasmic C-terminal portion of CpsC required for CpsD autophosphorylation was essential for localization at mid-cell and that the CpsCD complex captures the polymerase Wzy at the division site. Furthermore, dephosphorylation of CpsD impaired both CPS synthesis and cell division itself (100). Collectively, these studies support a model whereby the CpsBCD system ensures that CPS and new cell wall synthesis are colocalized, thereby enabling the newly synthesized cell wall to be promptly masked by CPS to prevent complement deposition at the site (99, 100).

Interestingly, the CpsBCD phosphorelay system has recently been shown to also be capable of phosphorylating and dephosphorylating the major pneumococcal autolysin LytA. LytA amidase activity was stimulated in the phosphorylated state, suggesting a regulatory link between CPS synthesis and LytA-dependent cellular autolysis (101). As mentioned previously, the presence of the pneumococcal capsule significantly impairs both adherence to, and invasion of, epithelial cells *in vitro* (89). However, electron microscopy studies have shown that pneumococci are capable of shedding their capsules at the point of epithelial cell invasion (102). Such capsule shedding is dependent on LytA and protects pneumococci from attack by cationic antimicrobial peptides released in the immediate vicinity by host cells (103). Thus, it may not be a coincidence that the LytA-dependent capsule shedding process is modulated by the CpsBCD phosphorelay (103).

Transcriptional Regulation of the *cps* Locus

The first direct evidence for transcriptional regulation of the *cps* locus in the host environment used quantitative reverse transcriptase PCR (RT-PCR) to show that the level of *cps* mRNA relative to 16S rRNA in pneumococci isolated from the blood of infected mice was approximately 4-fold higher compared to that in pneumococci grown *in vitro* (104). RegM, a homologue of the staphylococcal catabolite control protein CcpA involved in the regulation of sugar metabolism pathways, was also shown to affect transcription of the *cps* locus, suggesting that the carbon source may also influence capsular expression (105).

The *cps* loci are arranged as single transcriptional units in all Wzy-dependent pneumococcal serotypes. The σ^{70} promoter (*cpsp*) is highly conserved, and the transcriptional start site is located about 20 to 30 nucleotides upstream of the initiation codon of the first *cps* gene, *cpsA* (48). The core promoter incorporating the -10 and -35 sequences is essential for *cps* transcription, but sequences immediately upstream also impact the level of transcript (106, 107). The upstream region presumably enables fine-tuning of *cps* transcription, which is necessary for optimal survival of the pneumococcus in diverse host niches (107). Furthermore, sequence polymorphisms in this upstream region result in differences between strains in *cps* transcript levels that correlate with the

Downloaded From Vet-eBooks.com

virulence profile *in vivo* (108). A recent study identified a GntR family transcriptional regulator CpsR (*cps* repressor), which is encoded elsewhere on the chromosome but directly binds to a region of DNA approximately 100 nucleotides upstream of the core promoter and represses *cps* transcription (109). A *cpsR* deletion mutant exhibited enhanced CPS production and systemic virulence in mice relative to the wild type but was attenuated in a nasopharyngeal colonization model (109). Interestingly, *in vitro* binding of CpsR to *cpsp* was competitively inhibited by Glc, leading to increased total CPS expression (109). This provides a mechanism whereby CPS expression could be increased *in vivo* when pneumococci enter the bloodstream, where Glc concentrations are maintained at high levels. The competence response regulator ComE has also been shown to be capable of binding to *cpsp* in its phosphorylated form *in vitro*, and a *comE* deletion mutant exhibited increased CPS production (110). Like CpsR, ComE repression of *cps* transcription was alleviated by Glc, but this effect was mediated by repression of *comE* transcription rather than by interfering with the binding of ComE to *cpsp* (110).

Phase Variation and Quorum Sensing

Pneumococci have been shown to undergo bidirectional phase variation between two distinct colonial morphologies, described as "opaque" and "transparent." The transparent phenotype exhibits increased *in vitro* adherence to buccal epithelial cells and cytokine-activated A549 cells relative to opaque variants of the same strain, as well as an enhanced capacity to colonize the nasopharynx of infant rats (111, 112). On the other hand, the opaque form is associated with massively increased virulence in animal models of systemic disease, and this correlates with increased production of CPS relative to cell wall teichoic acid compared with the transparent phenotype. Phase variation also correlated with alteration in the levels of several surface proteins (113). A recent study has shown that the underlying mechanism involves a type I restriction-modification system (SpnIII) with a genetic locus containing inverted repeats that enable spontaneous rearrangement of alternative specificity domain genes. This generates six different SpnIII target specificities, each with distinct genome-wide DNA methylation patterns, gene expression profiles, and virulence phenotypes (114). Moreover, pneumococci were shown to readily switch between SpnIII alleles during progression of disease in a murine model. Differentially expressed genes included the CPS biosynthesis locus *cps*, various sugar transporters, the Mn transporter *psaBCA*, and *luxS* (114). The *luxS* gene is of particular interest because it encodes synthesis of the ubiquitous quorum sensing molecule autoinducer 2 (AI-2), which is known to be an important regulator of biofilm formation and virulence in pneumococci (115). Recent studies showed that AI-2 accumulating in the extracellular compartment is sensed by the pneumococcal fructose-specific phosphotransferase system component FruA, leading to upregulation of the galactose (Gal) ABC transporter and the Leloir pathway, presumably by phosphorylation of the regulator GalR (116). This entire process is repressed in the presence of Glc. However, Gal is an important carbon source *for S. pneumoniae* in the respiratory tract, where Glc is very scarce, and AI-2-mediated quorum sensing is essential for Gal uptake and metabolism. The Leloir pathway converts Gal to Gal-1-P and then to Glc-1-P, the precursor for all the activated nucleotide sugars required for CPS synthesis. In the absence of Glc, Leloir pathway upregulation increases total CPS production and confers a hypervirulent phenotype *in vivo* (116). Two other proteins involved in sugar metabolism have been shown to affect CPS production. PGM is the phosphoglucomutase, which catalyzes the conversion of Glc-6-P (derived from imported Glc when it is available) to Glc-1-P, and GalU is a Glc-1-P uridylyltransferase that catalyzes the formation of UDP-Glc from Glc-1-P. Pneumococcal mutants in which either the *galU* or the *pgm* genes were disrupted produced almost no CPS and exhibited growth defects (12, 67). Glc-1-P is also a precursor for synthesis of other cellular structures, such as teichoic acid, so limiting the supply of this precursor would be expected to impact heavily on CPS production in the pneumococcus. Indirect modulation of CPS production by controlled availability of precursors or cofactors may be one of the regulatory mechanisms used by the pneumococcus.

CONCLUDING REMARKS

In this article we have summarized the current state of knowledge of the CPS of *S. pneumoniae*, with particular reference to the genes encoding biosynthesis of this most important of all pneumococcal surface antigens. Notwithstanding the insights gained from the elegant classical genetic studies of CPS production carried out before the early 1970s, research in the past 2 decades has been revolutionized by the advent of modern methods for gene cloning, DNA amplification, and high-throughput sequence analysis. The complete nucleotide sequences of the *cps* loci of all of the known serotypes are available, and although the functions of many of the individual genes in these loci await confirmation by conventional biochemical and genetic analysis, access to the enormous body of information on sequence databases now available, combined with knowledge of the chemical structures of many of the CPS repeat units, has enabled accurate predictions of function for a significant proportion of these genes. It has also been possible to predict the mechanisms of CPS biosynthesis in pneumococci by analogy with those operating in Gram-negative bacteria. The existence of two distinct mechanisms of CPS biosynthesis in *S. pneumoniae* has already been recognized. However, much remains to be learned about the precise molecular events involved in both of these processes and about how CPS production is regulated in response to the microenvironmental conditions to which pneumococci are exposed *in vivo*. Given the importance of capsules to the virulence of *S. pneumoniae* and several other Gram-positive pathogens, such conserved components of the CPS biosynthesis machinery may prove to be useful targets for novel antimicrobial strategies. Furthermore, the availability of thousands of complete pneumococcal genome sequences in recent years is providing insights into the continuing evolution of diversity of pneumococcal CPS serotypes, particularly in the face of strong immune selection provided by PCVs. A better understanding of these processes will undoubtedly inform ongoing refinement of pneumococcal vaccination strategies.

Streptococcus pneumoniae: Invasion and Inflammation

ALLISTER J. LOUGHRAN, CARLOS J. ORIHUELA AND ELAINE I. TUOMANEN

20

INTRODUCTION

Streptococcus pneumoniae (the pneumococcus) is a leading cause of otitis media (OM), community-acquired pneumonia, bacteremia, and meningitis. The pneumococcus is a human-specific pathogen which colonizes the nasopharynx and spreads between hosts through aerosols and potentially through the contamination of objects with mucosal secretions if the bacteria is living within a biofilm (1–3). Rates of carriage vary from 5 to 10% of healthy adults to 20 to 40% of healthy children. However, these numbers can vary widely based on where the samples are collected (4–7). Risk factors associated with higher rates of carriage include race (particularly Australian Aboriginals and Native Americans) (8–12), infancy (13, 14), season, with higher carriage during winter months (13), and crowded areas such as childcare centers, with estimates suggesting that 40 to 60% of children who attend childcare are colonized (15). Duration of colonization decreases with age and varies from 2 weeks to 4 months (14, 16, 17). The introduction of pneumococcal conjugate vaccines has reduced carriage rates for serotypes covered by the vaccine, while nonvaccine serotypes have emerged to occupy this empty niche (18). Nasopharyngeal colonization is usually asymptomatic (19).

Invasive pneumococcal disease (IPD) occurs as a result of the spread of bacteria from the nasopharynx to other parts of the body, including the lungs, blood, and brain. Infants, the elderly, and immunocompromised individuals are at an increased risk for developing IPD (20–22). Pneumococcal models of invasive disease must account for not only the commensal nature of the bacteria, but also the wide spectrum of disease the pneumococcus is capable of causing. Colonization is a prerequisite for IPD, and while the incidence of infection is relatively low, high rates of colonization result in extensive morbidity and mortality that is a global concern. Worldwide, it is estimated that *S. pneumoniae* is responsible for 15 cases of IPD per 100,000 people per year (23) and over a million deaths annually. As of 2004, in the United States, it is estimated that the pneumococcus was responsible for more than 1.5 million cases of OM and 800,000 cases of pneumonia (24). Direct medical costs resulting from infections totaled $3.5 billion (24). The World Health Organization estimates that close to half a million children under the age of 5 years die annually as a result of *S. pneumoniae* infection (https://www.cdc.gov/pneumococcal/global.html). Pneumococcal bacteremia and meningitis are also responsible for significant mortality, particularly in the elderly, for whom rates may be as high as 60% and 80%, respectively (25).

In this article, we review the colonization and spread of *S. pneumoniae* from one anatomical site to another. We also discuss the mechanistic basis of inflammation and cytotoxicity resulting from invasive pneumococcal infection.

TRAFFICKING OF PNEUMOCOCCI THROUGH THE RESPIRATORY TRACT

Interactions with Epithelial Cells of the Nasopharynx

For over a century, *S. pneumoniae* has been categorized by serology, with distinct serotypes identified on the basis of the more than 90 immunologically and chemically distinct polysaccharide capsules that surround and protect the bacteria from phagocytosis (26). The capsular polysaccharide (CPS) is also the basis of the current pneumococcal vaccines. Prior to the introduction of the 13-valent pneumococcal conjugate vaccine in 2010, studies found that only a small subset of the many capsular types was responsible for the majority of IPD isolates (27). The vast majority of pneumococci colonize the nasopharynx for up to 6 weeks and are then cleared with no systemic symptoms in the host (1, 28). IPD is thought to occur most frequently early after the acquisition of a new capsular serotype, as evidenced by shifts in the strains most commonly isolated from IPD patients after vaccine introduction (22, 29–31). Furthermore, attack rates are higher for serotypes that are carried for shorter periods of time versus those that colonize for extended periods (28).

S. pneumoniae undergoes spontaneous phase variation alternating between a transparent and opaque colony phenotype which can be visualized microscopically by oblique transmitted light (32). The various phenotypes occupy different niches based on selection, with the transparent phenotype being the predominant phase in the nasopharynx (32), while the opaque phase is isolated from blood samples (33). The transparent phenotype expresses increased amounts of phosphorylcholine (ChoP) (34) and choline-binding protein A (CbpA) on the surface (35), both of which function as adhesins and contribute to the ability of the bacteria to colonize the nasopharynx. The opaque phenotype expresses increased levels of capsule and pneumococcal surface protein A (PspA), which are important factors for survival in the blood. Phase-variation is one of the mechanisms by which the pneumococcus alternates between an

doi:10.1128/microbiolspec.GPP3-0004-2018

Downloaded From Vet-eBooks.com

adhesive phenotype best suited for the nasopharynx and a phagocytosis-resistant phenotype that can survive in the blood.

