Genomics and Genetics of *Streptococcus pneumoniae*

FRANCESCO SANTORO, FRANCESCO IANNELLI AND GIANNI POZZI

22

The first complete genome sequence of the pneumococcal type 4 strain TIGR4 was published in 2001. To date (February 2018), GenBank hosts 37 complete pneumococcal genomes and more than 8,000 draft genome sequences. The genetics of *Streptococcus pneumoniae* began with the discovery of bacterial transformation by Griffith in 1928 and subsequent identification of DNA as the genetic material by Avery, MacLeod, and McCarty in 1944 (1). Many of the *S. pneumoniae* strains commonly used in genetic studies are derivatives of the clinical strains obtained by Avery in 1916 (Table 1) (2–4).

PNEUMOCOCCAL GENOMES

In 2000, the Institute for Genomic Research (TIGR) released the first complete genome of serotype 4 invasive strain TIGR4 (formerly known as JNR.7/87 [5]) for BLAST search and for download. The work describing the genome sequence was subsequently published in 2001 (6). In the same year, two more *S. pneumoniae* genomes were published: (i) the genome of strain G54, an Italian clinical isolate serotype 19F strain (7, 8), first released as a draft genome in 31 annotated DNA contigs (9) and later completed (GenBank accession no. CP001015), and (ii) the complete genome of R6 (10), an unencapsulated derivative of the type 2 Avery's strain D39 (11). Six years later, in 2007, the genome sequence of D39 was completed and released (12).

Of the 37 pneumococcal genomes hosted in GenBank, 9 were obtained by Sanger sequencing and the rest by next-generation sequencing or by combining Sanger with next-generation sequencing technologies (Table 2).

The next-generation sequencing technologies with relatively low costs and high throughput produced more than 8,000 pneumococcal genomes, but only 14 were closed and completed. This is essentially because short sequence reads, such as those obtained by Illumina sequencing, are inherently incapable of covering and closing gaps located in long repeated regions (13). Long read sequencing technologies such as PacBio and Nanopore sequencing could be used to close the draft genome sequences. On the other hand, the database redundancy due to inflation of essentially identical pneumococcal genomes impairs database exploration and data retrieval. In addition, automated gene annotation tends to add redundancy and to amplify annotation errors. To overcome difficulties in pneumococcal database exploration, it is suggested that you perform homology searches using the online tool Microbial Nucleotide BLAST (https://blast.ncbi.nlm.nih.gov/Blast.cgi?PAGE_TYPE=BlastSearch&BLAST_SPEC=MicrobialGenomes), selecting the complete genomes database, and if necessary, extending the search to draft genomes. Alternatively, a stand-alone database containing only genomes of interest can be created and efficiently searched.

Table 2 shows the main characteristics of the 37 complete pneumococcal genomes. Sequenced strains include Avery's classic strains D39 (type 2) and A66 (type 3) and their derivatives (1, 14); the remaining strains are clinical isolates from both invasive and noninvasive diseases or carriage. Four clinical strains belong to lineages that have contributed to the global spread of antibiotic resistance, namely, Spain-23F-1 (ATCC700669), Spain-6B-2 (670-6B, ATCC700670), Hungary19A-6 (ATCC700673), and Taiwan 19F-14 (ATCC700905) (15). Pneumococcal genome analysis showed that the median genome size is 2,085 kb and the average GC content is 39.6%. There is a strong bias in gene orientation, and the large majority of the genes are transcribed in the same direction as the DNA replication (6). The genome of *S. pneumoniae* contains a large number of carbohydrate uptake systems belonging to the ATP binding cassette (ABC) superfamily and to the phosphoenolpyruvate-dependent phosphotransferase system family; notably, these transport systems and the respective operons are components of the variable part of the pneumococcal genome (16). Energy generation relies essentially on substrate-level phosphorylation and glycolysis (17); genomic analysis suggests that *S. pneumoniae* can catabolize a wide array of sugars, as confirmed by fermentation experiments demonstrating that pneumococci were able to metabolize at least 32 carbohydrates, including 6 polysaccharides (16). Comparative genomics of *S. pneumoniae* indicates that there is a core genome formed by about 70 to 80% of sequences common to all strains (18, 19), whereas intraspecies variability is essentially due to (i) allelic variants of genes present in all pneumococcal genomes, as in the case of the capsule genes, *psp*C, and *psp*A (20–23), and (ii) DNA sequences which are "added" to the pneumococcal genome and belong to bacteriophages and other mobile genetic elements (MGEs). This added DNA, known as mobilome, (i) is uniquely present in a strain (or a group of strains), (ii) typically shows a different GC content from the rest of the bacterial genome, (iii) is an insertion of heterologous DNA into the bacterial chromosome, as demonstrated in early work by Guild and collaborators (24), (iv) is not strictly part of the pneumococcal genome but is shared with other bacterial genomes, and (v) contains a higher ratio of open reading frames whose putative gene products are of unknown function. From a genomic perspective, correct definition, careful manual

TABLE 1 Properties of classic *S. pneumoniae* laboratory strains

Strain	Capsule[a]	Relevant properties[b]
D39	Type 2^+	Clinical isolate (1928); virulent; $pDP1^+$; *comC1*
R36	Type 2^-	D39 passaged 36× in anti-type 2 serum (1944); does not revert to Cps^+ (see R36A, below); Hex^+; $pDP1^+$
R36N	Type 2^-	Colony variant of R36 (1944); nontransformable; $pDP1^+$
R36NC	Type 2^-	Transformable derivative of R36N (1947); *Dpn*I; Hex^+; $pDP1^+$
R36A	Type 2^-	Colony variant of R36 (1944); deletions demonstrated in type 2 capsule locus (45); Hex^+; $pDP1^-$
R6	Type 2^-	Single-colony isolate of R36A (1962); *Dpn*I; Hex^+; $pDP1^-$
R6x	Type 2^-	R6 transformed to the Rx Hex^- phenotype (1973)
Rx	Type 2^-	R36A transformed to type 3 capsule (1949) and subsequently isolated as a spontaneous "unencapsulated"' derivative (1959) (but see Rx1, below); Hex^- (*hexB*$^-$); $pDP1^-$
Rx1	Type 3*	Highly transformable derivative of Rx; contains the type 3 *cps* locus, a 5′ deletion of *ali*A (*plp*A), and a point mutation in *cps3D* responsible for reduced production of capsule (23, 25); virulence is not restored by transformation to type 3 capsule; *Dpn*0; Hex^- (*hexB*$^-$); $pDP1^-$
A66	Type 3^+	Clinical isolate (1928); virulent; donor in 1944 transformation studies of Avery et al.; *Dpn*I; *comC2*

[a]The *cps* genotype is indicated, and the symbols indicate whether the strain is encapsulated (+), unencapsulated (–), or intermediate (*).
[b]Numbers in parentheses indicate the date of original description. The *Dpn*0 phenotype in Rx1 is apparently due to a mutation in the *Dpn*I-encoding locus. Hex phenotypes are described in references 3 and 147. *com*C alleles are described in reference 7.

annotation, and phenotypic characterization of the most common MGEs of a bacterial species are essential for improved performance of comparative genomic studies. For instance, open reading frames of uncharacterized MGEs are automatically annotated as "conserved hypothetical proteins," because they are found in many different bacterial genomes as part of the mobilome. The mobilome includes plasmids, prophages, transposable elements comprising integrative and conjugative elements (ICEs), pathogenicity islands, and insertion sequences (Table 2, Table 3). Pneumococcal genomes also contain three families of small interspersed repeats, namely, BOX, RUP (repeat unit of pneumococcus), and SPRITE (*S. pneumoniae* rho-independent terminator-like element) (25–27). As evidenced from the genome sequences, BOX and RUP are present in more than 100 copies and are found almost exclusively outside of coding regions, and SPRITE elements are also found in intergenic regions but are less represented (about 30 copies/genome). Their functions are unknown, although RUP elements are thought to be mobilizable by the IS*630*-Spn1. The BOX element comprises three subunits of 59, 45, and 50 bp (box A, box B, and box C, respectively), although not all are present in every copy and modulate gene expression (28).

Pneumococcal Population Structure

In the past few years, several studies have investigated the genomes of pneumococcal strain collections from diverse settings. These studies characterized different pneumococcal lineages, i.e., groups of isolates with high genomic similarity. Within the same lineage, ICEs were generally conserved, while sequence variation occurred by recombination of small fragments of DNA and by loss or acquisition of prophages (29). As expected for a naturally competent bacterium, the sequence variation in pneumococcal populations essentially arose from recombination and not by accumulation of base substitutions (30). Recombination events occurring upon horizontal DNA transfer were detected at a relatively small number of loci, such as *psp*A, *psp*C, and the *cps* locus. These loci encode for surface-exposed structures of the bacterial cell, which are under selective pressure imposed by the human host. In particular, *psp*A and *psp*C have a mosaic structure that typically evolves by consecutive recombination events (20, 21). The *cps* locus is located between the conserved *dexB* and *ali*A genes and exhibits high variability, with more than 90 serotypes identified that are encoded by different allelic variants (22). Recombination events, leading to serotype switch, are relatively frequent in pneumococcal populations (191 events were detected in a collection of 3,095 carriage isolates [31]) and can also lead to loss of the whole locus or to its acquisition by unencapsulated pneumococci. Different lineages have been identified even among unencapsulated pneumococcal carriage isolates, which may act as a gene reservoir (32). Other highly recombinogenic loci are those under selective pressure from antibiotics, such as the penicillin binding protein genes *pbp1a*, *pbp2b*, and *pbp2x* encoding cell wall synthesis enzymes or the dihydrofolate reductase gene *fol*A. Allelic variants of *pbp* are responsible for the reduced susceptibility to beta-lactam antibiotics, while variants of *fol*A are responsible for cotrimoxazole resistance.

Genomic variability among isolates belonging to different lineages is mainly due to variation in accessory regions, which contain a wide array of genes, including some important virulence factors (33). Comparison of invasive and noninvasive pneumococcal isolates shows that the invasive potential of a strain is often correlated with the presence or absence of a few specific accessory regions. The pneumococcal pathogenicity island 1 (PPI1) is a highly variable accessory region that is present in about two-thirds of pneumococcal isolates (34). It has a lower GC content than its surrounding regions, and it is composed of (i) an operon coding for an ABC iron transporter (35), (ii) the *pezAT* toxin-antitoxin system (36), (iii) a putative lantibiotic production locus, and (iv) the *nplT* neopullulanase gene. Variants of PPI1 show different levels of virulence in mouse models; in particular, the PPI1 locus from highly virulent isolates contains both *pezAT* and *nplT* and shows enhanced fitness in blood, lungs, and nasopharinx (37). The *pezAT* toxin-antitoxin system is a two-gene operon that codes for a labile PezA antitoxin and a stable PezT toxin (36). The toxin targets the cell wall synthesis pathway, and the antitoxin blocks its activity. The system impairs competence development and makes pneumococcal cells more susceptible to beta-lactams and to lysis in the stationary phase (38).

[a]MGEs (ICEs and prophages) were searched using Microbe BLAST against *S. pneumoniae* complete genomes. Insertion sites of MGEs and sequences of Tn*5253* and Tn*916* were used as query sequences. When available, publications linked to sequences were used to retrieve the MGE content of genomes. Phages are grouped according to the classification in reference 140.

Downloaded From Vet-eBooks.com

Two other important pneumococcal recombination hotspots are the insertion sites for the ICEs Tn*5253* and ICE*Sp*23FST81. These ICEs share homology in the conjugation machinery module and both carry *tet*(M) and *cat* genes but are inserted at different sites since they possess different recombination modules (39–41). The insertion site of Tn*5253* is located downstream of the IgA protease gene *zmpA* (SP_1154, TIGR4 genome), where extensive variability is detected, with the possible insertion of the *zmpA* paralog *zmpD* (42). The insertion site of ICE*Sp*23FST81 is located upstream of the conserved gene *rplL* (SP_1354, TIGR4 genome), which codes for the L7/L12 ribosomal protein. This region contains fragments of homology with ICEs, possibly indicating that it has been a target site for these elements for a long time (29).

It is worth noting that regions of PPI1 are homologous to fragments of ICE Tn*5253*, which also carries two copies of *pezAT*. PPI1 lies in a chromosomal recombination hotspot and is itself a hotspot of recombination, since it can accumulate mobile gene clusters, including the Ω*cat*(pC194) element. Ω*cat*(pC194) is part of Tn*5253* and is able to integrate within PPI1 (40).

HORIZONTAL GENE TRANSFER

Both transformation and conjugation have been described in *S. pneumoniae*. Transformation serves as the primary, and perhaps sole, means of transferring chromosomal genes. Conjugation occurs with plasmids that are capable of self-transfer or mobilization and with ICEs that are integrated into the chromosome. The latter mediate their own transfer but do not cotransfer linked chromosomal markers. Transfer of transformation of ICEs and chromosomal genes are the major mechanisms known to be involved in the spread of antibiotic resistance in *S. pneumoniae*. Generalized transduction has not been observed, although a process termed pseudotransduction, which involves properties of both transduction and transformation, has been described for one pneumococcal bacteriophage (10).

Transformation

Natural transformation in *S. pneumoniae* can be divided into several stages: (i) induction of competence, (ii) binding of double-stranded DNA to the cell surface, (iii) digestion of bound DNA into discrete double-stranded fragments, (iv) uptake of single-stranded linear DNA, (v) binding of the internalized DNA by single-stranded binding proteins, and (vi) recombination of homologous DNA into the chromosome by a single-strand replacement mechanism. Successful transformation of plasmids requires the uptake of two complementary, overlapping DNA strands. Essentially any DNA can be taken up, because no specific recognition sequences are required. Most DNA that is not homologous to the pneumococcal chromosome or that cannot replicate independently is degraded and becomes part of the nucleotide precursor pool. Occasionally, DNA that is not homologous to the chromosome but that is physically linked to DNA that is homologous can be inserted into the chromosome by a process known as homology-assisted illegitimate recombination (43).

Competence development

S. pneumoniae is competent for transformation for only a brief period during the early exponential phase of growth (44). The specific point at which competence is induced is determined by both the cell density and the culturing conditions. Maximal transformation efficiencies are usually observed in a rich medium containing calcium and serum or albumin, at a starting pH of about 7.0 to 7.2. Under optimum culture conditions, transformation of a given marker from a donor chromosomal DNA preparation can be observed in up to 10% of the recipients. Alterations in the starting pH affect both the timing and efficiency of transformation (45). A low pH tends to prevent the development of competence, whereas higher pH values result in multiple waves of competence that occur over a broader range of cell densities and rarely reach the peak efficiency. Under optimum conditions, cotransformation of two unlinked chromosomal markers occurs near the frequency expected for two independent events, indicating that essentially all cells in the culture become competent (46). Cotransformation of unlinked markers during subsequent, postpeak waves of competence occurs more frequently than expected, indicating that only a fraction of these cells are actually capable of being transformed (45). Genomic analysis of cotransformation shows that upon selection of an antibiotic marker, up to two secondary, unselected recombination events can occur within the same genome (47).

The development of competence is mediated by the synthesis and the release of the competence factor (44), a small peptide that induces expression of genes encoding transformation-related proteins. The great majority of *S. pneumoniae* strains contain one of the two main alleles of *com*C, the gene that encodes the competence-stimulating peptide (CSP) (7, 48). The 41-amino-acid translation products from *comC1* and *comC2* each contain an identical 24-amino-acid N-terminal leader sequence that possesses a Gly-Gly processing site common to peptide bacteriocins. The remaining 17 amino acids, which represent the mature, active peptides of CSP-1 and CSP-2, differ at eight positions. Sequence analysis of encapsulated strains representing multiple capsular serotypes has shown that each has either a *comC1* or *comC2* allele, which are both highly conserved. In general, however, transformation of encapsulated isolates is not readily observed under the growth conditions described above. In many cases, the failure to transform is related to the presence of the capsule, which reduces or blocks competence for genetic transformation (49, 50). Noncompetent cultures, as well as many encapsulated strains, can be induced to competence by the addition of CSP-1 or CSP-2 (7).

The identification of the *comC1* and *comC2* alleles and their respective peptides has made possible the transformation of a large number of encapsulated isolates. The efficiencies of transformation can vary widely, but many strains (approximately 50% of those tested) have not been transformed. These observations suggest that other factors are also important in the induction of competence and the ability of recipients to be transformed. Genomic screening shows the presence of other minor *com*C alleles which are present in less than 5% of analyzed pneumococcal strains (51, 52).

During competence development the CSP serves as the peptide pheromone signal. The induction of competence leads to transient restriction of most cellular protein synthesis, with high-level expression of a small set of proteins involved in transformation. Microarray analysis showed that the expression of more than 100 genes is regulated by CSP, and of those only a minor fraction are clearly necessary for transformation (53–56). CSP-responsive genes exhibited four patterns of expression: early, late, and delayed gene induction and gene repression (53, 57). Early genes include those involved in competence induction, whereas late genes include those necessary for DNA processing. Heat shock proteins, proteases, and chaperones occur among the delayed

[c]Alternative number of bp, depending on the copy.

genes, possibly reflective of a stress response. Repressed genes include ones encoding ribosomal proteins and carbohydrate/amino acid metabolism enzymes.

The events and genetic loci involved in detecting and responding to the CSP signal are summarized in Fig. 1. Export and maturation of CSP is mediated by an ABC transporter encoded by the *comAB* locus (58). *com*C is the first gene in an operon with *comD* and *comE*, which encode the histidine kinase sensor and response regulator components, respectively, of a two-component signal transduction system (59). ComD has been proposed to be the CSP receptor (58) and has been demonstrated to retain CSP on competent cells (60). Allelic variation at the N-terminal sensor domain of ComD has been reported and is responsible for CSP pherotype specificity (51, 61). Expression of *comCDE* is enhanced approximately 40-fold upon addition of exogenous CSP (59). Maximal expression of *comAB* and *comCDE* occurs within 5 to 10 min after addition of CSP and returns to near basal levels by 15 to 20 min (54, 57). Loss of *comE* abolishes competence induction and *comCDE* expression (59). Binding of CSP to ComD is predicted to activate ComE via phosphorylation, and mutations in ComD that apparently alter its conformation and lead to constitutive phosphorylation also result in constitutive competence (62). The activated ComE binds to conserved target sequences, consisting of two 9-bp direct repeats separated by 12 bp, located upstream of the –10 regions of the *comAB*, *comCDE*, and *comX* promoters (63, 64). The latter gene encodes the alternative sigma factor ComX, which allows core RNA polymerase to recognize competence-specific promoters (63, 65). These promoters contain a com- or cin-box (TACGAATA) located –10 from the transcription start site and a T-rich region at –25 (66). They are located upstream of a number of loci, including *cin-rec*, *cel*, *cfl*, *cgl*, *coi*, and *ssb*, that are involved in the later stages of competence and whose expression is induced in parallel (54, 59, 66). ComX thus serves as the link between the competence induction pathway (*comAB* and *comCDE*) and the DNA processing components (63). It is an unstable protein that is not detected in noncompetent cultures but is apparent by 7.5 min after induction with CSP and about 3 min before the expression of ComX-dependent genes is detected (65). During competence, levels of the major sigma factor, Sigma A (RpoD), are decreased relative to ComX, and the molar amount of ComX exceeds that of Sigma A by approximately 2-fold. ComX may replace Sigma A during competence, thus explaining the preferential expression of competence-related genes during this time (65, 67). An additional factor, ComW, is necessary to maintain adequate levels of ComX, through an effect on either translation or stability, and may also increase the activity of ComX in transcription of the late competence-specific genes (68, 69).

CiaH and CiaR are the sensor and response regulator components, respectively, of a two-component signal transduction system that may be involved in calcium sensing (70, 71). CiaR is necessary to repress competence expression, although it is not clear whether the activated or nonactivated form is involved. Deletion of CiaR results in constitutive *comCDE* expression and competence (56, 72, 73), whereas point mutations in *ciaH* result in no CSP being exported and a failure to respond to exogenously added CSP (71). Enhanced expression of stress response genes occurs in CSP-induced CiaR mutants, along with growth restriction and stationary phase autolysis (56). Mutations that affect stress response proteins can also lead to competence expression (74, 75), and it has been suggested that CSP might be an alarmone that signals environmental stress (72). The Cia system, as well as the oligopeptide permeases encoded by the *ami* and *ali* (also referred to as *plp*) loci, may be involved in sensing the environment. Mutations in the *ami* and *ali* loci, and especially those in more than one locus, affect the spontaneous development of competence but do not alter the response to exogenous CSP induction (57, 76).

Genetic transformability has been proposed to be induced by antibiotic stress. Fluoroquinolones, kanamycin and streptomycin antibiotics, and the DNA-damaging agent mitomycin C induce the expression of the late competence gene encoding a single-stranded DNA binding protein (77). Furthermore, antibiotics, DNA-damaging agents, and other compounds affecting DNA replication have been found to upregulate the expression of genes located near the chromosomal origin of replication, including the *comCDE* operon (78). There has long been evidence for a macromolecular inhibitor that causes the cessation of the competent phase (44). The mechanism by which competence is abruptly shut off remains unknown, but mRNAs of the ComX-dependent loci decay in parallel, and the process requires ComX (54, 63). Other genes or loci necessary for specific steps in transformation have been described and are discussed in the appropriate sections below. Mutant analyses have also identified several additional loci whose precise points of involvement

Downloaded From Vet-eBooks.com

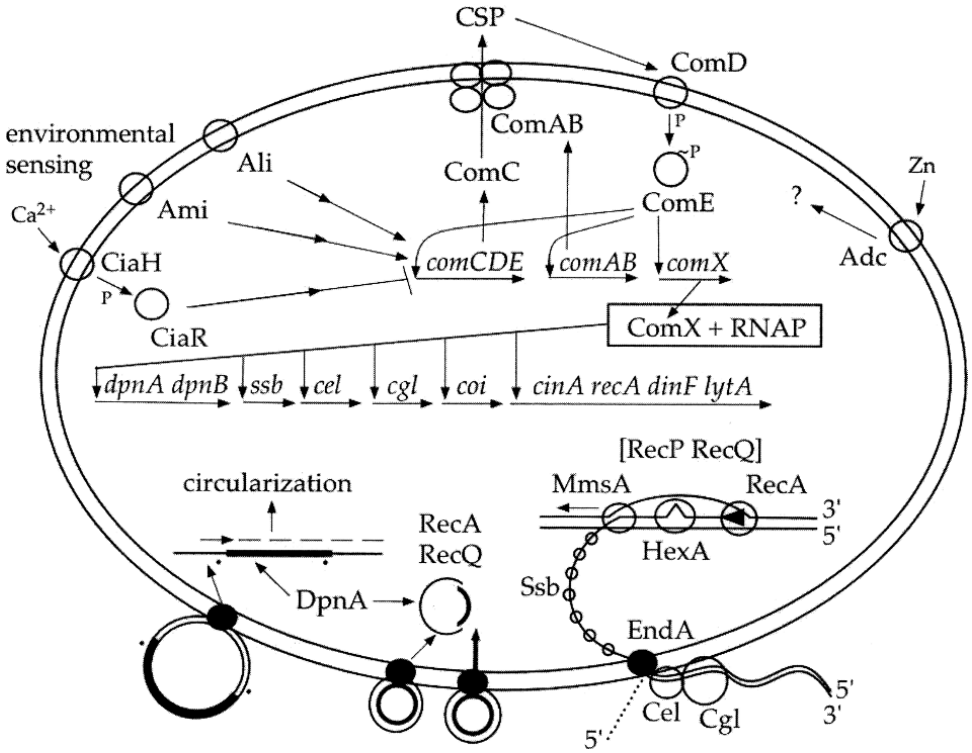

FIGURE 1 Transformation. The model is based on information discussed in the text. In some cases, the putative regulation of gene expression may be either direct or indirect. Phosphorylation of response regulator molecules by their cognate histidine kinase sensors is indicated by P. Uptake and integration of linear DNA is shown in the lower-right portion, with monomer and dimer plasmid uptake shown in the central and lower-left portions, respectively. Plasmid uptake occurs by the same mechanism as linear DNA uptake. For monomers, complementary overlapping strands pair, and DNA synthesis completes the double-stranded circular molecule. For the dimer, a small fragment of the complementary strand can serve as a primer for DNA synthesis, and circularization can occur as described in the text. Dots on the dimer molecule indicate homologous sites.

are not entirely clear. For example, Adc mutants transform poorly unless Zn is added, and the addition of CSP in the absence of Zn does not induce competence. Therefore, the effect is likely downstream of induction and may be related to transmission of the signal from ComD to ComE (79).

DNA release, binding, and uptake

CSP induction results in the release of transformable DNA from competent cells (80–83). The release is dependent on the major autolysin, LytA, and the autolytic lysozyme, LytC. Double-stranded DNA can bind to competent cells at multiple locations (50 binding sites have been estimated) (84), where it is subjected to single-strand nicks. A constitutively expressed membrane-associated endonuclease (EndA) converts the nicks into double-strand cuts, resulting in fragments with a median length of about 7 kb (85–87). Nucleolytic digestion of one strand occurs in the 5′ to 3′ direction, while the other strand is taken into the cell in the 3′ to 5′ direction (88). Entry and degradation occur at equivalent rates of ~100 nucleotides per sec at 30°C (88). Binding and subsequent uptake of a single large molecule may occur at multiple independent sites. Hence, even though digestion results in fragments of relatively small size, linkage of markers hundreds of kilobases apart can be detected using carefully prepared DNA. The average small size also does not preclude the uptake and integration of large DNA fragments or of large heterologous regions flanked by sequences homologous to the recipient chromosome, as evidenced by the exchange of genetic cassettes encoding the capsular polysaccharide biosynthetic enzymes (47).

It has been proposed that EndA is part of a DNA uptake complex (86). The predicted products encoded by several genes induced by CSP and required for efficient transformation are homologous to proteins involved in DNA binding, uptake, and the assembly of DNA transport machinery in *Bacillus subtilis*. These genes are contained in the *S. pneumoniae* loci originally referred to as *cel* or *cilE*, *cgl* or *cilD*, *cilC* or *cclA*, *cilB*, and *cfl* (59, 63, 66). They have since been referred to in a manner consistent with their *B. subtilis* homologs (89). The *B. subtilis* ComG proteins are primarily membrane associated, but some may be processed and translocated to the cell wall. They appear to have a role in allowing the DNA to traverse the peptidoglycan and reach the DNA binding protein, ComEA (90). In *S. pneumoniae*, inactivation of ComGA (*cilD*, *cglA*) eliminated DNA binding and degradation, whereas inactivation of ComEA (*cilE*, *celA/B*) eliminated degradation and internalization of DNA, but low-efficiency binding still occurred. EndA thus cannot access DNA in the absence of these proteins, and they are postulated to be necessary for the surface attachment and deep binding, respectively, of the DNA (89, 91). In these same studies, ComEC (*cilE*, *celA/B*) and ComFA (*cfl*) mutants were found to bind and degrade DNA, but not to internalize it, suggesting a role in membrane transport.

Chromosomal integration

Once inside the cell, the DNA is contained in an eclipse complex, where it is protected from cellular nucleases by interaction with a 19.5-kDa single-strand binding protein and no longer has transforming activity (92, 93). Homologous recombination into the chromosome proceeds by a single-strand replacement mechanism that involves RecA activity and is affected by the Hex mismatch repair system (see below). Purified RecA mediates single-stranded DNA-dependent nucleoside triphosphate hydrolysis and nucleoside triphosphate-dependent DNA strand exchange (94). CSP induces expression of the *recA* operon, which consists of *cinA-recA-dinF-lytA* (95, 96). In competent cells, all of these genes are induced from a promoter located upstream of *cinA*, whereas in noncompetent cells, lower levels of transcription proceed from other promoters. The induction of *lytA*, which encodes the major pneumococcal autolysin, is consistent with the observation of DNA release and autolytic activity during the competence phase. LytA is not, however, necessary for transformation (96). *dinF* encodes a putative multiantimicrobial extrusion family protein which is involved in quinolone efflux (97), while in *Escherichia coli dinF* is expressed in response to DNA-damaging agents (96). In *S. pneumoniae* CinA (also called CogA) may have a role in facilitating the localization of RecA to the membrane (98), while in *B. subtilis* it is localized in the nucleoid and is not involved in competence (99).

Mutations in at least four other loci are known to affect chromosomal integration. *mmsA* encodes a helicase (RecG homolog) that is proposed to be involved in branch migration of the three-stranded heteroduplex integration intermediate (100). *recP* is required for chromosomal but not plasmid transformation, although it is not clear how its predicted product, a transketolase, is involved. *recQ* is required for both chromosomal and plasmid transformation, but its role has not been further characterized (101, 102). Internalized strands of donor DNA are complexed with SsbB, an about 15-kDa single-stranded DNA binding protein, and *ssb* mutants have a 3- to 5-fold reduction in transformation frequency (66, 93).

Plasmid transformation

Transformation of plasmids proceeds by the same pathway as that for chromosomal DNA. The efficiency (based on donor DNA concentration) is lower, however, because two separate uptake events that involve complementary and overlapping single strands must occur to obtain a circular, partially double-stranded molecule that can then be completed through DNA repair synthesis (Fig. 1). Consequently, plasmid DNA linearized at a unique site cannot be recircularized and established in the recipient cell. The frequency of plasmid transformation is enhanced by the use of dimers as opposed to monomers (103). Indeed, the highest frequencies of plasmid transformations are obtained using $RecA^+$ *E. coli* strains as a source of multimeric plasmids. In these situations, only a small fragment of the complementary strand is necessary to provide a primer for synthesis of a molecule that can be more than one monomeric unit in length when using the dimer/multimer as a template. A recombination event between homologous regions can then restore the circular plasmid. Alternatively, as suggested by Saunders and Guild (103), intramolecular circularization may occur by pairing of a single-strand region of the incoming DNA with a newly synthesized complementary strand and displacement of the template strand. A ligation reaction would restore the circular molecule. The first possibility would be expected to be RecA dependent, whereas the latter likely would not. Whether the transformation of dimers is dependent on RecA has not been determined. Defects in RecA do, however, decrease the efficiency of monomer transformation (84). In addition, RecQ is necessary for efficient plasmid transformation, but RecP is not (101, 102).

The establishment of plasmids can also be facilitated by the presence in the recipient cell of regions homologous to the incoming plasmid (104). Thus, plasmids containing cloned fragments of *S. pneumoniae* DNA are readily transformed, because the homologous chromosomal regions can serve as primers for DNA repair synthesis, if the original double-strand cut occurred within the cloned region of the plasmid. Likewise, plasmids with homology to endogenous plasmids are transformed at high frequency.

Artificial transformation

Replicating plasmids can be introduced into *S. pneumoniae* by electroporation. Unlike plasmids taken up via the natural transformation pathway, they are subject to restriction by the *Dpn* system (see below), indicating that double-stranded DNA is transformed (105). Recombination of markers into the chromosome is not observed, even when competent cells are used as recipients or when DNA is made single-stranded prior to transformation. Electrotransformation of plasmids containing regions homologous to the *S. pneumoniae* chromosome is, however, enhanced in competent cells in a RecA-dependent manner, indicating that pairing between homologous DNAs does occur during this process (106).

Conjugation

S. pneumoniae can serve as both a donor and recipient in the conjugation of plasmid DNA and ICEs (24, 107). Transfers are DNase resistant and require stable cell-to-cell contact. Both capsulated and unencapsulated strains can serve as conjugation donors or recipients, and transfer frequency is strain dependent (40, 108–110). Although no indigenous conjugative plasmids have been identified, several plasmids from other streptococci, including pIP501 of *Streptococcus agalactiae*, have successfully been conjugated into *S. pneumoniae* and then retransferred to other pneumococcal and streptococcal recipients. In addition, nonconjugative plasmids such as pMV158 can be mobilized both to and from *S. pneumoniae* (107).

ICEs that can insert at either multiple sites or only at specific sites have been identified in *S. pneumoniae*. ICEs are transferred in a process that likely involves excision to form a circular intermediate that is nicked and then transferred as single-stranded DNA to recipient cells. Tn*1545*, a 25.3-kb conjugative transposon first detected in *S. pneumoniae*, encodes resistance to tetracycline [*tet*(M)], kanamycin, and related aminoglycosides (*aphA-3*) and to macrolide-lincosamide-streptogramin B type antibiotics (*ermAM*). It is closely related to the *tet*(M)-carrying element Tn*916* from *Enterococcus faecalis* (111, 112). Precise excision of Tn*1545* from the chromosome is mediated by the transposase-encoded proteins Xis-Tn and Int-Tn, which are structurally and functionally similar to the Xis and Int proteins of bacteriophage λ. Excision results in a nonreplicating, circular intermediate that can integrate at another site in the resident chromosome through the action of Int-Tn or can mediate its own transfer to other recipients (113). Numerous other Gram-positive bacteria can serve as both recipients and donors for Tn*1545* transfer (112). Transposition occurs in these organisms, as well as in *E. coli* in which the transposon has been introduced on a plasmid. Integration involves site-specific recombination within a short region of

Downloaded From Vet-eBooks.com

nonhomologous DNA and can occur at multiple locations. Specificity is for AT-rich regions and may be related to conformational aspects of the target DNA sequence (110, 114). The family of Tn*916* genetic elements includes many members which share the same general organization but have insertions, deletions, or substitutions of DNA regions relative to Tn*916* (115). Insertions are mainly due to the acquisition of insertion sequences and nonconjugative transposons, such as Tn*917*, the MAS (macrolide-aminoglycoside-streptothricin) element (116), or the MEGA element (macrolide efflux genetic assembly) (117), which carry additional antibiotic resistance genes (118). In *S. pneumoniae*, Tn*916* family elements can be found alone in the chromosome or inserted in larger, composite ICEs such as Tn*5253* and related elements (110, 119).

Tn*5253* [formerly known as Ω(*cat-tet*)], the first ICE identified in *S. pneumoniae*, is a 64,528-bp element in which two distinct genetic elements are integrated, Tn*5251* and Ω*cat*(pC194) (24, 40, 120, 121). Integration of Tn*5253* into the pneumococcal chromosome occurs within a single target site (*attB*) (122). The entire Tn*5253* is capable of conjugal transfer to other streptococci, where it also integrates at a single target site (40). Tn*5251* is 18,033 bp in size, encodes the tetracycline resistance determinant *tet*(M), and is a member of the Tn*1545*/Tn*916* family. Tn*5251* produces circular intermediates, and a deletion in Tn*5253* and is capable of independent conjugal transfer to different bacterial species (110). Ω*cat*(pC194) is a 7,627-bp element and contains a linearized copy of the *cat*-containing staphylococcal plasmid pC194. This element is flanked by two long direct repeats which mediate its excision from Tn*5253* with formation of a circular intermediate. The element is not able to transfer by conjugation but is capable of intracellular mobility, integrating by homologous recombination at an ectopic location in the pneumococcal chromosome corresponding to the PPI1 locus (40).

Tn*1207.1* is a 7,244-bp-long genetic element that carries the *mef*(A)-*msr*(D) macrolide efflux genes and specifically integrates into a specific GA dinucleotide located in *celB*, thus impairing competence (123, 124). Tn*1207.1* is not capable of conjugal transfer but can be transferred by transformation. Three open reading frames, located at the 3′ end of Tn*1207.1*, show homology to the UV resistance genes of Tn*5253* (123). A complete copy of Tn*1207.1* is present at the 5′ end of Φ1207.3 of *Streptococcus pyogenes*, formerly known as Tn*1207.3* (125, 126). Φ1207.3 is 52,491 bp in size; it is integrated into the *comEC* gene of *S. pyogenes* and can be transferred to *S. pneumoniae*, where it inserts into the *comEC* homolog *celB* at the same GA nucleotide of Tn*1207.1* (126).

Pseudotransduction

Although true generalized transduction has not been observed with pneumococcal phages, Porter et al. (10) described a process that involved phage packaging of pneumococcal DNA and subsequent transfer to recipient cells via the transformation pathway. Termed pseudotransduction, the process includes several features consistent with generalized transduction. The phage, PG24, could package different chromosomal regions into DNase-resistant phage particles that adsorbed to recipient bacteria. Gene transfer was inhibited by blocking adsorption with phage-specific antiserum or by trypsin treatment of the phage. Successful gene transfer, however, was dependent on the ability of the recipient cells to become competent and on the presence of the membrane endonuclease (EndA) required for DNA processing and entry via the transformation pathway. Frequency of transfer was affected by the Hex phenotype of the recipient, indicating entry of single-stranded DNA and heteroduplex formation between the donor and recipient DNAs. DNase sensitivity of the process occurred at the time of competence development, further indicating that the bacterial DNA was released from the phage at the outside surface of the cell and not injected into it, as occurs for the phage DNA. Transfer of DNA by pseudotransduction rather than standard transformation permitted the entry of longer fragments, presumably owing to protection of the DNA from excessive cuts by EndA while maintained at the cell surface in the phage head.

Plasmids and Bacteriophages

Plasmids have been detected in a small number of *S. pneumoniae* isolates. Most are either identical or very similar to pDP1, a cryptic 3-kb plasmid first identified in the capsule type 2 strain D39 and a number of its descendants (4, 127). Approximately 3% of over 600 strains examined carry a member of this plasmid family (see reference 128 and references therein). The plasmids belong to a family of rolling-circle plasmids that includes pC194 (4, 128–130). Small plasmids unrelated to pDP1 have occasionally been noted (108), but as with pDP1, no specific functions have been detected (127). The presence of pDP1 or other plasmids is unrelated to the capsular serotype, restriction system, antibiotic resistance profile, clinical infection, or other phenotypes. Plasmids from other Gram-positive bacteria are capable of replicating in *S. pneumoniae* and have been used for both transformation studies and cloning (49, 50, 103, 104).

Bacteriophages that infect *S. pneumoniae* can be readily isolated from clinical samplings (131). The ω, Cp, and Dp groups contain virulent phage that were isolated directly from human throat swabs (132–135). Pneumococcal phages are different in their ability to infect other species of oral streptococci: Cp-1 and Dp-1 are able to infect *Streptococcus mitis* and *Streptococcus oralis* (136, 137), while ω phages do not infect other oral streptococci (135). Temperate phages appear to be present in many pneumococcal isolates and occur in a wide variety of capsular serotypes (138–140). However, as shown using isogenic derivatives of encapsulated and unencapsulated strains, the presence of the capsule prevents infection by virulent ω phages under laboratory conditions (141), suggesting that natural infections may occur when capsule production is reduced, as is expected to occur during colonization of the nasopharyngeal cavity (142, 143).

The properties of some pneumococcal phages are shown in Table 4. Some important similarities between many of the phages have been noted, and the complete nucleotide sequences have been determined for the genomes of many phages, including Dp-1, EJ–1, Cp-1 and its variant SOCP, and MM1 and its variants MM1-1998 and MM1-2008 (132, 137, 140, 144). Comparison of the complete sequences of 10 pneumococcal temperate bacteriophages identified 3 distinct groups of prophages. All prophage genomes are organized in functional modules: (i) the lysogeny module, (ii) the replication module, (iii) the packaging module, (iv) the morphology module, and (v) the lysis module (140). The lysogeny module codes for integrase genes, which determine the site specificity of phage integration. Three main prophage integration sites are present in the pneumococcal chromosome and are located in intergenic regions between (i) SP_0019 and SP_0020 (TIGR4 genome), (ii) SP_0020 and SP_0021 (TIGR4 genome), and (iii) SP_1563 and SP_1564 (TIGR4 genome). Cp-1 and HB-3, as well as their related phages, contain a terminal protein covalently linked to the 5′ end of each DNA strand. In the case of Cp-1, the terminal

[a]Activity of the N-terminal domain of the lytic enzyme.
[b]Substrate bound by the C-terminal domain of the lytic enzyme.

protein serves as a primer in initiation of DNA replication for the linear molecule. The mechanism resembles that of adenovirus and *B. subtilis* phage φ29, with which Cp-1 has structural similarity. As in these other viruses, the DNA of Cp-1 and related phages contains inverted terminal repeat structures. A number of the pneumococcal phages are also related by the structural organization of their lytic enzymes. Cp-1, Cp-9, Dp-1, and HB-3 require choline in the pneumococcal cell wall for adsorption and cell lysis. Lytic enzymes have a modular structure composed of a catalytic domain and a specific binding domain, which localizes the catalytic domain of the enzyme on the substrate. Phage lytic enzymes contain a C-terminal choline-binding domain homologous to those of the choline-binding proteins of *S. pneumoniae*, including pneumococcal autolysin. The N-terminal domain of HB-3 has amidase activity that is virtually identical to that of the host autolysin, whereas the N-terminal domains of Cp-1 and Cp-9 lytic enzymes encode a lysozyme. Dp-1 codes for a hydrolase similar to that found in the *Lactococcus lactis* phage BK5-T. The C-terminal region of the Cp-7 lytic enzyme does not encode a choline-binding domain; hence, this phage does not require choline-containing cell walls for infection. Phage lytic enzymes represent examples of modular evolution, in which catalytic domains and binding domains are shuffled and generate new mosaic alleles.

DNA REPAIR

Incoming DNA that contains either transition mutations or small (<6-bp) deletions or insertions is usually corrected to the recipient DNA sequence by the action of the Hex mismatch repair system (145). Incoming markers can thus be observed to transform at either high efficiency (transversions and large deletions/insertions), low efficiency (transitions and small deletions/insertions), or intermediate efficiency (transversions and single-base deletions/insertions). The substrate for repair is the heteroduplex integration intermediate formed between the donor and recipient DNA. Recognition of a single-strand break in the donor DNA, followed by recognition of the mismatch, triggers activity of a 3′ to 5′ exonuclease that creates a gap of up to several kilobases in the donor DNA. The gap is then repaired using the recipient DNA as a template. Thus, a high-efficiency marker located adjacent to a low-efficiency marker may also be repaired. The same system functions to repair errors in DNA replication and is analogous to the Mut system of *E. coli*. Unlike the Mut system, however, the Hex system does not require recognition of unmethylated sequences in hemimethylated DNA. In *S. pneumoniae*, the products of at least two unlinked genes, *hexA* and *hexB*, are essential for the repair system. HexA (homologous to MutS) recognizes the mismatched base pair, but the role of HexB has not been demonstrated. By analogy with its *E. coli* homolog, MutL, it is likely to interact with HexA and other proteins in the mismatch repair complex and stimulate their activities (146, 147). In Hex$^-$ cells, mismatches are not repaired, and high-efficiency transformation of all markers, as well as a high spontaneous mutation rate, are observed. The high transformation efficiency of many of the commonly used *S. pneumoniae* strains is due, in part, to the fact that they are Hex$^-$, as the result of a mutation in *hexB* (147) (Table 1).

Expression of the *hex* genes is not enhanced during competence, and saturation of the system can occur with an excess number of mismatches, leading to the incorporation of low-efficiency markers. In addition, saturation is observed using donor DNA from the related *S. mitis* and *S. oralis*. Thus, the Hex system does not serve as a barrier to interspecies gene exchange, and its role in transformation, unlike that in DNA replication repair, has been proposed to be fortuitous (148).

S. pneumoniae also encodes a MutY-like adenine glycosylase, which repairs A/G mismatches to CG. MutY mutants exhibit a mutator phenotype, where the frequency of AT to CG transversions is enhanced (149).

S. pneumoniae generally lacks a UmuDC-dependent SOS response involved in error-prone repair of UV-damaged DNA (150), although transposon-encoded UmuC and UmuD homologs can mediate this response in cells harboring ICE Tn*5253* (151). Despite the lack of a LexA homolog in the *S. pneumoniae* chromosome, the purified *S. pneumoniae* RecA is able to cleave the *E. coli* LexA (94). Uptake of either homologous or heterologous DNA during transformation results in lysogenic induction of the temperate bacteriophage HB-746 in RecA$^+$ but not RecA$^-$ cells. Similarly, prophage induction by mitomycin C is dependent on a functional

Downloaded From Vet-eBooks.com

RecA. Both observations are consistent with an SOS-like repair system that is controlled by RecA (152). The spontaneous mutation frequency is significantly increased in cells undergoing transformation with homologous or closely related DNA but is unaffected when nonhomologous DNA is transformed (153). These observations further suggest the existence of an error-prone SOS-like repair system. The repair of double-strand DNA breaks requires RexAB, the functional homologs of the *E. coli* RecBC (154).

RESTRICTION-MODIFICATION SYSTEMS

Most *S. pneumoniae* isolates contain the genes necessary for expression of either the *Dpn*I or *Dpn*II restriction system. The genes for each of these systems are located at the same site in the respective chromosomes, thus forming genetic cassettes that can be exchanged as units between strains (155). The *Dpn*I endonuclease (DpnC) cleaves double-stranded DNA containing the methylated sequence 5′-GmeATC-3′, whereas the *Dpn*II endonuclease (DpnB) cleaves unmethylated DNA of the same sequence. In addition to their respective endonucleases, the *Dpn*I gene cassette encodes a second protein (DpnD) of unknown function, while the *Dpn*II cassette encodes the adenine methyltransferases, DpnA and DpnM, that are necessary for methylating the host DNA to prevent restriction (156). DpnM acts only on double-stranded DNA, whereas DpnA can methylate both double- and single-stranded DNA (157).

The major function of the *Dpn* system is to protect the cell against entry of phage DNA. Neither of the *Dpn* endonucleases attacks single-stranded DNA or hemimethylated double-stranded DNA. Thus, natural transformation of chromosomal DNA is not affected. In contrast, plasmid transformation is affected to some extent, with an approximately 50% reduction observed for transfers between strains of differing *Dpn* types as compared with transfers between strains of the same type (157). The lack of complete restriction of methylated plasmids by *Dpn*I cells apparently results from the mechanism of plasmid uptake, which can give rise to large segments of hemimethylated DNA following DNA synthesis to restore both strands of the incoming plasmid. Complete restriction of nonmethylated plasmids by the *Dpn*II system is prevented by the action of DpnA, which methylates incoming single-stranded DNA. Expression of *dpnA* is induced by CSP and initiates at a com-box sequence (158). In the absence of such methylation, restriction of the newly restored plasmid that is not methylated on either strand apparently occurs faster than methylation of the double-stranded DNA by DpnM. Single-stranded, unmethylated plasmid DNA introduced by conjugation into *Dpn*II cells is also severely restricted, presumably because synthesis of the complementary strand by enzymes transferred with the DNA occurs more rapidly than protective methylation of the single strand by DpnA (157). The introduction of plasmids by electroporation, or other methods that involve the uptake of double-stranded DNA, is also strongly affected by the *Dpn* system (105).