ChoP decorates the cell wall (Fig. 1) and serves as a docking group for a set of 15 secreted proteins, termed choline-binding proteins (CBPs) (36). Among the CBPs, CbpA is a major pneumococcal adhesin (37) expressed predominantly in the transparent phenotype (35). Pneumococci lacking CbpA are not only largely unable to bind to the nasopharynx, but also have a diminished capacity to colonize the lower respiratory tract and cause pneumonia (35, 38). *In vitro*, CbpA mutants show decreased binding to both nasopharyngeal epithelial cells and activated type II human lung cell lines (37). Similarly, the CBPs LytB, LytC, CbpD, CbpE, and CbpG also contribute to nasopharyngeal colonization when tested in rat pups. LytB functions as a glucosaminidase (39), whereas LytC is a lysozyme (40) and CbpE is a choline esterase; all three enzymes are active on the bacterial cell wall (37). CbpG is a serine protease that in addition to contributing to nasopharyngeal colonization is required for development of high-grade bacteremia (41).

Other virulence factors affecting the capacity of the pneumococcus to colonize the nasopharynx include sIgA1 proteases (42). IgA antibodies are the predominant type found at mucosal surfaces and serve to aggregate and opsonize pathogens. sIgA1 proteases neutralize the activity of sIgA by cleaving the Fc portion of human IgA1 (43). Hydrolyzed sIgA1 also contributes to pneumococcal adhesion. Fab fragments remaining on the surface of the bacteria after sIgA proteolysis neutralize the negative charge of the capsule and enhance adherence (42).

The two-component system CiaR/H is required for efficient colonization and regulates gene expression in response to oxidative stress (44). Among the many genes regulated by CiaR/H is *htrA*. HtrA, or high-temperature requirement A, is a heat-inducible serine protease that has both proteolytic and chaperone activities. HtrA assists in survival in the presence of environmental factors such as oxidative stress, osmotic

stress, and elevated temperatures (45). Deletion of the CiaR/H operon results in a 25-fold decrease in levels of *htrA* expression and a 1,000-fold decrease in the number of bacteria colonizing the nasopharynx. Deletion of *htrA* alone results in a 100-fold decrease in nasopharyngeal colonization, indicating that CiaR/H regulates other factors that contribute to colonization (44). Microarray analysis during bacterial adhesion to epithelial cells *in vitro* has revealed a number of genes with enhanced expression, including CbpA and HtrA (46).

A second regulator important in nasopharyngeal colonization is RlrA, which regulates the transcription of the pilus-1 structural subunit genes *rrg*(A to C) (47, 48). Pili are found in only 20% of *S. pneumoniae* strains but are common in strains belonging to antibiotic-resistant clones (49, 50). Piliated strains show stronger adherence to lung epithelia cells and out-compete nonpiliated strains in mixed infection models (47). Furthermore, introduction of the pilus-1 locus into a nonpiliated strain increased adherence to the lung epithelial cells (47). Pilus-1 expression levels have been shown to change during the different stages of infection, with higher expression during early colonization and lower expression as the disease progresses (51).

Other pneumococcal factors that may aid adherence and colonization of the nasopharynx include PspK, SlrA, and PmpA. PspK, pneumococcal surface protein K, has been suggested to help in the colonization of the nasopharynx in unencapsulated strains by mediating adherence to epithelial cells (52). PspK has also been shown to bind the sIgA but does not appear to be involved in invasion (discussed in further detail below) (53). The surface-associated lipoproteins SlrA and PpmA have both been shown in mutagenesis studies to be important for nasopharynx colonization, but they do not appear to play a significant role in invasive disease (54, 55).

Another strategy employed by the bacteria to colonize and remain in the nasopharynx is formation of a biofilm. While the specific role of biofilm formation in pneumococcal infection is not well understood, it confers increased resistance to antimicrobial peptides and may promote sharing of genetic information between the bacteria as a result of proximity (56). Although bacteria in a biofilm are often metabolically dormant, when they are dispersed, they may be more virulent. Bacterial release from a biofilm can be triggered by changes in the microflora, inflammation, or viral infection (57). These released pneumococci were found to be phenotypically different from planktonic or biofilm bacteria and had an increased ability to disseminate and cause infection (58, 59). These release events represent a potential switch between asymptomatic colonization and invasive disease.

Ascension into the Middle Ear

OM is a highly prevalent pediatric disease and the primary cause of physician visits by small children. As many as 80% of children have presented with at least one case of OM (60). Along with *Moraxella catarrhalis* and *Haemophilus influenzae*, the pneumococcus is a primary cause of OM and is isolated in 30 to 40% of culture positive middle ear infusions (61–63). OM is thought to result when pneumococci in the nasopharynx ascend the eustachian tube and gain access to the middle ear (Fig. 2). Alternatively, it has also been suggested that OM is caused by the blocking of the eustachian tube resulting in a decrease of oxygen and increased dampness on the middle ear surface. While the mechanism is disputed, the transition from colonization of the nasopharynx to OM strongly correlates with accompanying viral infection (64). Typically, OM presents with earache, fever, nasal congestion, a feeling of fullness in the ear, and muffled hearing.

The ability of *S. pneumoniae* to ascend the eustachian tubes involves neuraminidases (61, 65). *S. pneumoniae* encodes two neuraminidases, NanA and NanB, with NanA being the major neuraminidase (66, 67). Neuraminidases cleave *N*-acetylneuraminic acid from glycoproteins and glycolipids on the eukaryotic cell surface. Neuraminidases can also cleave mucin, reducing the viscosity of this barrier and permitting the bacteria to access the epithelium. At the epithelium, neuraminidase cleaves oligosaccharides on the host cell surface, exposing cryptic receptors and enhancing bacterial adherence (66, 67). Support for this mechanism is seen in chinchilla infection models whereby clearance of a neuraminidase-deficient mutant occurs twice as quickly as wild-type *S. pneumoniae*. Furthermore, structural changes in the cell surface carbohydrates of eustachian tube epithelial cells occur following infection with wild-type pneumococci compared to its isogenic *nanA* mutant (68, 69).

Once the pneumococcus is in the middle ear, inflammation is triggered by pneumolysin and cell wall components (70). Pneumolysin is a potent pore-forming toxin that directly kills host cells and activates complement. In addition, cell wall components activate Toll-like receptor (TLR) signaling and the alternative pathway of complement. Pneumolysin strongly contributes to hearing loss and cochlear damage during OM (71, 72). Guinea pigs infected with wild-type *S. pneumoniae* or a mutant deficient in neuraminidase demonstrated significant damage to the reticular lamina, sensory hair cells, and supporting cells of the organ of Corti. Guinea pigs infected with a pneumolysin-deficient mutant had no visible damage. The contribution of pneumolysin and cell wall to inflammation will be discussed in more detail later in this article.

CbpA/pIgR-Mediated Invasion in the Upper Respiratory Tract

Once attached to epithelial cells, the pneumococcus is able to translocate across the mucosal barrier by coopting the polymeric immunoglobulin receptor (pIgR) (73). Mucosal epithelial cells transport IgA and IgM in a vesicle moving from the basolateral to the apical surface by binding to pIgR. On the apical surface, pIgR is cleaved and immunoglobulins are secreted into the lumen. Cleaved pIgR is subsequently shuttled back to the basolateral surface (74). *S. pneumoniae* translocates through epithelial cells by hijacking pIgR on the apical side of the host cell, resulting in transport as the receptor is endocytosed and recycled to the basolateral surface (Fig. 3). The pneumococcus binds to pIgR by ligating the motif YRNYPT of CbpA (75). *In vitro*, CbpA alone is sufficient to mediate translocation across a cell as latex beads coated with CbpA are endocytosed (73). *In vivo*, this interaction manifests as decreased nasopharyngeal colonization in mice lacking pIgR and the reduced capacity for *S. pneumoniae* mutants lacking CbpA to enter the bloodstream (76).

Accessing the Lower Respiratory Tract

Development of pneumonia is contingent on the ability of *S. pneumoniae* to establish a lower-respiratory-tract infection despite host defenses that either kill or clear the aspirated bacteria. The first barrier is the mucociliary escalator, which works mechanically to keep aspirated particles and microorganisms out of the lungs. As is true for many respiratory viruses, neuraminidase plays an important role in initiating bacterial pneumonia. As indicated, neuraminidase-deficient

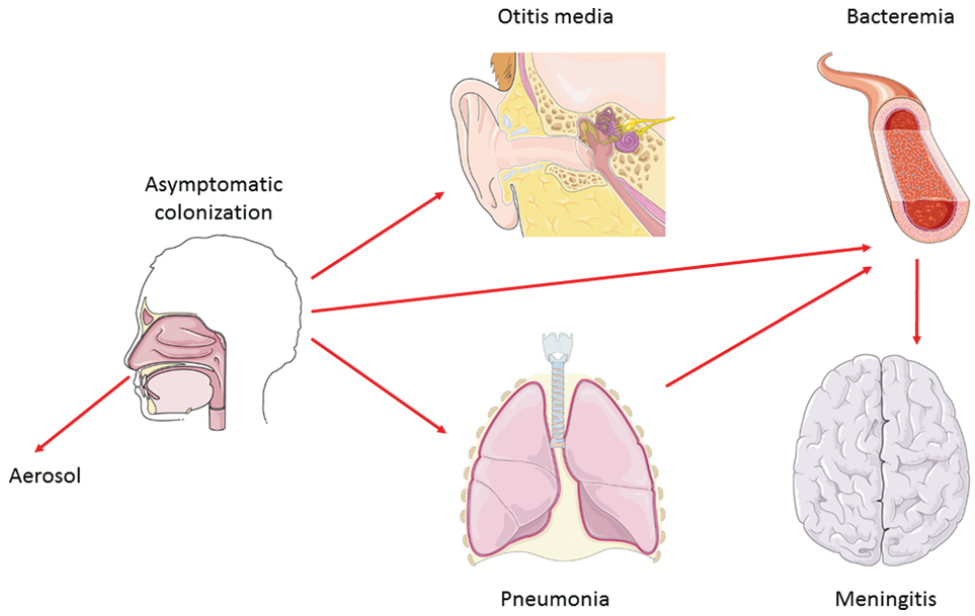

FIGURE 2 Schematic depiction of the spread and progression of *S. pneumonia* infection. Carriage of the pneumococcus occurs in the nasopharynx and is usually asymptomatic in healthy individuals. The bacteria are spread by aerosol from the nasopharynx of carriers. The pneumococcus can spread from the nasopharynx to a number of different tissues. In children the bacteria usually causes otitis media. Invasive diseases generally start in the lungs and spread to the blood, with the most serious complication being meningitis. The switch from asymptomatic colonization to invasive disease in healthy individuals usually occurs when there is a disruption in the innate immune defenses. (This figure contains some artwork produced by Servier Medical Art [http://smart.servier.com/] under Creative Commons license 3.0).

pneumococci do not cleave mucin efficiently and have a diminished capacity to adhere. Mutants deficient in *nanA* have a reduced capacity to bind to chinchilla tracheas *ex vivo* (77) and are attenuated in their ability to cause a lower-respiratory-tract infection following intranasal challenge (38).

The second step in adjusting to the environment of the lung involves changes to the bacterial surface that promote bacterial adherence to epithelium. The respiratory epithelium produces copious antibacterial peptides that kill bacteria on contact. Recent evidence indicates that pneumococci counteract this defense by shedding capsule, which results in relative resistance to the killing by antimicrobial peptides (78). This process is driven by the bacterial autolytic enzyme, LytA. Although LytA has long been known to promote autolysis in response to antibiotics, this new role of the enzyme drives capsule loss without bacterial lysis. Loss of capsule permits a close interaction of the bacteria with host cells, leading to successful initiation of infection.

Pneumococcal adhesion to eukaryotic lung cells is a two-step process that initially entails a loose interaction with host cell surface glycoconjugates followed by a tighter, more secure interaction with host cell protein receptors that promote internalization. During the initial stages of infection, *S. pneumoniae* and other respiratory tract pathogens such as *Pseudomonas aeruginosa* and *H. influenzae*, bind to *N*-acetylgalactosamine β1-3 galactose (79). Neuraminidases cleave the sialic acid and expose *N*-acetylgalactosamine β1-3 galactose and other ligands on the host cell surface (69, 80). The efficient removal of sialic acid by neuraminidases can be reduced by the amount and position of acetylation on sialic acid. It is thought that the major pneumococcal esterase, EstA, deacetylates the sialic acid and increases the release of sialic acid by NanA (81). *In vitro*, pneumococci adhere more efficiently to tissue culture cells treated with neuraminidase (77). The synergism observed in a pneumococcus and influenza coinfection may be the result of enhanced adherence mediated by neuraminidase activity (82). It has long been known that influenza primes the lungs for the development of a secondary bacterial infection. This synergism has been successfully modeled in mice, where pretreatment with influenza readily enhances severe pneumococcal pneumonia, leading to death despite challenge with a dose that is usually insufficient to infect an otherwise healthy mouse (83–85). Mechanistically, superinfection likely occurs as a result of neuraminidase expressed by influenza stripping sialic acid from the mucosa and exposing bacterial receptors. Oseltamivir, a neuraminidase inhibitor, has been shown to prevent pneumococcal superinfection in this postinfluenza pneumococcal challenge model (86).

Interactions in the Alveoli

As pneumonia progresses, the respiratory epithelium is denuded, exposing the underlying extracellular matrix of the bronchioles and alveoli. Surface-bound bacterial proteins such as PepO, PavA, PavB, PfbA, PclA, and PsrP all contribute to attachment through interactions with the extracellular matrix (87–90). Once established in the alveoli, inflammation is particularly intense, resulting in consolidation of the affected lobes. Consolidation progresses through stages of engorgement and red hepatization during which capillaries and epithelial cells become inflamed, and fluid and erythrocytes accumulate in the alveoli in a fibrin mesh (red hepatization). Subsequently, the lungs darken (gray

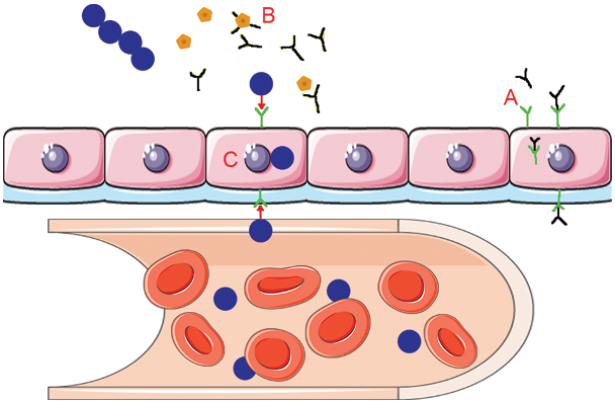

FIGURE 3 Schematic representation of the pneumococcus hijacking the pIgR/IgA system to cross the mucosal epithelia into the blood. (A) Mucosal epithelial cells transport IgA (black) from the basolateral to the apical surface using the receptor pIgR (green). This receptor is then endocytosed and recycled back to the basolateral surface to transport more IgA. (B) To protect itself from IgA, the pneumococcus produces the protease sIgA1 (yellow), which cleaves the host IgA into Fab fragments. (C) The choline-binding protein, CbpA (red), binds to the empty pIgR and shuttles the pneumococcus from the apical side to the basolateral side of the epithelial cells. (This figure contains some artwork produced by Servier Medical Art [http://smart.servier.com/] under Creative Commons license 3.0).

hepatization) as leukocytes enter the lesion and the bacteria are engulfed by macrophages. Resolution continues for several days as capsule-specific antibodies provide efficient opsonization and inflammatory mediators dissipate (91).

Pneumococcal cell wall, pneumolysin, and hydrogen peroxide are the virulence determinants that mediate the greatest inflammation and cytotoxicity observed in the lungs (92–94). Challenge of mice with purified pneumolysin or cell wall TLR ligand products is sufficient to cause edema and influx of neutrophils that recapitulate pneumonia (95, 96). Multiple studies clearly demonstrate that deletion of the genes that encode autolysin, pneumolysin, or the enzyme that produces hydrogen peroxide greatly attenuate the ability of the bacteria to survive and replicate in the lungs (38, 92, 94, 96–98). The contribution of these virulence products is discussed in greater detail below.

INVASION OF PNEUMOCOCCI INTO THE BLOODSTREAM

Access to the Bloodstream

During red hepatization, infected alveoli overflow with bacteria, edema fluid, and erythrocytes wrapped in a fibrin mesh. Fibrin strands pass through interalveolar connections, also known as the pores of Kohn, from one alveolus to the next, and the lymphatics are dilated and filled with cells and fibrin. When infection reaches this stage, a mouse becomes bacteremic. Access to the bloodstream by *S. pneumoniae* may occur through several pathways, including via the lymphatics, via cell damage to the epithelial and endothelial cells, and via direct invasion of endothelial cells. Most likely, all three pathways contribute to bloodstream invasion in an infected animal.

Although the pneumococcus can directly invade cells, this occurs at relatively low efficiency compared to bacterial pathogens that are commonly thought of as invasive, such as *Salmonella* and *Shigella* species (99). Invasion is dependent on activation of the host cell by pneumococcal cell wall components and pneumolysin and results in *de novo* expression of host defenses such as platelet activating factor receptor (PAFr), C3, and other factors. PAFr, a receptor abundant on lung cells, recognizes ChoP on its natural ligand, the chemokine PAF. The surface of the bacterium mimics this by decorating the cell wall with ChoP. CV-1 origin SV40 (COS) cells expressing PAFr have been shown to bind more bacteria than COS cells not expressing PAFr (99). Studies have also colocalized PAFr with adherent bacteria on the surface of human cells (100). PAFr binding is not limited to the pneumococcus; other respiratory pathogens such as *Haemophilus* spp., *Neisseria* spp., and *Pseudomonas* spp. also express ChoP on their surfaces in a phase-variable manner (101, 102). The pneumococcus can also bind the PAFr on other tissues (103, 104). In defense against the widespread expression of ChoP on respiratory pathogens, the host deploys C-reactive protein, an acute-phase reactant that activates complement and opsonizes the bacteria (105). Thus, phase variation of the amount of surface-bound ChoP serves as a mechanism by which the pneumococcus switches from a more adherent form (high ChoP) suited for the mucosa to one that is more resistant to phagocytosis (low ChoP) and well adapted to the bloodstream.

Unlike PAF, the binding of pneumococcus to the PAFr does not result in the activation of a G-protein-mediated signal transduction pathway (100). Rather, pneumococcal uptake requires activation of extracellular signal-regulated kinases consistent with activation by β-arrestin. Uptake of the pneumococcus into a vacuole involves clathrin followed by recruitment of β-arrestin scaffold, Rab 5, and then Rab 7 and Rab 11. Rab 5 is involved in early endocytosis, Rab 7 is found in the late endosome, and Rab 11 is responsible for vacuole recycling (106). Overexpression of arrestin in endothelial cells enhances colocalization of the bacteria with Rab 7 and Rab 11 and increases survival of the pneumococci normally killed by the lysosome. Thus, it is currently thought that association of β-arrestin with the PAFr vacuole complex contributes to the successful translocation of the bacteria away from the lysosome (100).

The pilus-1 system may also be employed in the escape from the lungs and peritoneal cavity into the bloodstream. RrgA, the major adhesive determinant of the pilus, has been shown to facilitate the spread of the bacteria to the bloodstream (107). RrgA binds the complement receptor 3 on macrophages and increases intracellular survival (107). The severity and progression of disease were shown to be affected in mice lacking complement receptor 3 and suggests that phagocytosis by macrophages may facilitate the spread of infection to distal sites (107). This theory is possibly further supported by the fact that ubiquitously expressed pneumococcal protein PepO may lead to an increase in macrophage phagocytosis (108).

Recently, a new macropinocytosis pathway was described that is independent of the PAFr and does not require ChoP (109). This pathway relies on actin interactions with the uptake vesicle independent of dynamin, clathrin, and caveolin (109) and represents a potential alternative pathway for bacterial translocation. However, without the requirement of ChoP it could be used by a wider group of bacterial pathogens. In model systems, roughly half of adherent pneumococci enter epithelial cells via micropinocytosis and half via PAFr. Thus, while the pneumococcus is the prototypical extracellular pathogen, intracellular translocation is an important part of its pathogenesis.

Survival in the Bloodstream

Once the bacteria escape into the bloodstream, CPS becomes the most important virulence determinant and is responsible for inhibiting phagocytosis. The chemical structure (serotype) and amount of CPS present on the surface of the bacteria contribute to the differential ability of different serotypes to survive in the blood (110–113). Mutants lacking capsule are essentially avirulent (111), requiring 10,000- to 100,000-fold more bacteria to kill a mouse than the encapsulated parent strain following intraperitoneal injection. It is believed that CPS inhibits phagocytosis by preventing phagocytes from physically reaching opsonizing serum components, such as complement, C-reactive protein, mannose-binding proteins, and antibodies that are deposited on the cell wall and by giving the bacteria a negative charge which repels a close association with leukocytes (32, 114, 115). Formation of antibody to the serotype-specific CPS marks the initiation of clearance of the infection, because antibodies to CPS are highly opsonic and are protective against subsequent pneumococcal challenge with the same serotype (116). The fact that capsular antibodies are so effective forms the basis of current effective pneumococcal vaccines.

Pneumococcal proteins also contribute to resistance to defenses in the serum. PspA has been demonstrated to inhibit complement activation mediated via the classical pathway on the bacteria surface (117, 118). Mutants deficient in PspA are cleared more rapidly from the bloodstream of XID mice compared to wild-type mice. XID mice lack the ability to form an antibody response to polysaccharides, and thus, clearance correlates with the amount of complement on the bacterial surface (119). PspA also protects bacteria from the bactericidal peptides of apolactoferrin; blocking PspA with antibodies enhances apolactoferrin killing (120). CbpA also has the ability to inhibit complement deposition by binding to C3 which blocks C3 cleavage and by binding to factor H (121, 122). PspA allows the bacteria to reduce C3 deposition, whereas factor H, a negative regulator of the alternative pathway, leads to interference in the formation of the C3 convertase. Factor H can also be bound by the pneumococcal surface protein Tuf (123). Furthermore, resistance to opsonophagocytic activity of neutrophils is mediated through the action of the exoglycosidases NanA, BgaA, and StrH, which decrease the amount of C3 being deposited onto the pneumococcal surface (124).

TRAFFICKING OF PNEUMOCOCCI INTO THE HEART, BRAIN, AND FETUS

Interactions with the Heart

Once in the bloodstream, pneumococci disseminate widely into many organs by the binding of bacterial CbpA to endothelial laminin receptor and ChoP to the PAFr. For instance, a common complication of severe bacterial pneumonia is cardiac dysfunction. Pneumonia and cardiac events may be closely associated with heart disease predisposing people to pneumonia or, potentially, pneumonia increasing the risk of heart disease; further studies are needed (125). Bacteremia delivers pneumococci to the cardiac vascular endothelium, where CbpA/laminin receptor-mediated translocation into the cardiac tissue occurs. In mice and nonhuman primates, cardiac damage ensues in the form of microscopic lesions in the myocardium (126, 127) caused by the release of pneumolysin and H_2O_2, with added pathology resulting from the influx of immune cells (126, 128). Immunization of mice with the CbpA protects the animals from cardiac damage (126). Importantly, pneumococcal cell wall products are also inhibitory to cardiac contractility (129), as is pneumolysin, which disrupts Ca^{++} signaling due to pore formation even if cells are not immediately killed (130). Once in the heart of the mouse, the bacteria use clathrin-mediated endocytosis to invade cardiomyocytes (131). Interaction between the pneumococcus and the heart is an emerging field.

Interactions at the Blood-Brain Barrier

Pneumococcal meningitis is by far the most devastating complication of IPD. Some estimates suggest that approximately one-third of affected individuals die (132–134) and half of the survivors suffer from permanent neurological sequelae (135–137). Severe damage occurs in the hippocampus, particularly in the dentate gyrus, with survivors suffering from hippocampal atrophy and defects in learning and memory (138). Neuronal damage is, in part, mediated by the response of the host defenses to bacterial products (139); for example, cell wall components are detected by host cells, and the influx of leukocytes leads to extensive inflammation (140, 141). Inflammation in the cerebrospinal fluid (CSF) exacerbates neuronal damage by releasing matrix metalloproteases such as MMP-9 (142), neurotoxic free radicals such as peroxynitrate (143), and proinflammatory cytokines that recruit more leukocytes (141). Ultimately, the overexuberant host response triggers caspase-dependent and -independent apoptosis of neurons (139). Blocking leukocyte entry into the CSF duringmeningitis decreases damage by approximately 50% (144, 145) and as such is the basis for treating individuals with pneumococcal meningitis with dexamethasone prior to antibiotic therapy. The other half of neuronal damage is directly due to cytotoxic compounds such as pneumolysin and hydrogen peroxide that damage the mitochondria and initiate apoptosis (146). These factors are reviewed later in the article. The extent of the host response to damage can be seen by the fact that introduction of purified cell wall alone into the CSF can lead to signs and symptoms of meningitis and ultimately to neuronal damage (147).

Pneumococcal invasion from blood into the CSF is thought to occur either in the choroid plexus or by crossing the blood-brain barrier in the cerebral capillaries that traverse the subarachnoid space. The pneumococcus is thought to initially bind to the blood-brain barrier endothelium through interactions of the NEEK motif of CbpA with the laminin receptor (148). Such binding to the laminin receptor is a common strategy of meningeal pathogens, including *H. influenzae*, meningococcus, prions, and several viruses. Studies with mice have determined that once bound to the endothelium, translocation across the barrier is dependent on the interaction between ChoP and PAFr (148–151). PAFr knockout mice were resistant to development of meningitis (100). Likewise, CbpA mutants were unable to cross the blood-brain barrier despite bacterial titers in the blood of 10^8 CFU/ml (38). Thus, the two-step process of recognition of laminin receptor on the cerebrovascular endothelium by homologs of CbpA followed by translocation across the barrier using surface ChoP binding to PAFr is a conserved process of invasion of the central nervous system that is shared by the most successful meningeal pathogens.

Interactions with the Placenta and Fetus

PAFr is found on a number of tissues, including the placenta during pregnancy. Infection and inflammation during pregnancy were shown to lead to postnatal cognitive deficiencies

Downloaded From Vet-eBooks.com

in a number of studies reviewed by Loughran et al. 2016 (103). The pneumococcus itself does not cross the placenta to the fetus. However, fragments of cell wall released during antibiotic treatment cross the placenta in a PAFr-dependent manner and accumulate in the developing fetal cortex in mice. Rather than neuronal death, as seen in postnatal meningitis in mice, the fetal brain responds with an increase in neuroproliferation (104). Neuroproliferation is increased by interfering with the levels of the cytostatic transcription factor FoxG1 as a result of cell wall interaction with TLR2. The abnormal brain architecture is associated with behavioral abnormalities in the postnatal period in mouse models. This leads to the possibility that bacterial products encountered during pregnancy may be associated with cognitive disorders in children.