A third allelic variant of the *Dpn* system has been recently identified in the Spain-23F-1 lineage. This system, named *Dpn*III, is constituted by the genes *m.dpnIII* and *r.dpnIII*, which have opposite orientation on the chromosome and code for an endonuclease and for a C5 cytosine-specific DNA methylase, respectively. The endonuclease recognizes and cleaves the specific 5′-GATC-3 sequence on double-stranded unmethylated or hemimethylated DNA, while the methylase recognizes the same 5′-GATC-3′ tetramer and generates a C5-methylcytosine. Genomic analyses and experimental transformation data suggest that this system limits horizontal transfer of unmethylated DNA (159).

A phase-variable type I restriction-modification system has also been identified in various strains of *S. pneumoniae*. This system contains three cotranscribed genes, *hsdR*, *hsdM*, and *hsdS*, which code for the restriction, methylation, and specificity subunits, respectively. The methylation subunit is an N6 adenine methylase, which is guided by the specificity subunit. The *hsdS* gene contains two variable regions which code for two target recognition domains and are able to recombine with two truncated *hsdS* genes located downstream. In a pneumococcal population, recombination generates six alleles of *hsdS* with different methylation target specificities (29, 160, 161). This system acts as an epigenetic switch, which is able to regulate gene expression, virulence, and phase variation (opaque versus transparent phenotype) in pneumococci (160).

TRANSCRIPTION PROMOTERS

The existence of extended –10 sites in promoter sequences was first noted in the *Dpn*II locus and was subsequently found to be relatively common in *S. pneumoniae*, in contrast to the relatively rare occurrence of such sequences in *E. coli*. The promoter of the *Dpn*II operon contains an extended –10 site (TATGGTATAAT) but does not have a –35 site. Analysis of 35 additional known or putative *S. pneumoniae* promoters revealed that 60% had the complete extended –10 consensus sequence (TNTGNTATAAT) and 71% had at least the TG motif of the extension. None lacked a –35 site, and those lacking a –10 extension tended to have –35 sequences close to the *E. coli* consensus (156). Numerous *S. pneumoniae* sequences exhibit promoter activity in *E. coli* but not in *S. pneumoniae*, apparently as a result of the AT richness of the *S. pneumoniae* DNA and of more stringent sequence recognition requirements of the *S. pneumoniae* RNA polymerase. Such requirements could be fulfilled by the extended –10 sequences. Excessive promoter activity of *S. pneumoniae* DNA in *E. coli* has been used to explain difficulties encountered in cloning pneumococcal sequences. While it is clear that difficulties exist, sequences with promoter activity strong enough to destabilize cloning vectors appear to be rare in the *S. pneumoniae* chromosome (162). The expression of toxic products, the use of large fragments or high-copy-number plasmids, and sequence-specific effects unrelated to promoter activity appear to be more likely causes.

GENETIC MANIPULATION

S. pneumoniae is a human pathogen, naturally competent for genetic transformation, and it can be easily manipulated at the genetic level. *S. pneumoniae* therefore represents a model for the study of bacterial genetics and pathogenesis.

Insertion-duplication mutagenesis has been the classical method to knock out genes in *S. pneumoniae* (163). In this procedure, a fragment of *S. pneumoniae* DNA is cloned into a plasmid that is able to replicate in *E. coli* but not in *S. pneumoniae*. The clone can thus be propagated in *E. coli* and be used to transform *S. pneumoniae*, where homologous recombination into the chromosome at the target site produces insertion by single crossover of the whole vector, with the consequent duplication of the cloned gene fragment and the acquisition of an antibiotic resistance determinant encoded by the plasmid vector. Target sequences of less than 200 bp can be used successfully, but larger fragments increase the frequency of transformation, owing in part to the higher likelihood of digestion of the surface-bound DNA within the

Downloaded From Vet-eBooks.com

cloned fragment. Transformation and subsequent integration into the *S. pneumoniae* chromosome result in gene disruption if the cloned fragment is an internal portion of a gene or in restoration of the entire gene if the fragment overlaps one end of the gene (Fig. 2). In the latter case, a mutant phenotype should not be observed unless the target sequence is part of an operon. The mutations produced with this method can display polar effects. Libraries of plasmids containing random fragments of pneumococcal DNA have been used to identify essential genes and mutants impaired in genetic transformation (63).

Transposon mutagenesis using Tn*916* has been employed in *S. pneumoniae* to inactivate the capsule locus (164). *In vitro mariner* transposon mutagenesis has proven to be a useful technique (72, 165). Here, target DNA is mutagenized *in vitro* using the *Himar1* transposase and a minitransposon containing an antibiotic resistance cassette flanked by *Himar1* inverted terminal repeats. Transposase catalyzes the integration of the resistance cassette in the target DNA, then gaps generated at the insertion site are repaired, and the mutagenic DNA is transformed to *S. pneumoniae* with selection for the antibiotic marker. Site specificity is minimal since the *Himar1* target site is any TA dinucleotide, and saturation mutagenesis appears possible. With this method, both site-specific or random mutagenesis can be performed. Site-specific mutagenesis is obtained using a linear PCR fragment as the target DNA, while for random mutagenesis the whole chromosomal DNA is used as a target. The latter technique allows the construction of libraries for the screening of essential genes (165).

Other techniques, employing PCR without the need of cloning, are less time-consuming and minimize the introduction of polar effects. A mutagenic construct containing an antibiotic resistance cassette flanked by DNA fragments located upstream and downstream of the locus to be mutagenized is assembled by splicing by overhang extension PCR and directly used in transformation (166). For the introduction of mutations that do not confer a selectable phenotype, direct transformation of a PCR unmarked mutagenic construct followed by screening using PCR can be used to identify mutants resulting from double crossover events. It is possible to introduce in-frame deletions, insertions, and single nucleotide substitutions in the bacterial chromosome (167). Introduction of unmarked mutations in encapsulated strains with low levels of competence is done using gene replacement techniques involving a negative selection (168). The Janus cassette, which contains a selectable kanamycin-resistance marker and counterselectable *rpsL*, which confers dominant streptomycin sensitivity in a streptomycin-resistant background, is first introduced by homologous recombination at the site of interest. DNA containing the desired mutation is then introduced, and mutants in which recombination has occurred to replace the Janus cassette are identified by their streptomycin-resistant and kanamycin-sensitive phenotypes. The Sweet Janus cassette contains a counterselectable marker that confers sucrose sensitivity and allows a reduction of the false-positive mutants that are isolated (169).

An alternative method for introducing unmarked mutations in the pneumococcal chromosome is the Cheshire cassette, which includes the resistance determinant *ermAM* and the *cre* gene encoding the site-specific recombinase of bacteriophage P1, under the control of the fucose-induced *fcsK* promoter. The cassette is flanked by the recombinase-specific recognition sequence and is introduced by transformation within the target gene. Upon addition of fucose in the growth medium, the recombinase gene is expressed and the cassette is excised (170).

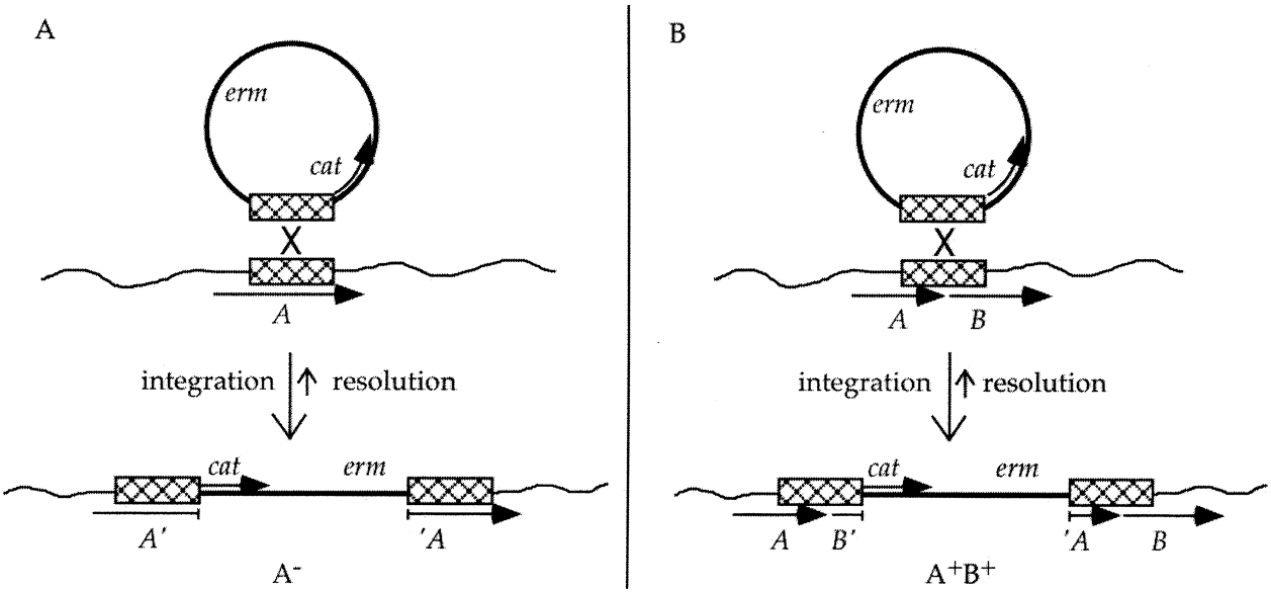

FIGURE 2 Insertion-duplication mutagenesis and restoration. (A) The effect of using an internal gene fragment to direct insertion of a nonreplicating plasmid into the chromosome. Duplication of the target fragment occurs, and the gene is disrupted by the plasmid insertion, resulting in an insertion-duplication mutation. (B) The target fragment overlaps the ends of two genes. Insertion results in duplication of the target fragment, but both genes are completely reconstructed, and the result is an insertion-duplication restoration. Both genes should be functional, unless they form part of an operon, in which case the plasmid insertion would be polar on the downstream gene. The figure shows a selectable erythromycin-resistance gene (*erm*) and a promoterless chloramphenicol-resistance reporter gene (*cat*).

Pneumococcal Vaccines

D. E. BRILES, J. C. PATON, R. MUKERJI, E. SWIATLO AND M. J. CRAIN

23

With the discovery of the pneumococcus in 1881, it became apparent that this Gram-positive pathogen was a major cause of serious and often fatal pneumonia (1). It is also a major cause of meningitis and otitis media in children. Pneumococci are the largest cause of community-acquired pneumonia in the developed world. According to the Centers for Disease Control and Prevention, in the United States the combined rates of invasive pneumococcal diseases has shown a decline since the introduction of the conjugate vaccines, with rates among the elderly declining from 59/100,000 in 1998 to 23/100,000 in 2015 and rates among children under 5 years of age falling from 95/100,000 in 1998 to 9/100,000 in 2016 (https://www.cdc.gov/pneumococcal/surveillance.html). The rate of meningitis in children in the United States is about 4 cases per 100,000 children, with a fatality rate of about 15% (2). In the developing world pneumococci are an important cause of childhood deaths due to bacterial respiratory infection following viral disease. The World Health Organization suggests that globally, such infections have been reported to have killed an estimated over 500,000 children in 2008 (http://www.who.int/immunization/monitoring_surveillance/burden/estimates/Pneumo_hib/en/). Recently, about one-third to one-half of pneumococci recovered from humans in the United States have been found to be at least partially resistant to penicillin, and penicillin-resistant strains are frequently also resistant to other common antibiotics (3). The rise of antibiotic resistance among pneumococci has already complicated treatment, especially of meningitis (4), and threatens to greatly increase the morbidity and mortality caused by pneumococci unless new control measures are developed.

It has long been recognized that the best management of most infectious disease is prevention. Vaccines offer the prospect of a highly cost-effective means of preventing morbidity and mortality caused by pneumococci. This article provides a concise summary of issues critical to the development and application of pneumococcal vaccines. There are several relatively recent reviews that address this topic in more detail (5–11).

In the preantibiotic era, vaccination attempts utilized whole killed pneumococci injected parenterally. Although such vaccines were sometimes protective in humans, they were also highly reactogenic. These killed vaccines were mainly used to elicit antibody in animals for passive treatment of infected humans (12). In 1933 it was clearly demonstrated that antibody to type-specific capsular polysaccharides (PSs) could be highly protective (13). However it soon became apparent that different strains of *Streptococcus pneumoniae* each expressed one of many different PSs. Most subsequent vaccine attempts focused on the use of mixtures of the isolated PSs to elicit protection (7, 14). However, the inability of young children to make adequate responses to most soluble PSs led to the eventual development and licensing of an immunogenic PS-protein conjugate vaccine for children (6, 15). However, the wide diversity of pneumococcal PS types, the failure of PS vaccines to protect against strains with PSs not in the vaccines, and the complexity and expense of highly valent conjugate vaccines have led to investigations of other much more cross-reactive pneumococcal antigens (primarily proteins) as potential vaccine candidates.

PNEUMOCOCCAL CAPSULAR PS VACCINE

During the 1930s, capsular PS was shown to be able to elicit protective antibodies. At that time it was generally assumed that capsular PS was the target of all, or most, protective antibodies (1, 13). Currently, over 90 distinct serotypes of capsular PS have been identified for pneumococci (16). Each strain can make only one PS, and for a strain to make a different PS requires a genetic transformation with DNA of another strain. Only about one-third of the greater than 90 serotypes occur with a significant frequency in adult infections, and the distribution of common serotypes is even more restricted in children (6, 17–20). Following the identification of capsular PSs as protection-eliciting molecules, vaccines comprising relatively pure PSs were used successfully in nursing homes and among military personnel in the 1940s. However, during this time antibiotics were becoming widely available, and these drugs diminished the perceived impact of pneumococcal infections. The two commercially available pneumococcal vaccines were withdrawn from production for lack of demand (7).

Despite a growing selection of antibiotics and increasingly sophisticated critical care technology, morbidity and mortality from invasive pneumococcal infections have remained high. Antibiotics and supportive care alone are not sufficient to completely eliminate the impact of pneumococcal disease because in many cases deaths occur so quickly that antibiotics are not effective (21). During the 1970s, renewed interest in pneumococcal vaccines (14) led to clinical trials of a PS vaccine in adults at high risk for invasive pneumococcal disease (IPD) in South Africa and New Guinea. Based largely on encouraging results from these trials, a 14-valent PS vaccine was licensed in the United States in 1977. The

doi:10.1128/microbiolspec.GPP3-0028-2018

Downloaded From Vet-eBooks.com

vaccine was expanded to 23 PS serotypes in 1983 and is licensed for use in adults in the United States (6, 7, 22).

Clinical trials examining the efficacy of the PS vaccine continued after licensure, with somewhat mixed, and controversial, results (7). A significant impediment to conducting the most rigorous controlled clinical trials has been the ethical concern of denying at-risk groups an approved and recommended vaccine. A recent systematic review and meta-analysis to examine the efficacy of the 23-valent vaccine (PPSV23) in adults >60 years of age, has shown a pooled vaccine efficacy of 73% (95% confidence interval [CI]: 10 to 92%) against IPD in clinical trials, 45% (95% CI: 15 to 65%) in cohort studies and 59% (95% CI: 34 to 74%) in case control studies (22). The higher efficacy of former trial data, with a 2.5-year follow-up, compared to the lower efficacy seen in the observational cohort and case control studies, with a 5-year follow-up, may reflect a waning protection over time (22, 23). Although the PS vaccine is cost-effective even when considering only bacteremic disease, this vaccine is not generally accepted to reduce the incidence of pneumococcal pneumonia or localized upper respiratory infections such as acute bronchitis, sinusitis, or otitis media (24).

A major drawback to the PS vaccine is the poor immunogenicity of PS antigens in children and elderly adults, primarily due to the vaccine eliciting a T cell-independent immune response (25). The response to PS varies by age and with the presence of certain underlying chronic medical conditions, most notably, infection with human immunodeficiency virus (HIV). Certain capsular PS serotypes in the 23-valent vaccine, such as types 6B, 9V, 19F, and 23F, induce relatively low amounts of specific antibody, which fall to prevaccination levels within 3 years (26). In addition to a reduced quantity of antibody, a significant number of elderly adults have impaired functional antibody responses to PS as defined by *in vitro* avidity and opsonophagocytosis assays (27, 28).

POLYSACCHARIDE-PROTEIN CONJUGATE VACCINES

Children less than 2 years of age are at increased risk for infections caused by encapsulated bacteria; consequently, this group had the highest incidence of invasive pneumococcal infections in the preconjugate era (27). Children in this age group do not consistently respond to PS antigens, which directly cross-link surface immunoglobulin on B cells and do not have an absolute requirement for T cell help (29–31). Whatever the underlying mechanisms, children less than 2 years old respond poorly to many of the common pneumococcal capsular types (32), and alternatives to purified PS antigens are needed to protect young children.

The ability to make antibodies to protein antigens appears quite rapidly after birth, and T cell-dependent antibody production is highly efficient. The development of PS-protein conjugate vaccines for children takes advantage of their ability to elicit T cell-dependent responses to PS covalently attached to immunogenic proteins. This strategy has proven highly successful in preventing both invasive disease and colonization with *Haemophilus influenzae* type b (33). The process of synthesizing conjugate vaccines requires chemical reactions, which covalently attach PS to protein; nonconjugated mixtures of peptides and PS do not induce T cell-dependent PS antibodies (34).

Immunization with PS conjugate vaccines induces effective memory antibody responses in infants and children, and antibody levels can be boosted with repeated immunization (35). A large clinical trial in infants using a four-dose schedule of immunization with a heptavalent conjugate vaccine proved this strategy to be highly effective in preventing invasive (bacteremic) disease (30, 36, 37). However, this conjugate vaccine has shown somewhat more modest efficacy in preventing pneumonia (15) and otitis media (38). The heptavalent pneumococcal conjugate vaccine (PCV7) was licensed in 2000 in the United States for use in all children less than 2 years of age and for high-risk children less than 5 years of age (37). Since the vaccine serotypes that colonize and infect children include most of the serotypes associated with antibiotic resistance, and since children carry pneumococci at a much higher frequency than adults, there are expectations that childhood immunization may reduce the transmission of antibiotic-resistant pneumococci in the entire population (39–42). It has been observed, however, that significant replacement carriage and otitis media occur with capsular types not present in the vaccine (38, 39, 42). Since the introduction of the 7-valent vaccine, a significant increase in invasive disease was seen among nonvaccine strains, which led to the introduction of the 13-valent conjugate vaccine in 2010 (43–45). However, despite the introduction of the new conjugate vaccine, strain replacement still persisted in carriage and invasive disease, with rates of invasive disease due to nonvaccine strains ranging from 57.8% in North America to 71.9% in Europe (46–50). Also of concern are observations that immunization with the conjugate vaccine alters the bacterial flora of the upper respiratory tract in children and has affected the pathogens recovered from children with carriage and acute otitis media (51, 52). A potentially worrisome trend has been noted in increased rates of carriage of *Staphylococcus aureus* in children immunized with the pneumococcal conjugate vaccine (51, 53).

According to 2015 data from the Centers for Disease Control and Prevention, adults over the age of 65 years had the highest risk of IPD in the United States (https://www.cdc.gov/abcs/reports-findings/survreports/spneu15.html). The distribution of pneumococcal serotypes commonly causing invasive disease in adults is much larger than that for children. The Advisory Committee on Immunization Practices recommended the current 13-valent conjugate vaccine for use, in conjunction with the 23-valent PS vaccine, in adults over the age of 65 years (54). This recommendation was based on the results of a large efficacy trial in the Netherlands, which showed 75% and 46% efficacy against vaccine type invasive disease and pneumococcal pneumonia, respectively, among people over 65 years (55). It is recommended that the 13-valent vaccine be administered prior to the 23-valent vaccine, because there is evidence that prior PS vaccine administration reduces the immune response to the conjugate vaccine (56, 57). The CDC is currently evaluating the efficacy of the stand-alone 13-valent conjugate vaccine or the conjugate vaccine in conjunction with the 23-valent PS vaccine in older adults in the United States. The 13-valent conjugate vaccine is also recommended for routine use among people over the age of 19 with immunocompromising conditions, functional or anatomic asplenia, cochlear implants, or cerebrospinal fluid leak (54, 58). Attempts are also underway to develop conjugate vaccines with much higher valence to broaden coverage of different serotypes (59, 60).

Strategies to enhance the immunogenicity of PS have been tested in small animal and human studies, but none have yet reached clinical application. A conjugate of type 6B PS and tetanus toxoid reduces carriage in mice when administered intranasally with the cholera toxin B subunit

Downloaded From Vet-eBooks.com

(61). T cell help during response to protein antigens involves binding of CD40 on B cells by CD154 expressed on T cells. Administration of anti-CD40 antibodies along with capsular PS results in predominantly high-affinity IgG antibodies, which is a hallmark of responses to protein antigens (62). Small amounts of interleukin 12 have been shown to be a potent adjuvant for pneumococcal PS in mice (63). Coadministration of immune modulators may prove to be an effective and practical strategy to enhance immune responses to PS. Unless substantial progress is made with protective protein antigens or protein-PS conjugates, novel methods for adjuvant responses to purified capsular PS will remain an important area of investigation into pneumococcal vaccines. One such approach has been the development of a multiple antigen-presenting system (MAPS), which combines various antigens, including PSs and proteins, in a synthetic acellular system (64). Such complexes of antigens in some ways mimic the pneumococcal whole-cell vaccine (WCV) with probably much less risk of undesired reactogenicity. The MAPS complex is highly efficient in generating a broad immune response, including B and T cell (Th1 and Th17) responses, and is particularly effective in the case of *S. pneumoniae*, because it circumvents the issue of covering multiple serotypes to avoid the serious problem of serotype replacement. An approach with multiple antigens that collectively protects against carriage, pneumonia, and sepsis, delivered through a mucosal route, would be expected to be optimally protective.

NONCAPSULAR PS VACCINES

Overview

Polyvalent pneumococcal vaccines based on purified PS have been available for over 3 decades, but their clinical efficacy has been limited by poor immunogenicity in high-risk groups (particularly young children). As discussed above, the problem of poor vaccine immunogenicity in children has been addressed by conjugation of the PS to protein carriers, thereby converting the PS from T cell-independent to T cell-dependent antigens. However, serotype coverage remains limited, and it is unlikely that significantly more than 13 to 15 of the 98 currently known serotypes will be included in future conjugate formulations. Nasopharyngeal colonization with *S. pneumoniae* is a virtual prerequisite for invasive disease. Data from the original conjugate vaccine trials indicated that, although carriage of vaccine types was reduced, the vacated niche was promptly occupied by nonvaccine serotypes known to cause invasive disease in humans (8). Such "replacement" carriage, as well as replacement disease due to nonvaccine serotypes, has occurred to varying extents in virtually all regions where conjugate vaccines have been widely used since the licensure of the original 7-valent formulation in 2000 and continued after introduction of 10- and 13-valent formulations (65–67). In addition, the cost of the conjugate vaccines remains very high; thus, without philanthropic support, their use in developing countries, where the need for effective pediatric vaccines is the greatest, will remain restricted. In view of this, much attention has focused on the possibility of developing vaccines based on pneumococcal protein antigens common to all serotypes (5, 68, 69). Such proteins, being T cell-dependent antigens, are likely to be highly immunogenic in human infants and able to elicit immunological memory. The pneumococcal proteins also have potential as carriers for the PS in the conjugate vaccines. The vaccine potential of various pneumococcal protein antigens are discussed further below.

PspA and PspC

Pneumococcal surface protein A (PspA) is produced by all pneumococci (70). The protein is important for virulence (71, 72); its presence on pneumococci prevents classical pathway complement deposition via C-reactive protein (CRP) and probably anti-PC antibody (72–74). PspA also appears to reduce phagocytosis of pneumococci even in the absence of C′ and antibody (75). Antibodies to PspA, however, strongly enhance complement deposition (73). PspA may also play a role on mucosal surfaces since it blocks killing by apolactoferrin (76). Antibody to PspA reverses this blockage and enhances killing by apolactoferrin (76). Although serologically variable when examined with monoclonal antibody, PspA is highly cross-reactive when examined with polyclonal sera (70, 77). Monoclonal and polyclonal antibodies to PspA can passively protect mice from otherwise fatal bacteremia and otherwise fatal sepsis caused by pneumococci (78, 79). Parenteral immunization with PspA has been able to protect mice against fatal infections, and this protection has been observed to be highly cross-protective regardless of PspA type (79–81). Intranasal and transdermal immunization with PspA has also been shown to protect against nasopharyngeal carriage in an adult mouse carriage model, raising the possibility that vaccines could be developed to prevent carriage and transmission of pneumococci in addition to invasive disease with pneumococci (45, 61, 82–86). A group in Japan has used PspA for the development of a mucosal vaccination protocol which does not use an immunogenic adjuvant or molecules that can follow the nerves from the nose into the brain. Their protocol and the transdermal route could be particularly important in moving PspA and other mucosal immunogens into humans as the vaccines routes able to elicit both mucosal and systemic immune responses (83, 84).

A number of pneumococcal proteins, including PspA, PspC, and LytA, are able to bind choline and share similar, and sometimes indistinguishable, choline-binding domains near the C-terminal ends of the proteins (87–90). The N-terminal end of PspA is composed of a largely coiled-coil α-helical sequence (89, 91) that is responsible for most of the cross-protective immunity elicited by PspA (92, 93). Paradoxically, this region also contains significant structural and serologic variability within the PspA molecule (92, 94). In spite of its variability at the amino acid sequence level, PspAs are very cross-reactive (70, 79) and can be divided into families based on their cross-reactivity and amino acid sequences (77, 94). Ninety five percent or more of clinical isolates belong to families 1 and 2 (77, 94, 95). Immunization of humans with a single recombinant family 1 PspA leads to antibodies that are able to protect mice from otherwise fatal infection with strains expressing either family 1 or family 2 PspAs (80). However, other data indicate that the best vaccine would probably contain PspAs from both family 1 and family 2 (81, 93, 96). In addition, it has been shown that the 80-120 amino acid long proline-rich domain in the middle of PspA, is also able to elicit protective antibody (97). The use of well-chosen alpha-helical and proline-rich domains in immunizing PspA molecules should ensure coverage of diverse PspAs.

The serum of virtually all adults, and most children over 7 months of age contains detectable antibody to PspA (98, 99). The levels of antibody are higher in adults than in children, and it is thus possible that natural antibodies to PspA will contribute more to the immunity to pneumococcal infection in adults than in young children. It is assumed that

Downloaded From Vet-eBooks.com

immunization to elicit high levels of antibodies to PspA will be able to enhance protection of young children and adults with waning immunity from infections with pneumococci.

PspC is a protein that has some similarity to PspA in its proline-rich and choline-binding domains (100). The gene for this protein was originally identified through its close similarity to PspA (101). However, the alpha-helical domain of PspC is more complex than that of PspA and is present as several very distinct alleles with distinct combinations of functions (102, 103). This protein has been independently discovered by others based on its ability to bind secretory IgA (SpsA) (104), choline (CbpA) (105), and factor H (Hic) (106). It has potential roles in colonization, adherence, and invasion (103–105, 107, 108). Immunity to PspC is able to protect against pneumococcal infection and carriage (103, 108). Recent studies have shown that the NEEK motif of PspC (CbpA) is able to bind to laminin receptors on the blood-brain barrier and thus is able to elicit protection against fatal pneumococcal infection and is suspected to be particularly important in protection against meningitis (109, 110).

Pneumolysin

All pneumococci produce pneumolysin, a potent 53-kDa thiol-activated pore-forming cytolysin. Pneumolysin is released from pneumococci especially during autolysis. This cell-free pneumolysin can attack any cell that has cholesterol in its plasma membrane (111). In addition to its cytotoxic properties, cell-free pneumolysin is capable of directly activating the classical complement pathway away from the pneumococcal surface and does so in the absence of specific antibody. Classical pathway activation by pneumolysin reduces the local concentration of reactive C3 and other classical pathway complement components. As a result, there is a local decrease in serum opsonic activity (112).

Structure-function analysis of pneumolysin has indicated that a domain toward the C terminus of the toxin (amino acids 427 to 437), which includes a unique cysteine residue, is critical for cytotoxicity (113). This cysteine motif is highly conserved among other members of the thiol-activated cytolysin family. Several single-amino-acid substitutions within this region (and other regions involved in cell binding and pore formation) reduce the cytotoxicity of pneumolysin by up to 99.9%. A separate region, which has a degree of amino acid homology with human CRP, is responsible for IgG binding and complement activation, and a mutation in this domain (Asp385→Asn) interferes with both properties (114).

Pneumolysin has a variety of detrimental effects on cells and tissues *in vitro*, which provide clues to its role in the pathogenesis of pneumococcal disease (111, 115). Complete inactivation of the pneumolysin gene in either a type 2 or type 3 pneumococcus has been shown to reduce virulence for mice challenged by both the intranasal and intraperitoneal routes (116, 117). Compared with the wild-type strain, intranasal challenge with the pneumolysin-negative pneumococci resulted in a less severe inflammatory response, a reduced rate of multiplication within the lung, a reduced capacity to injure the alveolar-capillary barrier, and a delayed onset of bacteremia (118, 119). Pneumolysin also plays a critical role after bacteremia has developed, by modulating the elicited inflammation to reduce its ability to keep bacteremia in check (120). Pneumolysin's ability to modulate inflammation may be related to its ability to stimulate Toll-like receptor 4 (121) and may contribute to chemotaxis of CD4 T cells (122). By using *S. pneumoniae* derivatives, in which the wild-type pneumolysin gene was replaced by mutated genes encoding toxins with point mutations affecting either or both of the cytotoxic and complement activation properties, it has been possible to confirm distinct roles for the two toxin activities in the pathogenesis of pneumococcal pneumonia (123–125).

These studies established the importance of pneumolysin in the pathogenesis of pneumococcal disease and identified it as a target for vaccination. It has been known for many years that immunization with purified pneumolysin protects mice against challenge with highly virulent pneumococci (126). Potential problems of toxicity have been overcome by site-directed mutagenesis of regions of the toxin essential for cytotoxicity and complement activation, as described above. Genes encoding these recombinant pneumolysin toxoids (pneumolysoids) have also been inserted into *Escherichia coli* expression vectors, permitting large-scale production of antigens at low cost (127). Sequence analysis of pneumolysin genes from a wide range of *S. pneumoniae* serotypes has confirmed that there is very little variation in primary amino acid sequences (>99% identity) (128, 129), so a single vaccine antigen should provide coverage against all pneumococci regardless of serotype. Indeed, immunization of mice with a pneumolysoid carrying a Trp_{433}-Phe mutation resulting in a >99% reduction in cytotoxicity (designated PdB) provided a significant degree of protection against all nine serotypes of *S. pneumoniae* that were tested (130). Moreover, mouse monoclonal antibodies to pneumolysin could protect against otherwise fatal infection following intranasal inoculation of *S. pneumoniae* (131). Humans are known to mount an antibody response to pneumolysin as a result of natural exposure to *S. pneumoniae* (132, 133). The expectation that human antibodies to pneumolysin may be protective is supported by evidence that purified human antibody to pneumolysin passively protects mice from challenge with virulent pneumococci (132) and by evidence that a lack of high levels of serum antibody to pneumolysin appear to predispose patients to pneumococcal pneumonia (133). Thus, it is anticipated that immunization of humans with pneumolysoid will increase resistance to pneumococcal infection. The protection elicited by a pneumolysin-containing vaccine may be enhanced by incorporation of other protection-eliciting antigens such as PspA, immunity to which enhances complement deposition and blood clearance (73, 134, 135).

Pneumolysin has also shown promise as a carrier for the otherwise poorly immunogenic PS in experimental conjugate vaccine formulations. Immunization of mice with pneumolysoid conjugated to type 19F PS elicited a strong and boostable antibody response to both protein and PS moieties and provided infant mice with a high degree of protection against challenge with *S. pneumoniae* (127, 136). Similar results have been reported for conjugates of native pneumolysin with type 18C PS (137). A comparison of tetravalent pneumolysoid-PS or tetanus toxoid-PS conjugate vaccines (incorporating PS types 6B, 14, 19F, and 23F) demonstrated that pneumolysoid was at least as good a carrier protein as tetanus toxoid and, in the case of type 23F, superior (138). Clearly, such antigens have the potential to evoke a significant anti-PS response, as well as an anti-virulence-protein response, thereby conferring comprehensive protection against pneumococcal disease in humans.

Other Choline Binding Proteins

Access to the pneumococcal genome sequence facilitated the search for additional vaccine antigens, because it enabled entire families of genes encoding proteins with recognizable

Downloaded From Vet-eBooks.com

structural features to be targeted (139). The choline binding proteins are good examples of this approach. Although several members of this family were previously identified by conventional techniques, such as elution from the cell surface with choline, a search of the genome sequence identified a dozen or so functional genes encoding proteins with choline-binding motifs. Site-specific mutagenesis was then used to demonstrate that five of the novel choline binding proteins (CbpD, CbpE, CbpG, LytB, and LytC) were involved in *in vitro* adherence to epithelial cells, nasopharyngeal colonization, or sepsis, thereby identifying them as vaccine candidates (140). LytB and LytC are unusual in that their choline binding domains are located in the N-terminal part of the molecule, while the C-terminal portions have murein hydrolase activity (141). Purified recombinant LytB and LytC were subsequently tested for protective efficacy as part of another large-scale study. Immunization with these proteins conferred significant protection against intraperitoneal challenge in mice, although the degree of protection observed was marginally less than that observed using PspA, which was used as a control antigen (142).

Another choline binding protein with cell wall modification (in this case amidase) activity is the major pneumococcal autolysin LytA. Mutatgenesis of the *lytA* gene prevents the autolysis of pneumococci that occurs spontaneously in stationary-phase cultures, or on addition of deoxycholate and also attenuates virulence in mouse models of sepsis. It might seem paradoxical that inactivation of what is essentially a suicide gene could have such an effect. However, LytA is largely responsible for release of cell-associated pneumolysin, inflammatory cell wall degradation products, and other cell-associated virulence factors, so prevention of autolysis might be of considerable benefit to the host (116, 118, 143). Exogenous antibody to LytA is capable of penetrating the surface layers of the pneumococcus and inhibiting autolysis and release of pneumolysin *in vitro*. Active immunization of mice with purified LytA also elicited a similar degree of protection as pneumolysoid against challenge with fully virulent pneumococci, but it conferred no significant protection against challenge with high doses of a pneumolysin-negative strain. This suggested that the LytA-induced protection is mediated largely through blockade of pneumolysin release (144).

Lipoproteins

The pneumococcal genome includes over 30 putative lipoproteins, with prolipoprotein signal peptidase recognition sequences (LXXC) (145). This so-called lipobox motif directs covalent attachment of a diacyl glycerol moiety to the N-terminal Cys residue of the mature protein, anchoring it to the outer face of the plasma membrane. Thus, they are located beneath the cell wall and the capsule in *S. pneumoniae*. These lipoproteins have diverse functions, the commonest being substrate binding components of ATP binding cassette (ABC) transport systems, and many are important for growth and survival of the pneumococcus *in vitro* and *in vivo*. Their cellular location suggests that they are not exposed on the cell surface to any significant extent, which in turn suggests that they are unlikely to elicit opsonic antibodies. However, this does not necessarily preclude their utility as vaccine targets, since exogenous antibody may diffuse through the capsule and cell wall layers and inhibit the biological function of the lipoprotein. Indeed, several pneumococcal lipoproteins have been shown to have potential as vaccine antigens, as discussed below.

Pneumococcal surface antigen A (PsaA)

PsaA is a highly conserved 37-kDa lipoprotein produced by all pneumococci. It was initially thought to be an adhesin based on sequence homology with putative lipoprotein adhesins of oral streptococci, but it is actually the metal binding component of an Mn^{2+}-specific ABC transport system (146). Defined *psa*A-negative mutants of *S. pneumoniae* are virtually avirulent for mice and exhibit markedly reduced adherence *in vitro* to human type II pneumocytes (147, 148). This is presumed to be a consequence of growth retardation due to an inability to scavenge Mn^{2+} *in vivo*, as well as pleiotropic effects on expression of a range of cellular processes or virulence factors. Intracellular Mn^{2+} appears to play a critical role in the regulation of expression of oxidative stress response enzymes and intracellular redox homeostasis, and *psa*A-negative pneumococci exhibit hypersensitivity to superoxide and hydrogen peroxide (147, 149).

One study has shown that parenteral immunization of mice with purified PsaA in the presence of strong adjuvants elicits significant protection against systemic challenge with *S. pneumoniae* (150). However, in other studies immunization with PsaA elicited only marginal protection and was less efficacious than pneumolysoid in an intraperitoneal challenge model (134, 151). The dimensions of PsaA (approximately 7 nm at its longest axis) (152) are such that if it is indeed anchored to the outer face of the cell membrane via its N-terminal lipid moiety, it is unlikely to be exposed on the outer surface of the pneumococcus. This is consistent with the fact that whereas the known surface-exposed domains of PspA and PspC are variable, the amino acid sequence of PsaA is highly conserved (153). Gor et al. (151) used flow cytometry to compare the surface accessibility of PsaA and PspA to exogenous specific antibodies in 12 *S. pneumoniae* strains. PspA was readily detectable on the surface of all strains, whereas PsaA was not. This directly correlated with the protective efficacy of either active or passive immunization with the respective protein or antibody; significant protection against systemic challenge was achieved using PspA or anti-PspA, but not using PsaA or anti-PsaA. Given the virtual absence of surface exposure, any protection elicited by immunization with PsaA is unlikely to be a consequence of enhanced opsonophagocytic clearance. Rather, it is presumably due to *in vivo* blockade of ion transport, which necessitates diffusion of antibody through the capsule and cell wall layers. Such penetration of antibody is likely to be concentration-dependent, and thus, high anti-PsaA titers may be required for protection. Moreover, accessibility of PsaA to exogenous antibody may be influenced by the thickness of the capsule, which may vary from strain to strain. Expression of pneumococcal capsule biosynthesis genes has also been shown to be upregulated during invasive infection (154). In contrast, pneumococci colonizing the nasopharynx are thought to downregulate capsule expression, thereby facilitating interaction between surface adhesins and the host mucosa. Consistent with this hypothesis, several studies have shown that intranasal immunization of mice with PsaA in the presence of strong mucosal adjuvants such as cholera toxin B subunit significantly reduces the level of nasopharyngeal carriage of *S. pneumoniae* (82, 155). A lesser but still significant reduction in susceptibility to carriage was also achieved by subcutaneous immunization of mice with synthetic lipidated multiantigenic PsaA peptides (156). Thus, at least in the nasopharynx, PsaA may be accessible to antibody. Immunization with a PsaA-cholera toxin B subunit fusion protein also significantly reduced carriage of *S. pneumoniae* in

Downloaded From Vet-eBooks.com

mice without significantly disturbing the oropharyngeal microflora (157).

Iron transporter lipoproteins PiuA and PiaA

Two other metal-binding lipoproteins have been proposed as pneumococcal vaccine antigens. These proteins, designated PiuA and PiaA, are components of two separate ABC iron transport systems. At least one of these proteins is required for optimal growth of pneumococci in iron-depleted media, and they are capable of acquiring iron from hemoglobin (158). Indeed, PiuA has been shown to be capable of directly binding both hemin and hemoglobin (159). PiuA and PiaA are produced by all pneumococci, and their genes are highly conserved (160). Mutagenesis studies have shown that both proteins contribute to virulence in mice using both lung and intraperitoneal models of infection (158). They are immunologically cross-reactive, and immunization of mice with either protein conferred a similar degree of protection against intraperitoneal challenge to that elicited by the pneumolysoid PdB. Moreover, immunization with a combination of PiuA and PiaA resulted in additive protection (161). Although a direct comparison has not been conducted, immunization with either PiuA or PiaA provided a higher degree of protection against systemic disease than that previously published for PsaA, using the same mouse model and *S. pneumoniae* challenge strain (134). Like PsaA, PiuA and PiaA are predicted to be attached to the outer face of the plasma membrane (159), and so the superior protective efficacy of the latter proteins ought not to be due to a difference in accessibility to exogenous antibody. However, Jomaa et al. (160) have shown by flow cytometry that both PiaA and PiuA are accessible to exogenous antibody in intact bacteria and that these antibodies stimulate *in vitro* opsonophagocytic activity, particularly in the presence of complement. They also reported that the antibodies did not appear to interfere with iron uptake *in vitro*. Mucosal immunization with PiuA and PiaA has also been shown to elicit antibody responses both in serum and respiratory secretions, which protected mice against intranasal challenge (162). The reason for the apparent difference in surface accessibility between PsaA and the two iron-binding lipoproteins is unclear, given their predicted location. One possibility is that in the latter two cases, at least a proportion of the proteins are released from the membrane and are then able to bind to more exposed domains on the pneumococcal surface, where they can interact with exogenous antibody more freely. Regardless of the underlying mechanism, available data suggest that PiaA and PiuA have more promise than PsaA as vaccine antigens, as least for prevention of systemic disease.

Pneumococcal Histidine Triad (Pht) Proteins

The pneumococcal histidine triad proteins are a recently recognized family of surface proteins that have an unusual polyhistidine motif, HXXHXH, repeated five or six times in their amino acid sequences. The prototype, PhtA, was discovered as part of a genome-wide screen for potential vaccine antigens (142). Over 100 proteins were expressed and tested for efficacy in a mouse model, and PhtA was 1 of only 5 that were protective. The others were the choline binding proteins LytB and LytC (discussed previously), a cell wall-associated serine protease PrtA, and another protein of unknown function, designated PvaA. Further examination of the pneumococcal genome sequence revealed three additional related open reading frames (designated PhtB, PhtD, and PhtE), each with five or six copies of the histidine triad motif. The four proteins range in size from 91 to 114 kDa and are closely related at the amino acid sequence level, exhibiting 32 to 87% identity; this similarity is strongest in the N-terminal regions (163). Although their signal peptides all contain an LXXC motif, this does not appear to function as a true lipobox, because they are not labeled by [^{3}H]-palmitate (164). Flow cytometric analyses have shown that the C-terminal regions are more readily accessible to exogenous antibodies (163, 164), suggesting that they are tethered via their N-termini. Analysis of deletion and point mutants subsequently identified a three-amino-acid region in PhtD (Q27-H28-R29) that is critical for surface attachment (165). The histidine triads are believed to form a novel Zn^{2+} binding motif (166), and the *pht* genes are regulated by the Zn^{2+}-dependent repressor AdcR (167). A major function of Pht proteins is to facilitate Zn^{2+} import via AdcAII, one of two Zn^{2+} binding lipoproteins associated with the AdcBC permease (168). Of the five His triad motifs in PhtD, that closest to the N-terminus appears to have the greatest impact on Zn^{2+} recruitment (169). Pht proteins may also inhibit complement deposition on the pneumococcal surface through binding of factor H (167). They exhibit substantial functional redundancy; significant effects on virulence in mouse models of pneumococcal sepsis, on AdcAII-dependent Zn^{2+} uptake, and on complement deposition *in vitro* were only observed when all four *pht* genes were deleted (167, 168).

There is a high degree of protein sequence conservation among individual Pht proteins from diverse *S. pneumoniae* serotypes (164), which combined with a degree of immunological cross-reactivity between the proteins augers well for broad strain coverage for these candidate vaccine antigens. Immunization with purified PhtA, PhtB, or PhtD has been shown to confer significant protection against intraperitoneal challenge with type 3, 6A, and 6B and one of two type 4 *S. pneumoniae* strains (142, 163). PhtD has also been shown to protect against intranasal challenge with a type 3 strain (170), while immunization with either PhtB or PhtE also protects against type 3 pneumococci in models of sepsis and pneumonia (164). In this latter study, immunization experiments with truncated PhtE fragments localized the protective epitopes to the more surface-exposed C-terminal region of the molecule. However, notwithstanding these promising results, the only direct comparative studies of the protective efficacy of Pht proteins with other well-characterized antigens indicate that the level of protection elicited is no better than that achieved by either PspA or pneumolysoid (142, 171).

Sortase-Dependent Surface Proteins

Sortase-dependent surface proteins of Gram-positive bacteria are identifiable by the presence of a C-terminal anchoring motif, which consists of a conserved LPXTG sequence, followed by a hydrophobic domain and usually a tail of positively charged residues. This motif is recognized by sortase, a membrane-localized cysteine protease which cleaves between the T and G residues and covalently links the processed protein to the peptidoglycan cross-bridges (172). In pneumococci, inactivation of the sortase gene releases known sortase-dependent surface proteins, such as the major pneumococcal neuraminidase NanA, and reduces adherence to pharyngeal cells (173). NanA-deficient mutants of *S. pneumoniae* have been shown to have a reduced capacity to colonize the upper and lower respiratory tracts of mice (174, 175) and the nasopharynx and middle ear cleft of chinchillas (176). An early study indicated that purified NanA had

Downloaded From Vet-eBooks.com

modest but significant protective efficacy (weaker than pneumolysin) in a mouse sepsis model (144). It was also shown to be protective against both carriage and otitis media in chinchillas (177, 178).

Significant attention has also been paid to pilus-like structures on the surface of *S. pneumoniae*, which contribute to virulence (179). These are encoded on the *rlrA* pathogenicity islet, which is present in some but not all clinical isolates. The *rlrA* islet encodes a transcriptional regulator, three pilus structural components (RrgA, RrgB, and RrgC), and three sortases (SrtB, SrtC, and SrtD) which are required for pilus assembly (179, 180). RrgB is the major pilin, while RrgA and RrgC are ancillary pilin subunits decorating the shaft and tip (181). Immunization of mice with purified RrgA, RrgB, or the combination of all three pilus proteins elicited significant protection against intraperitoneal challenge with the *S. pneumoniae* strain from which the proteins originated (182). However, the utility of pilus proteins as stand-alone vaccine antigens is limited by the fact that there are three sequence clades of the *rlrA* islet, each associated with distinct *S. pneumoniae* clonal groups. At the amino acid sequence level, RrgB is the most divergent, with only about 50% identity between clades (183), and the extent of cross-protection is unknown. Moreover, *rlrA*-positive pneumococci account for only about 30% of strains, and the majority of these belong to serotypes covered by PCV7 (183, 184). Interestingly, a second pneumococcal pilus locus has recently been described, and this was present in about 16% of strains, again belonging to discrete clonal groups, all but one of which lacked *rlrA* (185). However, the vaccine potential of these distinct pilus proteins is uncertain.