INFLAMMATION AND CYTOTOXICITY

Intense inflammation is a hallmark of pneumococcal disease, and the pneumococcus serves as a prototype for understanding the molecular mechanisms of inflammation in response to Gram-positive bacteria (152, 153). Inflammatory components released by the pneumococcus include peptidoglycan, teichoic acid, pneumolysin, hydrogen peroxide, and a number of other secreted proteins. Alone, several of these factors have been shown to trigger inflammation and are cytotoxic (see above). In concert, these factors trigger inflammation through multiple inflammatory cascades, including the TLR pathway, the chemokine/cytokine cascade, the complement cascade, and the coagulation cascade. In a naive host lacking serotype-specific antibodies, these cascades hasten the accumulation of leukocytes, which are ineffective in phagocytosing pneumococci coated in capsule. The increased white blood cells at the site of infection lead to an even greater release of proinflammatory mediators without efficient clearance of the bacteria.

Inflammation

The key surface component recognized by the innate immune system is the cell wall (Fig. 4). The pneumococcal cell wall is composed of the peptidoglycan network with teichoic acid attached to roughly every third *N*-acetylmuramic acid residue (154). When tested in animals, peptidoglycan and teichoic acid can elicit inflammation and recapitulate many of the symptoms of pneumonia, otitis media, and meningitis (147, 152, 155). Although CPS is effective in protecting the bacteria, the CPS itself is not inflammatory (156). Components of the bacterial cell wall can mediate inflammation through multiple pathways. At the cellular level, peptidoglycan and teichoic acid bind to pattern recognition molecules such as lipopolysaccharide-binding protein and peptidoglycan recognition proteins. These complexes in turn bind to TLR-2 on the surface of epithelial and endothelial cells, monocytes, and macrophages (157, 158). Cross-linking of TLR-2 triggers intracellular signaling that activates transcriptional regulators such as NF-κB. NF-κB expression then results in production of proinflammatory cytokines such as interleukin-1β (IL-1β), IL-6, IL-8, and tumor necrosis factor (159). Nod receptors in the cytoplasm may also modulate inflammation by binding to intracellular peptidoglycan (160, 161). The importance of Nod receptor activation for resolution of the infection is supported by the need for the expression of the chemokine receptor CCR2 to efficiently recruit macrophages to the site of infection for bacterial clearance (162). Activation of epithelial and endothelial cells results in recruitment of effector cells such as neutrophils and macrophages, altered vascular permeability, and creation of a serous exudate.

Cell wall components not only cause inflammation through interaction with cells but also activate several complement pathways. Antibodies specific to bacterial proteins on the cell surface activate the classical pathway (117). Similarly, CPS and cell walls bind to hydrolyzed C3 and activate the alternative complement pathway (156, 163, 164). The classical and alternative pathways result in release of C3a and C5a, both of which are chemoattractants and potent anaphylactic molecules leading to inflammation. Cell wall also activates complement via the lectin-binding pathway. Mannose-binding lectin, a member of the collectin family, binds to carbohydrates such as *N*-acetyl-glucosamine, a constituent of peptidoglycan (165). The binding of mannose-binding lectin to the bacterial cell results in the formation of a C3 convertase on the surface of the bacteria and deposition of C3b. Mannose-binding lectin deficiency is associated with an increased risk of invasive pneumococcal infection (166). Finally, C-reactive protein bound to cell wall ChoP also activates the classical complement cascade by binding C1q (167). This results in additional opsonization and further release of the C3a and C5a. Pneumococcal PepO can disrupt this process by binding to C1q, increasing bacterial survival (168). However, PepO expression in the lungs has been suggested to trigger release of the chemoattractant IL-8 and IP-10, which leads to neutrophil recruitment and contributes to the host response pathology (169).

Complement activation is not limited to the surface of the bacteria; cell wall fragments released by the bacteria following lysis and during cell wall turnover are also capable of activating complement (170). Likewise, pneumolysin released into the milieu also activates complement (171). Pneumolysin binds to the Fc portion of immunoglobulins and activates the classical pathway. It has been suggested that cell wall components, pneumolysin, and other proteins such as PepO are released by the bacteria to deplete complement (168, 172, 173). This would have the most direct impact during blood stream infections and in the lungs. Release of cell wall components is mediated by the murein hydrolase, LytA. LytA is responsible for pneumococcal lysis in the stationary phase as well as in the presence of antibiotics (174). Furthermore, it has been shown that LytA is important for the release of capsule in response to antimicrobial peptides found on the epithelial surface (78). Autolysin-mediated lysis is responsible for the spike in inflammation observed immediately following antibiotic treatment of meningitis. Autolysin-negative mutants may have reduced virulence compared to the wild type as a result of the inability of the mutant to release cell wall (CW) or the inability to shed the capsule, leaving the bacterium sensitized to the antimicrobial peptides (78, 175).

Although complement is crucial for the opsonization of the bacteria, it also leads to the formation of the membrane attack complex (MAC) formed through the action of C5, C7, and C9, which form a hole in cellular membranes in a fashion similar to pneumolysin. The pneumococcal glycolytic enzyme phosphoglycerate kinase has been shown to inhibit MAC formation by blocking C9 polymerization (176). Gram-positive bacteria, such as *Streptococcus*, are also in general more resistant to MAC killing than their Gram-negative counterparts since they lack an outer membrane, leaving MAC to form on the thick peptidoglycan wall.

Cytotoxicity

In addition to the pathology derived from inflammation, the pneumococcus can directly damage eukaryotic cells. The principal mediators of cytotoxicity are pneumolysin and

Downloaded From Vet-eBooks.com

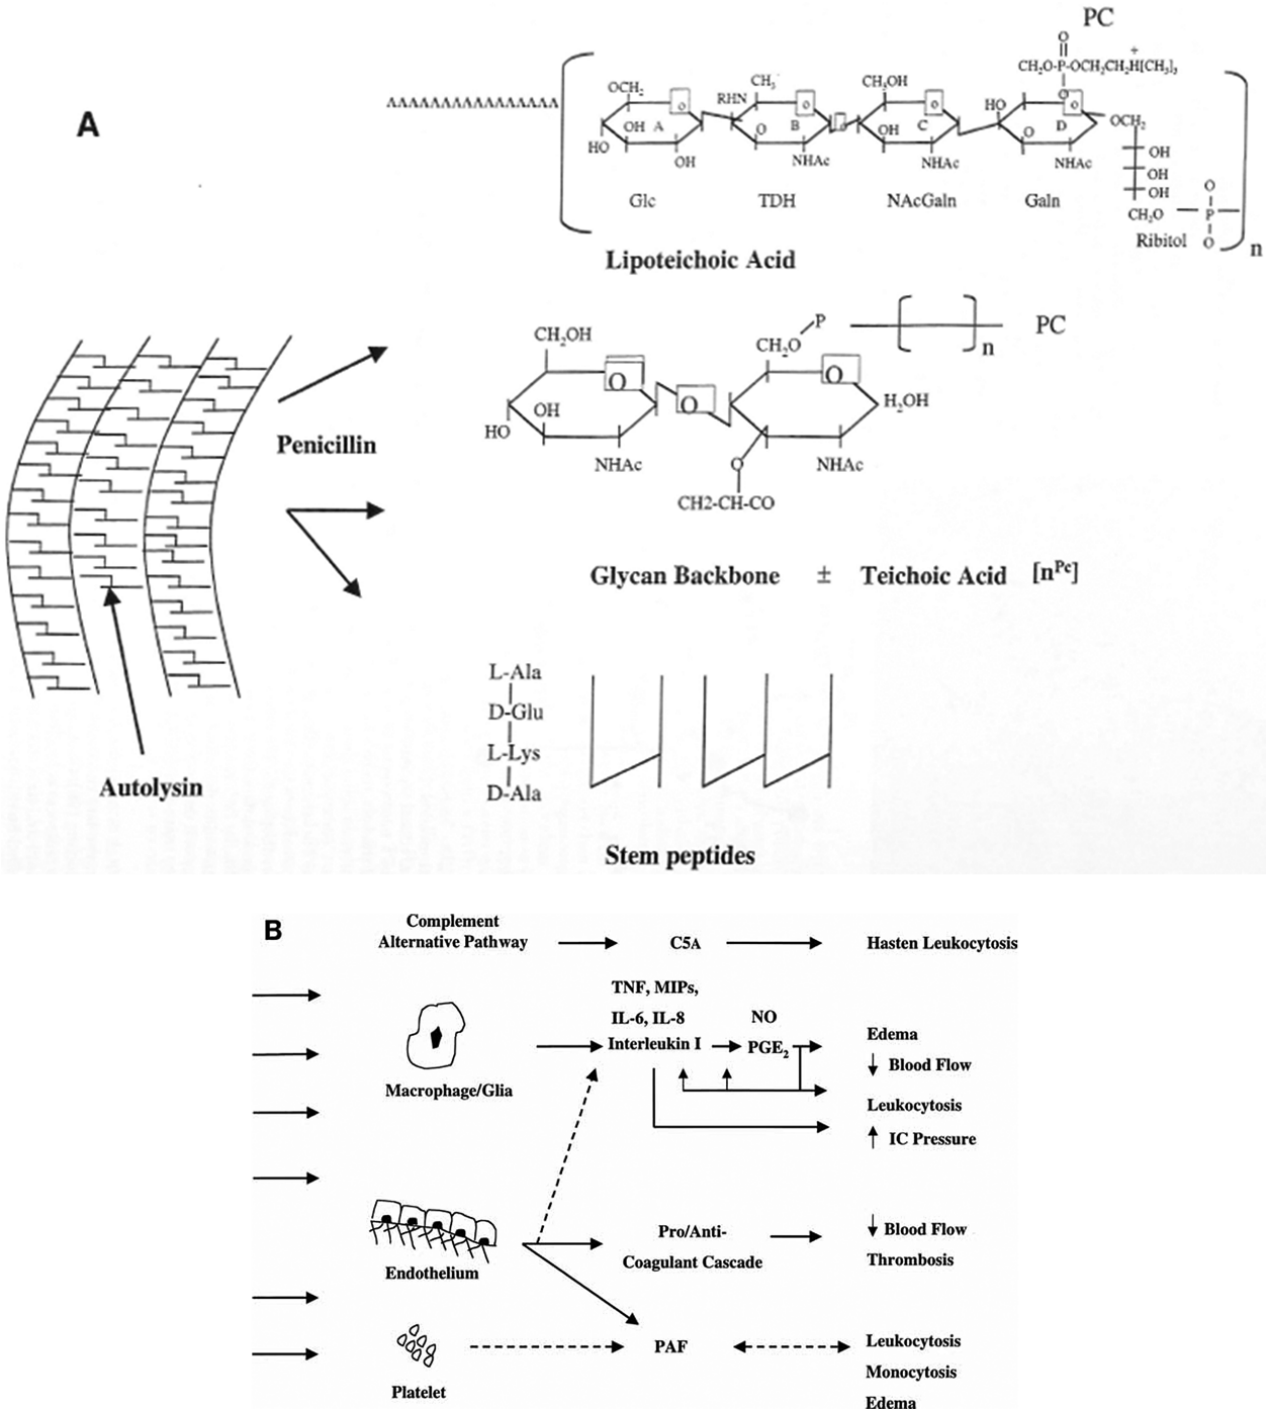

FIGURE 4 Structure of the pneumococcal cell wall and its relationship to inflammation. (A) Penicillin induces cell wall degradation by the autolysin releasing cell wall fragments such as lipoteichoic acid, glycan polymers with and without teichoic acid, and small stem peptides. All teichoicated species contain ChoP, a key component increasing inflammatory activity. (B) All of these components interact with a variety of human cells, which in turn produce inflammatory mediators. Particularly important in this response is the platelet activating factor (PAFr). These mediators combine to produce the symptomatology of pneumococcal infection, including changes in blood flow, fluid balance in the tissue, and leukocytosis. Glc, glucose; TDH, trideoxyhexose; NAcGaln, *N*-acetylgalctosamine; Galn, galactosamine; L-Ala, L-alanine; D-Glu, D-glucose; L-Lys, L-lysine; TNF, tumor necrosis factor; NO, nitric oxide; PGE2, prostaglandin E2; IC pressure, intracranial pressure; MIPS, macrophage inflammatory protein.

hydrogen peroxide (72, 92, 93, 146, 177). Pneumolysin has long been recognized as a principal virulence factor of the pneumococcus (Fig. 5). Studies using a variety of challenge routes and animal models have convincingly demonstrated that pneumolysin-deficient mutants are drastically attenuated (38, 92, 96, 177). The mechanism responsible for pneumolysin secretion from the bacteria is poorly understood. While it was initially thought that pneumolysin was

Downloaded From Vet-eBooks.com

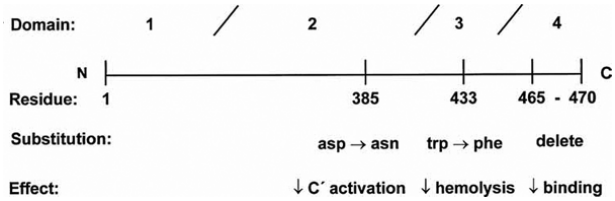

FIGURE 5 Domain structure of pneumolysin. Pneumolysin has three functionally separate domains: one activating complement, one causing hemolysis, and the other binding to cholesterol. Site-specific mutations alter these properties individually (191, 192).

only released as a result of autolysis (178), it has also been shown to have an independent route, because mutants lacking the autolytic enzyme, LytA, show the same pattern of release as the wild-type bacteria (179, 180). Pneumolysin is a pore-forming toxin that kills cells via necroptosis, a programmed mode of necrosis. At high concentrations, pneumolysin, like other pore-forming toxins, triggers necroptosis due to ion dysregulation (181, 182). Critically, pneumolysin-mediated cell death has been shown to be preventable using drugs that block RIPK1, RIPK3, or MLKL, the signaling pathway involved. The toxin binds to cholesterol on the surface of the host cell and oligomerizes to form pores as large as 30 nm in diameter (183). This results in Ca^{++} and K^{+} dysregulation. At lower concentrations, the toxin has a variety of effects on different cell types. Pneumolysin has been demonstrated to slow ciliary beating of epithelial cells (184), disrupt tight junctions (185), and inhibit the capacity of neutrophils and macrophages to kill by inhibiting oxidative burst (186, 187). Disruption of the alveoli-capillary barrier contributes to the leakage that allows serous exudates to enter the lungs and the bacteria to cross into the blood stream (188). In the middle ear, pneumolysin is responsible for damage to the cochlea and hair cells, contributing to hearing loss (72). During meningitis, pneumolysin causes neuronal damage mediated by an influx of extracellular calcium triggering apoptosis (146). Chelating extracellular calcium inhibits the release of apoptosis inducing factor (AIF) and protects cells from pneumolysin-induced apoptosis *in vitro*.

Hydrogen peroxide (H_2O_2) is a major product of pneumococcal metabolism and damages host tissues. H_2O_2 is the result of the activity of the enzyme pyruvate oxidase (SpxB), which decarboxylates pyruvate to produce acetyl phosphate, H_2O_2, and CO_2 (38, 97). Mutation of *spxB* dramatically attenuates virulence in the respiratory tract but not in the blood stream (38). Studies of the cytotoxic effects of H_2O_2 are not as comprehensive as those for pneumolysin. Nonetheless, H_2O_2 also contributes to mitochondrial damage of neurons, resulting in apoptosis (146), and inhibits beating of ciliated ependymal cells lining the ventricular system of the brain and cerebral aqueducts (189, 190). It is also required for cardiac damage (131).

CONCLUDING REMARKS

The ability to invade and cause pathology in such varied organ systems while also avoiding killing by the immune system makes *S. pneumoniae* a highly successful pathogen. Asymptomatic colonization allows the pneumococcus to persist in the population, and extensive serotype diversity complicates the development of effective vaccines. The successful invasion strategy of ChoP/PAFr and CbpA/laminin receptor shared by a number of major respiratory pathogens coupled with cytotoxic pneumolysin makes the pneumococcus a prototypic pathogen for studying host pathogen interactions.

Phase Variation of *Streptococcus pneumoniae*

JING LI AND JING-REN ZHANG

21

INTRODUCTION OF PHASE VARIATION

Phase variation, a type of phenotypic variation, refers to reversible, ON-and-OFF production of a molecule, structure, or complex characteristic (1). Since Andrewes' description of "diphasic salmonellas" (2), the first report of phase variation in bacteria, phase variation has been discovered in many bacteria, particularly pathogens. Our current understanding of the genetic and molecular basis of phase variation is almost entirely based on the studies of virulence determinants. Examples include variable generation in surface proteins (3–5), fimbriae/pili (6), flagella (7–9), capsule (10, 11), modification of lipopolysaccharides and lipooligosaccharides (12–14), and colony morphology (15–17). This type of phenotypic variation in pathogenic bacteria permits the selection of variants with optimal adaption or fitness in an individual host or distinct host environment. Phase variation is particularly common in Gram-negative pathogens, such as *Escherichia coli*, *Salmonella typhimurium*, *Haemophilus influenzae*, *Campylobacter jejuni*, and pathogenic *Neisseria* (18).

Phase variation is also reported in several Gram-positive bacteria. In *Staphylococcus* spp., previous studies have shown variations in the expression of polysaccharide, intercellular adhesin (19), colony morphology (20), biofilm/biofilm associated protein (21, 22), and antibiotic resistance (23). The bistable expression of pilus has been described in *S. pneumoniae* and *Streptococcus gallolyticus* (24–27). The gene encoding the virulence factor InlA of *Listeria monocytogenes* is also prone to frameshift in its 5′ homopolymeric tract of adenine nucleotide, leading to the ON-and-OFF expression of the protein (28). The variation in colony morphology has been documented in numerous *Streptococcus* spp. (29–31), but the switch in colony opacity of *S. pneumoniae* represents the best-characterized case (see below).

The vast majority of the well-described phase variations are caused by one or combinations of the following four major mechanisms: DNA inversion, homologous recombination, slipped-strand mispairing, and differential DNA methylation (illustrated in Fig. 1).

Variation by DNA Inversion

The Hin recombinase-catalyzed inversion in *S. typhimurium* is the first report of the genetic/molecular mechanisms behind bacterial phase variation. In the context of the "diphasic salmonellas" observation (2), Zieg *et al.* (32, 33) first discovered that the Hin recombinase drives reversible switch of the orientation of the flagellin promoter sequence and alternates the transcription of two flagellin-encoding genes, thereby leading to switch in the biochemical and antigenic characteristics of the flagellum. Similar but more complex DNA-inversions of the promoter-associated sequences have since been identified to drive phase variation in the type 1 fimbriae of *E. coli*. The orientation of the promoter sequence of *fim*A, the structural gene of type I pilin, is capable of DNA inversions, which are catalyzed by two independent tyrosine recombinases, FimB and FimE (6). FimB catalyzes the reactions in both directions, whereas FimE drives the inversion from the "ON" to the "OFF" orientation (34, 35). Promoter sequence inversions are also responsible for phase variation in the polysaccharide antigens of *Bacteroides fragilis* (36–38) and surface proteins of *Mycoplasma* species (4, 39, 40). Lastly, bacteria regulate the frequency of DNA inversion as an adaptive response to environmental conditions. It has been demonstrated that the inversion frequency of the *fim*A promoter is modulated by temperature, media, sialic acid, and nutrient availability (41–43).

Variation by Programmed Homologous Recombination

The phenotypic switch between the piliated and nonpiliated phases of *Neisseria gonorrhoeae* represents one of the best-characterized cases in this category. *N. gonorrhoeae* possesses a transcriptionally active *pilE* locus for producing the pilin of the *N. gonorrhoeae* type IV pilus and homologous *pilS* (transcriptionally silent) sequences located elsewhere in the genome. The RecA-dependent homologous recombinations between the *pilE* and *pilS* sequences sometimes truncate the 5′ region of *pilE*, leading to the production of "nonfunctional" *pilE* alleles, inactive pilin, and ON-to-OFF variation of the pilus structure. However, further recombinations of the nonfunctional *pilE* alleles with the *pilS* sequences may yield a functional *pilE* allele, giving rise to an OFF-to-ON (piliated) variant of the bacterium. Similar programmed homologous recombinations have been described for phenotypic variations of surface-exposed proteins in pathogenic *Borrelia* spp. (44–46).

Variation by Slipped-Strand Mispairing

The vast majority of the well-described phase variation cases are mediated by slipped-strand mispairing (18). This type of phase variation is always associated with the sequences containing homopolymers (stretches of the same nucleotides) or

doi:10.1128/microbiolspec.GPP3-0005-2018

Downloaded From Vet-eBooks.com

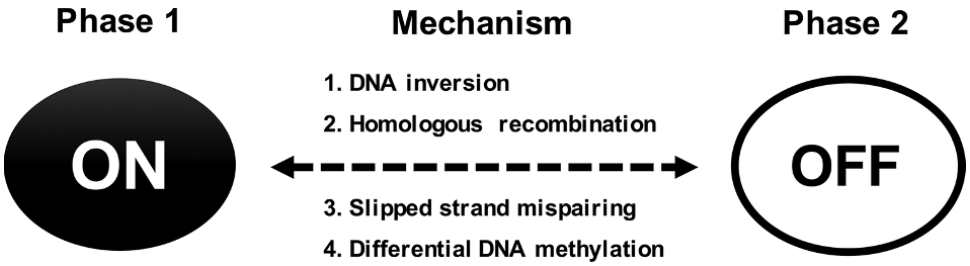

FIGURE 1 Overview of the major mechanisms behind reversible ON-and-OFF phase variation in bacteria.

multimeric repeats. These sequences are prone to transient mispairing during DNA replication, leading to insertion or deletion of one or multiple nucleotides/repeat sequences in the genome of the progeny cells. Mispairing in the promoter and coding sequences may alter transcription of downstream gene(s) and translation (frame shifting) of target genes, respectively. Sequence addition or deletion in the stretch of the cytosine bases adjacent to the promoter region of the *opc* gene is responsible for the ON-and-OFF switch of the Opc outer membrane protein in *N. gonorrhoeae*. While the variants with 12 or 13 bases in the poly(C) tract produce the maximal level of Opc (Opc++ phenotype), those with less than 10 or more than 15 bases fail to produce the protein (Opc– phenotype). Interestingly, the cells with 11 or 14 cytosines in the tract produce an intermediate level of *opc* mRNA and Opc protein (Opc+ phenotype). A similar mechanism of strand slippage also governs the variation in the LKP fimbriae of *H. influenzae*. Tandem repeats of teichoic acid bases in the sequence immediately upstream of the promoter region control the transcription of the *hif* gene cluster, which encodes the LKP fimbriae. The *hif* transcription and fimbriae production reach the maximum when there are 10 teichoic acid repeats. In contrast, the variants with 11 and 9 copies of the di-nucleotides produce reduced and undetectable fimbriae, respectively. Therefore, slipped-strand mispairing not only controls the ON-and-OFF variation, but also regulates the volume of the target molecules.

Disrupting the reading frames of the coding sequences by slipped-strand mispairing causes phase variation in many bacteria. One of the well-characterized examples is the ON-and-OFF variation in the outer membrane protein II of *N. gonorrhoeae* (47). The coding region of its signal peptide contains variable copies of the CTCTT; alteration in the number of tandem repeats leads to frameshifting of the P.II gene. The capsule variation in *Neisseria meningitides* occurs by frameshifting of the *siaD* capsule gene due to expansion and contraction of the poly(C) tract (10). In Gram-positive bacteria, the variable number of the TTTA tetranucleotide repeat appears to be responsible for the phase variation of poly-*N*-acetylglucosamine expression in *Staphylococcus aureus* (19). Reversible expansion and contraction in the number of repeat sequences was also reported in the capsule biosynthetic genes of *S. pneumoniae* (48–50); these events cause an ON-and-OFF switch in the enzymatic activity of the corresponding proteins, leading to phase variation in capsule production.

VARIATION BY DIFFERENTIAL DNA METHYLATION

Methylation status of bacterial genomes represents an epigenetic mechanism that modulates expression of certain genes and associated phenotypes (51–53). Phase variation in P fimbriae of uropathogenic *E. coli* is one of the best-studied examples of this kind (54). *E. coli* cells exhibit reversible phase variation of P fimbriae under certain conditions. This phenotypic switch is determined at the transcriptional level by different methylation patterns of the GATC loci in the promoter region of the fimbriae biogenesis gene (*pap*) locus. Similar methylation-dependent phase variation occurs in the expression of outer membrane protein-antigen 43, which is important for biofilm formation and pathogenesis of *E. coli* (55).

Phase variation also occurs in the DNA methyltransferase (Mod) genes of type III RM systems, also referred to as phasevarions (53). It is controlled by expansion and contraction of nucleotide repeats in the *mod* genes. The ON-and-OFF switch in the production of DNA methyltransferases leads to corresponding alteration in the methylation pattern of bacterial genomes. In *H. influenzae* (56), *Helicobacter pylori* (57), and pathogenic *Neisseria* (58), phase variation in the *mod* genes is associated with changes in stress response and virulence. We and others have recently discovered a complex epigenetic mechanism of phase variation in the type I RM systems of *S. pneumoniae* (52, 59, 60). A series of DNA inversions among homologous *hsdS* genes (encoding the sequence specificity subunit of the RM system) generate HsdS variants, each of which recognizes a unique DNA methylation sequence. Because the HsdS subunit defines the sequence specificity of DNA methylation in the type I RM systems, DNA inversions in the *hsdS* genes generate progeny cells with distinct patterns of genome methylation in an originally clonal population. One of the *hsdS* alleles defines the opaque colony morphology, while the pneumococcal variants with the other alleles produce transparent colonies (52) (see below). This DNA inversion in the *hsdS* genes thus combines the power of DNA rearrangements and differential methylation in phase variation.