Other sortase-dependent pneumococcal surface proteins have been proposed as vaccine candidates, including hyaluronidase (Hyl) and the IgA1 protease (Iga). The latter is of interest because its sortase motif is located in the N-terminal region of the molecule, but it is nevertheless essential for proper function and surface localization (186). However, although these proteins have been shown to contribute to pathogenesis using either *in vitro* or *in vivo* models, Hyl is at best a weak protective antigen (187), while Iga is yet to be tested individually for protective efficacy.

Other Protein Vaccine Candidates

A number of other apparently surface-associated pneumococcal proteins with at least theoretical vaccine potential have been identified, in most cases using immunoproteomic approaches. This list includes proteins that lack export or anchorage signals and would have been predicted to be cytoplasmic and hence dismissed by previous motif-based searches. Examples include metabolic enzymes such as enolase (which also binds plasminogen) (188), 6-phosphogluconate dehydrogenase (a putative adhesin) (189), fructose-biphosphate aldolase, and glyceraldehyde-3-phosphate dehydrogenase (190), as well as the heat-shock protease ClpP (191). Another candidate is the putative proteinase maturation protein PpmA (192), although its degree of surface exposure and protective efficacy has been questioned (151).

Giefing et al. (193) conducted a comprehensive study of the antibody repertoire induced in humans during natural pneumococcal infection by extensive screening of *E. coli* display libraries representing the entire *S. pneumoniae* proteome with carefully selected panels of convalescent patient sera. Sequence analysis of reactive clone inserts identified not only proteins that reacted consistently with the sera, but also the key epitopes therein. Over 140 immunoreactive proteins were identified, and many of the vaccine candidates referred to above, most notably PspA, PspC, PhtA/B/D/E, NanA, Iga, LytC, and LytA, were detected with high frequency. Interestingly, about 20% of the proteins represented unknown gene products and thus may have been missed in previous motif-based *in silico* screens. A subset of the identified proteins was selected on the basis of further seroreactivity screens of synthetic peptides, surface localization, and opsonophagocytic studies using epitope-specific hyperimmune mouse sera and PCR-based gene distribution analyses. Twenty selected proteins were then purified and tested for protective immunogenicity in mouse models of sepsis and pneumonia. Significantly, two proteins (PcsB and StkP) provided a degree of protection similar to that seen for PspA. Both are highly conserved and appear to play an important role in cell separation and/or formation of division septa. PcsB and StkP both protected against a variety of challenge strains and were superior to PspA when the challenge strain expressed a dissimilar family/clade of PspA (193).

A recent study evaluated the vaccine potential of 52 pneumococcal proteins selected on the basis of genetic conservation across disease-causing serotypes and bioinformatic prediction of antibody binding to the target antigen (194). Seven proteins induced protective responses in a murine infection model, namely, the Pht family proteins PhtB, PhtD, and PhtE and the sortase family proteins PrtA, NanA, PavB, and Eng.

From the above it can be seen that there are a number of pneumococcal proteins that exhibit potential as vaccine antigens. However, assessment of their protective efficacy has generally been carried out in different laboratories using a variety of animal models and challenge strains. Relatively few direct comparative protection studies have been performed to determine which of these proteins provides the strongest protection against the widest variety of *S. pneumoniae* strains.

Combination Protein Vaccines

The vast majority of the pneumococcal proteins under consideration as vaccine antigens are directly or indirectly involved in the pathogenesis of pneumococcal disease. Mutagenesis of some combinations of virulence factor genes, for example, those encoding pneumolysin and either PspA or PspC, PspA, or PspC or all three genes, has been shown to synergistically attenuate pneumococcal virulence in animal models, suggesting that the respective proteins function independently in the pathogenic process (195, 196). This strongly suggests that immunization with combinations of these antigens might provide additive protection. Moreover, there may be differences in the relative protective capacities of the individual antigens against particular *S. pneumoniae* strains, particularly for surface-exposed antigens that exhibit some degree of sequence variation. Thus, a combined pneumococcal protein vaccine may elicit a higher degree of protection against a wider variety of strains than any single antigen.

Immunization of mice with a combination of the pneumolysoid PdB and PspA provided significantly increased protection against intraperitoneal challenge than immunization with either protein alone. However, combining either protein with PsaA did not result in enhanced protection (134). The potential benefits of combination protein vaccines are also well illustrated using a mouse model of nonbacteremic pneumonia, which closely reflects the commonest form of pneumococcal respiratory disease in humans (135). In this system, subcutaneous immunization (using alum adjuvant)

Downloaded From Vet-eBooks.com

with either PdB or PspA, but not PsaA, significantly reduced numbers of *S. pneumoniae* in the lungs 7 days after challenge. A significant additional reduction in bacterial load was achieved by immunization with a combination of PdB and PspA, but not when either protein was combined with PsaA (135). These findings contrast with those obtained using mucosal (intranasal) immunization with the same proteins with cholera toxin B subunit as the adjuvant. As discussed previously, immunization with either PspA or PsaA, but not PdB, reduced the level of carriage of *S. pneumoniae* after intranasal challenge, and the combination of PspA and PsaA was more effective than either antigen alone (82). These findings suggest that PsaA is either more important for survival of *S. pneumoniae* in the nasopharynx than in the lung or that it is more accessible to exogenous antibody in the former niche. On the other hand, pneumolysin appears to play only a minor role during the colonization phase but is clearly important once the organism has been aspirated into the lungs. Thus, optimum vaccine formulation will be dependent upon the mode of vaccine delivery and the stage of the pathogenic process being targeted for immunoprophylaxis. In a more recent study, a variety of multivalent protein-based vaccines comprised various combinations of full-length or peptide regions of the immunogens pneumolysin, PspC/CbpA, or PspA. Optimum protection against multiple challenge strains in models of sepsis, pneumonia, and meningitis was obtained using a combination comprising pneumolysin toxoid with an L460D substitution, with two protective peptide epitopes from PspC/CbpA (known to be involved in binding to the host polymeric immunoglobulin receptor and the laminin receptor, respectively) fused to the N- and C-termini, as well as a polypeptide derived from the conserved proline-rich region and SM1 regions of PspA (197).

Only a handful of other pneumococcal protein combinations have been tested for additive protective immunogenicity. Immunization with both the iron transporters PiuA and PiaA was more effective than either antigen alone (161). A combination of pneumolysoid (PdB), PspA, and PspC has also shown stronger protection than single or paired antigens (171). In that study, combinations of PhtB and PhtE were less protective than those involving two or more of PdB, PspA, and PspC, and inclusion of PhtB did not improve the protection imparted by either PdB/PspA or PdB/PspC (171). Additive protection relative to individual components has also been demonstrated for a trivalent formulation comprising another pneumolysin toxoid (PlyD1), PhtD, and pneumococcal choline binding protein A (PcpA) in an infant murine otitis media model (198). Clearly, additional comparative studies of the protective efficacy of the better-characterized proteins, as well as the more recently identified vaccine candidates (both singly and in combination), are desirable to enable informed decisions on the optimum formulation of a protein-based pneumococcal vaccine. However, further development of some potentially efficacious combinations has been frustrated by the intellectual property landscape surrounding individual components, which impacts freedom to operate for commercial partners taking experimental vaccine formulations forward into the clinic.

Of the pneumococcal combination protein vaccines that have reached phase II human trials, the PlyD1/PhtD/PcbA formulation referred to above has been shown to be safe, well-tolerated, and immunogenic in adults, toddlers, and infants (199). A formulation comprising the currently licensed 10-valent PS conjugate vaccine, supplemented with chemically detoxified pneumolysin (dPly) and PhtD was also safe and immunogenic in infants (200, 201), but this vaccine formulation did not reduce nasopharyngeal carriage of non-conjugate vaccine serotypes (202). A cell-free protein extract from a derivative of *S. pneumoniae* TIGR4 expressing a nontoxic pneumolysin gene, enriched for various conserved surface proteins by anion exchange, was also safe and immunogenic in adults at phase I (203).

PNEUMOCOCCAL WHOLE-CELL VACCINES (WCV)

An alternative strategy for eliciting non-serotype-dependent protection is immunization with a simple vaccine comprising killed nonencapsulated pneumococci that display critical protein antigens on their surface. A study looking at historical data from the 1918 influenza pandemic showed that WCVs had the ability to confer cross-protection against different pneumococcal serotypes and that such vaccines were protective against influenza-associated pneumonia (204). A WCV comprising a chemically killed *lytA*-deletion mutant of *S. pneumoniae* Rx1 expressing nontoxic pneumolysin has also been shown to elicit protection against sepsis and nasopharyngeal carriage in mouse models. Protection against sepsis was dependent on antibodies to noncapsular antigens, while prevention of carriage required CD4+ T cell-dependent responses (205, 206). The WCV approach has potential cost advantages over the currently licensed conjugate vaccines and the various multicomponent purified protein formulations currently in clinical development. A chemically killed WCV formulation was safe and immunogenic in a phase I trial and is in further clinical development (207).

Another study has used γ-irradiation to inactivate a similar unencapsulated *S. pneumoniae* strain. Intranasal vaccination with this WCV (without adjuvant) elicited serotype-independent protection in lethal challenge models of pneumococcal pneumonia and sepsis. Vaccine efficacy was shown to be reliant on B-cells and interleukin-17A responses. Interestingly, immunization promoted interleukin-17 production by innate γδ T cells, not T helper 17 (Th17) cells (208). Further enhancement of immunogenicity was observed when this vaccine was coadministered with a γ-irradiated influenza virus vaccine that also provides heterotypic protection against the virus (209).

MUCOSAL IMMUNITY

The development of vaccines that can elicit mucosal immunity could be very important because (i) mucosal immunity is thought to provide the best protection against carriage (61, 210), (ii) nasopharyngeal carriage is the human reservoir for pneumococci, and herd immunity depends on immunity to carriage (39, 82, 210), (iii) at least a short duration of carriage is required prior to almost all invasive disease (211), and (iv) epidemiologic data suggest that meningitis frequently occurs with strains of capsular types which seldom cause sepsis but which are readily carried (50, 212, 213). In the section above about PspA and PspC, mucosal immunity studies are described that used a cationic cholesteryl group-bearing pullulan nanogel, which greatly enhanced mucosal immunity in mice and, like many other recent enhancers of mucosal immunity (214, 215), is not transported to the brain (83, 84).

CONCLUSIONS

The ongoing high global morbidity and mortality associated with pneumococcal disease and the complications caused by increasing rates of resistance to antimicrobials have under-

Downloaded From Vet-eBooks.com

pinned extensive efforts in recent years to develop more effective vaccination strategies against *S. pneumoniae*. These efforts have benefited from a better understanding of the mechanisms of pathogenesis of pneumococcal disease and the advances made possible by the advent of recombinant DNA technology and access to genome sequence data. The polyvalent PS vaccines have doubtless prevented a large number of deaths from invasive disease in recipients belonging to those patient groups for whom this vaccine is currently recommended. The newer PS-protein conjugate formulations confer a very high degree of protection in young children against the included serotypes and may also have an impact on the prevalence of drug-resistant strains. However, there is now general acceptance that this vaccination approach is not without its drawbacks, and as explained above, the initially substantial clinical benefits that are expected to be derived from widespread use of conjugate vaccines may diminish with time. It will take many years for the overall impact of conjugate vaccines on disease burden and the population biology of *S. pneumoniae* to become apparent. At the very least, use of the conjugate vaccines will buy time for development of less expensive, largely non-serotype-specific vaccines based on combinations of protein antigens. It must be emphasized, however, that the success of these protein vaccines is not dependent upon real or perceived failure of the conjugates. Rather, the two approaches should be viewed as complementary, each having an important role to play in global prevention of pneumococcal disease. Nor should development of parenteral protein vaccines impede future research on mucosal- or DNA-based delivery systems, which may further improve presentation of protective antigens to the immune system, thereby optimizing host responses and herd immunity.

Pathogenicity of Enterococci

ELIZABETH FIORE, DARIA VAN TYNE AND MICHAEL S. GILMORE

24

INTRODUCTION

Enterococci are hardy, Gram-positive cocci that are common residents of the gastrointestinal tracts of nearly all land animals, including humans. While they are a core member of the microbiome, they are also capable of causing a variety of severe infections, most often among antibiotic-treated hospitalized patients with perturbed intestinal microbiota. Here, we present an overview of the pathogenicity of enterococci and discuss the most prominent features of this hospital-associated pathogen.

The origin of the term "enterococcus" dates to the end of the 19th century when Thiercelin described a saprophytic Gram-positive coccus of intestinal origin capable of causing infection (1, 2). In the same year, a very detailed picture of enterococcal pathogenesis was reported by MacCallum and Hastings (3), who isolated and characterized an organism (now believed to be a cytolytic strain of *Enterococcus faecalis*) from a lethal case of acute endocarditis. Termed *Micrococcus zymogenes* by these authors, bacteria recovered from the blood and cardiac tissue of the patient and inoculated into pure culture were able to recapitulate elements of endocarditis in animals, satisfying Koch's postulates and establishing *Enterococcus* as a bona fide pathogen of humans and animals. From these early descriptions, the paradigm of enterococci as a commensal opportunist was established. More than a century later, enterococci are widely recognized as leading hospital pathogens (4, 5).

Infections occurring mainly among hospitalized patients and caused by microbes of the genus *Enterococcus* (most notably, *E. faecalis* and *Enterococcus faecium*) include urinary tract infections, bacteremia, intra-abdominal infections, and endocarditis (6). Enterococci are now the third most common hospital-acquired pathogen, causing 14% of hospital-acquired infections in the United States between 2011 and 2014, an increase from 11% in 2007 (4, 7). In addition to hospital-acquired infections, enterococci are responsible for 5 to 20% of community-acquired endocarditis (8).

This review focuses on the mechanisms by which enterococci cause human disease, with particular attention given to advances in the field since the last edition of this text (9). Additional perspectives and information may be found in the complete volume on enterococcal biology (10).

BIOLOGY AND CHARACTERISTICS

Enterococci can be easily isolated from a wide range of hosts, including invertebrates, insects, and mammals (Fig. 1). This host range highlights the ability of enterococci to survive a diversity of innate host defenses in the gut (11). In humans, enterococci are one of the earliest colonizers of the infant gut, and as a result are core members of the intestinal microbiome (12, 13). They are also common among commensal microbiota of domesticated and wild animals and can cause infections in these animals as well (14–16). Due to their widespread occurrence among humans and animals, they are readily isolated from the environments inhabited by those hosts, often associated with plants, soil, and water (17, 18). Because of their numerous auxotrophies, enterococci persist in the environment but do not likely proliferate to high numbers there.

Enterococci were formerly classified as group D streptococci (19) but were given genus status in 1984 (20) based on nucleic acid hybridization studies that showed a more distant relationship to the streptococci. The genus *Enterococcus* contains over 50 species and appears to have branched from its last common ancestor approximately 425 million years ago (21). Members of this genus are endowed with intrinsic properties that confer the ability to survive host defenses and compete in the intestinal tract and then persist and spread in the natural environment or hospital, leading to colonization of new hosts. Among these traits are the ability to grow over wide temperature and pH ranges, survive desiccation, and grow in the presence of 6.5% NaCl and 40% bile salts (17).

ANTIBIOTIC RESISTANCE

The challenge of disease caused by enterococci is compounded by their limited susceptibility to antibiotics, due to both intrinsic and acquired antibiotic resistances. Enterococci are intrinsically resistant to cephalosporins, aminoglycosides, lincosamides, and streptogramins (6, 22). Intrinsic resistance of enterococci undoubtedly positions them well to acquire additional resistances on mobile genetic elements. In the antibiotic-treated patient, enterococci accumulate to high numbers (23) and coexist in intimate association with other overtly antibiotic-resistant microbes, the precise environment

doi:10.1128/microbiolspec.GPP3-0053-2018

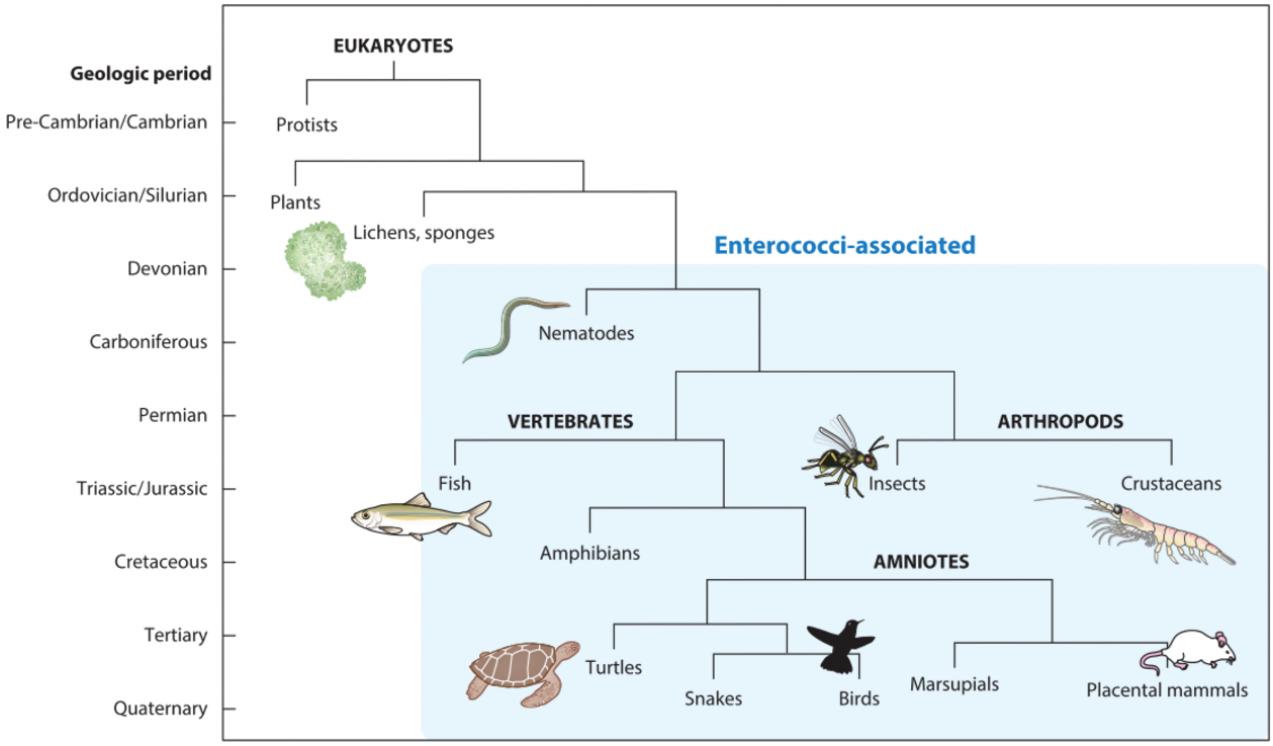

FIGURE 1 Animal hosts that have been associated with enterococcal colonization. A simplified tree of life with blue shading indicating animals from which enterococci have been isolated. Corresponding geologic periods are indicated on the left. Reproduced with permission from reference 11.

to enhance the probability of contact between enterococci and other species harboring new resistances on mobile elements, leading to element acquisition.

Because enterococci are not killed by many β-lactams, new approaches to treatment were sought. The discovery that aminoglycosides were synergistic with β-lactams and could achieve cidality (24) resulted in combination therapy becoming the standard of care. However, only a few years later, aminoglycoside resistance in enterococci was reported (25) and found to be due to the acquisition of a plasmid-borne resistance factor. High-level resistance to aminoglycosides is conferred by aminoglycoside-modifying enzymes, especially a bifunctional enzyme (26), and mobile elements conferring this trait have spread throughout the enterococci (27). Further compromising combination therapy, enterococci that expressed a β-lactamase have been identified (28), but these remain surprisingly rare.

Vancomycin was introduced in the late 1950s (29) and because of its limited spectrum and intravenous dosing received limited application in hospitalized patients with β-lactam allergies and infections due to organisms with other antibiotic resistances (30). Vancomycin was found to be effective against aminoglycoside-resistant enterococci (31) and became a leading alternative therapy in the late 1970s and early 1980s (32). However, vancomycin resistance emerged in the mid-1980s—first in Europe (33, 34) and then in the United States (35). Enterococci resistant to vancomycin are now globally disseminated, with as many as 80% of *E. faecium* isolates being resistant to vancomycin in some hospitals (4, 36).

The rapid rise of vancomycin resistance in enterococci at the beginning of the 21st century raised alarms, because it represented the loss of an important bactericidal, last-line therapy. Daptomycin was shown to be effective against vancomycin-resistant enterococci (VRE) (37), but its value was found to be limited by the rate of daptomycin resistance development during the course of treatment (38–40). Resistant isolates had mutations in several genes that affect cell membrane composition and charge, including the cardiolipin synthase *cls*, the glycerophosphoryl-diester-phosphodiesterase *gdpD*, and the stress-sensing response component *liaF* (41, 42). Confounding a precise understanding of its mechanism of action, *Staphylococcus aureus* was observed to alter different pathways in achieving daptomycin resistance (43). Furthermore, resistance-conferring mutations derived in enterococci *in vitro* only partially overlap with those that arise *in vivo*, potentially because of differences in lipid incorporation from the environment into the enterococcal membrane (44). Lipidomic studies of daptomycin-resistant strains showed differences in lipid profiles compared to sensitive strains, particularly in phosphatidylglycerols, cardiolipins, and glycolipids (45).

Linezolid, the first oxazolidinone antibiotic, was approved by the FDA in 2000, and its introduction into clinical use was quickly followed by the emergence of linezolid-resistant VRE strains in the United States in 2001 (46) and in the United Kingdom in 2002 (47). Sequencing of the resistant isolates revealed a G2576U mutation in the 23S ribosomal RNA subunit (48). This mutation was also seen in resistant organisms isolated from a gnotobiotic mouse model of infection (49), where its occurrence was found to depend on the dose of antibiotic that reached the intestine. A linezolid-resistant isolate from Thailand subsequently was shown to have acquired the *cfr* methyltransferase on a plasmid, leading to methylation of position A2503 in the 23S rRNA and causing high-level resistance (50).

A third antibiotic that has found utility in treating VRE is the glycylcycline tigecycline. It has been used successfully, alone and in combination with other antibiotics, to treat

Downloaded From Vet-eBooks.com

VRE infection, but resistance has also emerged. A study of 73 tigecycline-nonsusceptible *E. faecium* and *E. faecalis* isolates collected from 2007 to 2015 found mutations in various efflux pumps that were identified and associated with tigecycline resistance (51). Serially passaged *E. faecium in vitro* in the presence of tigecycline selected for mutations in ribosomal protein subunit *rpsJ*, but this mutation has not yet been functionally validated (51, 52). Nonetheless, enterococci appear able to evolve resistance to antibiotics of all classes that have so far been introduced to practice.

ENVIRONMENTAL PERSISTENCE

As implied by the clonality of infection, epidemiological studies highlight person-to-person transmission of endemic strains within the hospital (53–55), implying that enterococci persist for extended periods in the hospital environment. Transmission occurs through contact with health care personnel and inanimate objects such as bedrails, nursing station keyboards, hospital drapery, and ear-probe thermometers (56). Enterococci are unusually resistant to common antiseptics and disinfectants, as well UV radiation, starvation, and desiccation (21, 57, 58). The ability to survive nutrient-poor environments as well as desiccation has led some to speculate that enterococci may enter a viable but nonculturable state as an adaptation to poor growth conditions (59–61), but details of such a mechanism have yet to be elucidated.

Studies have examined the environmental ruggedness mainly of *E. faecalis* (62–70), which develops tolerance to otherwise lethal levels of bile salts and detergents, such as sodium dodecyl sulfate, if first subcultured in the presence of sublethal levels (62). This phenomenon likely contributes to the ability of enterococci to survive the cleaning regimens employed in most hospitals as part of infection control programs. Regulatory systems govern the adaptive response to environmental insults (71, 72). In a study by Hancock and Perego (71), inactivation of a response regulator, designated RR06, led to an increased sensitivity to heat stress (growth at 46°C), as well as detergent stress (0.003% sodium dodecyl sulfate). Le Breton et al. (72) showed that another response regulator, RR10, negatively regulates the heat shock proteins DnaK and GroEL. Inactivation of the *rr10* gene resulted in acid sensitivity but also enhanced survival at 50°C.

To identify the genetic contributors to this intrinsic ruggedness, a spectrum of enterococcal species, including clinical isolates as well as species never reported to be associated with human infection, were compared for resistances to chemical compounds as well as environmental stresses (21). All enterococci were found to be intrinsically much more resistant to most insults than other related microbes, indicating that many of the underlying traits were acquired as the genus branched from its ancestors. The two enterococcal species that are most pathogenic to humans, *E. faecalis* and *E. faecium*, showed the greatest resistance to desiccation and starvation (21). These two species also show high levels of resistance to the common hospital disinfectants chloroxylenol and chlorhexidine. The molecular mechanisms that contribute to these phenotypes were narrowed to a set of 126 genes that distinguished enterococci from ancestors (21). Additionally, the two-component system ChtRS was recently identified as in important regulator of chlorhexidine resistance in *E. faecium* (73).

PATHOGENIC MECHANISMS

For enterococci to cause disease, several barriers must first be overcome. An initial barrier is the ability to overcome colonization resistance provided by competing microbes, and host defenses such as gastric acid and bile, and colonize the intestinal tract. From this reservoir the bacteria can amplify in number and spread to sites vulnerable to infection. A basic prediction from such a model is that the probability of infection should be a function of the intestinal burden of bacteria in the gut reservoir—the more bacteria, the greater the probability of contamination of a potential infection site in numbers large enough to overcome host defenses. Indeed, colonization of the gastrointestinal tract has been shown to be directly associated with risk of infection (23, 74). Infection occurs when enterococci overwhelm host defenses, when they replicate at rates that exceed clearance, and when pathologic changes result through direct toxin activity, or infection occurs indirectly by bystander damage from the inflammatory response (75, 76).

HUMAN COLONIZATION

Enterococci are core but numerically minor members of the human microbiome (77). The occurrence of two species, *E. faecalis* and *E. faecium*, in similar abundance, suggests that neither evolved in humans but, rather, likely entered the primate lineage early and from organisms consumed from lower in the food chain. Both *E. faecalis* and *E. faecium* are found in relative abundance in human feces (10^5 to 10^7 organisms per gram) (78) but typically represent less than 1% of the total microbial population (17). "Colonization resistance" (79) is a term applied to the challenge an organism faces in colonizing a stable, established community. It is a main mechanism of innate defense of the gastrointestinal tract. Colonization and proliferation of hospital-adapted lineages of enterococci are usually associated with antibiotic-induced disruption of the community structure (80). Therefore, effectively managing the human microbiome in health and disease represents a theoretically promising strategy for preventing hospital infection.

A primary barrier to invading the gut consortium and colonization by orally acquired microbes is gastric pH, which is inhospitable for most microorganisms, including enterococci. Compromise of this barrier enhances the oral acquisition of enterococci from a contaminated environment. In the intensive care unit setting in particular, patients are placed on H_2-receptor antagonists as prophylaxis for treating stress ulcers; the consequence of this action is a pH increase from pH 2 to pH 3.5 to 5.3, depending on the antagonist employed (81). In a study by Başaran et al. (82), H_2-receptor antagonists were shown to promote colonization of the small bowel, as well as translocation of enteric bacteria from the intestinal tract to extraintestinal tissues.

Several studies have examined the ability of enterococci to tolerate acidic pH (64, 83). Flahaut et al. (64) demonstrated that exposure of *E. faecalis* to a sublethal pH level (pH 4.8) for 15 to 30 minutes protected the organism from a normally lethal challenge at pH 3.2, suggesting an adaptive response to changing acid stress. Suzuki and colleagues (83) showed that an *E. faecalis* mutant defective in F_1-F_0 H^+-ATPase activity was unable to grow at a pH of <6. The H^+-ATPase is used to regulate the cytoplasmic pH of *E. faecalis* by proton extrusion, and this enzyme has been shown to be activated at low pH (83). Teng et al. (84) identified a two-component regulatory system, termed EtaRS, which appears to be involved in acid stress response and virulence. Inactivation of the response regulator, EtaR, results in increased acid sensitivity and decreased virulence in a murine peritonitis model.

Colonization resistance is also imposed by the stability of a mature complex community of gut microbes. The use of

Downloaded From Vet-eBooks.com

broad-spectrum antibiotics, many of which possess little or no antienterococcal activity, destabilizes this community by removing susceptible members (85–87), opening opportunities for invasion by new organisms. In a study designed to examine the persistence and density of colonization by vancomycin-resistant *E. faecium* in a murine model, Donskey et al. (88) showed that suppression of the anaerobic microflora by the use of antimicrobials that target this microbial population resulted in increased colonization density and prolonged VRE persistence. This observation highlights the importance of the anaerobic flora in suppressing enterococcal growth within the intestinal microenvironment. Several other studies have also examined factors that lead to overgrowth of enterococci, especially VRE, in the gastrointestinal tract of hospitalized patients. Treatment with broad-spectrum antibiotics, especially cephalosporins and metronidazole, to which enterococci are intrinsically resistant, leads to clearance of commensals and overgrowth of enterococci (80, 89). In extreme cases, hospitalized patients treated with these antibiotics develop a near monoculture of VRE in their intestine and are at high risk for enterococcal bacteremia and other enterococcal infections (80). Factors that limit the outgrowth of *E. faecium* in the antibiotic-perturbed gut include reduced expression of the host innate immune factor RegIIIγ, which results indirectly from the loss of Gram-negative members of the gut microflora (90). RegIIIγ production relies on signaling through Toll-like receptor-5 and interleukin-22 (IL-22), and supplementation of Toll-like receptor agonists has been shown to restore RegIIIγ expression and suppress *E. faecium* growth (90). In mice, the IL-22 signaling pathway and, in particular, the IL-22 receptor has been shown to be required for *E. faecalis* colonization resistance. *Il22ra1*$^{-/-}$ mice were observed to be particularly susceptible to *E. faecalis* overgrowth and subsequent systemic dissemination (91). This restriction of *E. faecalis* outgrowth is controlled in part by fucosylated glycans, which are downregulated in *Il22ra1*$^{-/-}$ mice. Oral supplementation of fucosylated glycans was shown to promote diversity of the gut microbiota and restore the growth restriction of *E. faecalis* (91).

In addition to antibiotic and host immune factors, hospital-adapted strains of enterococci are endowed with properties that allow them to colonize microniches that are likely less suitable for colonization by commensal strains. For example, some hospital-associated strains of *E. faecalis* contain an additional bile salt hydrolase (92). *E. faecalis* also produces extracellular superoxide (93), leading to DNA damage in colonic epithelial cells (94) and chromosomal instability (95), potentially relating to local inflammation, changes in the nutritional properties of the mucosa, and development of colorectal cancer. Enterococci also have been associated with inflammatory bowel disease, Crohn's disease and ulcerative colitis. Enterococcal abundance, particularly of *E. faecium*, is higher in fecal samples from Crohn's disease patients compared to healthy controls (96, 97). Increased *E. faecalis* abundance and anti-*E. faecalis* antibodies have also been observed in ulcerative colitis patients (98). Germ-free IL-10 knockout mice colonized with *E. faecalis* develop chronic inflammatory bowel disease-like symptoms (99), highlighting the bacteria's ability to perpetuate gut inflammation. A subset of virulence factors in *E. faecalis*, including the metalloprotease GelE, enterococcal polysaccharide antigen Epa, and cell surface-associated lipoprotein Lgt, were shown to influence induction of inflammatory bowel disease in these mice (Table 1) (99).

Enterococci must compete with other microbes in the gut for space, binding sites, and nutrients. Enterococci have long been known to be prolific producers of bacteriocins, many of which are encoded by mobile elements (100, 101). Plasmid pPD1, harbored by some *E. faecalis* strains, encodes a bacteriocin that inhibits other *E. faecalis* strains, eventually leading under some conditions to strain replacement *in vivo* (102). Importantly, the bacteriocin-expressing strain was able to reduce the intestinal load of VRE in a cocolonization study, highlighting the potential therapeutic value of such agents.

The apparently hasty accretion of mobile elements by enterococci affects their ability to compete in surprising ways. It was recently shown that commensal *E. faecalis* is able to induce self-killing of the vancomycin-resistant strain V583, through the production of the pheromone peptide cOB1 (103). This pheromone induces a cascade of events that involves expression of conjugation-associated functions on a pheromone-responsive plasmid resident within V583, which

TABLE 1 Enterococcal virulence factors

Virulence factor	Description	Reference(s)
Cytolysin[a]	Hemolysin/bacteriocin, lyses a broad range of eukaryotic and Gram-positive cells	128, 126, 129, 218
Gelatinase[a]	Secreted zinc metalloprotease	216, 221, 222
Serine protease[a]	Secreted serine protease	216, 221, 222
Hyaluronidase[b]	Degrades hyaluronic acid	236
Esp[a,b]	Cell wall anchored protein, enhances biofilm formation and colonization of bladder epithelium	92, 237
Aggregation substance[a,b]	Cell wall anchored protein, involved in conjugation and adhesion to eukaryotic cells	128, 132, 214, 267
Ace[a,b]	Cell wall anchored protein, collagen binding protein	135, 136, 138, 139
Epa[a,b]	Enterococcal polysaccharide antigen, anti-phagocytic cell wall polysaccharide	200
Cps[a,b]	Capsular polysaccharide, antiphagocytic cell wall polysaccharide	194, 196
LTA[a,b]	Lipoteichoic acid, enterococcal group antigen, binding substance for conjugation	214, 268
Toxic metabolites[a,b]	Reactive oxygen species: extracellular superoxide, hydrogen peroxide	94, 239

then engage in a lethal cross talk with a gene or genes in another mobile genetic element in the chromosome of V583, inducing death of V583 by an as yet unknown mechanism.

The ability to obtain nutrients within the competitive environment of the gut is an important aspect of enterococcal colonization efficiency (104). Within *E. faecium*, the two main clades, A and B, differ in the availability of carbohydrate utilization pathways. Strains in clade A1, which includes most infection-associated strains, express more transporters and metabolic pathways for the utilization of carbohydrates derived from the gut mucosa, as opposed to the diet, such as mucins and epithelial cell glycosidic surface decorations (104). Inactivation of a phosphotransferase system related to this ability reduced gut colonization in an antibiotic-treated mouse model (104, 105). Clade B strains do not possess this pathway (104), highlighting ecological differences between pathogenic and commensal strains. Meanwhile, clade B commensal *E. faecium* strains outcompete clade A strains in the murine intestinal tract in the absence of antibiotics (106).

Antagonisms within the gut community also influence colonization. Among commensals, *Barnesiella* species have been observed to be antagonistic to enterococcal colonization (107). Colonization resistance to VRE could also be artificially effected with a four-species cocktail containing *Bacteroides sartorii*, *Parabacteroides distasonis*, *Clostridium bolteae*, and *Blautia producta* (108). To colonize and establish residence within the gut, then, multidrug-resistant strains of enterococci must successfully navigate the hazards of innate host defenses and enter a destabilized consortium lacking overt antagonists.

TRANSLOCATION FROM THE GUT INTO THE BLOODSTREAM

Enterococal overgrowth in the colon increases the chance, by simple numeric probability, of dissemination into the bloodstream and contamination of other body sites in numbers large enough to establish infection (Fig. 2). Mechanisms that contribute to enterococcal translocation are still being discovered. In some cases, enterococci may be phagocytosed by intestinal epithelial cells, dendritic cells, or other tissue-resident leukocytes and transported across the intestinal wall to the underlying lymph system. Failure to kill the phagocytosed organism could then lead to abscess formation in reticuloendothelial organs and systemic spread (109). Gentry-Weeks et al. (110) showed that *E. faecalis* possesses the ability to survive for up to 72 hours in peritoneal macrophages. Wells et al. (111, 112) induced intestinal *E. faecalis* overgrowth by antibiotic treatment and observed organisms adhering to epithelial surfaces of the ileum, cecum, and colon. They also showed that enterococci possess the ability to translocate from the intestinal lumen into the mesenteric lymph nodes, liver, and spleen (111, 112).

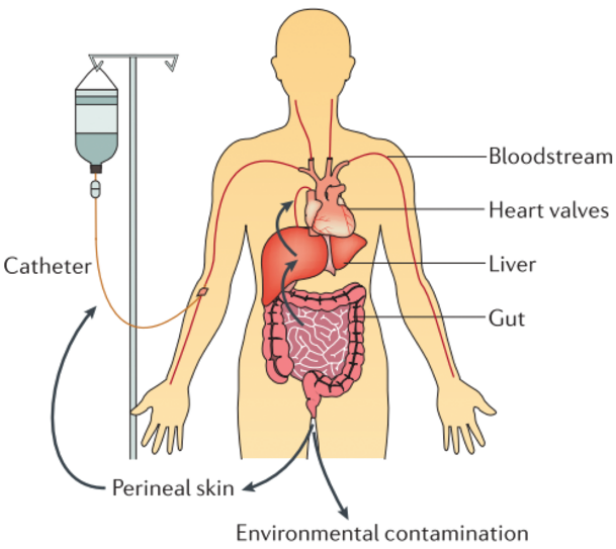

FIGURE 2 Routes of dissemination of enterococci from the intestinal reservoir of a hospitalized patient. Bacteria from the intestine can seed infections throughout the body and contaminate surfaces, leading to patient-to-patient spread. Reproduced with permission from reference 122.

Bacteria also diffuse through the gut barrier at low levels, and enterococci may gain access to the bloodstream that way. Inert particles the size of bacteria, and without any special properties, penetrate the gut mucosal barrier (113); special invasive properties do not appear to be essential for at least some level of translocation into the bloodstream. In a healthy, immune-competent host, innate defenses are well equipped to eliminate such invaders. So long as the microbes leaking into the bloodstream and occurring in the lymphatics are easily killed, such as the predominating anaerobes in the healthy gut community, there is little ill effect. However, because enterococci persist in phagocytic cells, their extraintestinal accumulation may more readily lead to infection, especially in an immunocompromised or disease-stressed patient.

A variety of enterococcal factors have been examined for their role in colonization and translocation out of the gastrointestinal tract. Olmsted et al. (114) found a plasmid-encoded surface protein, aggregation substance (AS), to promote internalization of *E. faecalis* by cultured intestinal epithelial cells (HT-29). To further dissect the functional domains of AS involved in internalization by HT-29 cells, Waters et al. (115, 116) examined the various domains of AS to determine their roles in this process. Surprisingly, the aggregation domain, and not the N-terminal RGD motif of AS, was found to be important for internalization by HT-29 cells (116). An additional finding from this study was the apparent requirement for a cofactor (likely lipoteichoic acid), because expression of AS in the binding substance mutant INY3000 failed to efficiently internalize. In a subsequent study it was shown that the amino-terminal aggregation domain of the protein could bind efficiently to purified lipoteichoic acid (LTA) as well as LTA purified from INY3000, suggesting that another cell component other than LTA was responsible for the cooperative internalization of *E. faecalis* by HT-29 cells (115).

BACTEREMIA

Enterococcal bloodstream infections (BSIs) are associated with a high level of mortality. In a recent large survey study of Canadian hospitals (117), the incidence of enterococcal BSI of hospitalized patients was 6.9 per 100,000, with most cases due to *E. faecalis* (4.5 per 100,000). The incidence of enterococcal BSI increased between 2008 and 2014 (9 to 14 per 100,000) in Switzerland (118), suggesting that enterococcal BSIs are on the rise. Overall, mortality from nosocomial enterococcal BSI is quite high, ranging from 25 to 50% (119, 120).

Most cases of enterococcal BSI are thought to result from translocation of enterococci from the gut into the bloodstream. Other routes of infection include along intravenous lines, endocarditis, urinary tract infections, and abscesses (109, 121, 122). The risk factors for mortality associated with enterococcal bacteremia include severity of illness (based on APACHE II scores), patient age, and use of third-generation

Downloaded From Vet-eBooks.com

cephalosporins or metronidazole (123). Huycke et al. (54) found that patients infected with hemolytic, gentamicin-resistant *E. faecalis* strains had a 5-fold increased risk for death within three weeks compared to patients with nonhemolytic, gentamicin-susceptible strains. Moreover, mode of treatment was not associated with outcome, discounting the direct contribution of aminoglycoside resistance. In another study, Caballero-Granado et al. (124) analyzed the clinical outcome, including mortality, for bacteremia caused by *Enterococcus* spp. with and without high-level gentamicin resistance. Mortality associated with high-level gentamicin resistance (29%) was not significantly different from gentamicin-susceptible strains (28%). Taken together, these two studies suggest that high-level aminoglycoside resistance itself does not explain clinical outcome and that the presence of other factors, such as the *E. faecalis* cytolysin (hemolysin), appears to contribute to enhanced lethality. In support of the latter finding, the *E. faecalis* cytolysin has been shown to result in acute toxicity in a number of animal models. Cytolysin significantly lowers the 50% lethal dose of the infecting strain for mice (125–127). As will be discussed later, the cytolysin also contributes to the acute toxicity of lupine endocarditis and endophthalmitis models (128, 129) and contributes to nematode killing in *Caenorhabditis elegans* (130).

URINARY TRACT INFECTION

In a nosocomial population surveyed between 2011 and 2014, enterococci were the most commonly isolated Gram-positive bacteria from catheter-associated urinary tract infections, with over 20,000 cases reported to the CDC National Healthcare Safety Network between 2011 and 2014 (4). Of these cases, just over 50% were caused by *E. faecalis*, followed by "other *Enterococcus* species" (~30%) and *E. faecium* (~20%). Most worrisome was the fact that ~85% of *E. faecium* isolates were vancomycin resistant, with the fraction of resistant isolates increasing each year (4).

A few studies have been aimed at understanding the interaction of enterococci with uroepithelial tissue (131, 132). Kreft et al. (132) showed a potential role for the plasmid-encoded AS in the adhesion of enterococci to renal epithelial cells. *E. faecalis* harboring the pheromone-responsive plasmid pAD1, or various isogenic derivatives, were better able to bind to the LLC-PK cultured pig renal tubular cell line than plasmid-free bacteria. Their findings also showed that a synthetic peptide containing the fibronectin motif, Arg-Gly-Asp-Ser, could inhibit binding. This structural motif mediates the interaction between fibronectin and eukaryotic surface receptors of the integrin family (133). Guzmàn and coworkers (131) analyzed the ability of strains of *E. faecalis* isolated from either urinary tract infections or endocarditis to adhere to urinary tract epithelial cells and to the Girardi heart cell line. Urinary tract infection isolates adhered to urinary tract epithelial cells *in vitro*, whereas strains from endocarditis adhered efficiently to the Girardi heart cell line, suggesting that environmental adaptations can facilitate interactions with host tissues. Shankar et al. (134) showed that the *E. faecalis* Esp surface protein colocalizes in the bladder, but not the kidneys, in an ascending urinary tract infection model, suggesting that the protein has tissue specificity for bladder epithelium. Tomita and Ike (135) showed that highly adherent enterococcal urinary tract infection strains recognize the extracellular matrix proteins fibronectin, laminin, and collagen types I, II, IV, and V. One of these strains, AS14, was subjected to transposon mutagenesis with Tn*916*, and mutants with altered collagen IV and laminin binding were identified. Out of 14 single transposon insertion mutants, 13 mapped to the Ace protein (136–140). The level of adherence of mutants to collagen IV and laminin was 1 to 2 orders of magnitude lower than the wild-type strain, but the level of adherence to fibronectin remained the same as that of the wild-type strain. The collagen binding proteins Ace (*E. faecalis*) and Acm (*E. faecium*) were originally identified because of their homology to the amino terminal end of Cna, the collagen binding protein from *S. aureus* (138, 139). The ability of most *E. faecalis* Ace-positive strains to adhere to collagen and laminin was highly dependent on growth temperature, with binding occurring at 46°C, but not at 37°C (136). No plausible explanation existed for this unusual binding phenotype until observations by Tomita and Ike (135) showed that gelatinase-positive *E. faecalis* strains adhered poorly to collagen and laminin due to the ability of the protease to cleave these proteins. Shiono and Ike (141) showed that some *E. faecalis* clinical isolates adhere efficiently to human bladder carcinoma cells, as well as to human bladder epithelial cells, and that these interactions could be inhibited by pretreating the bacteria with fibronectin or trypsin.

More recently, several studies have identified a pilus in *E. faecalis* (140, 142–145) and have shown that Ebp pili are important for adhesion to the urinary epithelium and urinary catheters through the binding of fibrinogen released into the bladder during catheterization (146–148). In a mouse model of catheter-associated urinary tract infection, *E. faecalis* infection could be blocked by the administration of antibodies raised against the tip subunit of the Ebp pili, EbpA (149). It is hoped that these antibodies could potentially be used to prevent infection in catheterized patients without the use of antibiotics.

ENDOCARDITIS

Of the infections caused by enterococci, infective endocarditis (IE) is one of the most therapeutically challenging (8, 150). Enterococci account for between 10 and 20% of all cases of IE (151, 152), with *E. faecalis* causing a majority of these. In IE, bacterial colonization of the endocardium leads to vegetations within the tissue and a biofilm-like matrix surrounding the bacteria, which is difficult to penetrate either by the immune system or by antibiotics (153–155).