PHASE VARIATION OF *S. PNEUMONIAE*

S. pneumoniae has been reported to undergo phase variation in colony opacity, encapsulation, and expression of the type I pilus. As the most important virulence factor of *S. pneumoniae*, polysaccharide capsule protects the organisms from mucosal agglutination and phagocytic killing (61, 62). However, like the immunogens of the current pneumococcal vaccines, the capsular polysaccharides are immunoprotective against pneumococcal disease (63). Besides extensive genetic variation of capsule types by natural genetic transformation, pneumococcus is able to switch between the encapsulated and unencapsulated states. Frequent variation in capsule production was first described in a type 3 strain (48). Reversible sequence

Downloaded From Vet-eBooks.com

duplications/deletions in the coding region of the first gene (*cap3A* or *cps3D*) of the type 3 capsule biosynthetic locus is responsible for frameshifting of *cap3A* and the acapsular phenotype. Additional sequence changes in the promoter and coding regions of *cap3A* were later found to cause reversible capsule ON-and-OFF variation (49). Similar capsule variants were later reported in type 8 and 37 strains (50), which are generated by expansions and contractions of repetitive sequences in the capsule biosynthetic genes *cap8E* (type 8) and *tts* (type 37), respectively. Because CapE (the first monosaccharide transferase) is conserved in the strains of other serotypes, this type of variation may occur in other types of pneumococcal capsule.

Independent studies have shown that the pilus of *S. pneumoniae* undergoes bistable expression or phase variation (25, 27). The pilus has been shown as an important contributor to pneumococcal pathogenesis (64, 65), although it is only produced by approximately 25% of strains (66). Immunization with pilus subunits confers protection against lethal pneumococcal challenge (67). The type I pilus consists of a main structural protein (RrgB) and two ancillary proteins (RrgA and RrgC). Transcription of *rrgA*, *rrgB*, *and rrg*C requires activation by the RlrA regulator (26). Basset *et al.* showed that phase variation in the pilus is controlled by an epigenetic mechanism, which is based on autoregulation of *rlrA* by a positive-feedback loop (26). The impact of the pilus phase variation on pneumococcal pathogenesis remains to be defined.

In 1994, Jeffery Weiser's laboratory first reported that single *S. pneumoniae* strains produce both opaque and transparent colonies on translucent agar plates supplemented with exogenous catalase (16). The opaque and transparent variants produce both types of colony when they are restreaked on agar plates. Visualization of phase variation in pneumococcal colony opacity requires careful examination of colony morphology with oblique, transmitted light and magnification on translucent medium (16). Under these conditions, differences in the ability of bacterial cells to pack tightly in a colony affect how light passes through the colony and the level of opacity. The variation appears to exist in all strains, but it is more readily appreciable in some isolates of certain serotypes. While strains of types 6A, 6B, 14, 19F, 23F, and 35B tend to yield easily observable opaque and transparent colonies, isolates of types 2, 3, and 4 do not form appreciable colony variants (52). In addition, different strains require different amounts of time for optimal visualization of colony variants (52, 68). We observed that the polysaccharide capsule of serotypes 2 and 4 blurs the phenotypic difference between the colony variants for an unknown reason (52). However, phase variation in colony opacity does not require the capsule because unencapsulated pneumococci also form both opaque and transparent colonies. Opacity variation is obscured on nontranslucent medium, such as blood agar. It is possible to detect sectored colonies resulting from phase variation during the clonal expansion of a single organism as it forms a colony. The frequency of switching is highly variable from isolate to isolate (range 10^{-3} to 10^{-6}/generation) under the same conditions. Likewise, the fraction of the opaque and transparent variants in a single isolate can differ dramatically, likely due to selection or induction by the environmental conditions. Microscopic analysis of the low-passage clinical isolates reveals that the single isolates from the middle ear produce a remarkably higher proportion of opaque colonies compared with those from the nasopharynx (69). The reasons for these types of site-specific effects remain to be defined.

CHARACTERISTICS OF PNEUMOCOCCAL OPACITY VARIANTS

Variation in Capsular Polysaccharides

The biochemical comparison of pneumococcal variants has focused on two major cell surface structures, the capsular polysaccharide and the C polysaccharide, or cell wall teichoic acid. Relatively small differences in the amount of capsular polysaccharide have been shown to have a major effect on the ability of the pathogen to cause infection (70). The opaque and transparent variants of the same strains are indistinguishable using type-specific antiserum in a Quellung reaction, suggesting that their capsules are antigenically identical. Immunoelectron microscopy demonstrated a larger and denser zone of immunoreactive capsular material in opaque pneumococci (71). Quantification of the capsular polysaccharides with type-specific monoclonal antibodies showed that opaque pneumococci have 1.2- to 22-fold more capsular polysaccharides than the related transparent variants depending on the strains tested (72). Production of capsular polysaccharide in the variants appears to be modulated by environmental conditions because the opaque variants produced significantly more capsule under conditions of reduced oxygen (73).

Variation in Cell Wall Polysaccharides

Opacity variation in unencapsulated pneumococci suggests that differences in the amount or composition of the capsule are not the sole factor responsible for phenotypic variation. The choline-containing cell wall teichoic acid and lipoteichoic acid (pneumococcal Forssman antigen) are the major carbohydrate-containing surface structures on the cell surface (74). Choline, which is imported exclusively from the extracellular environment, is essential for the growth of both transparent and opaque variants. It is estimated that approximately 90% of the choline incorporated into cells is localized to the cell wall teichoic acids, with the remainder in the lipoteichoic acid, which is anchored in the plasma membrane (75). Analysis of choline incorporation revealed that transparent variants incorporated 3- to 8-fold more of the radiolabel choline per cell in the cell wall teichoic acids compared with opaque variants of the same strain (16). This finding was confirmed by multiple immuno-assays (76, 77). Additional evidence that the teichoic acid structure mediates changes in colony opacity comes from mutational analysis of the genes involved in choline incorporation. *S. pneumoniae* contains two copies of *licD*, shown in *H. influenzae* to function as an nucleotide diphosphate-choline transferase, which correlates with the expression of two choline residues/teichoic acid repeat units (78). Loss of *licD2* was associated with decreased uptake of radiolabeled choline and an altered colony phenotype.

These findings suggest that either the structure of the teichoic acid or the amount of teichoic acid per cell is subject to variation, since the only significant reservoir of cellular choline is the teichoic acids. Differences in teichoic acid structure could account for these observations if the amount of choline per teichoic acid chain varied owing to either differences in the average number of repeating units per chain or the number of choline residues per repeating unit. Either of these differences in structure would be expected to affect the size distribution of teichoic acid chains. Western blots using TEPC-15 showed a ladder-like array of doublet bands, which represents chains with differing numbers of repeating units (77). The opaque and transparent variants displayed the same

Downloaded From Vet-eBooks.com

pattern in the migration of each chain or in the average chain length. However, the intensity of reactivity for each band was greater for the transparent variant. This observation suggests that the higher amount of choline in transparent pneumococci is a result of increased teichoic acid chain units per cell rather than variation in structure or average number of repeating units per chain. Since the cell wall-associated teichoic acid is covalently attached to the muramic acid in the peptidoglycan and only a fraction of the muramic acids appear to be linked to a teichoic acid chain, the differences in the amount of teichoic acid may reflect more muramic acid residues with teichoic acid chains in transparent pneumococci.

Variations in Proteins

The relationship of several previously identified cell surface proteins to opacity variation has been examined. The role of cell lysis or autolysis in this phenomenon was considered because of several observations: (i) opaque colonies are dome shaped, whereas transparent colonies are umbilicated after equivalent incubation conditions; (ii) electron micrographs of organisms grown under identical conditions revealed that there was breakdown of the cell wall structures only in the transparent cells (16); (iii) opaque organisms undergo spontaneous lysis more slowly and are more resistant to the detergent deoxycholate (79). Autolysis occurs once the bacteria reach stationary phase through the enzymatic degradation of the cell wall primarily by the major murein amidase, LytA (an autolysin). Differences in rates of autolysis could result from variations in the peptidoglycan substrate or the expression of the amidase. The hydrolysis of purified cell walls of opaque and transparent organisms as determined by high-pressure liquid chromatography analysis of stem peptides released by treatment with amidase was indistinguishable (80). This result made it unlikely that differences in autolysis could be attributed wholly to variations in the cell wall. Consistent with relatively faster autolysis in transparent variants, they also showed a higher amount of LytA in immunoblotting detection. Mutants in which the *lytA* gene has been interrupted have altered colony morphology but are still capable of displaying phenotypic variation. This indicated that autolysin is only one of the factors that contribute to phase variation in colony opacity.

Other surface proteins are associated with opacity variation. PspA, a choline-binding protein and one of the major pneumococcal cell wall-anchored proteins (81), is present in greater quantities in opaque variants (72). PspA binds to lactoferrin (82, 83) and contributes to systemic pneumococcal infection in mice by inhibition of complement activation (81, 84). In contrast, CbpA, another choline-binding protein, is more abundant in transparent variants. CbpA, also known as PspC (85) or SpsA (86), binds to an array of host molecules such as secretory immunoglobulin A (86), polyimmunoglobulin receptor (87), complement factor H (88, 89), and complement component C3 (90). It is required for pneumococcal colonization in the nasopharynx of infant rats (91). More recently, analysis of the pneumococcal genome sequence has revealed a number of additional genes whose translation products have sequences related to the choline-binding domain (92, 93). Thus, the family of choline-binding proteins may be more extensive, and differences in their expression on the cell surface seem likely considering the variation in the choline anchor.

Microarray analysis has revealed 24 genes with significantly different expressions between opacity variants of independent strains (94). Among the 21 genes with increased expressions in the transparent variants, 11 are predicted to be involved in sugar utilization, including at least 2 sortase-anchored surface exoglycosidases. Seven of these genes are located in a single locus of pneumococcal genome, including the gene encoding the neuraminidase NanA. NanA is able to desialylate human airway glycoconjugates, such as human lactoferrin, secretory component, and IgA. These host factors bind to the surface of the pneumococcus *in vivo* during pneumococcal pneumonia. The efficiency of desialylation was increased several fold in the transparent variants and enhanced for host proteins binding to the surface of *S. pneumoniae*. Since deglycosylation affects the function of many host proteins, NanA may contribute to a protease-independent mechanism to modify bound targets and facilitate enhanced survival of the bacterium during colonization. Other gene products known to vary with colony opacity did not show differences in mRNA levels in the microarray analysis, suggesting that transcriptional regulation is not the primary mechanism controlling opacity phenotypes.

Using high-resolution two-dimensional protein electrophoresis, Overweg *et al.* showed that compared with transparent variants, the opaque variants overexpress one protein and underexpress two proteins (95). The protein overexpressed in the opaque variants is similar to elongation factor Ts of *H. pylori*. One of the two underexpressed proteins in the opaque variants was homologous to the proteinase maturation protein PrtM of *Lactocobacillus paracasei*, a member of the family of peptidyl-prolyl cis/trans isomerases. A consensus lipoprotein signal sequence suggests that the putative proteinase maturation protein A, designated PpmA, is located at the surface of the pneumococcus and may play a role in the maturation of surface or secreted proteins. The second underexpressed protein was identified as pyruvate oxidase, SpxB. The lower SpxB expression in opaque variants probably explains the reduced production of hydrogen peroxide, a reaction product of SpxB, in this variant (96). Although it was subsequently shown that production of hydrogen peroxide varies consistently with colony morphology, one of the strains analyzed using high-resolution two-dimensional protein electrophoresis was found to have a frameshift mutation in *spxB*, resulting in loss of its function (96, 97). Consistently, mutants in *spxB* and *spxR* (the transcriptional activator of *spxB*), also display the opaque phenotype (98). Since *spxB* is the main producer of hydrogen peroxide and this byproduct inhibits the organism's growth as colonies, some variations in colony morphology may be a consequence of differences in SpxB or its activity (99).

Other Characteristics Associated with Pneumococcal Phase Variation

Membrane property analysis by Aricha *et al.* showed that the opaque and transparent variants carry the same types of fatty acids but differ in their proportions (100). The opaque variants possess a relatively lower degree of unsaturated fatty acids in the cell membrane. Consistently, the opaque variants display higher levels of microviscosity (an increase from 27% to 38%) for the cell membrane of opaque variants.

One of the most thoroughly studied aspects of pneumococcal biology is natural genetic transformation, referring to the ability of the organism to take up and incorporate exogenous DNA. As a variable trait between the two colony variants, the pneumococci derived from transparent colonies are much more competent in natural transformation (101). The transformation frequency of the transparent variants was 9- to 670-fold higher than those of their opaque counterparts. These differences were independent of the DNA incorporated and inversely correlated with the amounts of capsular

Downloaded From Vet-eBooks.com

polysaccharide. Genetic transformation therefore tends to select for a less-encapsulated subpopulation with a transparent phenotype.