Several virulence factors have been identified as playing a major role in the pathogenesis of enterococcal IE, with adhesion to host tissues by cell surface adhesins among the best characterized. In *E. faecalis*, AS represents a class of large, pheromone-inducible surface proteins involved in mediating cell-cell adhesion as the first step in conjugal plasmid transfer (156). These proteins also appear to be key players in both attachment to heart tissue and the development of biofilm during IE. Three highly related AS proteins have been well studied in this regard, including Asa1, Asc10, and Asp (155, 157, 158). All three proteins appear to aid in cell-cell adhesion and contribute to the exopolymeric matrix that accumulates within the biofilm.

The EfaA antigen is another adhesin that was originally identified as being expressed in serum but not broth culture (159), and database homology searches revealed extensive sequence similarity with several streptococcal adhesins. Shepard and Gilmore (160) showed that of all the suspected *E. faecalis* virulence factors, EfaA resulted in the most dramatic increase in expression when serum-grown and broth-grown *E. faecalis* were compared. It is now known that EfaA forms part of a putative ABC-type transporter specific for manganese, along with EfaB and EfaC. Because manganese is tightly sequestered within the mammalian host, it is not unexpected that *E. faecalis* grown in serum would require the

Downloaded From Vet-eBooks.com

induction of a high-affinity manganese transporter, EfaABC. The induction of the *efaCBA* operon occurs at relatively low manganese levels, because under high manganese levels the product of the *efaR* gene, a manganese-responsive transcriptional regulator, represses transcription from the *efaCBA* operon (159). More recently, EfaR inactivation has also been shown to impair the ability of *E. faecalis* to form biofilms, survive inside macrophages, and tolerate oxidative stress (161).

Pili encoded by the Ebp gene cluster in *E. faecalis* have also been shown to be important for both adherence and biofilm formation in IE (162). High titers of antibodies against the EbpABC proteins in patients with enterococcal IE have been demonstrated, indicating that they are expressed at high levels within the host during infection (162). Other important virulence factors in *E. faecalis* IE include the metalloprotease GelE (163), collagen-binding adhesin Ace (164), fibronectin-binding protein EfbA (165), cytolysin (128), and phosphotransferase system permease BepA (Table 1) (166). A review of the many virulence factors that play a role in *E. faecalis* endocarditis was recently published (167).

In *E. faecium*, less is known regarding specific virulence factors and the roles they play in IE. However, the enterococcal surface protein Esp and the collagen-binding protein Acm have been shown to be important for the pathogenesis of *E. faecium* IE in a rat model of infection (168, 169). In infected animals, *E. faecium* strains that lack either Esp or Acm were recovered at lower numbers than their wild-type counterparts. Antibodies against both proteins have also been detected in patients diagnosed with *E. faecium* IE, and pretreatment of bacteria with anti-Acm antibodies derived from an infected patient was shown to reduce the ability of the bacteria to bind to collagen (162, 168). It seems that targeting the adhesive and biofilm development properties of enterococci, in addition to treatment with antibiotics, may be a promising method of treating enterococcal IE in the clinic.

SURGICAL SITE INFECTIONS

Enterococci are common causes of surgical site infection at all anatomical sites (170), including the eye (129, 171). The eye affords a unique opportunity to visualize the evolution of such an infection using readily available equipment. Small numbers of organisms injected into the vitreous of a rabbit (129) or mouse (172), can be directly studied using an ophthalmoscope or slit lamp, and declining organ function can be measured quantitatively by electroretinography (173). Enterococci rapidly proliferate at this site, with a 10-μl injection of enterococci suspended in phosphate-buffered saline remaining as a light-refracting bead. After a few hours, the small bead acquires a coat of fibrin. About 12 hours later, the microvessels in the retina begin to dilate and subsequently turn white as they become coated with adherent neutrophils. After about 24 hours, neutrophils can be seen streaming from vessels in the optic nerve head to the infection nidus. These measurement parameters allow various steps in the pathogenesis of infection to be dissected and the roles of various traits expressed by the bacterium to be defined. In this model, the enterococcal cytolysin makes a profound contribution to organ destruction, which is not salvaged by otherwise effective antimicrobial or anti-inflammatory therapy (173). In contrast, identical infections initiated with isogenic cytolysin knockout strains resolved completely with antimicrobial and anti-inflammatory therapy, with little loss of organ function. Using this model, GelE and SprE proteases, both controlled by the Fsr quorum-regulated system, were observed to make measurable contributions to virulence in the rabbit model of endophthalmitis (174).

ROOT CANAL FAILURE

Due in part to its resistance to many disinfectants and antiseptics, *E. faecalis* is an important cause of root canal failure (175, 176). This is particularly true in cases of chronic and persistent periradicular lesions leading to root canal failure, where *E. faecalis* was isolated in 24 to 77% of cases (176). Genetic analysis of *E. faecalis* strains isolated from infected root canals suggests that these strains, while not clonal, are highly related and may share additional traits that lead to efficient colonization of the oral cavity (177, 178). Calcium hydroxide, a common disinfectant used within the root canal, has been shown to be ineffective at killing *E. faecalis* on its own (179), as have other disinfectants such as EDTA and citric acid (180, 181). It appears that the bacteria can resist starvation within the root canal for long periods of time and are then able to be resuscitated by serum that enters the canal from the alveolar bone and periodontal ligament (59). Provided with an adequate food supply, *E. faecalis* may utilize proteases such as SprE and GelE, and the collagen binding protein Ace, to bind to dentin and form biofilms (182). Once the infection is established, the most efficient treatments include prolonged washing of the canal with sodium hypochlorite or chlorhexidine solution (176). Using chlorhexidine or sodium hypochlorite washes during the initial procedure are thought to be the best options for preventing *E. faecalis* infection of the root canal and preventing failure.

IMMUNE EVASION

For enterococci to maintain an infection, they must successfully evade both specific and nonspecific host defense mechanisms. Other Gram-positive pathogens possess attributes that allow them to survive in the host in spite of powerful nonspecific host defenses mediated primarily by professional phagocytes, i.e., neutrophils, monocytes, and macrophages. These factors include antiphagocytic polysaccharide capsules, antiphagocytic surface proteins, such as the group A streptococcal M protein, and various secreted toxins with direct phagocytic cell toxicity. The most important cell type for clearing bacteria during the early innate immune response to enterococcal infection is neutrophils, with complement and antibody-mediated killing also playing a role (183). Neutropenic mice are less able to clear *E. faecium* from their bloodstream compared to their wild-type counterparts and show higher inflammatory cytokine levels after intraperitoneal infection (184).

Numerous studies have characterized the host response to enterococcal infection (183, 185–187). *E. faecalis* has been found to be able to actively cleave the complement protein C3, mediated by the metalloprotease GelE, leading to reduced phagocytosis and higher rates of bacterial survival (188). In a case report, Bottone and colleagues (189) isolated three highly mucoid encapsulated strains of *E. faecalis* from patients with urinary tract infections. These mucoid isolates appeared to persist longer in the mouse following intraperitoneal injection compared to nonmucoid controls, but crude mortality was not changed, suggesting a role in preventing or delaying phagocytic clearance (190). Once phagocytosed, *E. faecalis* is able to resist intracellular killing in both polymorphonuclear leukocytes and macrophages (110). In polymorphonuclear leukocytes, opsonized bacteria are more readily killed than unopsonized cells, and AS appears to limit opsonization, leading to survival within phagosomes (191). Recent studies examining *E. faecalis* survival in macrophages showed that phagosomes containing *E. faecalis* did not acidify or fuse with autophagosomes, leading to greater bacterial survival (192). *E. faecalis* is also able to survive the oxidative

Downloaded From Vet-eBooks.com

burst within macrophages, which is in part mediated by the production of catalase (112, 193). Survival within macrophages may also allow for bacterial translocation across the intestinal epithelium, leading to dissemination of *E. faecalis* throughout the body (112).

Several studies have examined the diversity of cell wall polysaccharides produced by *E. faecalis* (194–197). Based on genetic and serologic data, *E. faecalis* capsular polysaccharides fall into four serogroups (197, 198). Antibodies to *E. faecalis* capsular polysaccharides do, however, cross-protect across the species boundary (196), because antibodies to *E. faecalis* capsular antigens are reactive with some *E. faecium* capsular antigens and mediate opsonophagocytosis. The genetic basis for *E. faecalis* capsular biosynthesis is encoded by the *cpsC-K* operon (194, 199). In addition to capsular antigens, Murray and coworkers identified another cell wall polysaccharide, called the enterococcal polysaccharide antigen, whose synthesis is encoded by the *epa* locus (200–202). This pathway appears to be widespread and conserved within *E. faecalis*, and it has been designated the *E. faecalis* group antigen (194), analogous to the streptococcal group antigens. Antibodies to the Epa polysaccharide have also been shown to promote opsonophagocytic clearance by neutrophils (200), but this prospect remains controversial (196). A recent study showed that inactivation of a predicted wall teichoic acid biosynthetic gene in *E. faecalis* caused differences in wall teichoic acid and Epa composition and led to increased susceptibility to complement-mediated killing by neutrophils (203). Finally, enterococcal cell surface-associated polysaccharides have been found to impact gastrointestinal tract colonization and infection in a variety of settings (99, 195, 204–207). The extent to which enterococcal surface-associated polysaccharides could be used as potential vaccines awaits further study.

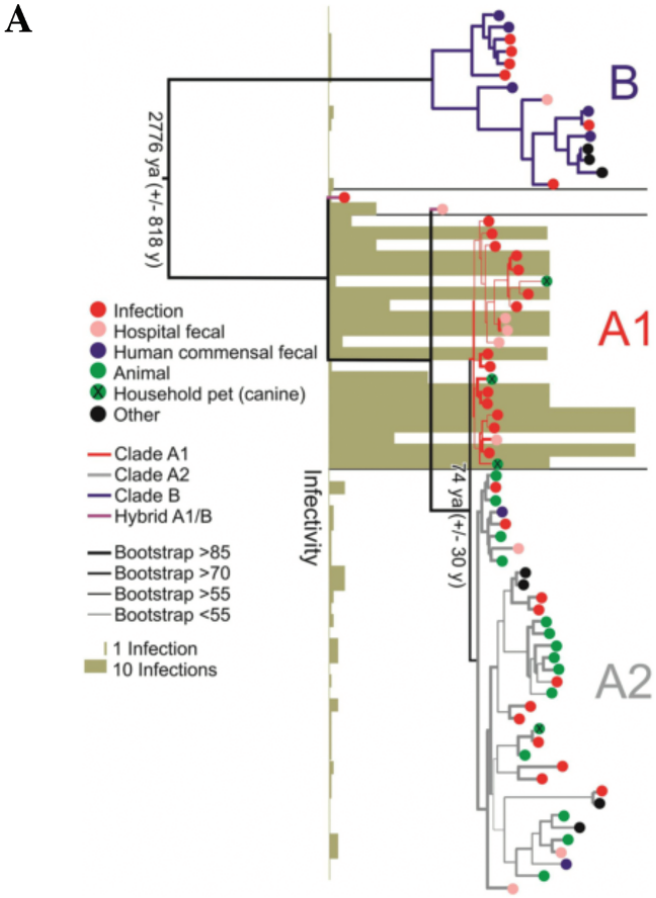
TISSUE DAMAGE

Following adhesion to host cell surfaces and evasion of the host immune response, the last step in the pathogenesis of enterococcal infection is the production of pathologic changes in the host. Such changes can be induced by the host inflammatory cascade or by direct damage as a result of secreted toxins or proteases, as well as the production of toxic metabolic byproducts. Each of these mechanisms has been observed in studies of *E. faecalis* pathogenesis.

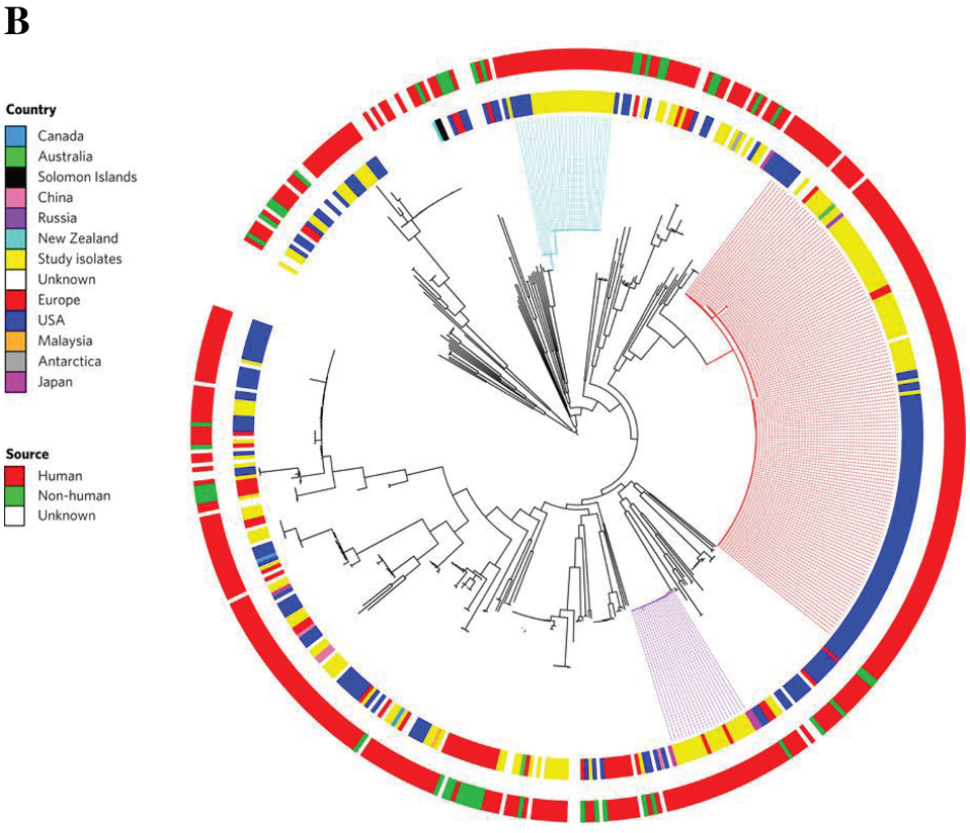
Indirect Tissue Damage

Enterococcal LTA, also known as the group D streptococcal antigen, has been implicated in a variety of biological processes (204, 208–211). Some properties ascribed to LTA include modulation of the host immune response and mediating the adherence of enterococci to host cells. Bhakdi et al. (212) found LTA from enterococci to be as inflammatory as lipopolysaccharide of Gram-negative bacteria, although more recent findings dispute this claim (213). Strains of *E. faecalis* defective in enterococcal binding substance (EBS) (which is at least partially derived from LTA) and also defective in the protein adhesin AS did not induce clinical signs of illness when injected intraventricularly into rabbits (214). While $EBS^{+}AS^{-}$ or $EBS^{-}AS^{+}$ strains caused signs of illness and pericardiac inflammation, all rabbits injected with the $EBS^{+}AS^{+}$ strain developed illness and died. Surprisingly little inflammation was observed in rabbits injected with the $EBS^{+}AS^{+}$ strain, despite the lethality observed. The authors state that such observations are consistent with the presence of a superantigen. The presence of LTA (EBS) and AS together may mediate effects on the host immune response that differ from those seen when either component acts alone.

Direct Tissue Damage



The enterococcal cytolysin and two proteases, a zinc metalloprotease (gelatinase) and a serine protease, are secreted factors well suited to contribute to disease severity (126, 128, 129, 215, 216). The enterococcal cytolysin is well established in several independent labs and animal models (126, 128, 129). The presence of the cytolysin has also been shown to promote the appearance of *E. faecalis* in the bloodstream (217). The genetics and biology of the enterococcal cytolysin have been reviewed elsewhere (218, 219). The toxin is genetically and structurally related to the lantibiotic family of bacteriocins but diverges from this family in that it possesses both bacteriocin activity and toxicity toward a variety of mammalian cell types. The cytolysin operon is typically encoded on large pheromone-responsive plasmids but has also been shown to reside within an *E. faecalis* pathogenicity island (134). The operon consists of six genes, designated $cylL_L$, $cylL_S$, *cylM*, *cylB*, *cylA*, and *cylI*, with each gene product playing an essential role in toxin synthesis, modification, secretion, activation, and immunity. Transcription of the operon is repressed by the products of a divergent operon encoding CylR1 and CylR2, and repression is alleviated by the accumulation of fully processed $CylL_S$, which serves as a quorum sensing molecule to prime the synthesis of more toxin components as cell density increases (220).



The most direct and quantitative evidence for pathologic damage attributable to the cytolysin was obtained using a rabbit model of endophthalmitis (129). This model was selected because a robust infection can be established with as few as 10 organisms due to the natural aberrations in the intraocular immune response. This limited response provides the offending bacterium an opportunity to adapt to *in vivo* growth conditions and environmental cues. Moreover, highly sensitive and quantitative measurements of the evolution of disease can be made. A role for the cytolysin in tissue pathology was unambiguously demonstrated by both a reduction in β-wave response and complete destruction of retinal architecture 24 hours postinfection (129).

Because of its broad protease specificity, the enterococcal gelatinase may also play a measurable role in systemic disease (127), as well as in a model of dental caries using germ-free rats (215). In the germ-free rat model, Gold et al. (215) showed that a proteolytic (Gel+) strain exhibited cariogenic activity, whereas three nonproteolytic strains exhibited little cariogenicity. Dupont et al. (127) showed a reduced 50% lethal dose for mice injected with gelatinase-producing (Gel+) strains, and these findings were subsequently confirmed using isogenic strains defective in protease production (216). On the same transcript as the *gelE* gene resides the *sprE* gene, which encodes a serine protease. Both proteases have been shown to play important roles in *C. elegans* nematode killing (221), lupine endophthalmitis (222), and murine peritonitis (216). As discussed previously, gelatinase has been shown to be important in *E. faecalis* biofilm formation (223, 224) and also appears to play a role in the degradation of the host extracellular matrix proteins collagen and laminin (135).

Both gelatinase and the SprE serine protease are regulated at the transcriptional level by a quorum sensing signal transduction system termed *fsr* (225). The *fsr* locus encodes a response regulator, FsrA, which is thought to be activated by

Downloaded From Vet-eBooks.com

phosphorylation at a conserved aspartyl residue by phosphotransfer from a histidine kinase, FsrC. The kinase is thought to undergo auto-phosphorylation upon sensing the accumulation of a peptide lactone quorum molecule (226), which is encoded at the carboxy-terminus of FsrB. Most if not all of the phenotypic effect of inactivating the *fsr* locus resides in the lack of protease production. While initially the only genes thought to be transcriptionally controlled by activated FsrA were *fsrB*/C and *gelE*/*sprE*, various studies have suggested that additional genes are controlled by the *fsr* locus (221, 222, 227). More recently, a third locus under the control of FsrA was identified (228); this locus encodes the antimicrobial peptide enterocin O16 (229).

There is some indication that clinical isolates of *E. faecalis* may be enriched for the proteolytic trait, because greater than 50% of isolates from both endocarditis and other clinical sources exhibited gelatinase activity, whereas only 27% of community fecal isolates possessed this trait (230). Studies that have explored the presence of *fsr* genes and *gelE* in epidemiology have found widely differing results (231–234). In addition to differences in sample size and setting, this could be because a large percentage of gelatinase-negative clinical isolates contain a 23.9-kb chromosomal deletion that results in the deletion of both *fsrA* and *fsrB* and yields a null protease phenotype (235). Because this represents a defined deletion, it is tempting to speculate why *E. faecalis* would delete these important virulence factors. Analogous to the description of the *E. faecalis* pathogenicity island, which is known to be modulated through the insertion and deletion of genetic information (92), the organism may simply choose to modulate its virulence for fear of overtly offending its host.

While *E. faecium* appears to lack both proteolytic and cytolytic activities, it has been shown to encode a hyaluronidase (236), which appears to be enriched in nonstool isolates. Hyaluronidase activity has yet to be demonstrated in these isolates, but it is conceivable that this trait is emerging within the *E. faecium* population. An *E. faecium* pathogenicity island has also been described, which contains an ortholog of the *E. faecalis esp* gene (237, 238). Apart from the *esp* gene and an *ara*C-like transcriptional regulator, none of the remaining open reading frames resemble those present in the *E. faecalis* pathogenicity island, and the nature of this element remains largely unknown.

TOXIC METABOLITES

In addition to secreted proteins, *E. faecalis* and *E. faecium* have also been shown to produce toxic oxygen metabolites that can cause cell or organ damage (94, 239). Using a worm model, Moy et al. (239) demonstrated that *E. faecium* produces hydrogen peroxide at levels that cause cellular damage. *E. faecium* transposon insertion mutants were identified which altered *C. elegans* killing activity and displayed altered levels of hydrogen peroxide production. Mutation of an NADH oxidase-encoding gene eliminated nearly all NADH oxidase activity and reduced hydrogen peroxide production and killing, whereas mutation of a gene encoding an NADH peroxidase resulted in enhanced levels of hydrogen peroxide and more rapid nematode killing. Depending on the culture conditions, *E. faecium* can produce hydrogen peroxide at varying levels, and this production appears to correlate inversely with nematode survival.

According to one study, the vast majority (87/91) of *E. faecalis* strains tested produce superoxide (O_2^-), whereas *E. faecium* isolates (5/13) did so less frequently (240). The study authors speculated that membrane-damaging effects of oxygen radicals might potentiate cellular damage to nearby intestinal epithelial cells. In proof, it was shown that the production of extracellular superoxide and hydrogen peroxide damages colonic epithelial cell DNA (94). The answer to why *E. faecalis* produces extracellular oxygen radicals stems from the fact that this oxygen radical is a byproduct of an incomplete respiratory chain. *E. faecalis* is capable of reconstituting a cytochrome complex in the presence of exogenous heme (241), enabling it to effectively respire. The fact that enterococci generate a byproduct that damages its host appears to be an unintended consequence of incomplete respiration.

COMPARATIVE GENOMICS OF *E. FAECALIS* AND *E. FAECIUM*: EMERGENCE OF PATHOGENIC, RESISTANT LINEAGES

With the development and widespread use of next-generation sequencing and comparative analysis of bacterial genomes, a great deal has been learned about the genetic makeup of pathogenic *E. faecalis* and *E. faecium* strains. The first enterococcal genome to be completely sequenced was a vancomycin-resistant *E. faecalis* strain isolated from an HIV-infected patient (35, 242). The genome of this isolate, termed V583, made apparent the importance of mobile genetic elements in the development of *E. faecalis* into a hospital-adapted pathogen (35, 242). When compared to a commensal-like *E. faecalis* strain, OG1RF (243), which harbors no known functional mobile elements, V583 was found to possess a genome more than 25% larger as the result of harboring three plasmids, a pathogenicity island (92, 243), and several integrated prophages (242).

First identified in the multiple drug-resistant strain MMH594 (92), the pathogenicity island has been shown to be widely distributed among hospital-adapted, pathogenic strains of *E. faecalis*. It encodes the virulence factors cytolysin and AS, ESP, and a variety of other elements believed to play a role in pathogenesis (92, 244). Overall, the trend of increased mobile genetic element content among multidrug-resistant, hospital-adapted strains holds true within *E. faecalis* and is strongly correlated with the absence of a functional clustered regularly interspaced short palindromic repeat-Cas system (245).

The population structures of *E. faecalis* and *E. faecium* have been widely studied, initially by multilocus sequence type and related techniques (246–249) and more recently by comparing sequences of entire genomes of many isolates of both species (104, 250, 251) (Fig. 3). These studies revealed a

FIGURE 3 Population structure of *E. faecium* and *E. faecalis* based on comparisons of whole genomes. (A) RAxML tree of 1,344 single copy core genes found in 73 *E. faecium* genomes, showing the clade structure of the *E. faecium* population. Reproduced with permission from reference 104. (B) Phylogeny of 515 *E. faecalis* isolates based on 1,293 conserved core genes found in 99% of isolates. The L1, L2, and L3 lineages are highlighted with red, purple, and turquoise lines, respectively. Reproduced with permission from reference 250.

Downloaded From Vet-eBooks.com

pronounced clade structure within the *E. faecium* species. The two main branches, clades A and B, are so divergent from one another that they approach the limits for designation as separate species (Fig. 3A) (104, 248). Most hospital-adapted *E. faecium* isolates belong to clade A and closely resemble strains isolated from agricultural and companion animals. Non-hospital associated human fecal isolates of *E. faecium*, on the other hand, mainly belong to clade B and appear to have diverged from clade A strains several thousand years ago (104, 248, 252–254).

In contrast to the pronounced clade structure of *E. faecium*, the population structure of *E. faecalis* is less discrete (Fig. 3B) (250, 251). A study of *E. faecalis* mainly derived from Great Britain revealed three dominant lineages, named L1, L2, and L3 (Fig. 3B) (250). However, these lineages are fairly closely related compared to the A and B clades of *E. faecium*. This finding supports previous work comparing a smaller set of *E. faecalis* genomes (253).

ANIMAL MODELS USED TO STUDY PATHOGENIC MECHANISMS

Several animal models have been developed to study different aspects of enterococcal pathogenesis. Using both invertebrate and vertebrate host organisms, many important discoveries have been made in identifying the roles of specific virulence factors in enterococcal disease (Table 1). Model organisms have also been employed in the discovery of novel antibacterial compounds. Here, we summarize the major advances in the establishment of relevant models of enterococcal disease; a more complete examination of models of enterococcal infection has been presented recently in two excellent reviews (255, 256).

Invertebrates

Invertebrate models of enterococcal infection have been very useful due to the ability to use large numbers of organisms in each experiment and because they are known to be natural hosts of enterococci in the environment. *C. elegans*, *Drosophila melanogaster*, and *Galleria mellonella* have all been used in different infection contexts, largely to examine the effects of virulence factors on lethality of the whole organism (130, 257, 258). It has been observed that there is good correlation between virulence factors in invertebrate hosts and in mammalian infection models (130, 221). Invertebrates, particularly *C. elegans*, have also proven to be very fruitful for high-throughput screening for novel antienterococcal compounds, because they allow for identification of bactericidal compounds with low host toxicity, as well as host immunomodulatory molecules that impact the course of infection (259).

Vertebrates

Several infection models have been established in small mammals for many of the most important enterococcal diseases. Two of the earliest infection models were developed for enterococcal IE, first in rabbits by MacCallum and Hastings in the first description of enterococcal disease (3) and later modified by Garrison and Freedman (260). Santoro and Levison developed a rat model of infection in the 1970s (261). Both the rabbit and rat IE models involve the insertion of a catheter into the heart valve followed by administration of bacteria. The introduction of a foreign body allows for initial adherence of enterococcal cells, resulting in a robust infection of the cardiac tissue. The determination of many important virulence factors for endocarditis have been shown using these animal models (128, 157, 255).

Intestinal colonization by *E. faecalis* and *E. faecium* has been studied in antibiotic-treated mice to model antibiotic treatment in hospitalized human patients. Generally, mice are treated with high concentrations of broad-spectrum antibiotics, particularly spectinomycin or metronidazole, to allow enterococcal invasion into the microbiota. Kommineni and colleagues obtained stable, long-term colonization of an introduced *E. faecalis* strain into an intact mouse microbiota through long-term administration of the bacteria in drinking water (102). Recently, studies examining the localization of *E. faecalis* within the intestinal tract have been performed in germ-free mice, allowing for direct visualization of bacteria in contact with intestinal tissue (262). How closely this localization resembles that of enterococci in a fully colonized animal has yet to be determined.

Mice have also been used with great success to study bacteremia and peritonitis caused by *E. faecalis* and *E. faecium* (126, 263). Urinary tract infection models, both catheter-associated and endogenous, have been established in female mice and were instrumental in identifying virulence factors, particularly adhesins, in enterococcal pathogenesis (134, 147, 264, 265). Finally, to study postoperative infections, Stevens and colleagues established a highly tractable rabbit endophthalmitis model in 1992 (266). This model involves the direct placement of small numbers of bacteria into the vitreous, directly behind the lens, where the evolution of infection can be easily observed by direct ophthalmoscopy as well as slit lamp biomicroscopy. This allows the influence of a number of virulence traits on the host-microbe dynamic to be assessed in real time (129).

From one of the first descriptions of enterococcal infection in 1899 (3) to the understanding of the role of virulence factors in disease and identification of novel antimicrobials, animal models have proven to be extremely important in the study of enterococcal pathogenesis, and their further development will continue to provide insight into diseases caused by enterococci.

CONCLUSIONS AND PERSPECTIVES

Enterococci are unusually well adapted for survival and persistence in a variety of adverse environments, including inanimate surfaces in the hospital environment and at sites of infection. This intrinsic ruggedness undoubtedly plays a role in providing opportunities for enterococci to interact with other overtly drug-resistant microbes and acquire additional resistances on mobile elements. The rapid rise of antimicrobial resistance among hospital-adapted enterococci has rendered hospital-acquired infections a leading therapeutic challenge. Having added about a quarter of a genome of additional DNA conveyed by mobile elements, there are undoubtedly many more properties that have been acquired that help enterococci persist and spread in the hospital setting and cause diseases that have yet to be defined. Much remains to be learned about these ancient and rugged microbes.

Enterococcal Genetics

KEITH E. WEAVER

25

Interest in enterococcal genetics began with three landmark discoveries: (i) identification of the first conjugative plasmids whose transfer systems are induced by an identifiable signal (1), (ii) identification of the first "transposons" capable of intercellular (conjugative) transposition (2, 3), and (iii) the acquisition of vancomycin resistance (4, 5). Since the most prevalent antibiotic resistance genes are located on plasmids and transposons, early work on enterococcal genetics focused heavily on mobile genetic elements (MGEs). Examination of the complete sequence of a vancomycin-resistant clinical isolate of *Enterococcus faecalis*, V583, reaffirmed the importance of MGEs in the evolution of this species, revealing that over a quarter of the genome consists of mobile and/or exogenously acquired DNA (6). Further genome sequencing has revealed extensive variability in the proportion of horizontally acquired DNA in *E. faecalis* strains, with the presence of clustered regularly interspaced short palindromic repeats (CRISPR) with CRISPR-associated (Cas) protein (CRISPR-Cas) loci playing an important role in regulating MGE acquisition (7, 8). More recent genomic analysis has revealed that MGEs are important drivers of genome diversity and evolution in *Enterococcus faecium* as well (9).

While work on enterococcal MGEs continues apace, other aspects of enterococcal genetics are beginning to come into sharper focus. While the basic mechanisms of chromosome replication, partition, and cell division remain poorly defined, progress on other chain-forming ovococci provides a framework for further detailed analysis. Meanwhile, substantial progress has been made in understanding transcription and posttranscriptional regulation of gene expression, intercellular communication, and global response via second messengers, particularly of genes involved in virulence of the two major pathogens of the genus, *E. faecalis* and *E. faecium* (for a comprehensive review see 10). This article will focus primarily on the most recent advances in this field, with references to detailed reviews where available. Unless otherwise stated, identification of *E. faecalis* genes orthologous to genes in other bacteria utilized the V583 genome for searches (6), and gene annotations where given will use the V583 designation.

CHROMOSOMAL REPLICATION, PARTITION, AND CELL DIVISION

The fundamentals of chromosomal DNA replication in enterococci are probably similar to those in the model organism *Bacillus subtilis* (11). The *E. faecalis* genome includes homologs of all known components of the typical Gram-positive DNA polymerase III (Pol III) holoenzyme, including a replicative DNA helicase (which is named DnaB according to the *Escherichia coli* convention rather than DnaC as in *B. subtilis*), helicase loaders, primase, clamp and clamp loaders, and DnaE- and PolC-type catalytic alpha subunits. Most have also been identified in the *E. faecium* genome. It has been proposed that PolC may be the primary leading strand DNA polymerase, while DnaE plays dual roles as the lagging strand polymerase and as an error-prone polymerase during DNA repair in *B. subtilis* and *Streptococcus pyogenes* (12, 13). The *E. faecalis* PolC and DnaE proteins have been purified and found to have characteristics similar to the *B. subtilis* homologs, even cross-reacting with antibodies generated against *B. subtilis* PolC and DnaE (14), suggesting that *E. faecalis* and *B. subtilis* enzymes are structurally and functionally similar. The putative enterococcal *ori*C has a bipartite organization with DnaA binding sites flanking the *dnaA* gene as in *B. subtilis* and distinct from *E. coli*.

In addition to DNA Pol III, the *E. faecalis* V583 chromosome also encodes a DNA Pol I homolog, two putative phage-encoded DNA polymerases, and one member of the mutagenic Y-family polymerases (15) that have been shown to be involved in lesion bypass in other organisms. Y-family polymerases are commonly found on bacterial plasmids (16), and all three of the plasmids in *E. faecalis* V583 encode at least one member of the family. The previously described *uvrA* gene of *E. faecalis* plasmid pAD1 (17) also belongs to this group and was shown to impart increased resistance to UV exposure.

Other genes associated with DNA repair present in the *E. faecalis* genome include homologs required for transcription-coupled DNA repair (*mfd*), nucleotide excision repair (*uvrA*, *uvrB*, and *uvrC*), mismatch repair (*mutS* and *mutL* homologs annotated as *hexA* and *hexB*, respectively), and numerous other nucleotide repair proteins, including seven potential *mutT* homologs. It should be noted that the previously designated *uvrABC* genes located on plasmid pAD1 (17) are not homologs of the excision repair enzymes that usually bear this name but are instead associated with a lesion bypass polymerase. Multiple homologs of genes involved in recombination repair were also identified, including genes for a LexA-like regulator, RecA, a RexAB DNA processing enzyme, a RuvAB Holliday junction helicase, a PriA replication restart primase, a RecFOR complex, and a variety of other recombination proteins. A recombination-deficient mutant of *E. faecalis*, UV202, has a phenotype similar to *recA*

doi:10.1128/microbiolspec.GPP3-0055-2018

Downloaded From Vet-eBooks.com

mutants in other bacteria (18). Sequencing and complementation analyses confirmed that this phenotype is due to a single point mutation that results in a G265D change in the RecA protein (19). Other putative recombinational repair proteins have not been characterized.

The *E. faecalis* genome includes topoisomerases I to IV, a *Streptococcus pneumoniae* condensin homolog, and a homolog for the nucleoid associated protein HU, suggesting that the chromosomal DNA is organized and compacted as in other bacteria. No replication terminator protein is annotated in the genome, and no identifiable homolog of the *B. subtilis* Rtp terminator could be identified. In fact, Rtp appears to be limited to the *Bacillus* genus, suggesting that proteins involved in termination of replication are poorly conserved. A single XerD homolog, involved in chromosome dimer resolution in other bacteria, is annotated in the *E. faecalis* genome, but several other integrase/recombinases have been identified that could play the role of the XerCD resolution recombinase. The C-terminus of the cell division protein FtsK has been implicated in organizing both the XerCD dimer resolution complex and the topoisomerase IV decatenation complex near the chromosomal replication terminus for efficient separation of daughter chromosomes in *E. coli* (20, 21). The C-terminal domain of *E. faecalis* FtsK is 42% identical to the C-terminus of *E. coli* FtsK, but the N-terminal domains of the two proteins are not similar, suggesting that they may play similar roles at the end of chromosomal replication but different roles in cell division.

The division/cell wall cluster of *E. faecalis* was identified in strain A24836 (22) and appears to be identical in the V583 genome (note that *divIB* and *ftsQ* are orthologs). This cluster includes *ftsZ*, the gene for the bacterial tubulin homolog essential for contraction of the cell membrane during cell division, two other cell division genes, *ftsA* and *ftsQ*, and several genes involved in peptidoglycan synthesis. There are also multiple *ftsW*- and *ftsK*-like genes in the V583 genome that may be involved in cell division. Details of the mechanism of FtsZ ring closure have been examined in *S. pneumoniae* (23–25) and may be applicable to enterococci.

In the model rod-shaped organisms *E. coli* and *B. subtilis* the primary systems responsible for division site selection and coordination with chromosome segregation are the Min and nucleoid occlusion systems (26, 27). In the Min system, the MinCD division inhibitor functions with a topological specificity determinant (MinE in *E. coli* and DivIVA in *B. subtilis*) to prevent division site placement at the poles, while nucleoid occlusion prevents septum closure over the bulk chromosomal DNA. Gram-positive cocci lack recognizable genes for MinCD and known nucleoid occlusion systems, and evidence suggests that nucleoid occlusion does not function in these organisms (28, 29). Recent work in *S. pneumoniae* suggests that proper origin placement and chromosome compaction drive division site selection, and a protein unique to the *Enterococcaceae* and *Streptococcaceae* families, MapZ (30), is required for proper perpendicular orientation of the division plane (31). The mechanism of origin placement remains unclear but may involve as yet unidentified proteins, coupling of transcription to segregation (32), or entropic effects (31).

The *S. pneumoniae* system provides a useful model for understanding enterococcal partition and cell division. Enterococcal division is at least superficially similar to streptococcal cell division, and the enterococcal chromosome includes orthologs for many of the important players, including genes for partition, chromosome compaction, and MapZ. But there are also several potentially significant differences. First, the *S. pneumoniae parB* gene, whose product is required for proper partition and recruitment of the nucleoid organizing protein Smc (33), is located immediately adjacent to the origin region and is not genetically linked to a gene for the ParA protein, which is normally essential for ParB-mediated partition function. The closest *S. pneumoniae parB* homolog on the *E. faecalis* genome (EF3298) is not closely linked to the putative origin region and has a clear *parA* partner (EF3299). Gene order at the *E. faecalis* and *E. faecium* origins conform more closely to that found in *B. subtilis* than in *S. pneumoniae* (34). Further, the homology between *S. pneumoniae* and enterococcal MapZ is primarily in the C-terminal peptidoglycan binding domain and does not extend to the transmembrane and cytoplasmic domains potentially involved in midcell divisome placement. While these observations may simply represent variations on a general theme, further research is required to determine how similar coordination of chromosome partition and cell division are in the enterococci and streptococci.

REGULATION OF GENE EXPRESSION

Like many other aspects of enterococcal genetics, regulation of gene expression was initially investigated in the MGEs of *E. faecalis*. These include the two-component signal transduction system (TCSTS) regulation of transposon-borne vancomycin resistance genes, signal peptide-dependent and antisense RNA-mediated regulation of conjugation, and antisense RNA regulation of plasmid-encoded toxin-antitoxin (TA) genes. The mechanisms of regulation of these systems will be examined in detail in later sections of the article. This section will focus on more recent advances in the understanding of the regulation of enterococcal chromosomal genes.

The *E. faecalis* genome encodes genes for RNA polymerase α, β, β', ω, and δ subnits and four recognizable σ factors. The σ factor genes include a putative housekeeping σ factor (*rpoD* or *sigA*), two members of the extracytoplasmic family (ECF), and a σ^{54}-like sigma factor (*rpoN*). σ^{54} is unique among bacterial sigma factors in that σ^{54} RNA polymerase is unable to form open complexes and initiate transcription without the help of ATP-dependent activator proteins (35). Such "enhancer binding proteins" are highly conserved, and genes encoding four such proteins have been identified in the *E. faecalis* genome (36). All belong to the LevR subfamily of σ^{54} activators, which includes a conserved DEAH helicase motif (37). Immediately downstream of each of these genes is a putative σ^{54} promoter and operons encoding four distinct sugar phosphotransferase systems (PTSs) of the mannose family (36). Mutation of σ^{54}, enhancer binding protein MptR, or PTS component MptD resulted in decreased sensitivity to class IIa bacteriocins, implicating MptD as the bacteriocin receptor and σ^{54} and MptR as its regulators (36, 38). V583 σ^{54} mutants showed increased biofilm formation while decreasing autolysis, cell death, and extracellular DNA release (39). This phenotype was independent of the four known enhancer binding proteins. Because biofilm development is believed to be dependent on extracellular DNA, it was proposed that σ^{54} mutants adapt an alternative matrix for biofilm establishment. The *E. faecium* genome also encodes an *rpoN* and five enhancer binding proteins of the LevR family, but the functions of the genes are so far undefined.

ECF σ factors generally facilitate transcription of genes involved in bacterial stress responses. They are sequestered by membrane-localized anti-σ factors and released by stress-induced anti-σ factor degradation by regulated

Downloaded From Vet-eBooks.com

intramembrane proteolysis (40, 41). The SigV ECF of *E. faecalis* was shown to contribute to survival following heat, acid, and ethanol stress (42) and to play a key role in lysozyme resistance and virulence (43). The gene adjacent to *sigV*, *rsiV*, encodes the anti-σ factor of the system (42) and is targeted by the Eep membrane-embedded zinc metalloprotease and at least one other unidentified protease for degradation in response to lysozyme and perhaps other stresses (44). The function of the second *E. faecalis* ECF σ factor is unknown.

TCSTSs have emerged as ubiquitous bacterial signaling systems for regulating gene expression in response to environmental conditions (45). The canonical TCSTSs are composed of a sensor histidine kinase (HK) that modulates a response regulator (RR) via phosphotransfer. The RR is frequently a transcriptional regulator. Analysis of the *E. faecalis* genome revealed the presence of 17 HK/RR pairs and 1 orphan RR (46). The best-characterized enterococcal TCSTSs are the Van system, required for regulation of vancomycin resistance genes (see below), and the Fsr system. The Fsr system regulates production of two proteases, gelatinase and serine protease, that are associated with virulence and biofilm formation (47–51). Fsr is a quorum sensing system that responds to the accumulation of a peptide lactone, designated GBAP (52). GBAP is the product of a small open reading frame, *fsrD*, that is processed and secreted by FsrB (53). GBAP is sensed at high cell density by the FsrC HK, which then activates the FsrB RR by phosphorylation. Phosphorylated FsrB then activates transcription from the *gelE-sprE* target promoter and the *fsrBDC* promoter, completing the autoinduction loop. The *fsr* system is analogous to the well-studied *agr* system of *Staphylococcus aureus* (54) except for the absence of the global small RNA (sRNA) regulator RNA III; FsrA appears to be the terminal regulator of the Fsr system.

The CroRS TCSTS is essential for PBP5-mediated intrinsic cephalosporin resistance in both *E. faecalis* and *E. faecium* (55–57). The CroS HK is a sensor of cell wall homeostasis and is stimulated to phosphorylate the CroR RR in response to a number of cell wall-active antibiotics. The CroR-regulated effector genes responsible for cephalosporin resistance have not been identified, but neither PBP5 itself nor its substrates appear to be the primary target. In some *E. faecalis* strains, cross-regulation is observed with a second TCSTS CisRS (56). The situation is further complicated by the involvement of a transmembrane serine/threonine kinase, IreK, its cognate phosphatase, IreP, and their substrate, IreB, which also modulate intrinsic cephalosporin resistance by an unknown mechanism (58–61).

The GrvRS TCSTS system, also known as EtaRS, is orthologous to the important *S. pyogenes* virulence regulatory TCSTS CovRS (62). In *E. faecalis* it has been demonstrated to be involved in virulence as well as resistance to low pH and high temperature (63). GrvRS has also been implicated in the regulation of the important extracellular matrix adhesin Ace (64), catalase (65), and the heat shock proteins DnaK and GroEL (66). It seems likely that the GrvRS regulon will continue to grow with further investigation.

Disruption of RR 04, 08, and 18 (as defined in 46) each resulted in sensitivity to heat, and transcription of HK-RR 07, 13, and 14 was induced by heat, suggesting that these TCSTSs may also play a role in stress resistance (66).

In *E. faecium* the EntKR TCSTS regulates expression of the bacteriocin enterocin A (67). EntKR is a quorum sensing system that responds to a small peptide produced from the same locus, designated EntF. There appear to be no close homologs to the EntKR system in *E. faecalis*. The ChtRS TCSTS contributes to resistance to both bacitracin and the disinfectant chlorhexidine (68), and CroRS is associated with intrinsic cephalosporin resistance (57). Clear homologs of *E. faecalis* HK-RR 01, 03, 04, 05, 07, 09, and 10 (as defined in 46) are present in the *E. faecium* genome sequence. In addition, a system with linked homologs of the *S. aureus agrA*, *agrB*, and *agr*C genes is present in *E. faecium*, but this system is not closely related to the *E. faecalis fsr* system. The *E. faecium* genome contains 10 more annotated RRs and 9 more HKs that either have no strong homology to counterparts in the *E. faecalis* genome or are no more closely related to *E. faecalis* genes than to genes from any other *Firmicutes*. Therefore, *E. faecalis* and *E. faecium* have about the same number of TCSTSs but not necessarily the same complement of homologs.

The *E. faecalis cyl* cytolysin-producing operon is induced by a quorum sensing mechanism operating through a two-component system, but in this case the sensor and regulator show no homology to HK/RR of typical TCSTSs (69). Active cytolysin is composed of two posttranslationally modified peptides, $CylL_L$ and $CylL_S$, the latter acting as the autoinducer of the system. CylR2 is a DNA binding protein that represses expression of the *cyl* operon encoding the structural genes for the toxin, an enzyme for modification of the toxin peptides, and an ABC transporter for secretion. The structure of the CylR2-promoter interaction has been determined (70). The $CylL_S$ inducing signal is transmitted to CylR2 via the membrane receptor CylR1. The system is sensitive to both bacterial cell density and the presence of target cells. Target cells are detected by preferential binding of $CylL_L$ from the dual toxin complex, releasing $CylL_S$ to induce the operon (71).

The *E. faecalis* genome includes numerous other putative regulatory proteins in a variety of other classes, but few of these regulators have been characterized. The *E. faecalis* version of the catabolite control protein gene, *ccpA*, has been mutationally inactivated and shown to regulate a variety of glucose starvation proteins and was capable of complementing a *B. subtilis ccp*A mutant (72). CcpA/P-Ser-Hpr binding to catabolite responsive elements (cre) in *E. faecalis* has been shown to participate in (i) the repression of citrate utilization operons through transcriptional inhibition of both the structural genes and the gene for the GntR-type citrate-responsive positive regulator CitO (73), (ii) the partial repression of genes for malate utilization, including *maeKR* encoding a malate response TCSTS (74), and (iii) repression of the agmatine deiminase pathway in cooperation with the mannose PTS and in opposition to the AguR-positive regulator (75). CcpA has also been shown to be important for the growth and virulence of *E. faecium* (76).

Metal homeostasis is frequently important in bacterial pathogens, and regulatory responses to copper and manganese have been investigated in the enterococci. Copper uptake in *Enterococcus hirae* is encoded in the four-gene *cop* operon consisting of the *copA* and *copB* genes, which encode proteins for copper uptake and efflux, respectively, *copY*, which encodes a copper-responsive repressor, and *copZ*, which encodes a copper chaperone that delivers copper from CopA to CopY (77). At low copper levels, CopY in complex with Zn(II) binds to DNA sequences overlapping the promoter as a dimer and inhibits transcription. At high copper levels, CopZ delivers Cu(I) to CopY, displacing Zn(II) and causing dissociation from the promoter. CopZ complexed with Cu(I) is subject to proteolysis, preventing excessive accumulation of intracellular copper, which can damage the cell. The Efa adhesin, encoded by the *E. faecalis efaCBA*

Downloaded From Vet-eBooks.com

operon, is regulated in response to manganese by the EfaR protein, a member of the DtsR/MntR repressor family (78). The EfaR binding motif was later identified in the promoter regions of 30 genes. *efaR* mutation impaired biofilm formation, survival in macrophages, and oxidative stress tolerance, suggesting that EfaR is an important modulator of virulence (79).

Four regulators, OxyR (80), PerR (81), Spx (82), and HypR (83), have been implicated in the response of *E. faecalis* to oxidative stress. HypR is the best studied of these regulators, acting as a transcriptional activator of at least six genes encoding catalase, glutathione reductase, two subunits of alkyl hydroperoxide reductase, thiol peroxidase, and HypR itself through binding to a "HypR box" (84, 85). HypR mutants are deficient in macrophage survival and virulence.

Transcriptomic analyses have identified a number of regulatory networks and putative regulatory proteins involved in the virulence of *E. faecalis*. These have been recently reviewed (10). Information relevant to stress responses in *E. faecalis* may also be found in a recent review on the stress physiology of lactic acid bacteria (86).

Posttranscriptional regulation by various RNA-mediated mechanisms has recently increased in prominence in the regulation of gene expression in bacterial cells. As in most other bacteria, the first examples of RNA-mediated regulation in enterococci were identified in MGEs (see below). More recently, a number of examples of RNA-mediated regulation were identified on the enterococcal chromosome. The best studied of these is regulation of the *eut* regulon, which encodes genes essential for ethanolamine (EA) utilization (87, 88) (Fig. 1). Regulation of the *eut* regulon requires a response to two regulatory inputs: the presence of EA substrate and the availability of adenosyl cobalamine (AdoCbl), a cofactor in the first enzymatic step of EA catabolism. The presence of EA is sensed by the EutVW TCSTS. Binding of EA by the EutW HK leads to phosphotransfer to and dimerization of the EutV RR. Unlike most other RRs, EutV is an RNA binding protein in the ANTAR family of antiterminator proteins (89). EutV~P dimers bind to and stabilize a dual hairpin structure in nascent RNA that precludes formation of multiple intrinsic terminators in four *eut* polycistronic RNAs, allowing transcriptional read-through into downstream *eut* genes. AdoCbl is sensed via a unique riboswitch located upstream of the *eutG* structural gene, designated EutX. In the absence of AdoCbl, EutX adopts a structure that allows read-through to a EutV~P dimer binding site. The relative abundance of EutX allows sequestration of EutV~P dimers, preventing mRNA binding and antitermination (+EA) (Fig. 1). AdoCbl binding to nascent EutX causes a conformational change that allows formation of an intrinsic terminator that stops transcription before the EutV~P binding site (+AdoCbl) (Fig. 1), allowing EutV~P dimers to perform their antitermination function (+AdoCbl,+EA) (Fig. 1).

Several other examples of posttranscriptional regulation have been identified in the enterococcal core genome. The *pyr* operon of *E. faecalis* appears to be regulated by PyrR via an attenuation mechanism similar to that described for *B. subtilis* (90). Bioinformatic analysis suggests that genes involved in amino acid biosynthesis and transport are subjected to T-box regulation in *E. faecalis* and *E. faecium* (91). A transcription attenuation mechanism for regulation of the *tetM* gene of Tn*916* was proposed to be based on the observation of (i) a short leader peptide encoded between the promoter and the TetM-encoding open reading frame, (ii) the existence of multiple alternative RNA secondary structures surrounding the leader peptide coding sequence, and (iii) the apparent extension of a short transcript upon induction with tetracycline (92). RNase J2 has been implicated in the regulation of

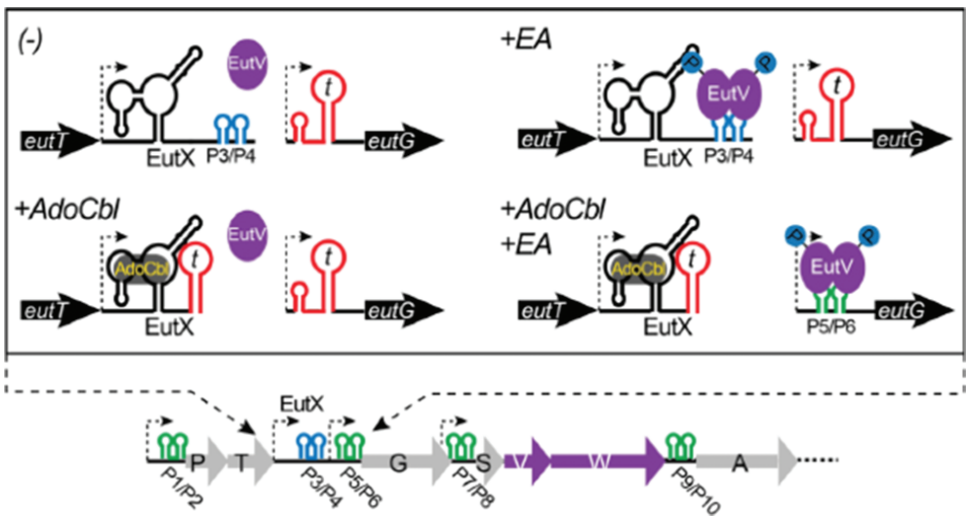

FIGURE 1 Model for EutV- and EutX-mediated regulation of the *eut* regulon. In the absence of either EA or AdoCbl (–EA), EutV~P dimers are not available to disrupt terminators upstream of *eut* genes. In the presence of EA but the absence of AdoCbl (+EA), the EutX riboswitch adopts a conformation that binds EutV~P dimers, titrating them away from the *eut* gene terminators. In the presence of AdoCbl but the absence of EA (+AdoCbl), EutX adopts an alternative conformation that is not competent for binding EutV~P dimers, but such dimers are absent due to the lack of EA. In the presence of both EA and AdoCbl (+AdoCbl, +EA), EutX is unable to bind EutV~P dimers, which then interfere with termination in *eut* transcripts, allowing the genes to be transcribed. (Adapted from reference 87.)

Downloaded From Vet-eBooks.com

the *ebp* pilus operon in *E. faecalis* independent of an effect on the level of the mRNA for EbpR, the transcriptional activator of the operon (93). Mutation of the *E. faecalis mjB* gene encoding RNase J2 was further shown to affect the expression of 62 genes and biofilm formation, bile salt resistance, and virulence in a model system (94).

Recently, a comprehensive map of all 5′ RNA ends in *E. faecalis* V583, discriminating processed from primary ends, was obtained by a combination of differential tagging and RNA-seq (95). This study identified 85 novel putative regulatory RNAs, which when added to those identified in previous studies (96, 97), brings the total number to >120. This includes putative *trans*-acting sRNAs and antisense RNAs as well as such functional RNAs as transfer-messenger and 4.5S RNA. The specific functions and targets of these putative sRNAs and antisense RNAs remains a mystery, although four have been implicated in modulating virulence and stress responses (98). *E. faecium* has also been subjected to experiments designed to detect putative regulatory RNAs with the identification of 61 sRNA candidates (99). Several of these RNAs were demonstrated to be induced or repressed during exposure to daptomycin or development of resistance to it. One putative sRNA, sRNA_0160, was demonstrated to be downregulated in the presence of daptomycin and repressed in a daptomycin-resistant mutant. Further work will be required to determine the target of this sRNA and its functional mechanism.

VANCOMYCIN RESISTANCE

Enterococci are intrinsically resistant to a variety of commonly used antibiotics and have acquired resistance to many others either by chromosomal mutation or acquisition of MGEs (100). As such, the enterococci provide a collection and distribution center for the dissemination of antibiotic resistance genes to other, potentially more pathogenic, Gram-positive bacteria. Dramatic evidence of this was provided by the characterization of the first high-level vancomycin-resistant *S. aureus* (VRSA) isolate (101, 102). Examination of the plasmid content of the VRSA isolate and coisolated vancomycin-resistant *E. faecalis* (VRE) and vancomycin-sensitive *S. aureus* (VSSA) strains suggested that a *vanA*-carrying transposon, Tn*1546*, was delivered from the VRE to the VSSA on a conjugative plasmid. The Tn*1546* then transposed to a plasmid resident in the VSSA, and the donating plasmid was subsequently lost. Further studies have implicated Inc18 plasmids, in particular, as the driving force for dissemination of vancomycin resistance to *S. aureus* (103). However, even though the Tn*1546*-bearing plasmids are conjugative in *S. aureus*, vancomycin resistance has not become widespread in *S. aureus* infections. A total of only 14 VRSA were isolated between 2002 and 2015 (104). Whether this is due to some fundamental incompatibility between vancomycin resistance and pathogenesis in this species or some bottleneck in *van*A transmission is unknown.

Vancomycin is a cell wall-active antibiotic that represents the last line of defense against many multiply resistant Gram-positive pathogens. Vancomycin and related glycopeptide antibiotics inhibit cell wall synthesis by binding to the terminal D-Ala-D-Ala dipeptide of peptidoglycan precursors, preventing their transfer from the lipid carrier to the cell wall by transglycosidases (105). Transpeptidases and D,D-carboxypeptidases involved in cell wall synthesis are also inhibited. VRE circumvent vancomycin action by substituting D-Ala-D-Lac or D-Ala-D-Ser for the D-Ala-D-Ala dipeptide, decreasing the affinity of peptidoglycan precursors for glycopeptides. Hydrolysis of pre-existing D-Ala-D-Ala dipeptides is also required for full resistance (106).

Unlike resistance to most other antibiotics, resistance to vancomycin involves the acquisition of a suite of enzymes required to reprogram peptidoglycan synthesis. Nine genotypically and phenotypically distinct systems designated VanA to VanE and VanG (reviewed in 107), VanL (108), VanM (109), and VanN (110) have been identified in VRE. Van gene clusters generally include three components: (i) a TCSTS, VanRS, required for sensing the presence of the antibiotic and inducing the resistance operon; (ii) an essential three-gene core encoding enzymes responsible for producing the D-Lac (VanH) or D-Ser (VanT) precursors, ligating those precursors to D-Ala (VanA to VanN), and eliminating D-Ala-D-Ala dipeptides (VanX, VanY, and/or a VanXY fusion); and (iii) accessory genes performing various and sometimes unknown roles. While the core and accessory genes are generally transcribed as an operon, the TCSTS is transcribed from a separate promoter (Fig. 2).

The VanC, VanE, VanG, VanL, and VanN systems all encode low-level vancomycin resistance by producing peptidoglycan peptides terminating in D-Ala-D-Ser. All encode a VanXY bifunctional dipeptidase/carboxypeptidase for degrading D-Ala-D-Ala, a VanT serine racemase for producing D-Ser, and their respective ligases. The VanC systems are responsible for the intrinsic resistance of motile enterococci, are chromosomally encoded, and do not appear to be on mobile elements. Although VanC systems appear to encode a TCSTS, resistance is either expressed constitutively or only sluggishly induced (111, 112). The VanE system is very similar to VanC in sequence and gene organization but is present in an *E. faecalis* strain (113). Although likely acquired from one of the intrinsically resistant enterococci, it is chromosomally located and could not be transferred to a vancomycin-susceptible strain. VanE is inducible in spite of a nonsense mutation in the gene for the VanS HK, suggesting some level of cross-talk with other cellular TCSTSs. The VanG system is also chromosomally located in an *E. faecalis* strain but resides on a large (~240 kb) mobile element that also encodes an *ermB* erythromycin resistance gene (114). The VanG system is inducible, probably due to the presence of a functional VanRS TCSTS. VanL and VanN were recently described, with VanN being the first D-Ala-D-Ser-producing system in *E. faecium* (108, 110).

The VanA, VanB, VanD, and VanM systems produce peptidoglycan precursors terminating in D-Ala-D-Lac. The VanA and VanB systems are widespread in both *E. faecalis* and *E. faecium*. In general, vancomycin resistance is more prevalent in *E. faecium* than in *E. faecalis* (115). Phenotypically, VanA-type resistance is characterized by high-level resistance to both vancomycin and teicoplanin, while VanB-type resistance provides variable levels of resistance to vancomycin only. Susceptibility to teicoplanin in the VanB system is due to a failure to induce the resistance genes in response to this antibiotic; VanB cells induced with vancomycin are resistant to both antibiotics. Genotypically, the VanA and VanB systems are quite similar (Fig. 2). Each encodes a VanRS TCSTS, a VanH pyruvate dehydrogenase for production of D-Lac, their respective ligase VanA or VanB, and separate VanX dipeptidase and VanY carboxypeptidase enzymes. Only the *vanH*, *vanA/B*, and *vanX* genes are essential for resistance. In addition, the VanA system encodes an additional gene, *vanZ*, which confers low-level resistance to teicoplanin by an unknown mechanism, and the VanB system encodes a gene, *vanW* (also present in VanG), of unknown function.

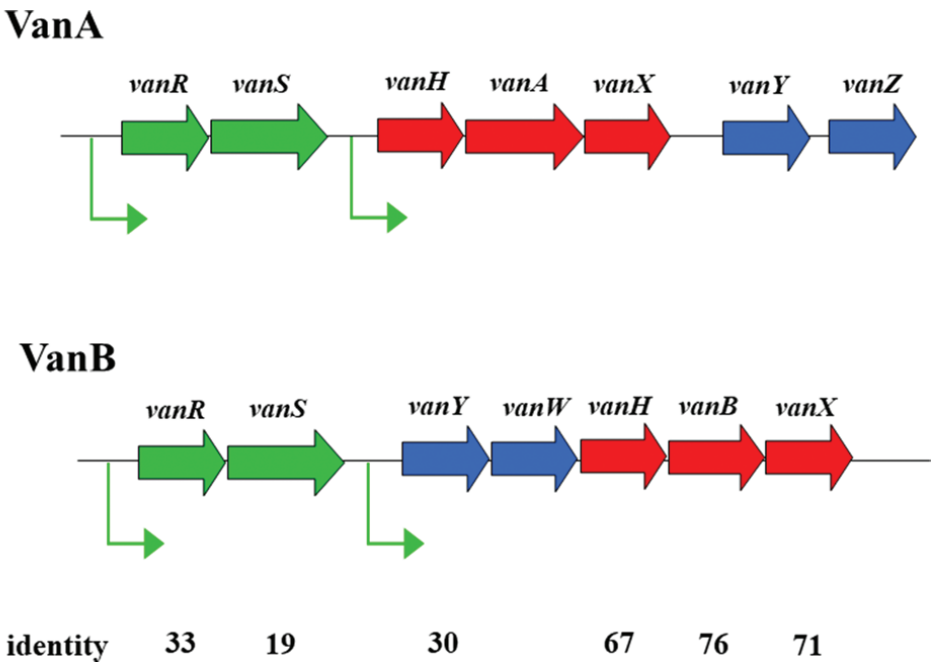

FIGURE 2 Organization of the VanA and VanB vancomycin resistance systems. Gene functions are color coded: green, sensory and regulatory; red, essential resistance genes; blue, auxiliary resistance genes. Detailed functions of each gene are described in the text. Green arrows show the position of the VanR inducible promoters. The percentage identity of the VanB genes to their VanA homologs is given below the individual VanB genes. Homologs have identical names in both systems except for the *vanA* and *vanB* ligases.

The VanRS TCSTS of the VanA and VanB systems have been extensively investigated, and reference 116 provides an excellent review. *In vitro* the VanRS system functions much like other TCSTSs. The HK, VanS, autophosphorylates its conserved histidine residue and then transfers the phosphate to the VanR RR (117). Phosphorylated VanR (VanR~P) produces a larger footprint and binds with higher affinity to its target promoters than unphosphorylated VanR, consistent with its *in vivo* role as a transcriptional activator (118). However, in the absence of VanS, dephosphorylation of VanR~P is unusually slow compared to related RR, and VanS stimulates dephosphorylation (117). In addition, VanR is capable of stimulating its own phosphorylation in the absence of VanS, using acetyl phosphate. These *in vitro* results are consistent with the observation *in vivo* that inactivation of VanS results in constitutive activation of vancomycin resistance rather than failure to induce expression. Apparently, VanR~P is the default condition *in vivo*, with phosphorylation occurring either by acetyl phosphate or by cross-talk with other cellular HK. The primary role of VanS, then, is to dephosphorylate VanR in the absence of the inducing signal (119, 120). The nature of the inducing signal is beginning to emerge. Given the differences in induction patterns and the poor conservation of VanS, the signal may be different for the VanA and VanB systems. Interestingly, single amino acid substitutions in the signaling domain of $VanS_B$ allow induction by teicoplanin (121). A recent report examining structural and activity effects on $VanS_A$ of a range of potential ligands including vancomycin, teicoplanin, and a variety of peptidoglycan precursers identified the likely inducers as the glycopeptides themselves (122).

Both the VanA and VanB gene clusters are frequently, if not always, associated with MGE. VanA is located on a Tn*3*-type transposon, Tn*1546*, and is frequently found on conjugative plasmids. In one *E. faecium* outbreak, a unique mechanism of facilitating horizontal transfer of VanA was observed (123). In this case, a nonconjugative Tn*1546*-bearing plasmid was observed to integrate into a pheromone-responsive plasmid via a mechanism involving a series of insertion sequences located outside of Tn*1546*. Conjugative transfer was enhanced by the fact that plasmid fusion occurred within a homolog of *prgX*, the central negative regulator of the pheromone response in pCF10-like plasmids (see below). The resulting insertional inactivation of *prgX* derepressed conjugation functions, and transfer occurred in the absence of pheromone. Tn*1546*-like elements have also been identified on plasmids related to the conjugative non-pheromone-responsive plasmid pMG1 (124) (see below). VanB has been localized on a variety of MGEs. In some strains, conjugative transfer of VanB has been associated with the movement of large (90 to 250 kb), chromosomally located elements that may be complex conjugative transposons (125). VanB was further localized on one of these elements to a 64-kb composite transposon, Tn*1547*, capable of transposition to plasmids under laboratory conditions. In other cases, VanB resistance was associated with conjugative plasmids (126), but the identification of similar genes on a variety of plasmids also suggested a transposon location. A VanB gene cluster was localized on a Tn*916*-like element designated Tn*5382* (127). Although independent mobility of this element was not demonstrated, it appears to be associated with a larger, 130- to 160-kb chromosomally located conjugative element. A similar element, designated Tn*1549*, was identified on a pAD1-like pheromone-responsive plasmid (128). Mobility of chromosomally located vancomycin resistance genes may also be accomplished by Hfr-like transfer

mechanisms as described below and in references 129 and 130.

Unlike VanA and VanB, VanD systems provide constitutive vancomycin resistance due to various lesions in the *vanS* gene (131–133). In spite of the presence of an apparently intact *vanX* gene, VanD systems produce very little VanX D-Ala-D-Ala dipeptidase activity. Nevertheless, peptidoglycan precursors in VanD strains contain very little or no D-Ala-D-Ala terminal peptides due to mutations in the chromosomally encoded *ddl* gene responsible for producing the D-Ala-D-Ala precursors (131, 133, 134). Thus, a combination of constitutive expression of VanD and mutation of the chromosomal *ddl* ensure vancomycin resistance. VanD systems have been found only in *E. faecium* and do not appear to be mobile.

The complex nature of the vancomycin resistance systems argues against their acquisition by accumulation of mutations or piecemeal acquisition of individual genes. More than likely, they were acquired *en masse* from a single source. In this context it is interesting to note that the gene organization and sequence of the VanA and VanB systems are highly similar to self-protection systems present in glycopeptide-producing species (135, 136).

Resistance to Other Antibiotics

In addition to vancomycin, enterococci express intrinsic and/or acquired resistance to a wide variety of other antibiotics, including daptomycin, aminoglycosides, rifampicin, quinolones, macrolide/lincosamide/streptogramin B, β-lactams, and linezolid. For information on the genetics of these resistance mechanisms and the MGEs with which they are associated the reader is referred to a recent extensive review (100).

PHEROMONE-RESPONSIVE PLASMIDS

The enterococci host a multitude of plasmids, including both theta and rolling circle replicating replicons (RCRs) (137). The majority of these plasmids fall into six classes based on conserved domains in their putative initiator proteins: three RCR classes (Rep_trans, Rep_2, and Rep_1) and three theta classes (Rep_3, inc18, and RepA_N). These plasmids have been further subdivided into 10 families (of 19 present in the *Firmicutes*) based on initiator sequence homology (138). RCR and inc18 plasmids generally have a broad host range and are widely disseminated in Gram-positive and even some Gram-negative bacteria. They have been extensively studied in bacteria other than the enterococci and have been the subject of several excellent reviews (137, 139, 140). Rep_3 replicons are ubiquitous in bacteria and include some of the best-studied bacterial plasmids, including F, P1, and pSC101 (141, 142). The RepA_N plasmids are a class of replicons broadly distributed among the *Firmicutes* but whose individual members have a narrow host range (143). They include both conjugative and nonconjugative plasmids ranging in size from 3.3 to 281 kb. RepA_N proteins have also been detected on streptococcal bacteriophages and integrated conjugative elements (ICEs). Of particular relevance to enterococcal genetics are the RepA_N replicons that encode conjugation systems that are induced by small peptide pheromones secreted by potential recipients, the pheromone-responsive plasmids. These plasmids replicate primarily in *E. faecalis* and remain one of only two plasmid systems in which a specific signal for induction of conjugation has been identified (the quorum sensing system of *Agrobacterium* Ti plasmids is the other [144]). These plasmids will be discussed below, but the reader is referred to detailed reviews that discuss their replication, stable inheritance, and conjugation (137, 145–150).

Pheromone-responsive plasmids range in size from 37 to 92 kb and are maintained at a low copy number in their native host. In general, the pheromone-responsive conjugation system works as follows. Conjugation in cells containing pheromone-responsive plasmids is normally repressed in the absence of an appropriate recipient. When cocultivated with or exposed to culture filtrates of plasmid-free cells, plasmid-containing cells respond by producing a plasmid-encoded surface adhesin called aggregation substance (AS). AS binds to a ligand called enterococcal binding substance that is present on the surface of both donor and recipient cells, leading to the formation of macroscopic cellular aggregates that provide the contact required for plasmid transfer. Once transfer is complete, production of the pheromone specific for the transferred plasmid is shut down in recipient cells by the combined action of two plasmid-encoded components: a peptide that competitively inhibits pheromone activity and a membrane protein that reduces pheromone secretion. These inhibitor mechanisms are specific for the cognate pheromone of the particular plasmid acquired; production of pheromone(s) specific for other plasmids continues, allowing the recipient to induce a mating response in other potential donors and continue to collect plasmids. A cartoon showing the relevant players involved in the pheromone response, how they interact, and the organization of the plasmid-encoded regulatory genes is shown in Fig. 3.

Regulation of the Pheromone Signal Transduction Circuit

All sex pheromones and inhibitors characterized to date are linear, hydrophobic peptides of seven or eight amino acids. The genetic determinants responsible for the production of five pheromones were identified in the *E. faecalis* V583 genome and found to be encoded within signal peptide coding sequences of different lipoprotein genes (151). The involvement of these genes in the production of pheromones specific for pAD1 (cAD1), pCF10 (cCF10), and pAM373 (cAM373) was confirmed by cloning and mutagenesis experiments (152–154). Mutations of the mature lipoprotein-encoding portion of the genes for cAD1 and cAM373, *cad* and *camE*, respectively, had no effect on pheromone production or mating potential, suggesting that the lipoproteins themselves are not involved in conjugation. Pheromone sequences are generally found at the C-terminus of the lipoprotein signal peptide, indicating that signal peptidase II is required for the initial processing step. Maturation of the pheromone is then completed by the site 2 protease Eep in most cases (155). As described above, Eep belongs to a family of intramembrane processing proteins involved in regulated intramembrane proteolysis in organisms as diverse as bacteria and humans (156). The plasmid-encoded genes for the inhibitor peptides (iAD1, iCF10, iAM373, etc.) encode prepeptides resembling unattached lipoprotein signal peptides (157) and therefore require only Eep for processing. Some variability is observed in the processing of specific pheromones, suggesting further complications and potential alternative pathways. For example, Eep-processed cCF10 is further processed by removal of three C-terminal amino acids by an unknown mechanism (153, 158), and Eep is not required for cOB1, cAM373, or iAM373 processing (155, 158). Interestingly, both cAD1 and cAM373 activities can be detected in some *S. aureus* strains. In both cases the responsible peptides are produced from the signal sequences of lipoproteins unrelated to those that produce the same pep-

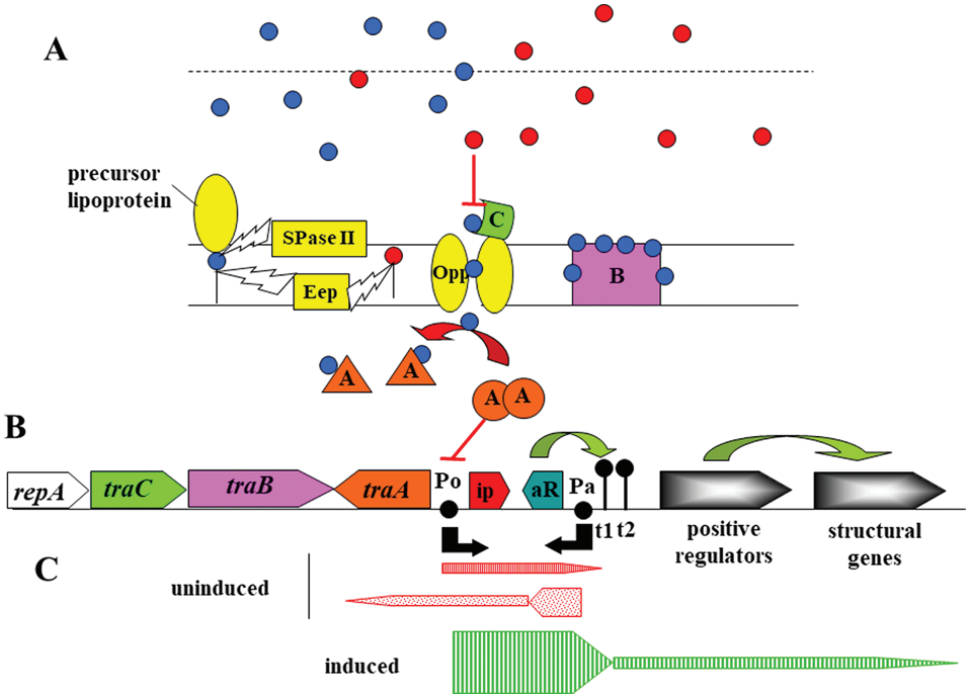

FIGURE 3 Regulatory circuitry of the pheromone response. (A) Events occurring at the cell surface. Important chromosomally encoded determinants are colored yellow with the exception of the pheromone itself, which is shown as blue circles. Plasmid-encoded determinants are color coordinated with their genes shown in panel B. The inhibitor peptide (ip) is shown as red circles and competitively inhibits pheromone binding to TraC. TraB inhibition of pheromone secretion is depicted here as sequestration, but may also involve peptide degradation. (B) Events occurring at the DNA level. Binding of pheromone by TraA links events at the cell surface with events at the DNA level. A conformational change in TraA due to pheromone binding is indicated by the change in shape of the molecule and the change in dimerization state, although more subtle conformational changes are likely. Pheromone-free TraA binds Po and inhibits transcription. Direction of transcription from Po and Pa is indicated by the arrows. The antisense RNA, generalized to aR in this figure, stimulates termination at t1, indicated by the green arrow. Positive regulatory elements vary between different pheromone-responsive plasmids, and their mechanisms of inducing downstream transcription of the conjugation structural genes may also vary. For simplicity, the more common gene names and order are used. It should be noted that the gene order of the *traC* and *traB* genes are reversed in pAD1. The RepA gene is shown to orient the reader relative to Fig. 4. (C) Events at the RNA level. Relative levels of RNA produced from the Po and Pa promoters under uninduced (red) and induced (green) conditions are depicted by the sizes of the arrows.

tides in *E. faecalis* (154, 159). Linear synthetic peptides of the appropriate sequence function as effective inducing signals for the cognate plasmids, indicating that no further processing is necessary. Hydrophobic septa- and octapeptide pheromones are pumped out of the membrane by a membrane ABC pump (160). Release of lipoprotein signal sequence fragments appears common among the *Firmicutes*, and perhaps pheromone-responsive plasmids evolved to take advantage of this process. It is interesting and perhaps surprising that so far, this efficient cell-cell communication system is mainly found in the species *E. faecalis* and is not more widespread.

Pheromones are imported into plasmid-containing cells by the chromosomally encoded oligopeptide permease (Opp) system in combination with a plasmid-encoded OppA homolog, TraC/PrgZ, that provides increased sensitivity and specificity for the cognate pheromone (161–164). The chromosomal Opp system transports sufficient pheromone to induce conjugation at high peptide concentrations, but TraC/PrgZ allows responses to pheromone levels of 10^{-10} to 10^{-11} M (161). Evidence indicates that inhibitor peptides compete with their cognate pheromones for TraC/PrgZ binding and that this at least partially accounts for their function (but see below) (102, 165).

Once inside the cell, pheromone is bound by a key negative regulatory protein, TraA/PrgX (161, 166). These proteins belong to the RRNPP (Rap, Rgg, NprG, PlcR, and PrgX) family of linear peptide pheromone-responsive regulators that are widespread in *Firmicutes* (167). Results with three TraA/PrgX proteins, those from pAD1, pPD1, and pCF10, show that the repressors bind both the stimulatory pheromone peptides and their cognate inhibitor peptides (166, 168, 169). In pPD1 and pCF10, both inhibitor- and pheromone-bound repressors bind the promoter required for expression of the conjugative apparatus (Po in Fig. 3) but with subtly different configurations that make the difference between preventing or allowing RNA polymerase binding (168, 170). In pPD1 this involves the binding of TraA to alternate sites within the promoter region (168). In pCF10 it involves subtle conformational changes in the peptide-bound PrgX tetramers that allow greater competition with

Downloaded From Vet-eBooks.com

RNA polymerase promoter binding in the inhibitor-bound than in the pheromone-bound state (170). Thus, competition between pheromone and inhibitor peptides occurs at two levels, import via TraC/PrgZ and interaction with repressor protein TraA/PrgX. The complex dual peptide regulation of TraA/PrgX systems is unique among RRNPP family members, giving rise to several interesting evolutionary questions that have been addressed elsewhere (148).

As shown in Fig. 3, even in the absence of pheromone, transcription from Po is not completely repressed. In fact, basal-level expression is required to maintain the uninduced state since the gene for the inhibitor peptide, ip in Fig. 3, is under Po control. In fact, results in pCF10 suggest that pheromone induction results in only a 5-fold or less increase in transcription from Po (147, 171). Thus, the pheromone response must rely on regulatory mechanisms beyond simple derepression of transcription from Po. Multiple lines of evidence suggest that this added layer of regulation occurs at the t1 terminator (Fig. 3), which separates the Po promoter from the rest of the conjugation genes. First, pPD1 TraA has been shown to bind to both t1 and t2 either alone or when iPD1-bound but not when cPD1-bound (168). It is proposed that this facilitates termination in the uninduced state, but precisely how this occurs is not known. Second, transcription from the Pa promoter results in the production of an antisense regulatory RNA (aR in Fig. 3) that binds to the nascent Po transcript, stabilizing a conformation including an intrinsic terminator. mD and Qa antisense RNAs have been identified and described in pAD1 and pCF10, respectively (172, 173), and their sequences and location are highly conserved in other pheromone plasmids. Details of this countertranscript-driven attenuation mechanism have been described for the pCF10 system (174, 175). In pCF10, PrgX and Qa are transcribed from Pa, and PrgX is required both for positive autoregulation of Pa and proper processing of Qa (171). In both the pAD1 and pCF10 systems, pheromone induction results in a significant decrease in antisense RNA production (176–178). Based on these observations, it was proposed that, under noninducing conditions, the level of antisense RNA is precisely poised to ensure that all Po transcripts adopt a termination-competent structure. Even a moderate increase in transcription from Po tips the balance in favor of antitermination by three amplification mechanisms: (i) titration of the Pa transcript by the excess Po transcript, (ii) transcriptional interference favoring the Po transcript and further reducing Pa transcript levels (179), and (iii) RNase III-mediated degradation of the complex between the Po and Pa transcripts, which reduces translation of TraA/PrgX (180). These overlapping regulatory mechanisms allow the cell to precisely set the pheromone:inhibitor ratio high enough to prevent fruitless induction of the costly conjugation apparatus but low enough to allow efficient transfer of the plasmid DNA when sufficient numbers of recipients are present. Tight regulation at t1 is most likely required to prevent transcription of strong downstream positive regulators. In the case of pAD1, this regulator is TraE1, which positively autoregulates its own transcription and is essential for expression of the downstream structural genes required for conjugation (177, 181). The pCF10 plasmid lacks a TraE1 homolog but produces several RNAs in the region immediately downstream of t1 and t2 that positively regulate downstream structural genes (182–184). The mechanisms of action of these regulators are unknown but may involve both stimulation of transcriptional read-through and translation.

The inhibitor peptide is essential for modulating the plasmid-containing cell's response to exogenous pheromone, but it is not sufficient to prevent self-induction by endogenously produced pheromone. A second plasmid-encoded protein, TraB/PrgY, is required to specifically reduce secretion of the cognate pheromone (185–187). The pCF10-encoded PrgY protein has been studied in detail (158, 188). It consists of four transmembrane domains with the N-terminal two-thirds of the protein located on the outer surface of the cytoplasmic membrane. The cCF10 pheromone binding region has been mapped to an approximately 120-amino acid region in the extracytoplasmic domain adjacent to the first transmembrane segment. PrgY has been proposed to function by specifically binding to cognate pheromone as it emerges from the membrane, either following or concomitant with cleavage by Eep. The protein then either degrades the peptide directly or chaperones it to a cell wall bound protease for degradation (147). Recent data favor direct degradation (G. Dunny, personal communication). TraB/PrgY proteins appear to be part of an orthologous family of proteins found in all domains of life but only spottily distributed (188). For instance, there are representatives in humans, plants, and Gram-negative bacteria but not in any other *Firmicutes* species outside of the enterococci. This phylogenetic distribution suggests that horizontal gene transfer has been critical for their distribution. No function has been assigned for any of the TraB/PrgY orthologs, but homology suggests that they are involved in some form of peptide signaling or processing. Interestingly, pAM373 appears to control extracellular pheromone levels without a clear TraB/PrgY homolog (189).

Altogether then, pheromone plasmids encode three proteins, TraC/PrgZ, TraA/PrgX, and TraB/PrgY, that bind their cognate pheromone yet are divergent enough to be able to selectively respond only to the pheromone specific for their encoding plasmid. Structural analyses of these proteins suggest that the pheromone binding pockets did not diverge from a single ancestral domain but rather evolved independently and convergently (148). Assuming that all pheromone plasmids descended from a single ancestor, divergence to respond to new pheromone and inhibitor peptides requires coordinated evolution of the binding pockets of all three proteins. How these specificity switches occur is an intriguing evolutionary question.

The Conjugation Apparatus

Downstream of the positive regulatory elements of pAD1, transcription of a contiguous region of ~20 kb is inducible by pheromone (190). In most pheromone plasmids, the first two genes of this region encode a surface exclusion protein and AS (191). Both proteins encode signal sequences and LPXTG cell wall-anchoring motifs and have been demonstrated to be present on the surface of only pheromone-induced plasmid-bearing cells (192). The surface exclusion proteins limit conjugation between strains harboring the same pheromone plasmid (193, 194). AS is essential for the cellular aggregation response to pheromone and efficient mating in broth but is not required for plasmid transfer on solid surfaces, suggesting that it is not an integral part of the mating pore (195). AS is a cell wall-anchored protein and is highly conserved in all pheromone plasmids except pAM373. pAM373 does not encode an entry exclusion function (196) and encodes an AS that is half the size of other AS proteins and shows only localized homology (189). AS facilitates intercellular aggregation by binding to an enterococcal binding substance which is present on the surface of both donor and recipient cells. Lipoteichoic acid

Downloaded From Vet-eBooks.com

(LTA) appears to be at least one component of enterococcal binding substance, since free LTA inhibits aggregation (197) and cells containing mutations affecting LTA are poor recipients (198). Mutagenesis and *in vitro* binding analysis of the AS from pCF10 has identified two distinct aggregation domains, one of which binds tightly to LTA *in vitro* (199, 200). However, pCF10 AS also binds LTA from *E. hirae* which does not aggregate with AS-expressing *E. faecalis* cells, suggesting that LTA binding may not be sufficient for aggregation. AS has also been implicated as a virulence factor in several pathogenicity models (201–205) and is induced by plasma by means of the pheromone-sensing machinery (206). A recent study demonstrated that the pCF10 surface exclusion protein, AS, and the product of the *prg*C gene immediately downstream all play roles in conjugation, biofilm formation, and virulence (207). Another gene located between the AS gene and *prg*C, designated *prgU*, encodes a small protein with an RNA binding fold that mitigates the toxicity associated with overproduction of AS and other related adhesins in multiple Gram-positive bacteria (208). Its mechanism of action remains to be determined.

Comparison of the sequences downstream of the AS gene of five completely sequenced pheromone-responsive plasmids, pAD1 (209), pAM373 (189), pCF10 (210), pTEF1, and pTEF2 (6), show a high degree of conservation in the presumed structural genes required for conjugation. Comparison of these sequences to those of conjugative systems of both Gram-negative and Gram-positive bacteria suggests that they are orthologous to the family of protein and DNA secretion machineries collectively referred to as type 4 secretion systems, or T4SSs (211). Functional studies of the products of these genes from pheromone-responsive plasmids are limited, but work on pCF10 has identified PcfC as the coupling protein responsible for bringing the nicked DNA substrate to the secretion apparatus (212, 213), PrgJ as a VirB4-like ATPase in the T4SS apparatus (214), and PrgK as a peptidoglycan hydrolase required to generate localized lesions in the cell wall for assembly of the T4SS (215).

Within the conserved region encoding the T4SS is a short segment of localized reduced homology. In pAD1, this region has been shown to encode a functional origin of transfer (*oriT2*) located between a relaxase gene, *traX*, and *traW*, the pAD1 coupling protein homolog (209). A similarly located *oriT* was identified in pAM373, and the two *oriT*s were found to be mobilized only by their cognate plasmids. Plasmid-specific single-strand nicking by the putative relaxase was demonstrated within a large, conserved inverted repeat in *oriT*. Specificity was imparted by nonconserved direct repeats, presumed to be the relaxase binding site, adjacent to the conserved inverted repeat (216). The relaxase of these plasmids is unique in that it lacks the "three-histidine motif" common to most other plasmid relaxases (217) and instead relies on a catalytic domain related to the PD-(D/E)XK family of restriction endonucleases for nicking activity. Thus, the pAD1 TraX relaxase is the prototype for a distinct family of relaxases designated MOB_C (218). pAD1 also contains a second *oriT* located within the *rep*A initiator protein gene that is similar to IncP-type *oriT*s (209), but this *oriT* is utilized with 1,000-fold lower efficiency than *oriT2* and its biological relevance is unclear. The pCF10 relaxase, PcfG, is unrelated to pAD1 TraX and instead is closely related to the pheromone-independent *Lactococcus lactis* plasmid pRS01 relaxase (210, 219, 220). A comparative study of the pCF10 and pRS01 systems identified related accessory proteins important for assembly of the relaxosome. In spite of clear sequence homology between the pCF10 and pRS01 relaxases and their target *oriT*s, each system effectively mobilized only its cognate target (221).

Replication and Stable Inheritance

On the opposite side of the pheromone-response regulatory module from the conjugation structural genes are the genes required for replication and stable inheritance (189, 222–224). The genes of the basic replicon include a replication initiator protein RepA/PrgW, a partition system RepBC/PrgPO, and an antisense RNA-regulated type I toxin-antitoxin (TA-1) module designated *par* (Fig. 4). The *repA*/*prgW* genes belong to the RepA_N family of replication initiator proteins, which along with their associated partition modules, have been recently reviewed (143). RepA_N initiator proteins are not restricted to pheromone plasmids and are widespread among conjugative and nonconjugative plasmids in the *Firmicutes*. The genes encoding RepA_N initiators encode a centrally located series of repeats whose organization and sequence vary between plasmids and, in some cases, have been demonstrated to function as an origin of replication (*oriV*) (225–228). Work on pAD1 has shown that (i) *oriV* is sufficient to support plasmid replication if its RepA_N initiator, RepA, is supplied *in trans*, (ii) the *rep*A gene itself is sufficient to support plasmid replication if RepA is overexpressed from an artificial promoter, and (iii) RepA binds specifically to *ori*V in double-stranded DNA and nonspecifically to single-stranded DNA (225). The pCF10 initiator protein, PrgW, binds cCF10 pheromone, and provision of cCF10 in a host not normally permissive for plasmid replication, *L. lactis*, allows plasmid establishment (229). The role of cCF10 in plasmid replication and whether this observation can be extended to other pheromone-responsive plasmids has not been determined. The mechanisms of strand opening, initiation of replication, and regulation of initiation frequency have yet to be determined for the pheromone-responsive plasmids. However, work with the RepA_N proteins of staphylococcal plasmids pSK41 and pTZ2162 may be instructive (230). Both domains flanking the central repeat region of these proteins adopt a structural fold similar to the DnaD primosome. However, the N-terminal domain has evolved to bind the *oriV* repeats bending the DNA and presumably facilitating separation of the DNA strands. The C-terminal domain retains primosome function and recruits DnaG primase to initiate replication. Furthermore, the N-terminal domain was also demonstrated to be capable of bridging two plasmid origins, suggesting that it could function in replication control by handcuffing (231). It had been previously proposed that the pattern of conservation of RepA_N proteins, with a highly conserved N-terminal domain and genus-specific conservation of the C-terminal domain, suggested a universally conserved function (e.g., origin binding) for the former and a genus-specific function (e.g., interaction with host replication proteins) for the latter (143). These results support that prediction. A second method of copy number control involving an antisense RNA that regulates expression of the initiator protein is superimposed on handcuffing in the staphylococcal plasmids (232). No analogous antisense RNA has yet been detected, either physically or bioinformatically, on the pheromone plasmids.

The pheromone-responsive plasmid partition systems are variants of the previously described type Ib class (233). Type I systems encode a well-conserved Walker-type ATPase designated ParA, a poorly conserved DNA binding protein designated ParB, and a centromere-like site to which ParB binds. In type Ib systems, the ParA component lacks a

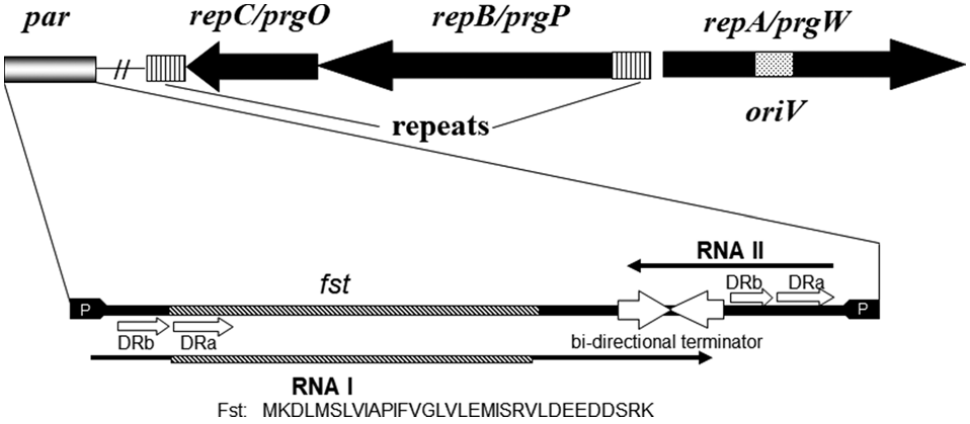

FIGURE 4 Genetic organization of a general pheromone-responsive plasmid replicon. Gene names are given as pAD1/pCF10. The stipled box within *repA/prgW* represents the origin of replication (*oriV*) to which the *repA/prgW* product binds. The lined boxes at each end of the *repB/prgP-repC/prgO* operon represent the likely centromere-like sites to which the *repC/prgO* products bind and, with the *repB/prgP* product, direct plasmid partition. The organization of the *par* region is blown up below the replicon. The arrowheads at each end of the locus marked P represent the promoters for the RNAI and RNAII transcripts. The extent and direction of transcription of the transcripts are shown above and below the genes for RNAII and RNAI, respectively. The *fst* gene is designated by the diagonally lined box, and the sequence of the peptide is shown at the bottom. DRa and DRb are direct repeats in the DNA sequence that provide complementarity between RNAI and RNAII when transcribed in opposite directions. Overlapping transcription at the bidirectional transcriptional terminator also provides complementarity.