IMPACT OF PHASE VARIATION IN COLONY OPACITY ON PNEUMOCOCCAL PATHOGENESIS

The biological differences among pneumococcal phase variants are characterized in animal models. In an infant rat colonization model, only the transparent variants were able to establish dense and stable colonization on the mucosal surface in the nasopharynx when the animals were intranasally infected with equal inocula (10^3 CFU) of opaque or transparent variants derived from the same strain (16). After challenge with a large inoculum (10^7 CFU) of an opaque variant, the pups gradually became colonized, but by the end of 7 days the opaque variant had been cleared and there was heavy colonization with transparent forms. This suggested that since such a large inoculum contained a small number of transparent variants, these were selected for from the heterogeneous inoculum. The role of the opaque variant in pneumococcal pathogenesis became evident when the variants were compared in a systemic infection model of adult mice (72). Infant rats are not highly susceptible to invasive pneumococcal infection. After intraperitoneal challenge with opaque or transparent variants derived from the same strain (10^7 CFU), all mice receiving the opaque organisms succumbed to the infection. In contrast, of the few mice that survived the infection with transparent organisms, splenic cultures revealed only organisms that had reverted to the opaque phenotype. This suggests that during invasive infection, there is a strong selection for organisms with the opaque phenotype. Similarly, opaque variants show enhanced survival compared to transparent variants of the same strain during experimental middle ear infection (otitis media) in the setting of inflammation induced by concomitant influenza A virus infection (102).

The animal experiments strongly suggest that the pneumococcus phase varies between at least two forms: one adapted for nasopharyngeal colonization and the other for events following colonization. The animal experiments therefore demonstrated the relevance of opacity variation to the pathogenesis of pneumococcal infection. Furthermore, observations in animals correlate with phenotypic differences in type-matched isolates simultaneously cultured from the nasopharynx (transparent phenotype predominant) and bloodstream (opaque phenotype predominant) of the same individual with pneumococcal infection (73).

CONTRIBUTION OF PHENOTYPIC VARIATION TO HOST CLEARANCE MECHANISMS

The elevated amounts of cell wall choline associated with the transparent phenotype may, in addition, promote clearance of the organism by the host. Human serum contains abundant natural antibody to choline and C-reactive protein (CRP), both of which recognize this structure and promote the *in vivo* clearance of the pneumococcus (103–105). CRP, an acute-phase reactant whose levels may rise 1,000-fold during inflammation, is capable of activating the classical pathway of complement by binding to C1q (106). CRP expression has also been described in leukocytes and in the human respiratory epithelium (107). Only transparent pneumococci appear to bind significant amounts of human CRP (108). Since cell wall choline binds to the receptor for platelet-activating factor on human cells (109), binding of CRP effectively inhibits the receptor for platelet-activating factor-mediated adherence to epithelial cells (110). These factors may lead to a selection of pneumococci with less cell surface choline (of the opaque phenotype) once an organism has bypassed the mucosal barrier.

The contribution of the capsular polysaccharide to the pathogenesis of pneumococcal infection has been ascribed to its antiphagocytic properties. The possibility that the increased virulence of opaque pneumococci could be due to the antiphagocytic effect of the higher amount of capsular polysaccharide associated with this phenotype was addressed in an opsonophagocytosis assay (108). For variants from an individual isolate, the amount of immune serum required for opsonophagocytosis by HL-60 cells in culture was proportional to the quantity of capsular polysaccharides. The average titer of serum required to achieve 50% killing was significantly greater for opaque compared with transparent variants. In addition, natural IgG2 antibody against choline is opsonophagocytic and more effective against transparent variants, which express increased amounts of the cell wall choline antigen and less antiphagocytic capsular polysaccharide (111). This suggests that the ability of opaque orga-

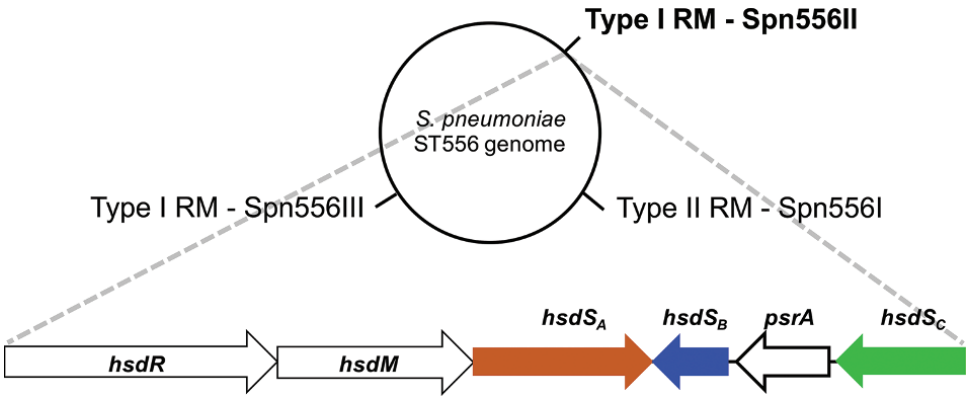

FIGURE 2 Genetic organization of the *cod* locus of *S. pneumoniae* ST556. The positions of three functional RM systems are indicated in the genome of ST556 according to a previous study (59). The gene order and other features in the *cod* locus are based on the published genome of the strain (accession no. CP003357) (122).

nisms to cause sepsis may be a result of diminished clearance by the combined activity of antibody, CRP, complement, and phagocytes.

MECHANISM(S) OF PNEUMOCOCCAL PHASE VARIATION IN OPACITY

Diversification of Pneumococcal Methylomes by DNA Inversions in a Type I RM Locus

Our laboratory recently identified an epigenetic mechanism that controls a reversible switch between opaque and transparent phenotypes (52). This mechanism depends on DNA inversion events among three *hsdS* genes of a conserved type I RM system in *S. pneumoniae*. Bacterial RM systems are well known for their classical function as defense systems against the invasion of foreign DNA. DNA methylation catalyzed by the DNA methyltransferases in RM systems protects bacterial genomes from self-cleavage by their restriction endonuclease counterparts. As one of the four major RM types, each type I RM system usually possesses three genes: *hsdR*, *hsdM*, and *hsdS* (encoding the restriction enzyme, methyltransferase, and sequence recognition protein, respectively). The three proteins form the functional methyltransferase (M_2S) and restriction enzyme (R_2M_2S) protein complexes (112). The S subunit in both protein complexes is responsible for DNA recognition specificity (112). We (52, 59) and others (60, 113, 114) identified a type I RM system in strains ST556 (Spn556II) and D39 (SpnD39III), which undergoes extensive DNA inversions in the three homologous *hsdS* genes. Because these DNA inversions control the phase variation in opacity, this type I RM locus was named the colony opacity determinant (*cod*) locus (52), while Manso *et al.* named the same locus in strain D39 SpnD39III (60). For the convenience of this discussion, we will follow our nomenclature. As illustrated in Fig. 2, the *cod* locus contains three homologous *hsdS* genes ($hsdS_A$, $hsdS_B$, and $hsdS_C$) and a DNA invertase gene (pneumococcal site-specific recombinase A, *psrA*), in addition to *hsdR* and *hsdM*. Although this locus is highly conserved among the genomes of all *S. pneumoniae* strains available to date, the sequence configurations of the three *hsdS* genes vary in the genomes of different strains (113, 114).

Some details of the DNA inversions in the *cod* locus were recently described in strains ST556 and D39 (52, 60). Since

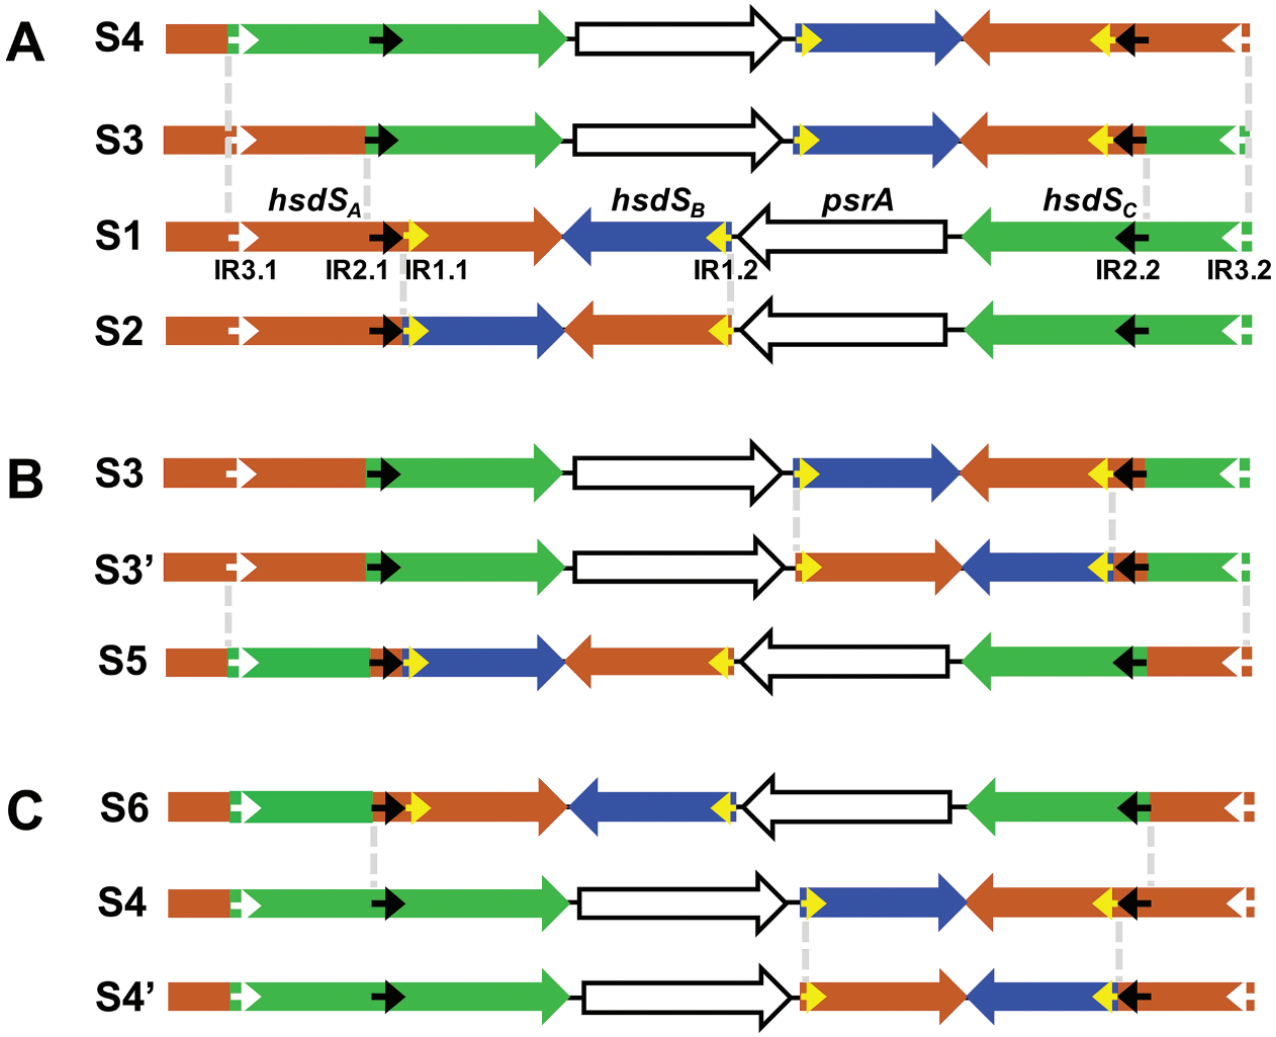

FIGURE 3 Unique genetic configurations generated by DNA inversions in the *cod* locus. The genetic orientations of the *hsdS* and *psrA* genes in the derivatives of forms S1 (A), S3 (B), and S4 (C) are illustrated by arrows. Each DNA configuration is given an S number. The sequence compositions of the *hsdS* genes are indicated by colors. The inverted repeats (IRs) in three *hsdS* genes are represented by yellow (IR1), black (IR2), and white (IR3) arrowheads. The inverted DNA segments are marked by dashed lines.

Downloaded From Vet-eBooks.com

the inversion reactions in this locus appear to operate in the same manner among different strains, we only summarize the major findings for ST556 in this article. As illustrated in Fig. 3, the three *hsdS* genes in the *cod* locus undergo different DNA inversions, designated configurations S1 to S6. The inverted sequences are demarcated by three pairs of inverted repeats, which are referred to as IR1 (15 bp), IR2 (298 bp), and IR3 (85 bp). While $hsdS_A$ carries the forward sequences of all three IRs (IR1.1, IR2.1, and IR3.1), the inverted counterparts of these repeat sequences are located in the coding sequences of $hsdS_B$ (IR1.2) and $hsdS_C$ (IR2.2 and IR3.2). The first three forms of DNA sequences in the *hsdS* loci (S2, S3, and S4) can be derived from three independent inversions of S1 (Fig. 3A). S2 is the product of DNA inversion within the coding sequences of $hsdS_A$ and $hsdS_B$. S3 and S4 were generated between $hsdS_A$ and $hsdS_C$. Four additional DNA configurations of *hsdS* loci (S3′, S4′, S5, and S6) can be further derived from DNA inversions in the S3 and S4 configurations. DNA inversions within $hsdS_B$ and $hsdS_C$ mediated by IR1.1 and IR1.2 in S3 lead to the generation of S3′. Similarly, S5 is derived from S3′ by an inversion of the sequence bounded by IR3.1 and IR3.2 (Fig. 3B). S4′ and S6 are generated from S4 by the DNA sequence inversion flanked by the pair of inverted repeat IR1 and IR2, respectively (Fig. 3C). In total, the DNA inversions in this locus generate six unique $hsdS_A$ alleles.