DNA-binding domain, and the centromere-like site is located upstream of the *parA-parB* operon where binding of the ParB component can autoregulate transcription as well as direct partition. The RepB/PrgP and RepC/PrgO proteins correspond to type Ib ParA and ParB proteins, respectively. In all four pheromone-responsive plasmids examined, including pAD1, pCF10, pPD1, and pAM373, a series of repeats is present upstream of the *repB/prgP* gene (Fig. 4), with at least one repeat overlapping a putative promoter sequence, suggesting that protein binding to the repeats could suppress transcription. A series of similar repeats is also located downstream of the *repC/prgO* gene (143, 150). Each plasmid has repeats with a distinct DNA sequence and organization. For example, pAD1 contains 26 TAGTARRR (R = purine) repeats upstream of *repB* in two clusters of 13 and 12 tandem repeats with a single isolated repeat overlapping the promoter. Three more tandem repeats are located downstream of *repC*. pCF10 contains six tandem ATATATNNN (N = any nucleotide) repeats upstream of *prgP* with a single isolated repeat overlapping the promoter and two sets of four tandem repeats downstream of *prgO*. Work with the pAD1 RepBC system indicates that it functions similarly to other partition systems (234). Thus, *RepBC*, with the flanking repeats, is capable of stabilizing heterologous plasmids, the upstream repeats act as a strong incompatibility determinant, RepC binds specifically and with high affinity to the repeats, RepB binds the repeats only in the presence of RepC and ATP, and RepC downregulates its own expression. Plasmids bearing either the full complement of 25 upstream repeats or the half site containing 12 repeats but not the downstream 3 repeats can be stabilized by *repBC* supplied *in trans*. Spontaneous expansion of the pAD1 *repB* upstream repeats has also been associated with loss of regulation of the conjugative response and constitutive aggregation (235). The molecular basis of this phenomenon is unknown but may not be directly related to the normal function of the repeats. RepB proteins are broadly distributed in the *Firmicutes* but are not phylogenetically congruent with the associated replication initiator proteins, suggesting mosaicism of partition and replication modules (143).

TA modules are ubiquitous on bacterial plasmids and function as stability determinants by programming plasmid-free segregants for death (236). To accomplish this, TA modules encode a stable toxin and an unstable antitoxin; as long as the plasmid is retained, antitoxin is continuously replenished and the cell is protected, but if the plasmid is lost, the antitoxin is degraded and the toxin kills the cell. There are now five classes of TA modules (237), but only two are currently relevant to enterococci. In TA-1 the antitoxin is an unstable small regulatory RNA that binds to the toxin message and suppresses its translation. In TA-2 the antitoxin is an unstable protein that binds to the toxin protein and inhibits its activity. A general review of these systems is available (238), and enterococcal TA systems have been reviewed (137). Only one TA system has been characterized on pheromone-responsive plasmids, the TA-1 *par* locus (see 137, 239–241 for extensive reviews). *par* encodes two convergently transcribed RNAs, RNAI and RNAII, initiating from each end of *par* and terminating at a common bidirectional intrinsic terminator (242, 243) (Fig. 4). RNAI encodes the toxic component of the system, a 33-amino-acid peptide designated Fst. RNAII is a 65-nucleotide small regulatory RNA that is the *par* antitoxin. Although the RNAI and RNAII genes overlap only at the terminator, each reads in opposite directions across a pair of direct repeats (DRa and DRb in Fig. 4). Therefore, RNAII contains regions of complementarity with both the 3′ and 5′ ends of RNAI. Furthermore, the RNAI repeats are positioned such that interaction with RNAII sequesters the translation initiation region of *fst*, preventing ribosome binding and translation (244, 245). Formation of the RNAI-RNAII complex proceeds in at least two steps, with the interaction initiating at a

U-turn motif in the RNAI terminator loop which stimulates interaction with the complementary sequences in the RNAII terminator loop. Interaction then extends to the repeats at the 5′ end, suppressing translation (246) (Fig. 5). An intramolecular stem-loop within RNAI that partially sequesters the *fst* ribosome binding site is required to inhibit translation until RNAII binding can be completed (244, 247). A long distance interaction between sequences near the 3′ end of RNAI and its 5′ nucleotides is responsible for the stability of RNAI relative to RNAII (248). Unlike most antisense RNA systems, binding of RNAI by RNAII results in formation of a highly stable complex rather than specifically targeting the complex for degradation (248, 249). Formation of such a stable complex allows the toxin-encoding RNAI to persist in plasmid-containing cells. Over time, however, RNAII is slowly removed from the complex to allow translation of *fst*. The mechanism of this preferential degradation of RNAII from the complex is unknown.

The Fst toxin sequence is shown in Fig. 4. It consists of a central hydrophobic region flanked by charged N- and C-terminal tails. Overexpression of Fst has been shown to be toxic in *E. faecalis*, *S. aureus*, *B. subtilis*, and *E. coli* (247, 250–252). In all four species overexpression results in condensation and mislocalization of the nucleoid and interference with proper partition and cell division. Membrane permeabilization is only a secondary effect. Internal expression of Fst and external addition of the lantibiotic nisin synergistically effect cell killing, suggesting that the two peptides have different but complementary effects on the cell envelope (252). Saturation mutagenesis experiments revealed that the central hydrophobic region and charged residues in the N-terminus were important for overexpression-mediated toxicity but that the C-terminal charged tail was nonessential (251). An atomic resolution structure determined in a membrane mimetic by nuclear magnetic resonance spectroscopy revealed that the essential hydrophobic region forms an α-helix that spans the membrane with the charged N- and C-termini protruding (253). The charged C-terminal seven amino acids were disordered and predicted to extend from the cytoplasmic side of the membrane. The authors suggested that the primary function of membrane insertion was to facilitate interactions with a specific target, rather than being directed against the membrane itself. They also predicted that the disordered C-terminus might become structured upon recognition of the target. This would appear to contradict results indicating that the C-terminal amino acids are nonessential for toxicity, but it should be noted that the expression system used in reference 251 could not distinguish levels of toxicity. Therefore, it is possible that the toxicity is substantially decreased in the truncated mutants and could even be an artifact of overexpression. This possibility is under further investigation.

TA-1 type toxins in general are small proteins, less than 60 amino acids, that have hydrophobic regions typical of transmembrane domains (254). These toxins have been divided into eight superfamilies, and Fst is the founding member of the Fst/Ldr family (255). The Fst members of this family are widespread among the *Firmicutes* and appear to be

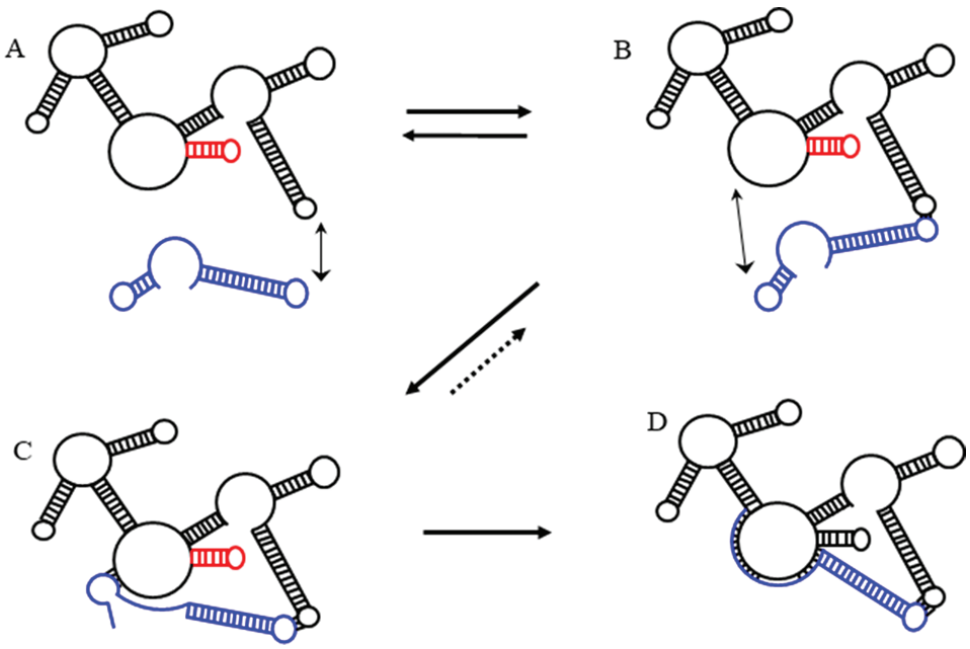

FIGURE 5 Model of RNAI-RNAII interaction. RNAI is the larger, black structure and RNAII is the smaller, blue structure. Stems, loops, and bulges are depicted in their approximate locations and sizes as determined by experimentation. The red stem-loop structure within RNAI sequesters the ribosome binding site and prevents translation until a complex is formed. The initial interaction occurs at a U-turn motif in the terminator loop of RNAI (A), followed by interaction between the complementary repeats in the 5′ end of each RNA (B and C). Since RNAII-mediated protection from the RNAI-encoded toxin occurs *in vivo* even when one of the repeats is mutated, the structure shown in panel C is apparently sufficient to prevent translation *in vivo*. Once complex formation is complete (D), the structure is extremely stable *in vivo* and *in vitro* perhaps due to the gap between the interacting repeats.

regulated and organized similarly to the pAD1 *par* determinant (251, 255, 256). The Ldr members are present in the γ-proteobacteria and are regulated in a manner more similar to *hok-sok* family members. In spite of their phylogenetic distance, Ldr overexpression has effects on nucleoid condensation and cell division similar to those Fst has in *E. coli* (247, 257). Like most other TA systems, the *par*-like Fst-encoding systems have both MGE and chromosomal members, and like other TA systems, the function of the chromosomal members is obscure. One of these chromosomal members, the toxin of which is annotated as EF0409, is conserved in *E. faecalis* genomes (251). For purposes of nomenclature, we have established a convention of using the locus or MGE name as a subscript for the relevant element. While the par_{EF0409} and par_{pAD1} systems show clear genetic similarity, the predicted RNAI-RNAII interaction sites are divergent, and it has been demonstrated that the antitoxins do not cross-protect (258). Par_{EF0409} is located between two paralogous mannitol-type phosphotransferase sugar transport systems, suggesting that it may be involved in regulating carbon flux. Transcriptomic analysis of cells overexpressing either Fst_{pAD1} or Fst_{EF0409} revealed that effects on the expression of a variety of transporters were predominant (258, 259), including effects on several genes for PTS components other than those to which par_{EF0409} is genetically linked. It was also observed that interference with the function of ABC transporters rescued cells from Fst_{pAD1} overexpression (259). Utilizing a novel expression vector, pCIE, that allows tight regulation and a large dynamic range of induction, the effects of low-level expression of Fst_{pAD1} and Fst_{EF0409} were compared. It was found that, while there was some overlap, overexpression of the two toxins had distinct transcriptomic effects (258). This suggests that the toxins have different targets or have distinct effects on the same target. Finally, overexpression of the Fst proteins is approximately 10-fold more toxic to mannitol-grown than to glucose-grown cells (K. Weaver, unpublished observation), strengthening the circumstantial link between *par* function and carbon flux. Somewhat surprisingly a mutant deleted for the par_{EF0409} antitoxin was isolated in *E. faecalis* strain EryS (98). The mutant strain showed increased virulence and improved survival in macrophages under several stress conditions. Proteomic analysis performed on this strain showed significant differences from the wild type, but these differences did not correlate with the transcriptome differences observed in strain OG1RF (258). These differences could be strain-related, due to differences between transcription and translation effects, or due to the accumulation of compensatory mutations in the deletion strain. Further investigation of the enterococcal *par* systems should elucidate the function of the chromosomal par_{EF0409} locus, determine the mechanism of action of the Fst toxins, and provide insight into the evolution of the *par*-like systems.

CONJUGATIVE TRANSPOSONS (ICES)

The enterococci carry the full range of transposon varieties found in other bacteria. Two Tn*3*-type transposons, Tn*917* encoding erythromycin resistance and Tn*1546* encoding vancomycin resistance, have been extensively studied (260, 261), and Tn*917* and its derivatives have been used for transposon mutagenesis in a number of Gram-positive organisms. The genome sequence of *E. faecalis* strain V583 revealed the presence of 38 insertion sequence elements, with IS*Ef1*, IS*256*, and IS*1216* being the most frequent (6). Both IS*256* and IS*1216* have been associated with simple composite transposons (123, 262) and large, complex, mosaic elements (263, 264). Many of these elements contain antibiotic resistance genes, and some are conjugative by means that have yet to be fully explained (see below). For a more detailed description of these elements see references 137 and 150.

The *E. faecalis* transposon Tn*916* was the first well-characterized self-conjugative transposon (2, 3) although large, conjugative chromosomal elements had been previously identified in other streptococci (265). Conjugative transposons were later found to be widespread in the lactic acid bacteria, and mechanistically similar but unrelated elements were identified in *Bacteroides* species (266). Characterization of new elements from both Gram-positive and Gram-negative organisms and the reinterpretation of data on older elements formerly classified as integrative plasmids have revealed that MGEs with characteristics similar to conjugative transposons (i.e., that excise from their chromosomal locus, circularize, transfer to a new host cell by conjugation, and insert in the recipient cell's chromosome without extensive replication) are probably as ubiquitous in bacteria as plasmids. Since the mobility of most of these elements is dependent on a tyrosine or serine recombinase rather than a DDE-type transposase and since many of them have relatively site-specific integration preferences, the appropriateness of the term "conjugative transposons" has been questioned and alternative names have been suggested, the most inclusive of which is ICE, for integrative and conjugative element (267). The full spectrum of ICEs has been described in detail in numerous reviews (268–271). This section will focus primarily on Tn*916* and related elements and other ICE-related issues specific to enterococci. A map of Tn*916* is shown in Fig. 6. For more detail on the Tn*916*-family of ICEs see references 272 and 273. For a comprehensive list of Tn*916*-like elements and other ICEs in enterococci see reference 137.

Unlike transposons using a DDE-type transposase, Tn*916*-like transposons are not flanked by direct repeats of target sequence. Preferred insertion sites tend to be AT-rich and possess intrinsic curvature, but the DNA sequence is not conserved and flanking sequences on each end are heterologous (274, 275). Unlike many other ICEs, Tn*916* has relatively little insertion site preference. Two transposon-encoded proteins, Int and Xis, are required for excision (276, 277). Int is a tyrosine recombinase (278) with N-terminal and C-terminal DNA binding domains (279). The N-terminal domain (Int-N) binds via a three-stranded β sheet to direct repeat sequences near each end of Tn*916* (280, 281). The C-terminal domain (Int-C) binds to the transposon termini as well as to target sequences. Int-C contains the conserved active site residues involved in nicking-closing. Like other tyrosine recombinases, Int produces staggered cuts at each end of the integrated transposon. One cut is made flush with the end of the transposon, producing a recessed 3′ end covalently jointed to Int via a phosphotyrosine linkage. The second cut is made 6 nucleotides into the host sequence, leaving a free 5′ OH that attacks the phosphotyrosine linkage at the other end of the transposon, resulting in circularization (282). Since the joint is derived from chromosomal DNA at each end that is not complementary, a 6-bp heteroduplex is formed in the circular intermediate, called the coupling sequence (283). The fact that Int must bind and cleave at the coupling sequences, which vary from insert to insert, may explain the wide range of conjugation frequencies (from $<10^{-9}$ to $>10^{-4}$ per donor cell) observed using different donor strains (284). How the coupling sequences affect conjugation frequency is not known, but it

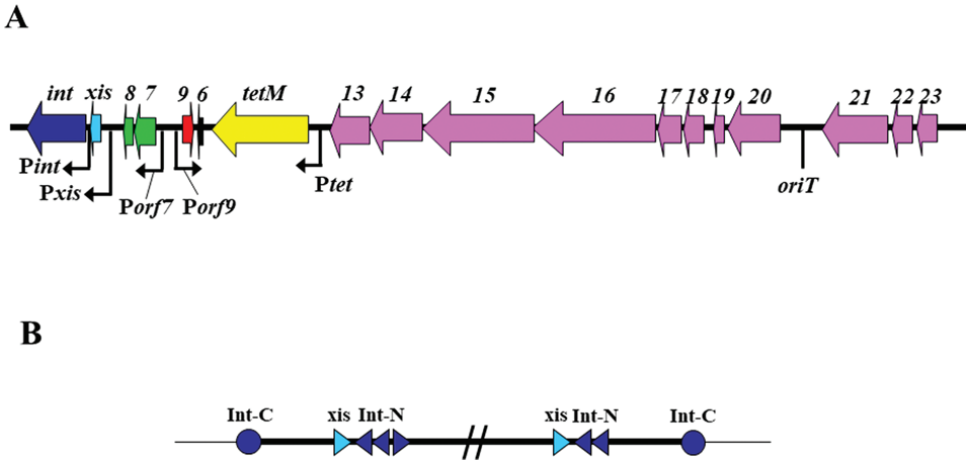

FIGURE 6 Genetic organization of Tn*916* and the relative positions of Int and Xis binding sites. (A) Functions of Tn*916* genes are color coded: blue, recombination; green and red, positive and negative regulation, respectively; yellow, tetracycline resistance; magenta, conjugation. Gene names and open reading frame numbers are shown above the individual genes. The origin of transfer is designated by the line between *orfs 20* and *21*, labelled *oriT*. Promoters and the direction of transcription are designated by labeled arrows below the gene line. (B) Binding sites for the Int-C and Int-N DNA binding domains and Xis are designated by marked circles and triangles. Int and Xis binding sites are color coordinated with the genes shown in panel A.

does not appear to be due to effects on integrase affinity (285) or on excision frequency (286).

Xis binds adjacent to the Int-N binding sites on both ends of the transposon (287) and stimulates Int-mediated excision of Tn*916* in *E. coli* (276, 288), *L. lactis* (289), *B. subtilis* (277), and *in vitro* (290). In *E. coli*, Xis binding to the left end is implicated in playing an architectural role similar to λ-Xis in excision of bacteriophage λ (291). HU protein plays a significant role in excision in *E. coli*, but no host factors affecting excision have been identified in Gram-positive hosts. Interestingly, Xis binding to the right end of Tn*916* inhibits excision, perhaps by competing with Int-N for binding, suggesting that Xis has dual roles in excision, both stimulating and inhibiting the process (292).

Once the circular intermediate is formed, the transposon is transferred to the recipient cell by conjugation. DNA strand transfer is initiated by nicking at *oriT* directed by the Orf20 relaxase and the Int protein (293, 294). While the Orf20 protein is responsible for strand nicking, Int functions as a specificity factor, conferring both strand and sequence specificity on its endonucleolytic activity (294). Although Tn*916* *oriT* bears similarities to IncP-type origins of transfer (293), Orf20 does not show similarity to any of the identified families of plasmid-encoded relaxase proteins (217). Instead, it appears to have similarity to the Rep_trans family of RCR initiator proteins and may represent a novel solution to the problem of conjugative nicking (217, 294). On the opposite side of the *oriT* from *orf20* is *orf21*, which encodes a product in the FtsK/SpoIIIE/coupling protein superfamily of DNA translocases. It is likely that Orf21 connects the *oriT*/Orf20 complex to the T4SS proteins encoded in *orfs14* to *16* (137). A combination of genetic analyses and DNA sequence determination have identified a number of genes involved in Tn*916* conjugation (295, 296), but the precise roles of none of these genes have been experimentally determined.

Tn*916* does not mobilize plasmids into which it has integrated, nor does it mobilize chromosomal genes adjacent to its integration site during intercellular transposition. This suggests that some mechanism suppresses utilization of the *oriT* site until after the transposon has excised from its host genome and circularized. Supporting this suggestion, induced expression of the transfer genes requires a functional *int* gene, and transcription is initiated from the *orf7* promoter, which since it is located at the opposite end of the transposon, is linked to the transfer genes only in the circular intermediate (297). Activation of the *orf7* promoter requires *orf7* and *orf8* and is repressed by *orf9*, but the mechanisms of regulation are unknown. Conjugation is also induced by the presence of tetracycline, which induces transcription of the *tetM* gene via ribosomal override of a transcriptional attenuator at its 5′ end (92). Transcription then proceeds through *tetM*, increasing transcription of the positive regulators *orf7* and *orf8* and blocking the *orf9* regulator presumably by antisense RNA interactions and/or transcriptional interference. This in turn increases transcription through *int* and *xis*, stimulating excision and circularization, leading to read through into the structural conjugation genes (272). Recent evidence suggests that subinhibitory concentrations of other ribosome-targeting antibiotics also stimulate Tn*916* conjugation and may contribute to its spread (298).

Once a copy of the transposon is transferred, integration into the recipient chromosome requires Int but not Xis (277). Since the known tyrosine recombinases function only on double-stranded DNA, replacement synthesis of the transferred strand presumably takes place prior to integration. Experiments with *int-* versions of Tn*916* where Int was provided *in trans* from a plasmid in the donor revealed that *int* gene expression was not required in the recipient for integration, suggesting that the Int protein might be transported with the transposon DNA (299). Recipients frequently acquire multiple copies of the transposon, and there is no evidence that Tn*916* expresses either an entry exclusion function or transposon immunity (145, 300). Interestingly, in cells harboring more than one copy of the

transposon, excision of one element transactivates excision and mobility of other elements located elsewhere in the genome (301).

Sequence analysis of known and putative ICEs in sequenced genomes suggests that these mobile elements are modular and that the modules may have different evolutionary histories (267, 302, 303). For example, Tn*5397* from *Clostridium difficile* is greater than 84% identical at the DNA sequence level to Tn*916* across all of the conjugation-related genes and the *tetM* gene, but Tn*916* Int is a tyrosine recombinase, while the recombinase protein of Tn*5397* is a serine recombinase. Conversely, the recombination module of the VanB transposon Tn*1549* is closely related to the Tn*916 int/xis* genes, but most of the conjugation genes are unrelated (128). Putative ICEs identified in the *E. faecalis* V583 genome sequence, EfaC2 and EfaD2, include conjugation-related genes apparently acquired from pAD1 and pAM373 (267). A more global analysis including plasmids, bacteriophages, and genomic islands as well as ICEs indicates that the degree of exchange between these elements is very high, suggesting that, rather than representing distinct groups, they represent a continuum of structures that maximize mobility under various circumstances (304).

OTHER FEATURES OF THE ENTEROCOCCAL MOBILOME

The above discussion focused on MGEs that are unique to the enterococci and/or were originally described in the enterococci, but the enterococcal "mobilome" is extraordinarily diverse and includes plasmids, insertion sequences, and transposons in a variety of families, group II introns, integrons, pathogenicity islands (PAIs), and bacteriophages. A recent review provides tabular lists of many of these elements (137). For a comprehensive overview of MGEs associated with the mobilome of clinically important *E. faecium* and *E. faecalis* lineages, the reader is referred to a recent report (305). Enterococcal phages have also been recently reviewed (306). Addressed below are some issues of particular interest related to the enterococcal mobilome.

Important Non-Pheromone-Responding Plasmids

pAMα1 is an ~10-kb multicopy tetracycline resistance plasmid that is a composite of two replicons (307, 308), an RCR replicon similar to *Bacillus cereus* plasmid pBC16 that carries the tetracycline resistance gene but does not function in *E. faecalis* and a putative theta-replicon similar to pS86 that supports replication in *E. faecalis*. Each component plasmid encodes a relaxase gene, and the junction sites contain *oriT* sequences recognized by them. The *oriT*/relaxase complex allows mobilization of the plasmid in the presence of another conjugative plasmid. The presence of the *oriT* sites at the plasmid junctions suggests that the fusion giving rise to pAMα1 occurred via a site-specific recombination event catalyzed by the relaxases as was previously observed in other plasmids (309, 310). Under tetracycline selection, cells accumulate pAMα1 derivatives containing tandem repeats of the pBC16 replicon, amplifying the tetracycline resistance gene. Amplification is initiated by a RecA-independent recombination event requiring at least one of the relaxase genes and both *oriT* sequences (311) followed by more extensive RecA-dependent amplification between redundant sequences in the duplicated region (312). Thus, the relaxases of pBC16 and pS86 perform three functions: (i) stimulate cointegration to form pAMα1, (ii) facilitate mobilization of the cointegrate, and (iii) trigger amplification of the tetracycline resistance gene in the presence of the antibiotic.

pMG1 is an ~65-kb conjugative plasmid originally isolated from *E. faecium* and encoding high-level gentamicin resistance (313). pMG1-like plasmids bearing Tn*1546* encoding the *van*A determinant have been associated with the spread of vancomycin resistance in enterococci (124, 314). Like the pheromone-responsive plasmids, pMG1 is capable of high-frequency transfer in broth. Unlike pheromone plasmids, pMG1 transfer is not induced by exposure to culture filtrates from potential recipient cells, conjugating broth cultures do not form macroscopic cellular aggregates, and transfer occurs freely between *E. faecium* and *E. faecalis* cells. Furthermore, no homology between pMG1 and the conjugative systems of pheromone-responsive plasmids or Inc18 plasmids was observed (313). Rather, sequencing results indicated significant homology of suspected conjugation genes to those from pXO2, the capsule-encoding plasmid of *Bacillus anthracis* (315, 316). Microscopic aggregates were observed during mating, and this phenomenon is related to a region of the plasmid encoding five open reading frames. One open reading frame encodes a large protein with similarity to a pXO2-encoded surface protein that could represent an "aggregation substance" unrelated to the pheromone plasmid AS (316). Genes potentially encoding the coupling protein, a VirB11-family protein, a relaxase, and the *oriT* were also identified. A gene designated *traA* appears to encode a key positive regulatory protein (317).

TA Systems

In addition to par_{pAD1} and par_{EF0409}, several other TA systems have been identified on enterococcal plasmids and chromosomes. *Par* homologs are present on several other enterococcal plasmids, although no chromosomal loci analogous to par_{EF0409} have been described outside of *E. faecalis* (215, 256). The *E. faecium* multiresistance plasmid pRUM (318) and the related vancomycin resistance plasmid pS177 (319) encode a TA-II locus designated Axe-Txe. Axe-Txe stabilizes heterologous plasmids in *Bacillus thuringiensis*, *E. coli*, and its native host. The Txe toxin belongs to the RelE superfamily of RNA interferases and was shown to cleave mRNA one base downstream of the AUG initiation codon (319, 320). Interestingly, Axe is more closely related to Doc, the antitoxin for the Phd toxin, than it is to RelB, the antitoxin most commonly associated with RelE toxins, supporting the hypothesis that TA-II systems have undergone extensive recombinatorial mixing and matching during their evolution (321). The ωεζ TA-II system is commonly present on the broad-host-range Inc18 plasmids (139), many representatives of which are present in enterococci (322), including the VanA-encoding *E. faecium* plasmid pVEF3 (323), pAMβ1 (308), and the pheromone plasmid pSL1 (324). Unlike most TA-II systems, the ε antitoxin does not autoregulate the locus. Instead, it is regulated by an independent regulatory component, ω, which also regulates the plasmid active partition locus and the copy control factor CopS (325). ζ-family toxins have been proposed to cause cell growth arrest by depleting ATP and GTP pools in the cell and may be associated with persistence to antibiotics (326). The ubiquitous *higBA* and *mazEF* chromosomally encoded TA-II systems are prevalent in *E. faecium* and *E. faecalis* clinical isolates, and *mazEF* has been suggested as a target for novel antibacterials (327).

In *E. faecalis* V583 a *mazEF* TA-II homolog is closely linked to a TA-I locus distantly related to *B. subtilis txpA-ratA* (328). Upstream of the *mazEF* locus is a direct repeat motif

that binds MazE and MazEF, suggesting that the locus is negatively autoregulated as is observed in other TA-II modules (329). It was also observed that ectopic expression of MazE or MazEF stimulated transcription of the *ratA* antitoxin RNA for the *txp-ratA* locus, and a sequence with similarity to the direct repeat motif was found upstream of the *ratA* gene. Thus, the MazE toxin suppresses the toxicity of both *mazEF*, by reducing overall transcription, and the *txpA-ratA* locus, by increasing synthesis of the *ratA* antitoxin, which then targets the *txpA* mRNA for degradation. Conversely, one would expect triggered degradation of MazE, by an as yet unknown mechanism, to activate toxicity of both systems. Thus far, this is the only example of coordinated regulation of TA-I and TA-II loci, and the complete system has been dubbed a TAI-II locus.

PAIs and Intercellular Transfer by Hfr Formation

PAIs are chromosomal regions containing large clusters of genes associated with bacterial virulence (330). Frequently, PAIs include genes associated with known MGEs, such as phage- and ICE-related integration/excision modules and plasmid-related conjugation genes, and some have been shown to be either independently mobile (331) or mobilizable by other MGEs (332). The first enterococcal PAI was identified in *E. faecalis* strain MMH594, and related islands were described in strains V586 and V583 (333). This PAI is ~150 kb long, encodes several pathogenicity factors, including the enterococcal surface protein (*esp*), cytolysin, AS, a bile acid hydrolase, various surface proteins, and general stress proteins, and contains numerous transposons. The PAI also contains phage-related integration/excision proteins, homologs of plasmid conjugation functions, and is flanked by 10-bp terminal direct repeats, suggesting that it could be independently mobile. Genomic analysis of clinical *E. faecalis* isolates revealed that PAI genetic composition is highly variable, suggesting the involvement of modular accretion during its evolution and dissemination (334, 335). Intercellular transfer of either portions of the PAI (336, 337) or the complete PAI (130, 338) has been demonstrated between *E. faecalis* strains and between *E. faecalis* and *E. faecium*. Complete transfer from V583 was shown *in vitro* to be independent of PAI-encoded mobility genes and to frequently include chromosomal genes outside of the element. This *in vitro* transfer was dependent on the conjugation functions of pTEF1 and pTEF2, two pheromone-responsive conjugative elements present in the same strain, suggesting that the plasmids mobilized the PAI via chromosomal integration, perhaps at IS*256* elements, followed by mobilization either by an Hfr- or F′-like mechanism (130). In contrast, precise excision, circularization, and recipient insertion of the PAI was observed in *E. faecalis* strain UW3114, suggesting that the PAI is capable of independent mobility (338), perhaps at a rate substantially lower than that mediated by mobilization. Interestingly, the PAI circular intermediate was not detected in V583, suggesting that an important component for self-mobilization may be absent in that strain or not expressed under the conditions tested. However, even in UW3114, a coresident pheromone-responsive plasmid, pLG2, was transferred in parallel with the PAI and may have facilitated its transfer, and the authors did not determine whether or which PAI genes might be required for mobility. So whether the *E. faecalis* PAI is fully self-mobile is still an open question, although genes associated with excision, integration, and transfer appear to be intact.

Similar *esp*-associated PAIs have also been identified in *E. faecium* that may be subject to conjugative transfer (337, 339, 340). Plasmid-mediated transfer of chromosomal determinants, including determinants involved in β-lactam and vancomycin resistance, has been demonstrated in *E. faecium* strain C68. Transfer in this case was mediated by pLRM23 and a second plasmid and appeared to proceed via cointegration of the plasmid with the donor chromosome, excision of the plasmid with neighboring chromosomal DNA, circularization in the donor prior to transfer, integration of the chromosomal segment into the recipient chromosome by homologous recombination, and subsequent loss of the unstable plasmid remnant (129). Whether this mechanism can also facilitate PAI transfer has not been determined.

Enterococcal Bacteriophage and Genome Defense Systems

Bacteriophages provide a sizable fraction of the mobilome of both *E. faecalis* and *E. faecium*, amounting to close to 10% of the genome of *E. faecalis* strain V583 (6) and 3 to 5% of seven sequenced *E. faecium* strains (340). V583 contains seven putative prophages, five of which have sufficient gene content to generate functional virions. The phage02 region was subsequently determined to be part of the core genome of *E. faecalis* and is likely no longer capable of mobilization (335). The phage07 region is capable of producing infectious virions but requires phage01 as a helper phage to provide packaging and structural elements (341, 242). Sequencing of multiple *E. faecalis* genomes has confirmed the variable presence of these prophage elements except for phage02 (335, 343, 344), and the OG1RF genome contains only phage02 (345).

Comparative genomic analysis of *E. faecalis* phages suggests that they have a modular structure much like bacteriophages infecting other bacteria (306). The modules consist of three transcriptional units, one encoding the lysogeny control functions, one encoding genes required for the lytic pathway, and a variable "cargo" region encoding potential lysogenic conversion genes, some of which could encode important virulence factors. Such cargo genes include a set of putative membrane proteins in the φEF11 phage (346) and a ferrochelatase gene and cold shock protein gene in phage04 (6). However, no systematic analyses have been performed to unequivocally link phage determinants to enterococcal pathogenicity (306). Laboratory studies have demonstrated a capacity for transduction by enterococcal phages, including interspecies transfer of antibiotic resistance, so the potential for phage effects on virulence does exist (347, 348).

CRISPR-Cas function as adaptive immune systems for bacteria, generally targeting the DNA of invading MGEs for degradation (see 349 for a recent review). Three distinct type II-A CRISPR loci have been identified in *E. faecalis*: CRISPR1 and 3 are complete functional loci with associated Cas genes, while the CRISPR2 locus is an "orphan" locus harboring repeats and spacers of the same family as CRISPR1 but lacking Cas genes (8, 345). CRISPR1-Cas and CRISPR3-Cas are variably present in *E. faecalis* genomes and never cooccur in the same strain, while CRISPR2 is ubiquitous and can thus be considered part of the core genome of this species. CRISPR1-Cas-related systems have also been detected in several environmental and nonclinical enterococcal species (350). Spacer sequences from all three CRISPR loci show identities to phage and plasmid sequences, suggesting that all have acquired MGE segments for genome defense (8). However, CRISPR2 only functions when the Cas genes of CRISPR1 are provided *in trans* (351), suggesting that strains containing only CRISPR2 should be more sensitive to MGE invasion. Indeed, the absence of complete CRISPR-Cas loci

is associated with larger genomes, higher percentages of horizontally acquired genes, greater antibiotic resistance, the presence of certain virulence factors, and high-risk multilocus sequence type (7, 8). Therefore, *E. faecalis* CRISPR-Cas loci, in cooperation with restriction-modification systems (351), are effective in limiting invasion by MGEs, but loss of CRISPR-Cas facilitates the evolution of pathogenicity by allowing greater horizontal gene transfer. Recently, a method for activating CRISPR2 and using it to modify the *E. faecalis* population structure was proposed (352).

A type II-A CRISPR-Cas locus has also been identified in *E. faecium*, related to the *E. faecalis* CRISPR1-Cas locus (8). Like in *E. faecalis*, the locus is not present in all *E. faecium* strains and is absent in most multiple antibiotic-resistant strains and in the major hospital-adapted clade of this species (353).

CONCLUDING REMARKS

From the beginning, enterococcal genetics has been focused on MGEs. Pioneering studies of the enterococci gave us one of the first examples of intercellular communication in the bacterial world in the pheromone-inducible conjugative plasmids and the first chromosomally located conjugative elements in the conjugative transposons, later to be named ICEs after their distribution was found to be ubiquitous in bacterial cells. Studies of the complex regulatory circuits controlling the pheromone response and the conjugative mechanisms of ICEs continue to inform those interested in the molecular mechanisms of gene regulation in prokaryotes in general. The importance of MGEs in enterococci became even more apparent with the emergence of vancomycin resistance and the multitude of ways the *van* gene clusters could be shared among enterococci and with other genera. Further studies identified the enterococci as a promiscuous hub for the dissemination of a wide variety of antibiotic resistance genes. The accumulation of genomic information on the enterococci has further revealed just how important MGEs are to enterococcal pathogenesis and evolution, particularly in the way that the CRISPR MGE defense system impacts the structure of *E. faecalis* and *E. faecium* populations.

Complicated regulatory schemes and important antibiotic resistance phenotypes are not limited to enterococcal MGEs, and progress is now being made on important systems in the core genomes, particularly those of of *E. faecalis* and *E. faecium*. Work is proceeding on the intrinsic mechanisms of antibiotic resistance in these organisms, and the complex transcriptional and posttranscriptional mechanisms of regulation of the EA regulon presage more interesting regulatory phenomena to be discovered. While roles for enterococcal TCSTSs are being defined, genomic analyses have revealed a plethora of potential sRNA regulators about which we know very little. To this point, most detailed genetic analyses have been performed *in vitro* or have focused on the effects of the various systems during pathogenic processes, but the enterococci are common intestinal bacteria, and it is likely that events occurring within the gut in the presence of the microbiota are more relevant to normal enterococcal physiology. Here again, studies with MGEs are likely to lead the way. Clearly, much remains to be discovered about the genetics of these interesting and clinically important Gram-positive bacteria.

THE ORAL ENVIRONMENT

Warm, moist, and rich in nutrients, the oral cavity provides an ideal environment for colonization by a community of bacteria, fungi, protozoa, archaea, and viruses, often in the form of a complex structure called biofilm or plaque (1). In addition, several microbial niches exist within the oral cavity (e.g., cheek, gingiva, teeth, tongue, palate) that vary in nutrient content, pH, oxygen tension, and shear force due to salivary flow and mastication. These physico-chemical characteristics select for suitable microorganisms for each oral niche such that the microbial compositions can differ greatly from one site to another. Saliva is the biological fluid of the oral cavity, and its microbial composition is a collection of bacteria that have shed from various oral niches. As an easily accessible body fluid, saliva can be used in assessment of general oral health, as the disappearance or emergence of certain taxa can indicate health or disease (2, 3). While biofilms from oral soft tissues, such as the tongue, cheeks, and palate, and the supragingival biofilm (plaque on tooth surfaces above the gum line) are constantly bathed in saliva and subjected to an array of environmental fluctuations, the subgingival plaque (plaque on tooth surfaces below the gum line) is a unique niche with less abrupt environmental fluctuations. In particular, with the gum serving as a physical barrier, the oxygen tension and shear forces are reduced, and gingival crevicular fluid (serum) serves as a major nutrient source (4).

TAXONOMY OF ORAL STREPTOCOCCI

Streptococci are found in almost every location in the human body and are the dominant species in the human oral cavity and upper respiratory tract. Species within the genus *Streptococcus* were initially differentiated based on hemolysis patterns on blood agar plates with β-hemolysis (complete lysis), α-hemolysis (partial lysis), and γ-hemolysis (nonhemolytic) (5). Many β-hemolytic species can be further differentiated by carbohydrate group antigens (Lancefield groups) (6), such as the classic human pathogens *S. pyogenes* (group A *Streptococcus*) and *S. agalactiae* (group B *Streptococcus*), which are the subjects of other articles. Historically, the oral streptococci were referred to as viridans streptococci (*Streptococcus viridans*) due to their high propensity to display partial hemolysis when cultured on blood agar plates, resulting in a green coloration surrounding the colonies. While the viridans streptococci or α-hemolytic designations are still used today to classify the oral streptococci, this term is not fully accurate, because some isolates can display β-hemolysis or completely lack any hemolytic activity (γ-hemolysis). As more streptococcal species were identified, it became apparent that additional criteria were required to separate the growing number of species, prompting the development of biochemical and physiologic tests to differentiate streptococcal groups (7, 8). Initially, there were seven named groups of streptococci based on carbohydrate fermentation tests, chain length, and growth on gelatin: *Streptococcus salivarius*, *Streptococcus mitis*, *Streptococcus anginosus*, *Streptococcus equinus*, *Streptococcus pyogenes*, *Streptococcus faecalis*, and *Streptococcus pneumoniae* (pneumococcus) (reviewed in reference 5). Eventually, *Streptococcus faecalis* was reclassified, and it is now a member of the genus *Enterococcus* (9, 10).

The advent of DNA sequencing introduced a new and more accurate approach to the identification of bacteria at the species level, and sequencing of the 16S rRNA region could be used to determine phylogenetic relationships (11). Initially, the oral streptococci were separated into four groups: anginosus, mitis, mutans, and salivarius, while the remaining streptococci isolated outside of the oral cavity were classified into either the bovis or pyogenic groups (12). Recently, using a more robust phylogenetic approach, Richards et al. separated the streptococci into eight distinct groups: mitis, sanguinis, anginosus, salivarius, downei, mutans, pyogenic, and bovis (Fig. 1) (13). Presently, oral streptococci are found in all groups except the pyogenic and bovis groups. The mitis group is the largest of the groups found in the oral cavity, currently with 20 species. Species within the mitis group have been challenging to differentiate based on 16S RNA sequence alone, particularly *Streptococcus oralis* and *S. mitis*. Recent efforts to reclassify many of the species within this group indicate that there are many strains that have been misclassified, and new species descriptions may soon emerge (14).

doi:10.1128/microbiolspec.GPP3-0042-2018

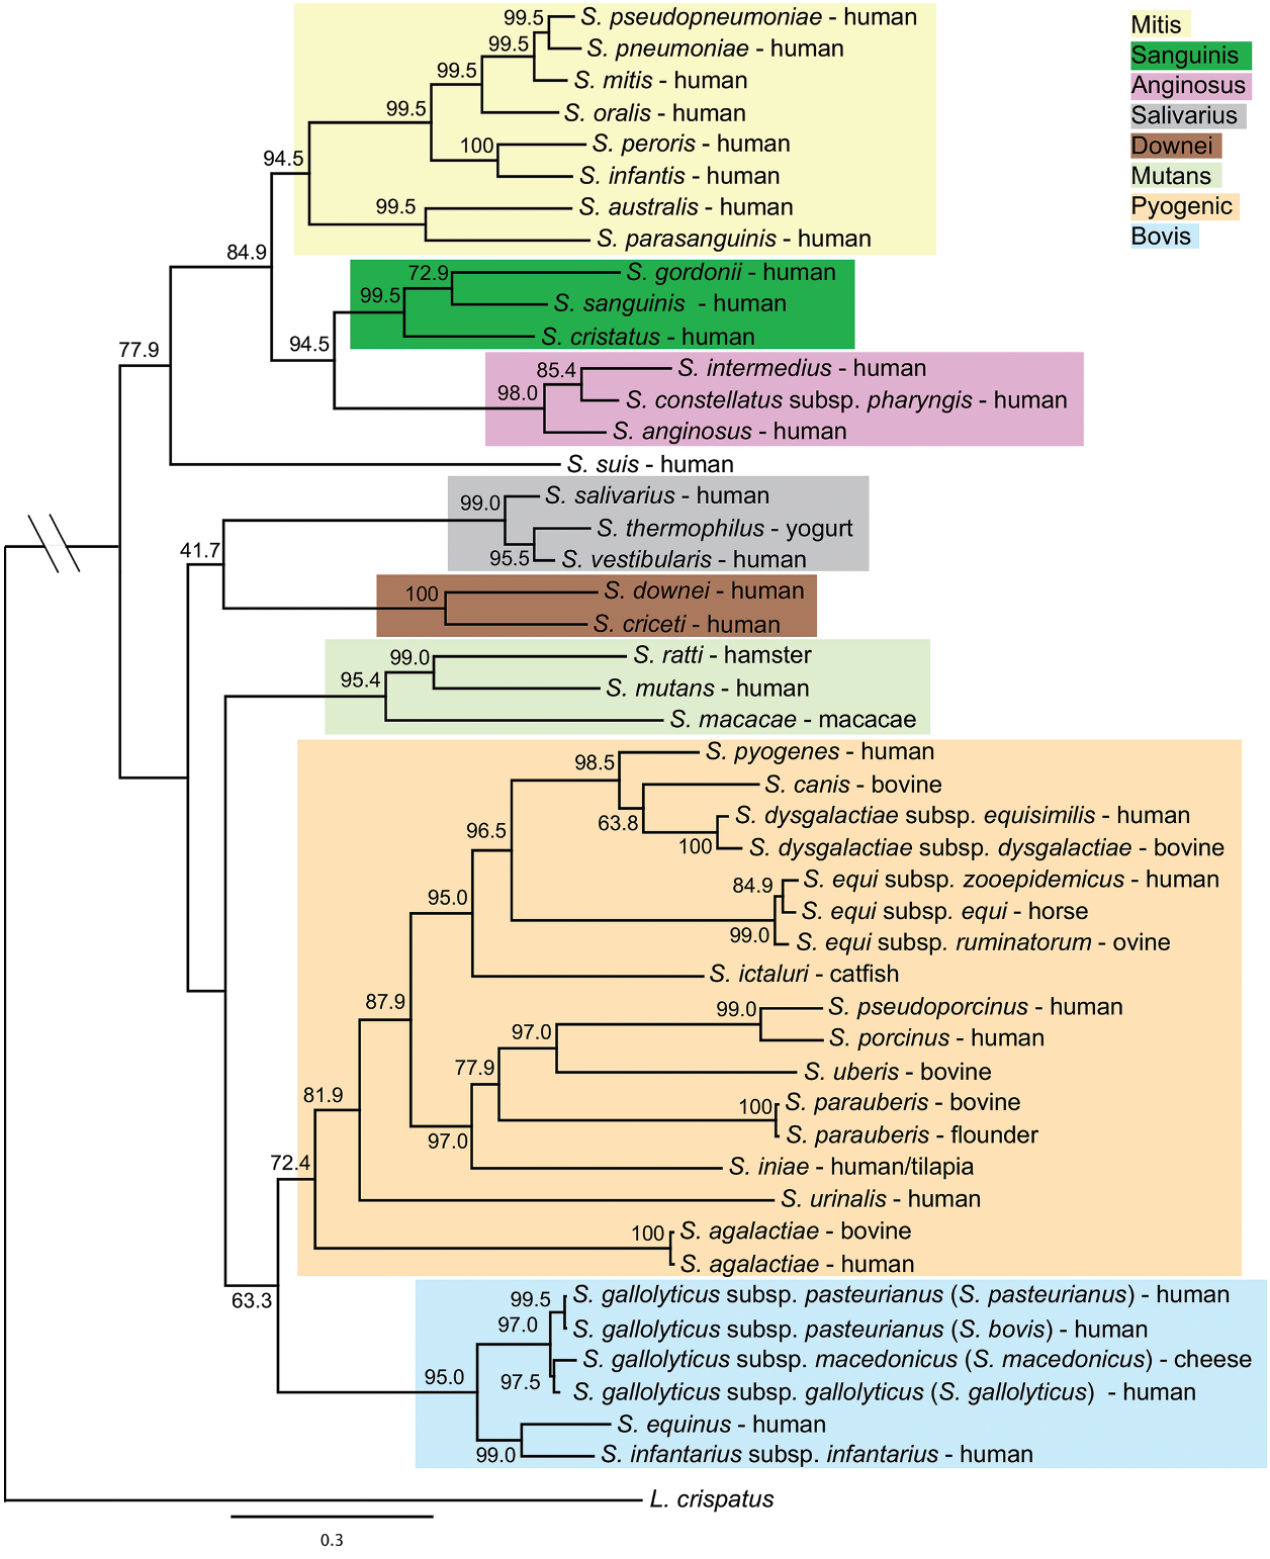

FIGURE 1 Phylogeny of the indicated streptococcal species derived from a core set of 136 concatenated genes. Numbers on branches show bootstrap support for each relationship. The color shading indicates the eight major groups.