Our recent study reveals that the PsrA invertase encoded by the *cod* locus catalyzes the DNA inversion between $hsdS_A$ and $hsdS_B$ (52). PsrA is homologous to the tyrosine family recombinases. While the deletion mutant of *psrA* does not show detectable inversion between $hsdS_A$ and $hsdS_B$, it is still capable of DNA inversion between $hsdS_A$ and $hsdS_C$. This result indicates that the inversions between $hsdS_A$ and $hsdS_C$ are driven by unknown invertases. It should be mentioned that our preliminary analysis indicated that only the $hsdS_A$ gene of the *cod* locus is cotranscribed from the promoter upstream of *hsdR* (Fig. 2), but $hsdS_B$ and $hsdS_C$ are transcriptionally silent (manuscript in preparation). Consistently, our sequencing analysis showed that $hsdS_B$ and $hsdS_C$ have no detectable impact on the DNA methylation pattern or methylome of *S. pneumoniae* (52). In this context, it appears that the functions of $hsdS_B$ and $hsdS_C$ are solely for donation of their unique sequences to $hsdS_A$.

Subsequent methylation sequencing of the $hsdS_A$ allele-locked strains reveals that each of the six $hsdS_A$ alleles generated by the DNA inversions recognizes a unique DNA sequence and thus determines a distinct pneumococcal methylome (Fig. 4) (52, 60). It is thus conceivable that these DNA inversions in the *cod* locus are able to diversify an originally clonal population into a heterologous pool of at least six epigenetic types. The bacterial cells in each of the epigenetic types possess a unique methylation pattern of genome DNA. Previous modeling analysis suggests that the S subunit (encoded by *hsdS*) in the type I RM system consists of two target recognition domains (TRDs), each of which recognizes one half of the type I RM methylation motif (115). Comparing the coding sequences of $hsdS_{A1}$ to $hsdS_{A6}$ shows alleles A1, A2, and A3 apparently to have the same first TRDs and the first halves of their methylation motifs (5′-CRAA-3′). Similarly, the first TRD shared by A4, A5, and A6 is likely responsible for 5′-CAC-3′ recognition. The second TRD at the terminals of the $hsdS_A$ alleles (indicated by three colors in Fig. 4) correspond to 5′-CTT-3′, 5′-TTC-3′, and 5′-CTG-3′.

Phase Variation in Colony Opacity by Epigenetic Switch

Microscopic analysis of the $hsdS_A$ allele-locked strains reveals that the methylome switch driven by the DNA inversions in the *cod* locus controls pneumococcal phase variation in colony opacity (52). Specifically, the methylome generated by the $hsdS_{A1}$ allele leads to the formation of opaque colonies, whereas the pneumococci carrying the other five $hsdS_A$ alleles or lacking the *cod* locus produce transparent variant (Fig. 5). In addition, the opaque colony associated with $hsdS_{A1}$ requires DNA methylation activity of the type I RM system because the mutants with the loss-of-function mutations in

$hsdS_A$ allele	Allele composite	Methylation motif	Colony opacity
$hsdS_{A1}$		5'-CRAAN$_8$CTT-3' 3'-GYTTN$_8$GAA-5'	Opaque
$hsdS_{A2}$		5'-CRAAN$_9$TTC-3' 3'-GYTTN$_9$AAG-5'	Transparent
$hsdS_{A3}$		5'-CRAAN$_8$CTG-3' 3'-GYTTN$_8$GAC-5'	Transparent
$hsdS_{A4}$		5'-CACN$_7$CTG-3' 3'-GTGN$_7$GAC-5'	Transparent
$hsdS_{A5}$		5'-CACN$_8$TTC-3' 3'-GTGN$_8$AAG-5'	Transparent
$hsdS_{A6}$		5'-CACN$_7$CTT-3' 3'-GTGN$_7$GAA-5'	Transparent

FIGURE 4 The unique methylome specified by each of the HsdS variants in the $hsdS_A$-locked strains. The sequence origins of each $hsdS_A$ allele for the three *hsdS* genes are color-coded as shown in Fig. 3. The methylated adenosine nucleotide in the DNA methylation motif identified by single-molecule real-time sequencing in each $hsdS_A$-locked strain is shown as a red character. The opaque and transparent phenotypes associated with the $hsdS_A$-locked strains in colony opacity are indicated in the right-hand panel. R = A or G, Y = T or C.

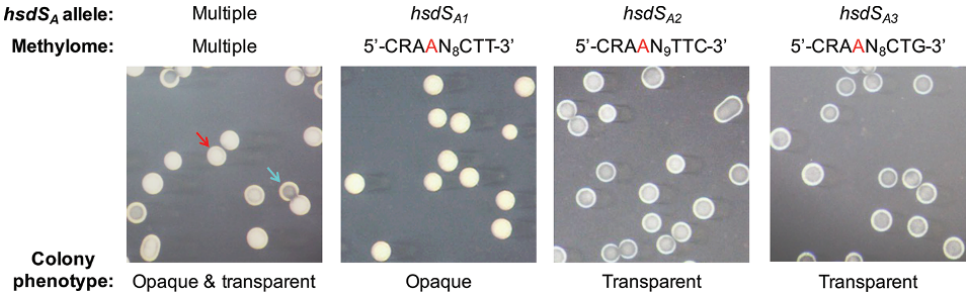

FIGURE 5 Colony phenotypes associated with strain ST556 and its $hsdS_A$-locked derivatives. The colonies were prepared and photographed under a dissection microscope as described (52). The representative opaque and transparent colonies in the wild-type strain are indicated by blue and red arrowheads, respectively.

the *hsdM* gene no longer form opaque colonies even in the presence of the $hsdS_{A1}$ allele. Finally, additional expression of the $hsdS_{A1}$ allele in the strain carrying $hsdS_{A2}$ or $hsdS_{A3}$ reverts the colony phenotype from transparent to opaque. This observation shows that the reversible switch of the $hsdS_A$ alleles by DNA inversion drives spontaneous phase variation between the opaque and transparent colonies. Together with other lines of evidence, this result indicating that DNA methylation of the pneumococcal genome at the 5′-CRAAN8CTT-3′ sequence and cellular conditions defined by the $hsdS_{A1}$ allele is the basis of the opaque colony phenotype; the loss of the $hsdS_{A1}$ allele by DNA inversions switches the pneumococci to the transparent or nonopaque phenotype (Fig. 6). The ON-and-OFF switch of the $hsdS_{A1}$ allele in the *cod* locus driven by DNA inversions results in the pneumococcal methylome variation between the methylated and nonmethylated states of the 5′-CRAAN8CTT-3′ motifs and thereby dictates phase variation between the opaque and transparent phenotypes. There are over 1,000 copies of the 5′-CRAAN8CTT-3′ motifs in the pneumococcal genome, but it remains to be determined which of these sites are involved in dictating the opacity variants. It is worth noting that in our preliminary experiments, the pneumococcal strains carrying the other $hsdS_A$ alleles (A2 to A6) also display unique phenotypes in other characteristics, although they share the transparent colony phenotype (manuscript in preparation). We believe that the DNA inversions in the *hsdS* genes drive additional types of phase variation, in addition to that in colony opacity.

To the best of our knowledge, this DNA inversion-driven epigenetic mechanism of pneumococcal phase variation is the first case in which DNA inversion and differential DNA methylation are combined to generate phenotypic variation. As discussed in the previous secions, DNA inversion or differential DNA methylation alone is able to produce phenotypic variants in bacteria, such as the DNA invertase-driven switch in the *Salmonella* flagellum (32, 33) and Dam methyltransferase-dependent phase variation in *E. coli* fimbriae (54). Both the DNA inversion and differential methylation mechanisms alone can produce limited numbers of variants, but DNA inversion in the *hsdS* methyltransferase genes in the *cod* locus of *S. pneumoniae* appears to take advantage of both the mechanisms, generating multiple types of phase variation in different biological traits. Because of the ubiquitous nature of the *cod*-like locus in archaeal and bacterial species (see below), the switch in colony opacity mediated by DNA inversion-driven epigenetic diversification in *S. pneumoniae* represents a novel mechanism of phase variation in the prokaryotes.

Other Characteristics of Phase-Locked Pneumococci

Because of the previously mysterious nature of the genetic and molecular mechanism behind the generation of pneumococcal opacity variants, the study of the biology of these variants has relied on pneumococcal populations that are prepared with natural opaque or transparent colonies of wild-type strains. The discovery of the epigenetic switch

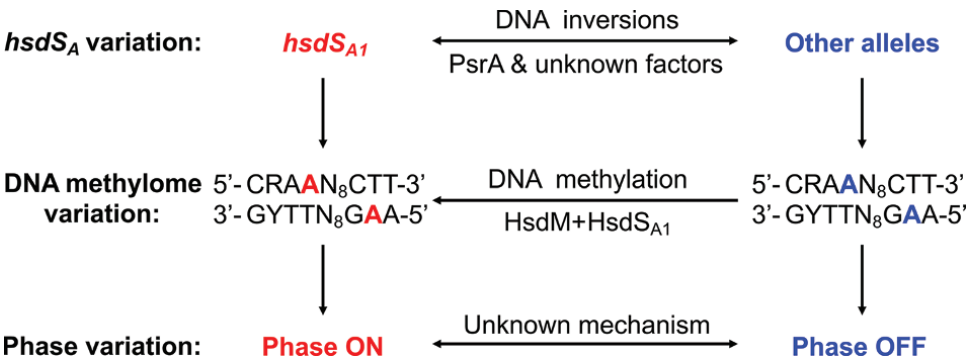

FIGURE 6 Diagrammatic demonstration of the relationship between an epigenetic switch driven by DNA inversion in the *cod* locus and phase variation in colony opacity. The methylated and unmethylated adenine nucleotides in the DNA motif by the $HsdS_{A1}$-associated methyltransferase are highlighted with red and blue characters, respectively. R = A or G, Y = T or C.

driven by DNA inversions in the *cod* locus has made it possible to generate $hsdS_A$ allele- or phase-locked strains for precise characterization of the biologic and pathogenic implications associated with the phase variants. The following is a summary of what has been learned with the phase-locked strains. First, the site-specific recombinations in the *hsdS* gene of the *cod* locus broaden the defense spectrum against the evasion of foreign DNA. The strains carrying a single $hsdS_A$ allele inhibit transformation with donor DNA molecules that are methylated by other $HsdS_A$ variants (52, 60). Second, in agreement with the previous observation of the natural opacity variants (116), the strains carrying $hsdS_{A1}$ are less adhesive than the transparent counterparts carrying the other $hsdS_A$ alleles in epithelial cell cultures (52). Likewise, opaque colony phenotype, $hsdS_{A1}$-locked pneumococci showed weaker colonization than locked allelic variants with the transparent phase (52). These results indicate that the phase variation driven by reversible ON-and-OFF switches of the $hsdS_{A1}$ allele generate pneumococcal variants with variable capacity in nasopharyngeal carriage (16). Third, the allelic variants expressing $hsdS_{A1}$, $hsdS_{A2}$, and $hsdS_{A6}$ in strain D39 grew more slowly than the other three isogenic variants in the mouse sepsis model (60), suggesting that allelic variation in the *cod* locus maximizes the range of pneumococcal fitness during invasive infection. Finally, unencapsulated pneumococci with deletions within the capsule biosynthesis locus still form colonies with these two phases (52), demonstrating that the capsule is not necessary for the phase variation in colony opacity. The $hsdS_A$ allele-locked strains have also been used to study the transcriptomes of the opacity variants (60, 117). Manso *et al*. found that the genes in the capsule biosynthetic locus are transcriptionally downregulated in the $hsdS_{A2}$ allelic variant of strain D39 compared with those of $hsdS_{A3}$, $hsdS_{A4}$, and $hsdS_{A5}$ (60). However, Oliver *et al*. showed that there is no significant difference in transcription levels of the capsule locus among the six corresponding $hsdS_A$ allele-locked variants of strain TIGR4 (117). This difference may be related to variations in bacterial strain, growth medium, or other conditions used in these studies.

The *cod*-Like Systems in Other Bacteria

The *cod*-like type I RM systems are found in many phylogenetically diverse archaeal and bacterial species, which includes the homologs of the *psrA* invertase gene and multiple copies of *hsdS* in the same locus. These include *Mycoplasma* (e.g., *Mycoplasma pulmonis* and *Mycoplasma bovis*), Spirochetes (e.g., *Treponema medium* and *Treponema denticola*), Gram-negative bacteria (e.g., *B. fragilis* and *Campylobacter upsaliensis*), and Gram-positive bacteria (e.g., *Enterococcus faecalis* and *Streptococcus agalactiae*). *M. pulmonis* has two type I RM systems, each of which undergoes DNA inversions catalyzed by the HvsR tyrosine recombinase between the *hsdS* genes (39, 118–120). Some of the DNA inversions generate HsdS allelic variants, which recognize distinct DNA sequences and thus result in variable restriction activities. DNA inversions of the *hsdS* genes have also been observed in *B. fragilis* (38), although there is no functional information on the bacterial variants. Although it remains to be determined whether these *hsdS* inversions in *M. pulmonis* and *B. fragilis* have any functional impact on bacterial methylomes and other aspects of biology beyond restriction, it is tempting to predict that these type I RM systems likely play important roles in epigenetic and phenotypic diversity among the prokaryotic organisms, based on the DNA inversion-driven pneumococcal phase variation (121).