MICROBIOME AND METAGENOMICS STUDIES: THE ORAL MICROBIOME

While initial attempts to define the oral microbiome relied on culture-based techniques, 16S rRNA sequencing has identified more than 700 microbial species residing within the oral cavity. It is estimated that roughly half of these species are nonculturable by current methods. The Human Microbiome Project (http://commonfund.nih.gov/hmp/), launched in 2012, aimed to define the core microbiome of 18 locations in the human body, including the oral cavity, and provided the first comprehensive analysis of bacterial diversity and abundance in humans (15, 16). Nearly all microbiome studies today use next-generation sequencing technologies based on 16S rRNA sequences to determine the community composition (17), and large manually curated databases, such as www.homd.org, are now available to aid in the identification of bacterial species unique to the oral cavity. Based on these studies, we now can clearly appreciate that there are distinct communities of organisms living on the different surfaces of the mouth, which vary significantly depending on the site of sample collection, health status, and behavior of the host (18–20). Thus, as indicated in the beginning of the article, slight variations in the local environment within the mouth can have profound effects on the composition of the resident organisms (18, 19). However, regardless of the individual sampled, streptococci are universally present in all sites of the oral cavity and are the dominant genus found in saliva and on soft tissues of the mouth (16, 18, 19). Critically, streptococci, especially members of the mitis group, are the first organisms detected in the mouth of newborn infants and are considered pioneer species (primary colonizer) that allow for the assembly of a complex microbiota.

Dental plaque is readily accessible on the surface of the teeth and therefore is one of the most well-characterized microbial communities in the human body (21, 22). Two of the most common human diseases, dental caries and periodontitis, are directly related to the presence and metabolic activities of dental plaque bacteria. A recent analysis that compared supragingival plaque microbiomes from carious lesions to healthy sites found substantial differences among children with different caries status (23). In particular, communities collected from dentin carious lesions contained notorious acidogenic (acid-producing) and aciduric (acid-tolerant) species, including *S. mutans*, *Scardovia wiggsiae*, *Parascardovia denticolens*, and *Lactobacillus salivarius* (23). In contrast, *Streptococcus sanguinis*, *Neisseria* species, and *Leptotrichia* species were found associated with samples collected from healthy sites. However, a decrease in species diversity was associated with dental caries progression, but an increased overall abundance of *S. mutans* has been demonstrated (24). Moreover, an association of *S. mutans* with other acidogenic species, such as *S. wiggsiae* and bifidobacteria, in severe early childhood caries has been shown (25). One study that focused on the microbiota that thrive at different pH ranges also found a decrease in microbial diversity in communities from acidic pH environments but found *Lactobacillus* spp., *Prevotella* spp., *Atopobium* spp., *Olsenella* spp., and *Actinomyces* spp. to be the most abundant taxa in dentinal caries (26). Microbiome studies of subgingival plaque identified high abundance of *Streptococcus parasanguinis*, *S. sanguinis*, *S. mitis*, *Streptococcus intermedius and Streptococcus infantis* associated with health (27–31). In diseased sites (gingivitis and periodontitis), a decrease in the proportions of health-associated *Streptococcus* (32) and an increase in anaerobic proteolytic bacteria such as *Porphyromonas gingivalis* is observed. However, *Streptococcus constellatus* and *S. intermedius* are often reported to be associated with periodontitis (33, 34).

Most microbiome studies are initially conducted with the intent of correlating the presence of disease with a particular signature microbiome. However, confounding factors such as genetic heterogeneity and phenotypic diversity within a species contribute to a more complex relationship between the presence of a particular bacterial species and the establishment of disease. Studies comparing the phenotypic diversity within streptococcal strains from the same species have identified major phenotypic variations among isolates that are directly related to virulence or properties associated with healthy biofilms (35, 36). For this reason, the combination of 16S rRNA community profiling with other "-omics" technologies (i.e., transcriptomics, proteomics, and metabolomics) is essential for a global understanding of the specific contributions of oral bacteria to health and disease (17), providing a better understanding of how complex communities function and interact (37).

SUGAR METABOLISM OF ORAL STREPTOCOCCI

Streptococci are well known for their ability to assimilate a large array of carbohydrates by glycolysis and for their enhanced tolerance to acidic pH. Employing the Embden-Meyerhof-Parnas pathway, streptococci convert one molecule of glucose or other equivalent carbohydrates (e.g., fructose) into two molecules of pyruvate, with the concomitant generation of two molecules of ATP and two molecules of NADH. Under the conditions of excess carbohydrates and oxygen limitation, streptococci tend to perform homolactic fermentation, reducing pyruvate into lactic acid and regenerating NAD from NADH. The production of lactic acid results in rapid acidification of the environment and allows streptococcal species to outcompete acid-sensitive microorganisms. When faced with carbohydrate limitation or increased oxygen tension, streptococci produce alternative fermentation products such as formate, acetate, and ethanol (38) (Fig. 2). In fact, streptococci lack the capacity for oxidative phosphorylation and electron chain transport systems and depend exclusively on substrate-level phosphorylation for energy production. Therefore, most streptococci are considered facultative anaerobes and susceptible to growth inhibition by oxygen.

Resulting from a reductive evolution as a consequence of adaptation to survival within human and animal hosts,

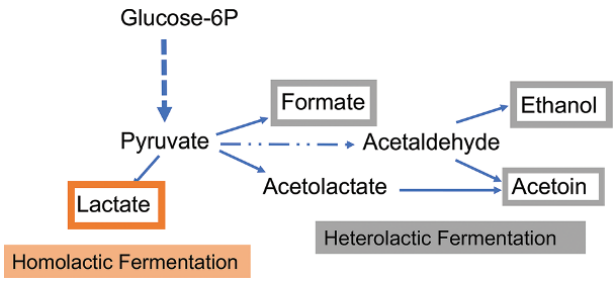

FIGURE 2 Simplified schematic of homolactic fermentation and heterolactic fermentation. While homolactic fermentation generates almost exclusively lactate, heterolactic fermentation generates formate, acetoin, ethanol, and reduced amounts of lactate.

streptococci possess an incomplete tricarboxylic acid cycle, or Krebs cycle, with some enzymes of the pathway being preserved in certain species, such as *S. mutans* and *S. gordonii*, and none present in species such as *S. pyogenes* or *S. pneumoniae*. Because metabolites of the tricarboxylic acid cycle are often precursors required for amino acid biosynthesis, it follows that varying degrees of amino acid auxotrophy exist for different streptococcal species. Another outcome of this reductive evolution is the fact that streptococci did not maintain a functional Entner-Doudoroff pathway, an alternative pathway that utilizes glucose-6-phosphate (glucose-6-P) to generate pyruvate through a series of enzymatic reactions that are distinct from glycolysis. Also, many species lack a complete pentose phosphate pathway (38), which represents a parallel process to glycolysis as glucose-6-P is oxidized and then decarboxylated into a five-carbon product, ribulose-5-phosphate (ribulose-5-P), yielding the important reducing equivalent, NADPH. Further metabolism of ribulose-5-P by the nonoxidative phase creates precursors for biosynthesis of nucleic acids, histidine, and aromatic amino acids. In bacteria lacking the oxidative phase of the pentose phosphate pathway (e.g., *S. mutans*), alternative reactions and enzymes (e.g., $NADP^+$-dependent glyceraldehyde-3-phosphate dehydrogenase or GapN) exist to compensate for the generation of both nucleotides and NADPH (39).

In contrast to these reductive evolutions, streptococci have maintained a significant arsenal of carbohydrate-uptake mechanisms, proteins, and enzymes of the sugar: phosphotransferase system (PTS) (40, 41) and the ATP-binding cassette transporter family (42). The PTS consists of two general enzymes, enzyme I and a phospho-carrier protein, HPr, and a series of multidomain, membrane-associated, substrate-specific sugar transporters called enzyme II. Using phosphoenolpyruvate as an energy source, enzyme I and HPr initiate a cascade of phospho-relay reactions that funnels phosphoryl groups, via various enzyme IIs, onto incoming carbohydrates (40) (Fig. 3). Recent sequencing projects of streptococci have uncovered large portions of these genomes as predicted carbohydrate transporters, many of which are apparent products of horizontal gene transfer and have origins

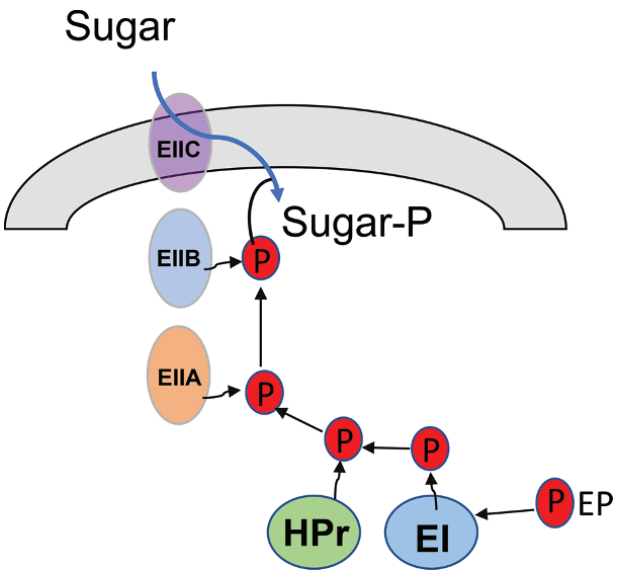

FIGURE 3 Simplified schematic of the phosphoenolpyruvate sugar:phosphotransferase system. EI, enzyme I; EII, enzyme II P, phosphate; PEP, phosphoenolpyruvate.

in related bacterial species (43–45). Together, these transporters allow metabolic flexibility when glucose, the preferred energy source for most streptococci, is not available. A major coordinator of these processes is the global regulator CcpA (catabolite control protein A). CcpA oversees carbon catabolite repression, a regulatory mechanism by which enzymes associated with catabolism of nonpreferred energy sources are repressed until glucose is no longer available (46, 47). When glucose is abundant, the cofactor HPr becomes phosphorylated at a serine residue. In association with this phosphorylated cofactor HPr(Ser-P), CcpA binds to the catabolite response element (*cre*) within the promoter region of a target gene to influence transcription (46). In addition to overseeing carbohydrate metabolism, CcpA has been associated with expression of virulence factors in streptococci (48–50). Notably, it has been demonstrated in some streptococci, e.g., *S. mutans*, *S. pyogenes*, and *S. pneumoniae*, that substrate-specific, CcpA-independent carbon catabolite repression plays profound roles in controlling carbohydrate prioritization and virulence expression (see references 51–55). Therefore, it appears that interactions among streptococci and with their host environment have shaped these bacteria for a successful lifestyle that specializes in carbohydrate catabolism and environment acidification. As such, infectious diseases and virulence associated with streptococci are often heavily dependent on their metabolic activities and, consequently, their ecological relationships with commensal bacteria in each particular biofilm environment (45, 50, 56).

MECHANISMS OF COLONIZATION

As important primary colonizers of the mouth, oral streptococci possess multiple high-affinity adhesins that mediate initial binding to tooth surfaces via interactions with substrates in the acquired salivary pellicle, including albumin, proline-rich proteins, glycoproteins, mucins, and sialic acid. Bacterial extracellular polysaccharides and extracellular DNA are major constituents of the plaque biofilm matrices whose production is triggered by bacterial adherence (57, 58). These macromolecules further facilitate bacterial colonization and accumulation of multicellular clusters. Salivary amylase also appears to play a role in bacterial colonization of mammalian oral surfaces since amylase-binding bacteria (such as *S. mitis*, *S. gordonii*, *S. salivarius*, and *Streptococcus cristatus*) were found to colonize only hosts with salivary amylase activity (59). Late colonizers, both Gram-positive and Gram-negative species, build upon the initial streptococcal foundation through a series of coaggregation and coadhesion events until a mature plaque is achieved within any given individual (60). Once established, the plaque community is relatively stable, and under healthy conditions, the different species in the community exist in homeostasis.

Colonization, as well as accumulation of oral streptococci on hard and soft tissue surfaces, is guided by a series of adhesin-receptor interactions and regulated in response to environmental cues, including the presence of other microbial species (61). The antigen I/II family of adhesins (SpaP, P1, PAc, SspA, SspB) is shared by most oral as well as several of the pyogenic streptococci (62). These proteins mediate binding to multiple host proteins, with the salivary glycoprotein gp340 (DMBT1) being the most widely studied. *S. gordonii* possesses two paralogs of antigen I/II, SspA and SspB, although the purpose for this duplication is not known (63). Notably, *S. gordonii* is a master of adherence and possesses numerous adhesive structures. Among them, GspB and Hsa are serine-rich repeat (Srr) glycoproteins that bind to sialylated glycans present on the soluble human salivary mucin MG2/MUC7, a

component of the mucosal pellicle (64), and the platelet glycoprotein GPIb (65, 66). Srr proteins are important for biofilm formation and have been identified in many other oral streptococci, including Fap1 of *S. parasanguinis* (67) and *S. oralis* (68), SrpA of *S. sanguinis* (69) and *S. cristatus* (70), and SrpA, B, and C of *S. salivarius* (71). Interestingly, Srr homologs are not present in the caries pathogen *S. mutans*. Genes encoding Srr family proteins are located within tightly coordinated genetic loci that also encode proteins that mediate their glycosylation, acetylation, and export (72–74). Notably, instead of the general secretion machinery utilized for other surface proteins, an alternative secretion system including SecA2 and SecY2 is dedicated to the translocation of this family of serine-rich proteins (67, 75). In addition, CshA of *S. gordonii* and CshA-like proteins of *S. oralis* and *S. sanguinis* are multifunctional fibrillar adhesins that bind to multiple host proteins, including fibronectin, and to other microorganisms (76, 77).

As detailed, production of extracellular glucans via the glucosyltransferases GtfB, GtfC, and GtfD is well known to facilitate adhesion of *S. mutans* to saliva-coated tooth surfaces (78). Secreted *S. mutans* Gtfs bind to the salivary pellicle and to other organisms, facilitating the recruitment of oral microorganisms to the dental biofilm. Although some other oral streptococci also express Gtfs, these enzymes have not been extensively studied like the Gtfs of *S. mutans*. A Gtf-negative mutant of *S. gordonii* showed diminished persistence on the teeth of sucrose-fed rats, although initial colonization was not affected (79). In addition, deletion of the single *gtf* gene of *S. gordonii*, *gtfG*, impacted its ability to form mixed biofilms with *Candida albicans* (80). *S. sanguinis* also produces water-soluble glucans from sucrose through a Gtf enzyme called GtfP. Its biofilm formation in monoculture in the presence of sucrose was significantly decreased upon inactivation of *gtfP* in *S. sanguinis*, although little effect on biofilm production was observed when the mutant strain was cocultured with other oral streptococcal species (81). Additional studies are necessary to firmly establish the contribution of Gtfs from non-*S. mutans* oral streptococci to oral colonization and biofilm assembly *in vivo*.

BETWEEN GOOD AND EVIL: WHEN THINGS GO WRONG

Dental caries, or simply cavities, is a multifactorial disease in which a carbohydrate-rich diet and the oral microbial composition play key roles in the development and progression of the disease. The common main culprits associated with dental caries are two species from the mutans streptococccci group, *S. mutans* and *Streptococcus sobrinus*, but other organisms can also be involved in the process, because caries-active subjects have been identified that do not harbor *S. mutans* or *S. sobrinus*. In healthy subjects, there is a balance between the numbers of cariogenic bacteria and non-cariogenic commensal species, with the latter keeping the cariogenic population in check through the production of alkali, hydrogen peroxide, or other inhibitory substances. However, frequent exposure to dietary carbohydrates creates a dysbiotic environment, in which the generation of organic acids such as lactic acid as fermentation by-products allows *S. mutans* and other aciduric species to outcompete less acid-tolerant commensal bacteria present in the dental plaque. Eventually, the repetitive acidification of environmental pH below the critical point (pH 5.5) leads to enamel demineralization and consequent cavitation of the tooth surface.

The distribution of oral streptococcal species differs within various ecological niches of the oral cavity (82). The mitis and sanguinis groups, including *S. oralis*, *S. mitis*, *S. gordonii*, and *S. sanguinis*, are the primary colonizers of the tooth surface and are commonly considered commensals, although all have been implicated in cases of infective endocarditis. Oral bacteria can reach the bloodstream not only during invasive procedures such as dental extractions and oral surgery but also after simple daily activities such as mastication, brushing, and flossing. Fortunately, our immune surveillance readily clears these bacteria from the bloodstream in a process that can take just a few seconds. However, in the rare occasions when these organisms successfully avoid the immune surveillance and cause systemic disease, interactions with platelets are especially important during the pathogenic process of infective endocarditis. Platelet binding by *S. mitis* was reported to be higher in strains that produce fewer exopolysaccharides, whereas high exopolysaccharide producers demonstrated less platelet aggregation (83). Another primary colonizer of the tooth surface that can cause transient bacteremia and endocarditis is *S. parasanguinis*. Its dual-function lipoprotein FimA participates in both metal transport (84) and adherence to fibrin, critical for vegetation formation on damaged heart tissue (85).

THE GOOD STREPTOCOCCI: COMMENSAL ORAL FLORA

In the human mouth, most microorganisms are embedded within a complex extracellular matrix known as biofilm or plaque (86). In a healthy individual, the oral biofilm is dominated by bacteria that are commensal in nature, engaging the host immunity in an intricate dialog that maintains a homeostasis integral to human health. Significantly, the commensal communities afford the host additional benefits by fending off pathogenic species. Dental health is often associated with a greater proportion of commensals with beneficial properties that include *S. gordonii*, *S. sanguinis*, and *S. parasanguinis*, some of which can cause opportunistic diseases at different body sites as discussed above, but in the mouth, their presence is generally associated with lower proportions of cariogenic *S. mutans* and oral health. In the case of dental caries, repetitive exposures to acidic pH values, reduced salivary flow, and a diet rich in fermentable carbohydrates are the known triggers of dysbiosis in dental plaque, tilting the balance toward acidogenic and aciduric populations (87). Here, we discuss a few mechanisms that are critical to understanding the antagonism between the commensal streptococci and dental pathogens: (i) production and neutralization of acids, (ii) generation of hydrogen peroxide (H_2O_2) that inhibits the persistence of *S. mutans*, and (iii) production and secretion of antimicrobial compounds.

Acid is the driving force behind dental caries, but pH in dental plaque is modulated in a complex way by the buffering capacities of salivary secretions, bacterial cells, certain foods, and the metabolic products of the microbiota. As previously mentioned, commensal streptococci are early colonizers of the oral cavity and play pivotal roles in moderating biofilm acidification by, among other things, generating large amounts of alkali from salivary and dietary substrates. A primary route for alkali generation by oral streptococci is the arginine deiminase system (ADS), which consists minimally of three enzymes: arginine deiminase, a catabolic ornithine transcarbamylase (cOTC), and a catabolic carbamate kinase (cCK). The ADS acts on free arginine to generate one molecule of ornithine and CO_2 plus two molecules of ammonia, with the concomitant production of ATP (88). Although free arginine is found in micromolar concentrations in ductal saliva, it is abundant in salivary

proteins and peptides (89). The pH-modulating effects of ammonia production benefit the commensals and other species that are generally less aciduric, or overtly acid sensitive. Another well-characterized alkali-generating mechanism is the urease system identified in *S. salivarius*, a three-part enzyme complex and a set of accessory proteins that break down urea to release ammonia and CO_2. The urease system could have considerable impact on oral bacterial ecology, given the millimolar concentration of urea present in saliva and gingival crevicular fluids. Of note, subjects with chronic renal failure, who secrete 10-fold more urea in saliva than normal individuals, rarely developed dental caries despite being on a carbohydrate-rich diet (90, 91).

Importantly, there are multiple reasons to believe that the ADS and arginine both have a potent influence on the promotion of a microbiota that is less cariogenic and that prevents caries pathogens from emerging in substantial numbers. In a mixed-species biofilm model containing arginine in the growth medium that included *S. mutans* and *S. gordonii*, activities of ADS provided a two-fold beneficial impact: they promoted the dominance of commensals and disrupted the biofilm matrix of *S. mutans* by interfering with exopolysaccharide production (92). Multiple clinical studies involving both children and adults support that arginine and elevated ADS levels are correlated with dental health, whereas low ADS activity appears to be strongly associated with active disease (35, 93–95). As a result, arginine has been incorporated into oral health products around the globe to promote oral health.

A second strategy employed by oral commensal streptococci to achieve a competitive advantage over oral pathogens is the generation of hydrogen peroxide (H_2O_2), which inhibits the growth of *S. mutans*, the periodontal pathogen *P. gingivalis* (96), and other oral pathogens. Among the known peroxigenic commensals, which include *S. oralis*, *S. mitis*, *S. sanguinis*, *S. gordonii*, and *Streptococcus oligofermentans*, there are multiple enzymatic pathways for the generation of H_2O_2. A dominant mechanism in dental biofilms appears to involve the enzyme pyruvate oxidase (Pox, encoded by *spxB*), which is present in many abundant commensal streptococci. Pox catalyzes the conversion of pyruvate and inorganic phosphate to H_2O_2, CO_2, and acetyl phosphate in the presence of oxygen. Thus, not only does the commensal gain a competitive advantage over H_2O_2-sensitive pathogens, but also, the acetyl phosphate provides a bioenergetics benefit as it is further metabolized, via acetate kinase, to acetate with the production of ATP. Moreover, the production of CO_2 contributes to some unknown degree the overall buffering capacity of the biofilm (97–99).

The H_2O_2-generating enzymes lactate oxidase (100, 101), L-amino acid oxidase (102, 103), and NADH oxidase are also present in some commensal oral streptococci. A lactate oxidase enzyme has been identified in *S. oligofermentans* that is capable of utilizing the lactic acid generated by the glycolytic activities of lactic acid bacteria to yield pyruvate and H_2O_2, which has the added benefit of removing a strong acid (lactate) from the environment. *S. oligofermentans* also encodes a Pox enzyme, but there is evidence to suggest that these enzymes may not work synergistically because of the way the genes are regulated (100). Notably, in *S. gordonii* and *S. sanguinis*, expression of *spxB* is sensitive to carbon catabolite repression by preferred carbohydrates such as glucose (104). Thus, it remains to be determined to what degree H_2O_2 production by Pox and other enzyme systems is active under conditions that are conducive to the formation of caries, i.e., when the host is consuming large quantities of readily metabolizable sugars. Likewise, since mature dental biofilms tend to be depleted for oxygen and have a low redox potential, Pox and other systems may exert their benefit primarily in the early phases of dental plaque development and have a more potent influence on the establishment of caries pathogens, whereas other pathways for competition become essential in more mature biofilms.

More recently, another mechanism whereby commensals may specifically affect the fitness of *S. mutans* has come to light. Most isolates of *S. mutans* carry the ComDE two-component system, which is required for the activation of transcription of a number of genes encoding lantibiotic and nonlantibiotic bacteriocins, small peptides that exhibit antimicrobial activity against other species. ComDE depends on a quorum sensing peptide, competence-stimulating peptide (CSP), for activity (105). *S. gordonii* DL-1 produces a protease, designated as challisin, which is able to degrade CSP and block the activation of bacteriocin gene expression by *S. mutans* (106). Interestingly, *Streptococcus* A12, a recently identified commensal with multiple strategies to interfere with *S. mutans* (105), also produces a challisin-like protease with similar activities against CSP and the ability to interfere with exopolysaccharide production by *S. mutans*. Notably, A12 can also block a second peptide-dependent signaling pathway (XIP-ComRS) that is highly conserved in *S. mutans* (105).

CONCLUDING REMARKS

As our understanding of oral infectious diseases evolves toward a multimicrobial, dysbiosis-based perspective, the field of oral microbiology has embraced a more holistic approach, exemplified by significant enhancements in our knowledge of molecular mechanisms underlying the physiological and ecological shifts that control the composition and activities of the microbiome in health and disease. Nevertheless, the metabolic plasticity, the ability to colonize multiple oral surfaces, and the production of inhibitory substances make oral streptococci key players in oral homeostasis and disease.

We thank Robert A. Burne for his careful reading and critical comments.

The Biology of *Streptococcus mutans*

J.A. LEMOS, S.R. PALMER, L. ZENG, Z.T. WEN, J.K. KAJFASZ, I.A. FREIRES, J. ABRANCHES AND L.J. BRADY

27

In 1924, J. Clarke isolated an organism from carious lesions and called it *Streptococcus mutans*, because he thought the oval-shaped cells observed were mutant forms of streptococci (1). However, it was in the late 1950s when *S. mutans* gained widespread attention within the scientific community, and by the mid-1960s, clinical and animal-based laboratory studies depicted *S. mutans* as an important etiologic agent in dental caries (2). The natural habitat of *S. mutans* is the human oral cavity, more specifically, the dental plaque, a multispecies biofilm formed on hard surfaces of the tooth. It has been largely accepted that the cariogenic potential of *S. mutans* resides in three core attributes: (i) the ability to synthesize large quantities of extracellular polymers of glucan from sucrose that aid in the permanent colonization of hard surfaces and in the development of the extracellular polymeric matrix *in situ*, (ii) the ability to transport and metabolize a wide range of carbohydrates into organic acids (acidogenicity), and (iii) the ability to thrive under environmental stress conditions, particularly low pH (aciduricity) (3). While *S. mutans* does not act alone in the development of dental caries, studies from several laboratories have convincingly demonstrated that *S. mutans* can alter the local environment by forming an extracellular polysaccharide (EPS)-rich and low-pH milieu, thereby creating a favorable niche for other acidogenic and aciduric species to thrive. As a human pathogen, *S. mutans* is also implicated in subacute bacterial endocarditis, a life-threatening inflammation of heart valves, while a subset of strains has been linked to other extraoral pathologies such as cerebral microbleeds, IgA nephropathy, and atherosclerosis.

Strains of *S. mutans* can be classified into four serological groups (*c*, *e*, *f*, and *k*) based on the composition of cell-surface rhamnose-glucose polysaccharide, with ~75% of strains isolated from dental plaque belonging to serotype *c*, ~20% to serotype *e*, and the remaining 5% classified as serotypes *f* or *k* (4). While biochemical and genetic approaches to dissect the biology of *S. mutans* have been used for at least the past 4 decades, the publication of the complete genome sequence of the *S. mutans* strain UA159 in 2001 (5) dramatically changed the landscape, and today, *S. mutans* is one of the best-characterized Gram-positive pathogens. In this article, we highlight some of the key studies that have led to our current understanding of *S. mutans* genetics, physiology, and virulence. For a historical perspective and complete survey of the field, we direct the reader to the review articles in references 2, 3, and 6–9.

GENETIC AND PHENOTYPIC HETEROGENEITY

The first *S. mutans* genome sequenced (serotype *c* strain UA159) was found to contain ~2.0 Mb of DNA and to encode approximately 2,000 genes (5). As the cost of next-generation sequencing technologies has gone down, genomes from dozens of *S. mutans* strains have been sequenced and assembled and are now available on public databases such as the NCBI (www.ncbi.nlm.nih.gov/assembly/?term=streptococcus+mutans). This influx of genome sequences has led to an increase in comparative genomic studies focused on *S. mutans* (10–13). One of the first such studies was based on the shotgun genome sequence from 57 geographically diverse *S. mutans* clinical isolates. This study concluded that the *S. mutans* pan-genome contains a minimum of ~3,300 possible genes and has a core genome (genes that are common to all strains) of 1,490 genes (14). This means that in any one *S. mutans* isolate, ~500 genes could be distinct from any other strain, perhaps significantly influencing virulence potential or fitness. The same group, using population demographic analysis based on single nucleotide polymorphisms of the core genes, determined that a large expansion took place in the *S. mutans* population between 3,000 and 10,000 years ago, which coincided with the advent of human agriculture and increased consumption of carbohydrates in the human host diet (14). This study also identified 73 unique core genes that are found only in *S. mutans* and not in its closest relatives, many of which are involved in carbohydrate metabolism and acid resistance (14). In a follow-up study, Palmer et al. (15) characterized 15 of the most genetically diverse isolates of the 57 strains sequenced by Cornejo et al. (14) and found great variation in the phenotypes directly related to virulence, including the ability to form biofilm in the presence of sucrose and the ability to tolerate low pH and oxidative stresses, suggesting that not all strains of *S. mutans* are equally virulent and providing a rational explanation for why attempts to correlate the carriage of certain genotypes of *S. mutans* with the incidence of dental caries has proven so difficult (10, 16–18).

doi:10.1128/microbiolspec.GPP3-0051-2018

Work to characterize the unique core and noncore genes is ongoing and will likely lead to a greater understanding of the physiology and diversity of *S. mutans* as a species. For example, one of the unique core hypothetical genes, SMu.1147, which encodes a small peptide, was found to regulate genetic competence and other traits of general importance to *S. mutans* virulence (19). In contrast, efforts to characterize the noncore genes indicate that they likely provide a competitive advantage under particular circumstances. Such is the case for a galactose-specific phosphotransferase system (PTS) transporter found in several strains (20). Among the many noncore genes of *S. mutans* identified in recent years, those encoding the collagen-binding proteins (CBPs) Cnm and Cbm were shown to confer adhesion to collagen and laminin, invasion of endothelial and epithelial cells, and virulence in the *Galleria mellonella* invertebrate model (21, 22) as well as in rabbit and rat models of infective endocarditis (23, 24). Epidemiological studies indicate that *cnm* is present in approximately 15% of *S. mutans* isolates, whereas *cbm* is rarely found (~2%) (21, 22). Genes encoding CBPs have an uneven distribution among the different serotypes and are found at higher frequency among serotype *e*, *f*, and *k* strains but are rarely present in serotype *c* strains (25). Notably, CBP^+ *S. mutans* strains are more frequently isolated from dental plaque of individuals with bacteremia and infective endocarditis, suggesting a correlation between the production of these adhesins and systemic infections (26). Interestingly, the presence of *cnm* in *S. mutans* strains isolated from saliva has been linked to IgA nephropathy, cerebral microbleeds, and cognitive impairment (27, 28). Finally, animal and clinical studies have suggested an association of CBPs in caries risk and severity (27, 29, 30).

CARBOHYDRATE METABOLISM

As a lactic acid bacterium, *S. mutans* relies exclusively on glycolysis for energy production (Fig. 1). A signature characteristic of this organism is its ability to metabolize a large variety of carbohydrates. The genome of the UA159 type strain encodes 14 phosphoenolpyruvate-dependent sugar: PTSs with specificities for various mono- and disaccharides, as well as two ATP-binding cassette (ABC) transporters involved primarily in internalizing oligosaccharides (5). Sucrose is a β2,1-linked disaccharide composed of glucose and fructose that has proven, for a number of reasons, to be the most cariogenic of all carbohydrates. *S. mutans* has evolved multiple pathways to catabolize sucrose for acid production (31), and several glycosyltransferase enzymes (Gtfs) convert sucrose into a glue-like extracellular polymer glucan that promotes the buildup of biofilms by way of cellular attachment to dental surfaces and other oral microorganisms (7). As discussed in more detail below, recent multispecies modeling studies have confirmed the unique roles of Gtfs in the formation of a heterogeneous, diffusion-limiting, low-pH matrix that is conducive to both dental demineralization and the eventual dominance by acid-tolerant species (7, 32).

Carbon Catabolite Repression

Most bacteria have evolved regulatory capacities that enable them to respond efficiently to changes in carbon source and thereby shift gene regulation, a phenomenon called carbon catabolite repression (33, 34). The majority of low-GC Gram-positive bacteria depend on a LacI-type transcriptional regulator called CcpA to ensure that catabolic genes for less preferred carbohydrates are suppressed when a preferred carbohydrate (normally glucose) is present. Interestingly, *S. mutans* deviates from this paradigm in that CcpA plays a less direct role. Instead, the glucose/mannose-PTS (EII^{Man}) system regulates the expression of catabolic operons required for assimilating secondary carbohydrates such as oligo- and disaccharides (35). Inactivation of *manL*, which encodes the A and B domains of the EII^{Man} permease, results in enhanced expression of the *fruAB* and *levDEFG* (EII^{Lev}) operons. These operons contain genes which encode two different fructanases, FruAB for hydrolyzing fructose polymers (36), and a fructose/mannose-PTS (37), respectively. As a result, a *manL* mutant demonstrates improved growth on media supplemented with fructose polymers such as inulin or levan (35). CcpA and its cofactor HPr-Ser-P are also involved in this regulation (38, 39). Whereas CcpA interacts directly with cognate *cis*-elements called *cre* (catabolite response element) near the *fruA* promoter, ManL influences *fruAB* and *levDEFG* expression independently of CcpA (39). It is now believed that EII^{Man}-dependent glucose transport influences carbohydrate metabolism via substrate-specific signaling, which occurs primarily at submillimolar concentrations of carbohydrate (38). However, substrate-level regulation is also influenced indirectly by CcpA under excess-carbohydrate conditions, since CcpA appears to regulate the transcription of *manL* (38, 39). A transcriptomic study of a *manL* deletion strain validated the key roles of EII^{Man} in global gene regulation (40), and transcriptional studies of a *ccpA* deletion strain revealed both a central role for CcpA in controlling carbon flux and the existence of a substantial network of CcpA-independent genes (41, 42).

Catch and Release

To further explore substrate-dependent carbon catabolite repression in *S. mutans*, Zeng et al. assessed the relative contributions of various sucrolytic enzymes (31). The majority (>95%) of sucrose encountered by *S. mutans* is believed to be internalized via the EII^{Scr} PTS (43, 44), while the rest is likely metabolized extracellularly by the glucosyltransferases (GTFs) and fructosyltransferase. Enhanced transcription of the *fruAB* and EII^{Lev} operons was observed in the presence of sucrose, with such activation requiring both the sucrose PTS (ScrA) and the LevQRST regulatory pathways. LevQRST is an unconventional four-component system that activates transcription of *fruAB* and EII^{Lev} in response to extracellular fructose or mannose (37, 45). Since free fructose was detected in the culture media of an *S. mutans* strain deficient in all extracellular sucrolytic enzymes after treatment with sucrose (46), it was hypothesized that following sucrose internalization and subsequent cleavage of sucrose-6-P into glucose-6-P and unphosphorylated fructose by the ScrB hydrolase, some of the fructose is released into the medium and can activate the LevQRST circuit but is insufficient to trigger CcpA-dependent carbon catabolite repression. Such a strategy of carbohydrate metabolism would be energetically efficient and avoid perturbing intracellular ATP levels, which is particularly important to a bacterium such as *S. mutans* that actively pumps protons out of the cell at the expense of ATP to maintain pH homeostasis. Interestingly, fructose may not be the only carbohydrate to be released and reinternalized by *S. mutans*. Recent studies have characterized maltose and maltooligosaccharide metabolism and demonstrated the presence of free glucose in the culture medium that is apparently reinternalized by way of the glucose-PTS EII^{Man} (47, 48). Transient expulsion of glucose was also observed when *S. mutans* was grown on a mixture of glucose and lactose (49). Considering diffusion limitations within biofilm matrices (50), hexose release may likely serve as temporary energy

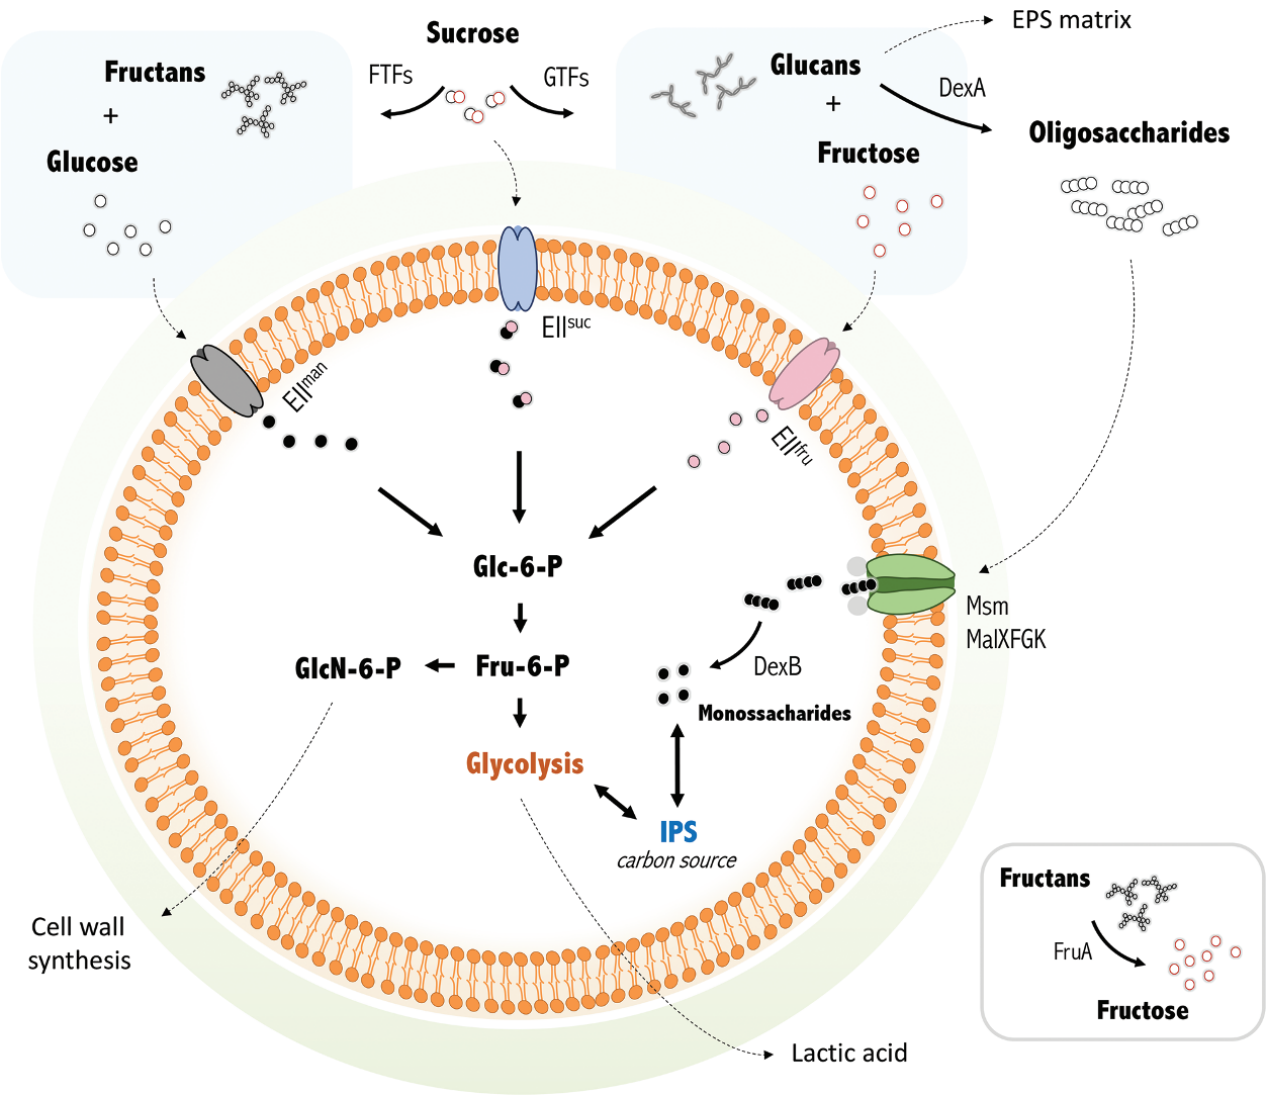

FIGURE 1 Carbohydrate metabolism in *S. mutans*. While *S. mutans* can metabolize a large variety of carbohydrates, the figure shows the metabolism of most common dietary sugars (fructose, glucose, and sucrose). Sucrose is a β2,1-linked disaccharide composed of glucose and fructose that has proven to be the most cariogenic of all carbohydrates. In the extracellular environment, sucrose is a substrate of glucosyltransferase (GTF) and fructosyltransferase (FTF) enzymes, which catalyze the production of glucans and fructans, respectively. The formation of glucans plays a key role in virulence, because they contribute to biofilm buildup by forming a glue-like polysaccharide matrix. Fructans serve as short-term extracellular carbohydrate sources and are degraded by the fructanase enzyme FruA, yielding fructose, which can be internalized for energy production. Glucans are susceptible to the action of an extracellular dextranase, DexA, which breaks down the α1,6-linkages, thereby yielding oligosaccharides (e.g., maltodextrans). After being transported into the cell, oligosaccharides are degraded into monosaccharides by the action of the DexB glucosidase. Oligosaccharides are primarily transported into the cells by ATP-binding cassette (ABC) transporters (e.g., Msm and MalXFGK transport systems), whereas monosaccharides (e.g., glucose and fructose) and disaccharides (e.g., sucrose) are predominantly taken up by the phospho-enolpyruvate:sugar PTS. In *S. mutans*, multiple PTSs can transport the same carbohydrate, with at least three PTSs being involved in fructose transport and several PTSs and permeases being involved in glucose transport. In the intracellular environment, carbohydrates are phosphorylated and processed to fructose-6-phosphate (Fru-6-P) and fermented by glycolysis with production of organic acids, mainly lactic acid. In addition, glucosamine-6-phosphate (GlcN-6-P) is synthesized from Fru-6-P and serves as an initial precursor for cell wall biosynthesis. Cells can synthesize an intracellular polysaccharide (IPS), a polymer of the glycogen-amylopectin type, when carbohydrates are in excess that can be stored as intracellular granules and are used as an energy source reserve during starvation.

storage and/or as a carbohydrate source for neighboring cells that may not be actively invested in metabolizing these disaccharides. This would thereby represent a bet-hedging strategy within the population and also contribute to a mutualistic relationship with other microorganisms that are closely associated with *S. mutans* (51, 52).

BIOFILM FORMATION

As a major etiological agent of human dental caries, *S. mutans* lives primarily in biofilms on the tooth surfaces, the so-called dental plaque. Strains of *S. mutans* produce up to three GTFs, GtfB, -C and, -D, that utilize the glucose moiety of sucrose as the substrate to synthesize glucose polymers of

glucans (also known as mutans) (Fig. 1) (7). GtfB synthesizes water-insoluble glucans rich in α(1-3)-linkages, GtfC produces a mixture of soluble glucans rich in α(1-6)-linkages and insoluble glucans, and GtfD makes primarily soluble glucans (often called dextran). These polymers, especially the α3,1-linked water-insoluble glucans, are major constituents of plaque biofilm matrices. Gtfs also bind to other oral microbes, even those that do not naturally express Gtfs, thereby converting them into *de facto* glucan producers (7). In addition, *S. mutans* encodes several surface-associated glucan-binding proteins, GbpA, -B, -C, and -D. Together, the Gtfs, Gbps, and adhesive glucans serve as an integrated scaffold for sucrose-dependent biofilm formation central to this organism's cariogenicity by promoting the local accumulation of microbial cells while forming a diffusion-limiting polymeric matrix that protects the embedded bacteria (Fig. 2).

S. mutans also possesses multiple high-affinity surface adhesins that enable colonization even in the absence of sucrose. One of the most widely studied adhesins is the dual antigen I/II, also known as P1, SpaP, or PAc. This structurally complex multifunctional adhesin mediates bacterial attachment to the tooth's salivary pellicle via interactions with the host scavenger receptor glycoprotein GP340 or DMBT-1 (53–55). The AgI/II family adhesins also interact with other

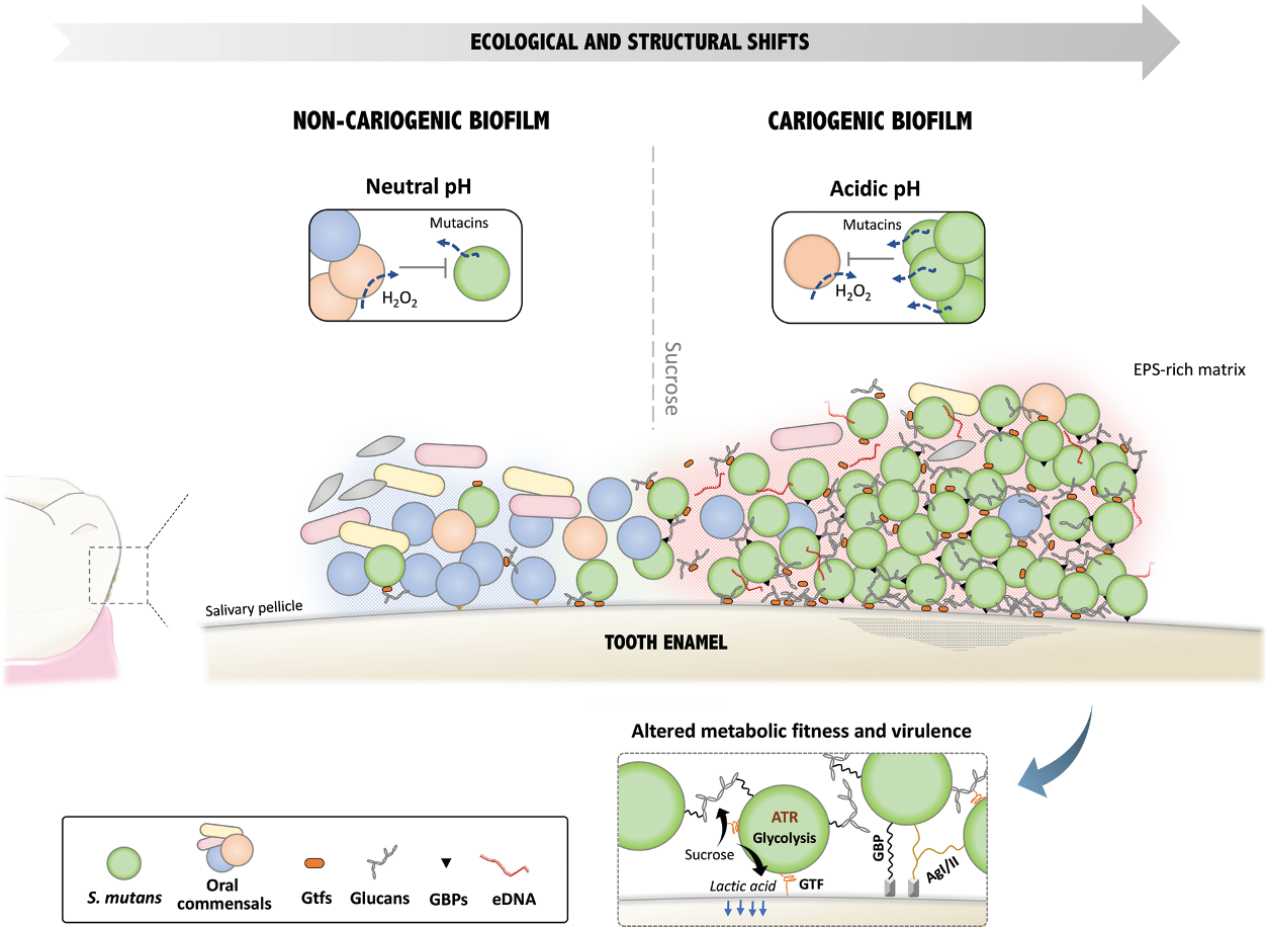

FIGURE 2 Biofilm formation and host-pathogen interactions in *S. mutans*. Early colonizers (e.g., *S. gordonii*, *Streptococcus mitis*, and *Actinomyces* spp. among others) attach to the tooth enamel via salivary proteins and start to form three-dimensional biofilms under noncariogenic conditions. At pH levels close to neutrality, production of H_2O_2 by peroxigenic bacteria and other antimicrobial products produced by oral commensals prevents the overgrowth of specific pathogens (e.g., *S. mutans*) on dental biofilms. Glycosyltransferases (GTFs) secreted by *S. mutans* adsorb onto the enamel pellicle or bacterial surfaces. In the presence of sucrose, GTFs catabolize sucrose to produce large amounts of insoluble and soluble glucans, which contribute to the buildup of a robust extracellular polysaccharide matrix (EPS), particularly insoluble components. The EPS matrix serves as an architectural scaffold for the biofilm structure, mediating tight adherence to the tooth enamel and bacteria, as glucans provide binding sites for *S. mutans* glucan-binding proteins (GBP) and other organisms. Extracellular DNA (eDNA) is another functional constituent of the oral biofilm matrix, forming nanofibers that connect cell to cell and cell to substratum and that contribute to biofilm structural integrity and stability. Continuous intake of sucrose by the host leads to a series of ecological and structural shifts that favor the growth of aciduric and highly acidogenic bacteria, such as *S. mutans*. These changes alter the oral biofilm metabolism so that copious amounts of organic acids are produced, contributing to a decrease in environmental pH. Once *S. mutans* becomes dominant, the secretion of large amounts of mutacins kills nearby competitors such as peroxigenic streptococci. The constant low-pH milieu surrounding the hydroxyapatite structure of the enamel leads to demineralization and initiates the carious process.

bacteria and host proteins such as fibronectin and collagen (53, 56). Relative to the wild type, a P1-deficient mutant demonstrates reduced binding to saliva or GP340-coated surfaces, aberrant biofilm formation, and reduced cariogenicity in a rat caries model (57, 58). In addition, P1 and WapA, another surface-localized adhesin, have been recently shown to form fibrillar amyloid aggregates (59). Amyloids are increasingly recognized as integral bacterial biofilm matrix components that interact with extracellular DNA (eDNA) and confer stability to the exopolysaccharide matrix (60). An *srtA* mutant lacking the only surface-anchoring sortase enzyme found in *S. mutans* is severely defective in biofilm development and does not produce amyloid, suggesting that fibril nucleation occurs at the cell surface (61). Treatment of *S. mutans* with known amyloid inhibitors inhibits biofilm formation via P1 and WapA-dependent mechanisms (59). In addition to P1 and WapA, a third amyloidogenic protein (SMU_63c) was recently identified. This secretory protein serves as an apparent negative regulator of biofilm cell density and genetic competence (59). Its production is associated with K^+ availability and influenced by growth phase (62).

Several cell envelope-associated proteins also contribute to *S. mutans* biofilm formation, including AtlA, RgpG, BrpA, and Psr. AtlA is an autolysin whose deficiency results in decreased autolysis and longer chain length and drastically reduces biofilm formation regardless of the carbohydrate used for growth (63). RgpG is the first enzyme of the biosynthetic pathway for rhamnose-containing glucose polymers, a major surface antigen of oral streptococci responsible for the different serotypes (64, 65). RgpG deficiency does not impair growth but leads to a pronounced reduction of cell surface antigens and major defects in cell morphology and cell division (65). RgpG-deficient mutants display long chains of swollen "squarish" dividing cells and form fewer biofilms irrespective of carbohydrate source. The BrpA and Psr proteins are members of the LytR-CpsA-Psr family of proteins that are widespread in Gram-positive bacteria (66–68). Deletion of *brpA* has little effect on growth but causes major impairment in biofilm formation. The *brpA* mutant is also less tolerant to acid and oxidative stresses and more susceptible to cell envelope antimicrobial agents, all of which likely contribute to its reduced biofilm phenotype. Psr also strongly influences *S. mutans* biofilm formation and acid tolerance, but unlike BrpA, Psr deficiency does not diminish oxidative stress tolerance or resistance to cell envelope antimicrobial agents. Both BrpA and Psr exhibit ligase functions for cell wall antigens, such as the rhamnose-containing glucose polymers, and thereby globally impact cell envelope composition. Deficiency of either BrpA or Psr results in a reduction of cell wall antigens and their concurrent accumulation in cell-free culture medium (65). Finally, eDNA is another functional constituent of the *S. mutans* biofilm matrix; eDNA forms nanofibers that connect cells to one another and to the substratum contributing to bacterial adherence and biofilm structural integrity and stability (69).

STRESS TOLERANCE

The ability of *S. mutans* to adapt to sudden and substantial environmental changes within the dental plaque is a key attribute that contributes to its status as the major etiologic agent of dental caries. Fermentable carbohydrates consumed by the host provide a substrate for *S. mutans* and other lactic acid bacteria that ultimately results in the production of acidic end products that accumulate within the biofilm. To thrive at low pH values, *S. mutans* mounts the so-called acid tolerance response, a robust transcriptional and physiologic adaptation mechanism that encompasses the induction of pathways that contribute to cytoplasm buffering and changes in membrane fatty acid composition, ultimately protecting the cellular machinery from acid damage and contributing to the survival of the bacteria during stress (Fig. 3) (3, 6, 70). Collectively, the different cellular processes that constitute the acid tolerance response contribute to the ability of *S. mutans* to maintain an intracellular pH that is more alkaline than the surrounding environment (ΔpH) by about 0.5 to 1 pH unit (71). Environmental acidification also triggers *S. mutans* to modify the composition of the plasma membrane in a way that may alter proton permeability. These modifications are accomplished by increasing the proportion of monounsaturated fatty acids (both by incorporating exogenous fatty acids and by *de novo* synthesis) and by increasing the length of the carbon chains composing these membrane fatty acids (72). Inactivation of the gene responsible for biosynthesis of monounsaturated fatty acids in *S. mutans*, *fabM*, results in extreme sensitivity to low pH, inability to maintain ΔpH, and reduced virulence in a rat caries model (73, 74). In addition to changes in fatty acid composition, the phospholipid cardiolipin has also emerged as an important contributor to acid tolerance, because deletion of the cardiolipin synthase (*cls*) increased acid sensitivity (75).

Alkalinization of the cytoplasm occurs either by pumping protons out of the cell or through the generation of neutralizing molecules. In *S. mutans*, the membrane-bound F_1F_0-ATPase (F-ATPase) is the primary mechanism by which protons are extruded to maintain pH homeostasis. The *S. mutans* F-ATPase is transcriptionally induced by low pH values and has an optimal pH of 6.0, which is lower than that of most streptococci associated with oral health (76, 77). Some oral streptococci utilize the urease enzyme (e.g., *Streptococcus salivarius*) or the arginine deiminase system (e.g., *Streptococcus gordonii*) to produce the neutralizing molecules ammonia and CO_2 in order to cope with acid stress. Although these pathways are absent in *S. mutans*, the agmatine deiminase system (AgDS), analogous to the arginine deiminase system, is present in this species (78, 79). The AgDS converts agmatine, a decarboxylated derivative of arginine found in dental plaque, to ammonia, CO_2, putrescine, and ATP. Though the AgDS does not appear to have a considerable impact on environmental alkalinization, the ammonia generated internally may contribute to neutralization of the cytoplasmic pH, while the ATP generated can be used to fuel proton extrusion via the F-ATPase (80). Malolactic fermentation converts malate, an acid commonly found in wine and in fruits such as apples, to the less acidic lactate and to CO_2. The CO_2 product can then be used for cytoplasmic neutralization by conversion to bicarbonate via carbonic anhydrase. In *S. mutans*, transcription of the genes encoding the malolactic enzyme and permease is acid-inducible, and malolactic fermentation activity was found to be optimal at an extracellular pH of 4.0 (81). Most importantly, malate was shown to protect *S. mutans* against acid killing and was associated with maintenance of ATP pools during starvation (82).

While the dental plaque environment was initially thought to be anaerobic, it is now known that the oral microbial community has a high capacity to reduce oxygen, resulting in the generation of toxic reactive oxygen species (83). Most *S. mutans* strains are susceptible to exposure to H_2O_2, which can be generated by metabolism of other species

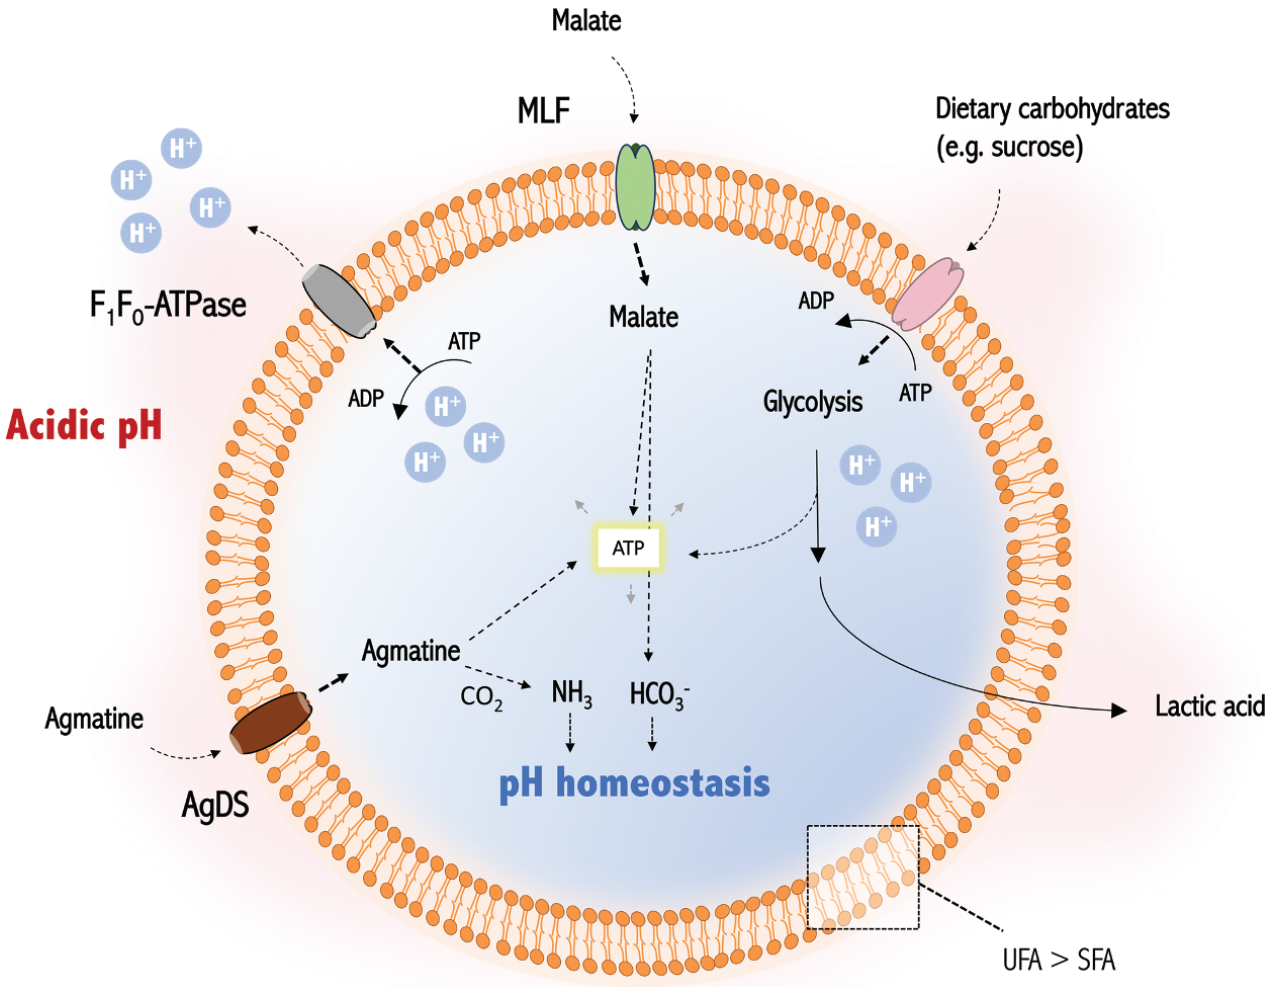

FIGURE 3 Acid stress tolerance mechanisms of *S. mutans*. The ability of *S. mutans* to catalyze fermentable dietary carbohydrates into organic acids can promptly drop the environmental pH. Exposure to sublethal low pH triggers an acid-adaptive response known as ATR (acid tolerance response), which is a robust transcriptional and physiologic adaptation mechanism for pH homeostasis through alteration of proton permeability, generation of neutralizing molecules, and changes in membrane fatty acid composition. The membrane F_1F_0-ATPase (F-ATPase) is transcriptionally induced by low pH and serves as the primary mechanism by which protons are extruded to maintain pH homeostasis. The modifications in membrane composition refer to an increase in the proportion of monounsaturated fatty acids (UFA) over saturated fatty acids (SFA) and in the length of the carbon chains composing the membrane fatty acids. Production of neutralizing molecules, such as ammonia and CO_2, is also an important way to cope with acid stress. In *S. mutans*, the agmatine deiminase system (AgDS) converts agmatine, a decarboxylated derivative of arginine found in dental plaque, to ammonia, CO_2, putrescine, and ATP. The ammonia generated internally may contribute to cytoplasmic buffering, while the ATP generated can be used to fuel proton extrusion via the F-ATPase. A decrease in environmental pH also triggers activation of malolactic fermentation (MLF), which converts malate to the less acidic lactate and to CO_2. The CO_2 product can then be used for cytoplasmic neutralization by conversion to bicarbonate (HCO_3^-) via carbonic anhydrase.

within the dental plaque, such as peroxigenic streptococci, or is contained as a component of oral hygiene and tooth bleaching products. Exposure to high levels of H_2O_2, and its more damaging breakdown products hydroxyl radical and superoxide anion, can rapidly cause irreversible cellular damage by triggering mismetallation of enzymes, by damaging proteins through oxidation of sulfurous amino acids and metal-binding sites, and by disturbing DNA integrity (84). Although oral streptococci lack catalase, *S. mutans* utilizes a number of scavenging and protective systems to prevent the accumulation of toxic reactive oxygen species. Among these are a manganese-dependent superoxide dismutase, an alkyl hydroperoxidase reductase, a thioredoxin reductase, and a glutaredoxin system (GshA/B/R) (85). Tight control of free iron in the cell is an important aspect of minimizing exposure to reactive oxygen species, because free radical formation is a direct result of the Fenton chemistry, when H_2O_2 comes into contact with ferrous iron. For this reason, the iron binding protein Dpr is a critical mediator of oxidative stress exposure in *S. mutans* (86, 87). Finally, the Spx regulators, SpxA1 and SpxA2, are responsible for the transcriptional activation of virtually every major oxidative stress response gene in *S. mutans* (85, 88). Not surprisingly, *spx* deletion strains were ill-equipped to tolerate oxidative challenges and caused fewer sulcal caries lesions in rats fed a highly cariogenic diet (85, 89, 90).

SIGNALING PATHWAYS

Two-Component Signal Transduction Systems (TCSTSs)

TCSTSs play important roles in bacterial adaptation, survival, and virulence by sensing changes in the environment and altering the expression of specific sets of genes to mount coordinated responses to environmental stimuli. In TCSTSs, a signal is sent by phosphotransfer between histidine senor kinases and their cognate response regulators, triggering the response regulators to dimerize and bind to conserved DNA motifs, ultimately tuning cellular functions such as biofilm formation, stress tolerance, and nutrient uptake (91). The genome of the type strain UA159 encodes 14 TCSTSs and one orphan response regulator with no genetic link to a histidine kinase (92). Among those, ComDE, LevRS, VicRK, and the orphan CovR regulator have been studied in some detail and shown to coordinate the expression of a number of virulence attributes. The LevRS system, which is important for management of carbohydrate metabolism, was introduced in the "Carbohydrate Metabolism" session, whereas the ComDE system, which is involved in the regulation of bacteriocin production and competence, is discussed in the next paragraph. VicRK influences acid and oxidative stress responses and competence and is the only TCSTS essential in *S. mutans* (93, 94). Several studies have proposed phosphotransfer cross talk between VicRK and the LiaFSR TCSTS, which contributes to surface adhesion, mutacin production, and the ability to tolerate environmental stresses, including cell envelope damage and heat shock (95–98). In addition, VicRK and CovR directly regulate genes implicated in the synthesis of and interaction with extracellular polysaccharides (7, 99). For example, transcription of *gbpB* is positively regulated by VicR (100, 101), while *gtfB*, *gtfC*, and *gbpC* are repressed by CovR (99).

Quorum Sensing (QS)

QS systems are communication networks that enable microbes to sense and respond to environmental conditions such as nutrient availability and population density, because signaling molecules naturally accumulate along with bacterial density. In Gram-positive bacteria, QS is coordinated by peptide pheromones, which serve as extracellular signaling molecules that trigger changes in gene expression and, ultimately, activation of a coordinated response by the population (102–104). In *S. mutans*, QS systems have evolved to regulate production of bacteriocins (known in *S. mutans* as mutacins), which are peptide antibiotics used in defense against other oral microbes (105–107) and in competence (natural transformation), a transient state in which the organism is primed to take up foreign DNA (Fig. 4). The competence-stimulating peptide signaling molecule (CSP) (also called the mutacin-inducing peptide) is encoded by *com*C. Once CSP has been secreted and processed, it is recognized by the TCSTS ComDE (104, 108, 109). Activated (phosphorylated) ComE regulates mutacin production by recognizing a conserved sequence in the promoter region of its target genes (95, 110, 111). Also sharing regulatory links with ComDE in *S. mutans* is another TCSTS, CiaRH, which contributes to biofilm formation, acid tolerance, and entry into competence, possibly by interacting with CSP (112). Among the consequences of ComE activation is the stimulation of *comRS*, the QS pathway directly responsible for competence activation via the alternative sigma factor ComX (also called SigX) (113, 114). Once exported to the extracellular space, the prepeptide ComS is presumably processed into the peptide pheromone XIP (*comX*- or *sigX*-inducing peptide) (114, 115). When imported back into the cell via the oligopeptide permease system, XIP is sensed by ComR, which binds to conserved inverted repeat sequences upstream of both *comX* and *comS*, thereby causing autoinduction of the ComRS pathway and activation of ComX-regulated genes. It is worth noting that while all *S. mutans* isolates sequenced to date possess a functional ComRS-ComX system, not all strains harbor a complete ComCDE pathway, nor are all isolates equally competent (15).

The mutacins produced by *S. mutans* are categorized as either lantibiotics (broadly active against Gram-positive bacteria) or nonlantibiotics (most active against closely related species), and production of these molecules is strain specific (116). Mutacins provide a competitive advantage to *S. mutans* by inhibiting the growth of neighboring bacterial species (117, 118). A close relationship exists between competence induction and mutacin production, because a threshold concentration of CSP activates ComDE to result in increased mutacin production (95, 111). Adding to the layers of regulation of mutacin production are two LytTR regulatory systems, HdrRM and BrsRM, which include a membrane-bound inhibitor protein that prompts the activity of the transcriptional regulator (119, 120). In this case, an overlap in the regulatory systems that govern mutacin production and competence is again observed because LytTR systems also induce competence through ComX (120, 121). A complete understanding of the environmental conditions that trigger these regulators and hence influence mutacin production is yet to be achieved.

Another *S. mutans* QS mechanism employs the autoinducer-2 (AI-2), the collective name for a group of furanones formed as a by-product of LuxS-mediated methyl metabolism (122). The lack of species specificity of AI-2 signaling molecules, which are produced by both Gram-positive and Gram-negative organisms, facilitates interspecies communication as population growth contributes to accumulation of AI-2. Deficiency of LuxS reduces the ability of *S. mutans* to tolerate acid and oxidative stress and to form biofilms, especially during growth in sucrose (123, 124). In agreement with those phenotypes, LuxS deficiency causes alterations in expression of a large number of genes, including those with known roles in stress tolerance response and biofilm formation (123–125). Addition of synthetic AI-2 to the growth medium can restore the phenotypes of LuxS mutants with regard to the stress tolerance response, biofilm formation, and the expression of selected genes (124, 125). To date, however, a specific receptor for AI-2 has yet to be identified (125).

Regulatory Nucleotides

The regulatory nucleotides (p)ppGpp and cyclic-di-AMP have also been shown to modulate biofilm formation and stress responses in *S. mutans* (126–128). Guanosine tetraphosphate (ppGpp) and guanosine pentaphosphate (pppGpp), collectively called (p)ppGpp, are the effector molecules of a conserved stress response referred to as the stringent response (129). Three (p)ppGpp-metabolizing enzymes have been identified in *S. mutans*: RelA is a bifunctional synthetase/hydrolase contributing to metabolism of (p)ppGpp, while two small alarmone synthetase enzymes, RelP and RelQ, harbor only the synthetase domain (130). In *S. mutans*, changes in (p)ppGpp pools affect biofilm formation, carbohydrate metabolism, and stress tolerance, suggesting an overlap between circuits that govern general stress tolerance and biofilm formation. While the mechanism is not completely understood,

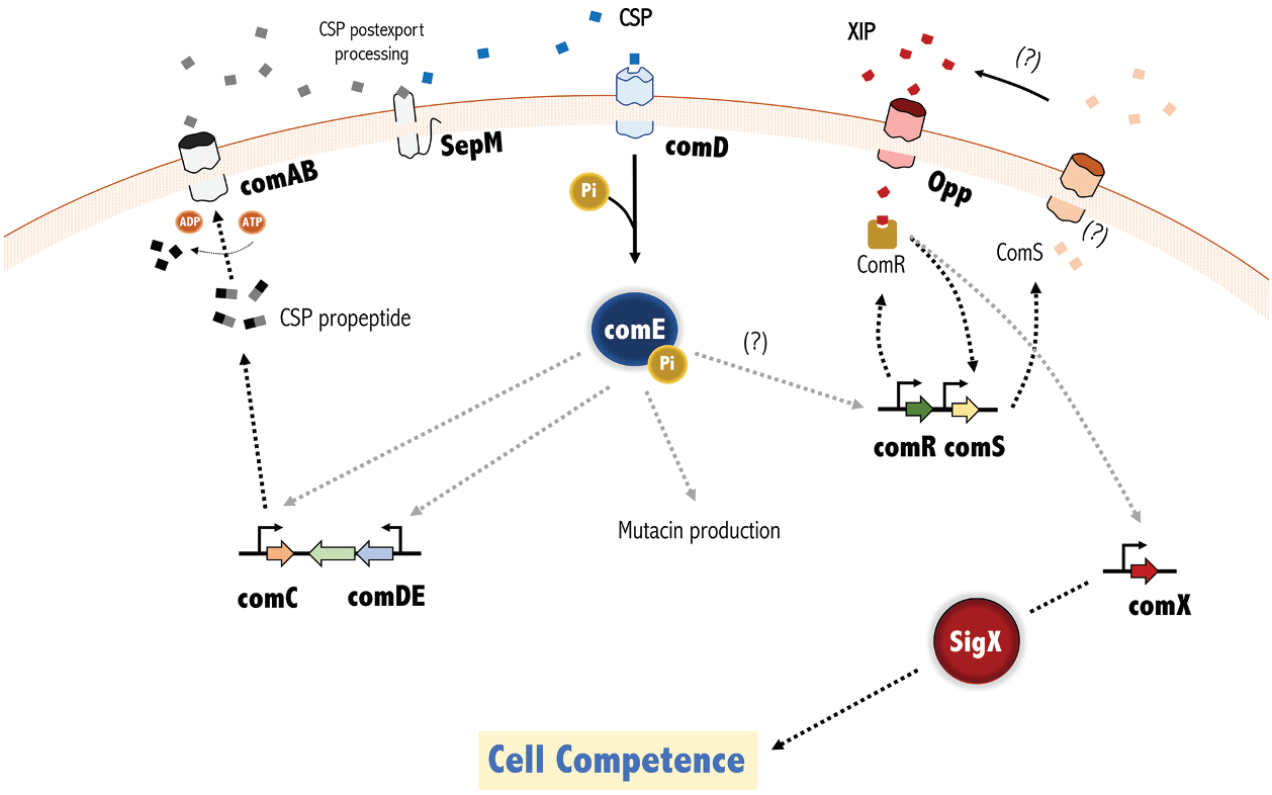

FIGURE 4 Quorum-sensing systems involved in the regulation of bacteriocin production and competence in *S. mutans*. Cell density, nutrient availability, and other environmental conditions induce the expression of *comC*, a gene encoding the competence-stimulating peptide (CSP) precursor. The CSP propeptide is cleaved off inside the cell and exported through a specific ABC transporter encoded by *comAB*. In the extracellular environment, CSP then undergoes a final postexport processing mediated by the SepM protease. Upon reaching a certain threshold, mature CSP is recognized by the two-component system ComDE, triggering a phosphorylation cascade. Activated (phosphorylated) ComE activates transcription of (i) *comC* and *comDE*, creating a positive feedback loop, (ii) genes involved in mutacin production, and (iii) by a yet-to-be-determined mechanism, *comRS*, the quorum-sensing pathway directly responsible for competence activation via the alternative sigma factor ComX. Once exported to the extracellular milieu, the prepeptide ComS is processed into the peptide pheromone XIP (*comX*- or *sigX*-inducing peptide). XIP is transported back into the cell via the oligopeptide permease system (Opp) and sensed by the Rgg-type regulator ComR. Activated ComR binds to both *comX* and *comS* promoters, thereby causing auto-induction of ComRS and activation of late (ComX-regulated) competence genes.

(p)ppGpp pools also modulate competence signaling through interactions with an ABC-type transporter, RcrRPQ, and at least one peptide encoded within *rcrQ* (126, 131). Cyclic di-AMP is an emerging second messenger in bacteria that has been shown to play important roles in bacterial fitness and virulence (132). In *S. mutans*, increased cyclic-di-AMP levels promoted biofilm formation through interactions with the VicRK-*gtfB* network that ultimately resulted in in the transcriptional activation of *gtfB* (128).

INTERSPECIES AND CROSS-KINGDOM INTERACTIONS

Interactions between *S. mutans* and certain members of the dental plaque community have been documented and have recently been shown to exert a major influence on the development and pathogenicity of plaque. These interactions can be synergistic, i.e., promote *S. mutans* growth, or antagonistic, i.e., inhibitory to *S. mutans*. A classic example of an antagonistic interaction occurs between *S. mutans* and members of the mitis streptococci group such as *Streptococcus sanguinis* and *S. gordonii*. Specifically, several members of the mitis group secrete millimolar concentrations of H_2O_2, which can be highly inhibitory to *S. mutans* (118). On the other hand, strains of *S. mutans* not only produce mutacins that are specific against mitis streptococci, but most are also generally more aciduric than species from the mitis group. This antagonistic relationship becomes more evident in dental plaque, whereby there is an inverse association between the abundance of oral commensal streptococci such as *S. sanguinis* and *S. gordonii* (abundant in healthy plaque) and that of *S. mutans* (abundant in caries lesions) (133) (Fig. 2).

While production of lactic acid by *S. mutans* is inhibitory to the growth of many acid-sensitive oral commensals, lactic acid serves as a carbon source for *Veillonella* spp., a prevalent genus in the oral cavity (134). Thus, it is thought that *Veillonella* may act as an "acid sink," preventing the dental biofilm from reaching extremely low pH values that even aciduric organisms such as *S. mutans* may not be able to survive. This nutritional mutualism may explain the close association of *Veillonella* with streptococci in the oral cavity, which excrete lactate as a waste product of carbohydrate fermentation. In dual-species biofilms, *S. mutans* and *Veillonella parvula* form distinctive structures and display increased resistance to chlorhexidine and other antimicrobials when compared to single-species biofilms (135, 136). Using a

three-species mixed culture, Liu et al. showed that the presence of *V. parvula* negated the growth inhibition of *S. mutans* caused by peroxigenic *S. gordonii* (137).

In addition to bacteria, the oral cavity is also colonized by yeasts. *Candida albicans* in particular is frequently found in the oral mucosa. Interestingly, *C. albicans* is often associated with *S. mutans* and detected in high numbers in cases of early childhood caries (138). Recent studies have shown that the *S. mutans* GtfB enzyme binds to mannan receptors on the *C. albicans* surface, leading to enhanced adherence and biofilm accumulation by *C. albicans* and thereby enhancing biofilm formation and cariogenicity (139, 140). At the same time, *C. albicans* synthesizes farnesol, which enhances extracellular polysaccharide production by *S. mutans* (52). In a rat caries model, coinfection with *S. mutans* and *C. albicans* led to higher levels of microbial carriage in plaque biofilms and significantly increased the cariogenic potential of dental plaque, resulting in aggressive disease onset and rampant caries lesions (140).

S. MUTANS AS A MODEL ORGANISM: SHIFTING LONG-STANDING PARADIGMS

Key advances in the field of bacteriology have come from studies with *Escherichia coli* and *Bacillus subtilis*, which represent the Gram-negative and Gram-positive bacterial paradigms, respectively. Despite the important contributions of these two species to bacteriology research, no model organism is a perfect representative of other species. In the case of Gram-positive organisms, *B. subtilis* is a free-living sporulating organism found in soil and plants but not in humans. Conversely, *S. mutans* is an obligate human pathogen with a biofilm-dependent lifestyle. It does not come as a surprise that a greater overlap in the mechanisms of gene regulation and metabolic pathways are observed between *S. mutans* and related Gram-positive pathogens that share a host-associated lifestyle. Such organisms, like *S. mutans*, generally have compact genomes with low GC contents. Like *E. coli* and *B. subtilis*, *S. mutans* is highly amenable to genetic manipulation and is therefore also easy to study and control in the laboratory setting. Among closely related streptococci, it has the most complete and sophisticated set of genetic tools that can be used in combination with simple and efficient *in vitro* and *in vivo* models to enhance our current understanding of *S. mutans* biology and beyond (141). As a result, a number of *S. mutans* investigations have challenged long-standing bacterial dogmas that were established based on work conducted with *E. coli* and *B. subtilis*. One such example is the signal recognition particle (SRP) pathway involved in cotranslational protein translocation (142). The first clue that protein transport in *S. mutans* differs from the established *E. coli* model came from the identification of an acid-sensitive transposon mutant in which *ffh* encoding the 54-kilodalton homolog of the eukaryotic SRP was insertionally inactivated. Subsequently, all three conserved bacterial elements of the cotranslational translocation SRP pathway, including the particle components Ffh and small 4.5S cytoplasmic RNA, along with the membrane-associated SRP receptor FtsY, were proven dispensable in *S. mutans*. This was noteworthy because the SRP pathway was long believed to be essential for viability in all living cells. An explanation for this surprise lay in the presence in *S. mutans* of two paralogs of the YidC/Oxa/Alb family of membrane-localized chaperone insertases found in bacteria, mitochondria, and chloroplasts. Unlike Gram-negative bacteria, most Gram-positive organisms possess two, if not more, YidC homologs. Another almost universal distinguishing feature between Gram-positive and Gram-negative bacteria, also discovered in *S. mutans*, is the SRP accessory factor YlxM, which interacts with both Ffh and scRNA and influences the GTPase activity of the Ffh/FtsY heterodimer, which is necessary for pathway component recycling once ribosome/nascent protein chain complexes are delivered to the membrane-localized SecYEG translocon (143). Another example occurred during the initial characterization of the enzyme responsible for the synthesis of (p)ppGpp in *S. mutans*, the effector molecule of the bacterial stringent response (see "Signaling Pathways" section). Before the work with *S. mutans*, the bifunctional RelA enzyme (also known as Rsh or Rel) was considered the sole enzymatic source of (p)ppGpp synthesis and degradation in all *Firmicutes*. The serendipitous finding that deletion of *relA* did not abolish (p)ppGpp production in *S. mutans* led to the discovery of two additional enzymes, RelP and RelQ, capable of synthesizing (p)ppGpp (130). Subsequent bioinformatics and genetic analysis revealed that these enzymes are ubiquitous in *Firmicutes*, and they were eventually found in other bacterial species.

S. MUTANS AS A THERAPEUTIC TARGET IN CARIES PREVENTION

While caries is a polymicrobial disease, selective targeting of *S. mutans* in dental biofilms is viewed as a suitable approach for its prevention. This is mainly because the synthesis of insoluble glucans from sucrose by *S. mutans* is central for the formation of a stable biofilm matrix that facilitates bacterial colonization of the tooth surface and, at the same time, serves as a diffusion barrier helping to maintain the acidic milieu within which cariogenic bacteria thrive (144). One of the current lines of thought in dental caries prevention is that it may be possible to halt the development of cariogenic biofilms by selectively targeting *S. mutans* such that the oral microbiome associated with health is not disturbed. Most of the early research conducted in the late 1960s into the 1980s focused on the development of anti-*S. mutans* vaccines. Despite some recent successes in animal models with vaccines containing or encoding single or a combination of antigens (145–148), emphasis on an immunoprophylactic approach has slowed somewhat due to the many challenges in obtaining long-term salivary IgA responses, safety concerns with antistreptococci antibody cross-reactivity, and providing species-specific protection without disrupting related beneficial commensal organisms. Over the past 2 decades or more, a number of natural products, such as propolis (149), curcumin (150), cranberry (151), and green tea extracts (152) among many others, have been shown to be effective against *S. mutans* biofilms and to prevent dental caries, although to date, none of these products has proven to be selective toward *S. mutans*. More recently, antimicrobial peptides (AMPs), small molecules, and probiotics have emerged as promising new approaches for the development of novel anticaries strategies that specifically target *S. mutans*. While AMPs kill bacteria indiscriminately, the selective killing of *S. mutans* by AMPs has been achieved by creating a synthetic peptide that combines a large-spectrum AMP with the *S. mutans*-specific CSP (153, 154). Phase 2 clinical trials recently showed that a single varnish application of one such peptide achieved significant reductions of *S. mutans* in the oral cavity (155). More recently, a small molecule derived from 2-aminotriazole (designated 3F1) was also shown to selectively disperse *S. mutans* biofilms (156). Most importantly, 3F1 was shown to reduce caries without disturbing the oral microbiome in a rat caries model. An alternative approach to combat *S. mutans* and therefore prevent dental caries may be

the use of alkalinogenic bacteria as a probiotic or the use of substrates for such alkalinogenic activities, e.g., arginine, as a prebiotic. This is because some oral bacteria can neutralize plaque pH by producing large quantities of ammonia by metabolizing arginine or urea, thereby creating an environment favorable to health-associated bacteria (157). A promising candidate is a highly arginolytic streptococcal strain, designated A12, isolated from supragingival plaque of a caries-free individual (158). Not only did the A12 strain neutralize acid by metabolizing arginine, but it was also shown to kill *S. mutans* by producing H_2O_2 and to interfere with signaling pathways that control bacteriocin production.

FUTURE PERSPECTIVES

Evidence accumulated over many decades has clearly shown that *S. mutans* is a major agent in dental caries vis-à-vis its capacity to orchestrate changes in the plaque microbiome via EPS and acid production. Thus, continued efforts to elucidate how *S. mutans* senses and responds to environmental cues through interconnected circuits that govern stress tolerance and biofilm formation can facilitate the identification of new targets for caries treatment and prevention. As the biology of *S. mutans* continues to be unraveled, a better understanding of the consequences of genomic and phenotypic heterogeneity among strains is an important area for development. Specifically, how *S. mutans* isolates with different properties contribute to the different stages of disease through synergistic or antagonistic interactions with the microbiome is a largely unexplored area. Future investigations should also consider the role of certain strains of *S. mutans* in systemic infections.

Genetics of *sanguinis*-Group Streptococci in Health and Disease

ANGELA NOBBS AND JENS KRETH

28

INTRODUCTION

Our view of oral streptococci has largely been influenced by the approach taken in the last century to identify etiologic agents of disease. As a consequence, beneficial aspects of streptococcal colonization of the oral cavity were initially overlooked. The first comprehensive analysis of the resident oral microbiota was accomplished in 2005 (1), and with this, a new picture began to emerge. With the availability of high-throughput sequencing techniques and an increased sensitivity in analysis methods, the presence of a defined microbiome associated with oral health has been shown (2). Alongside this, "omics" techniques have revealed that prevalent oral diseases such as caries and periodontal disease are polymicrobial in nature and the result of microbial dysbiosis (3, 4). Even more striking, the metabolic output of these mixed microbial communities seems to be more relevant than their precise microbial composition (4). This is also reflected by the fact that the severity of caries and periodontal disease is heavily influenced by the synergistic interactions of the individual members of the polymicrobial consortium, including metabolic cross-feeding and interspecies signaling with transcriptional adjustment to the metabolic output. Thus, the ecological context of the microbial community seems to be of importance to understanding oral health and disease development. As a consequence, polymicrobial diseases cannot be explained by the behavior of one bacterial species and certainly cannot be treated like diseases that follow Koch's postulates (5–7). Novel approaches to combat oral polymicrobial diseases should therefore focus on the bacterial community that is present in the healthy oral cavity. Since oral streptococci are abundant during initial colonization of the tooth (8, 9), their function is to provide a favorable environment for incorporation of later species and to support accretion of the mature oral biofilm, which in general has a health-protecting function (10, 11).

One of the oral *Streptococcus* species that is repeatedly isolated in great abundance as part of the health-associated microbiome is the initial colonizer *Streptococcus sanguinis* (12–14). Because of the strong association of *S. sanguinis* with oral health, this commensal can serve as a model to understand how an individual species is able to interact with other members of the bacterial community to shape the composition of a benign oral biofilm. *S. sanguinis* is in general classified as a non-spore-forming, catalase-negative, chain-forming coccus. *S. sanguinis* is non-beta-hemolytic but is able to produce a green coloration on blood agar plates, referred to as alpha-hemolysis, which is a consequence of hydrogen peroxide (H_2O_2) production (15). *S. sanguinis* has been placed in the *mitis* group of streptococci based on 16S rRNA sequence analysis; however, it has also been classified in its own group together with *S. gordonii* and *S. parasanguinis* (15). A more recent analysis using the housekeeping genes *rpoB*, *sodA*, *ddl*, and *gdh* showed a more distant relationship with *S. parasanguinis* but confirmed the phylogenetic relationship with *S. gordonii* (16). Here, we present the *sanguinis*-group streptococci in the context of molecular commensalism, highlighting those aspects of their biology that are important for health-associated biofilm development, including polymicrobial interactions and regulatory and mechanistic events (Fig. 1).

MOLECULAR DETERMINANTS OF *S. SANGUINIS* AS A COMMENSAL PIONEER COLONIZER

Initial colonization is intimately linked to the adhesion capabilities of oral streptococci. *S. sanguinis*, together with *S. gordonii*, *S. oralis*, and *S. mitis*, are well adapted for initial colonization. These streptococci express a multitude of bacterial surface proteins, named adhesins, which are able to interact with salivary proteins covering the tooth surface (17–19). *S. sanguinis* seems to be particularly well equipped with adhesins that recognize this salivary pellicle (20). Overall, initial colonization has two important consequences. First, the ecological niche is occupied, which plays a significant role in the process of colonization resistance and the exclusion of potential incoming pathogens. Second, initial colonization shapes the overall composition of the biofilm, since the pioneer colonizer can produce metabolic products or provide a substratum for compatible partner species. Initial biofilm development requires the formation of macromolecular complexes. Complex formation is facilitated through electrostatic interactions of salivary proteins with the tooth surface to form the acquired enamel pellicle, a process that occurs within seconds after a clean enamel surface is exposed to saliva (21). Microbial attachment to the acquired enamel pellicle is then mediated via protein-protein

and lectin-like interactions. The protein content of the acquired enamel pellicle is thus a major determinant of colonization sequence, dictating the strength of microbial adhesion as well as localization, since pellicle proteins seem to differ according to anatomical site (22).

A prominent protein in saliva and the acquired enamel pellicle is α-amylase, which is responsible for the catalytic hydrolysis of starch (23, 24). Amylase-binding proteins have been identified in several oral streptococcal species (24). The best studied is the amylase-binding protein A (AbpA) in *S. gordonii* (25). Mutation of AbpA results in deficient biofilm formation and bacterial adhesion *in vitro* (26). Although the sequenced reference strain *S. sanguinis* SK36 seems to encode an *abpA* homolog in a similar chromosomal context with its accessory sortase, *srtB* (27), its function is currently unknown. Interestingly, *S. sanguinis* is able to bind directly to surface-bound amylase and *vice versa* (24). This function has been shown to be mediated by long filamentous pili organized in a four-gene operon (ssa1631 to ssa1634) that encodes three pilin subunits (PilA-C) and a dedicated sortase (SrtC) for cell-surface anchoring of the pilin structural proteins (28). Pili are relatively long and thin appendages, and the pili of *S. sanguinis* can be as long as 1 μm, as shown by immune-gold staining of PilA (28). This poses a potentially interesting dynamic with AbpA, which is strictly confined to the outer cell surface, as shown for *S. parasanguinis*, also with immune-gold labeling (27). Taking into account that pili are flexible, one could hypothesize that binding to amylase in acquired enamel pellicle is possible even when the molecule is scarce, since the pili could serve as a flexible "arm," latching onto free amylase within saliva. A recent publication demonstrating that amylase in acquired enamel pellicle is actually less abundant than that in saliva (29) is in agreement with this hypothesis, suggesting an advantage of a flexible arm over a rigid arrangement on the bacterial surface. The pili also showed binding to other salivary proteins, and their deletion diminished biofilm formation on saliva-coated surfaces (28). However, the mutant was still able to bind amylase, albeit with lower efficiency (28), suggesting that other surface proteins are also able to bind amylase, possibly the aforementioned AbpA homolog (27). A pilus-bound amylase also offers the advantage of retaining about 50% of its enzymatic function (30). Gaining access to the amylase substrate starch through a flexible pilus would increase the chance for

hydrolysis of the alpha-1,4-glycosidic linkage into glucose, maltose, and maltodextrins, promoting sugar uptake and subsequent metabolism by simply increasing the accessible radius of the cell.

Two major mucins are found in saliva, MUC7 (low molecular weight) and MUC5B (high molecular weight) (31, 32). The majority of mucins are synthesized and secreted by the submandibular and sublingual glands, as well as minor glands located in the palatal, buccal, and labial mucosae. Mucins are heavily glycosylated glycoproteins and form a lubricating, viscoelastic coating on all oral surfaces. They are abundant proteins in saliva and the acquired enamel pellicle (31, 32). Both MUC7 and MUC5B contain sialic acid as a glycoconjugate, and this can be targeted by *S. sanguinis* SK36 sialic-acid-binding adhesin SrpA (33). SrpA contains a subdomain in its binding region that is similar to the V-set Ig-like fold adopted by mammalian Siglecs (sialic acid-binding immunoglobulin-like lectins) (34, 35). Indeed, Siglec-like domains have been identified in potential adhesins of several *S. sanguinis* isolates and other oral streptococci (34). Glycoarray dot blots with human salivary samples and naturally occurring glycoconjugates have demonstrated a high specificity of *S. sanguinis* SK36 SrpA for MUC7 but no binding to MUC5B. This is in contrast to *S. gordonii*, which showed, in general, better binding to several glycoconjugates, including MUC5B and amylase (34), which are known to form a heterotypic complex (36). As mentioned above, amylase and MUC5B seem to be depleted in the acquired enamel pellicle compared to saliva (29), but this was not seen for MUC7. Thus, the specificity of binding to MUC7 within the acquired enamel pellicle may go some way to explaining why *S. sanguinis* seems to be one of the first oral colonizers and is found in greater abundance than *S. gordonii*. The glycoarray also revealed an interesting role for divalent cations Ca^{2+} and Mg^{2+} in the binding of *S. sanguinis* SK36 to MUC7, as well as to other glycoconjugates (34). Chelation of Ca^{2+} and Mg^{2+} decreased binding to several of the tested components. This was also observed with two *S. gordonii* strains (34), suggesting a dominant role for divalent cations in the binding process of not only *S. sanguinis*, but of other oral streptococci to salivary components and the acquired enamel pellicle. This is further supported by the increased abundance of proteins known to bind divalent cations such as Ca^{2+} in the acquired enamel pellicle compared to saliva (29). Interestingly, *S. sanguinis* encodes a surface-associated, dual-function protein that bridges substratum attachment and interactions with divalent cations. SsaB is able to bind to saliva-coated hydroxyapatite through an unknown mechanism (37), but its principal function seems to be the transport of divalent cations (38). While this transport was demonstrated to be specific for Mn^{2+} and Fe^{2+}, playing a pivotal role in oxidative stress defense (38), other divalent cations such as Ca^{2+} and Mg^{2+} might still be able to interact with SsaB to facilitate binding to the acquired enamel pellicle.

Recently, the ability of *S. sanguinis* to be motile on surfaces such as solidified agar has been reported for several strains. Spreading zones after prolonged incubation can be observed around colonies, indicating active movement (39). Whether or not this so-called twitching motility has any function or is used as a means to disseminate within the oral biofilm is not yet clear. However, the *pil* locus that encodes the type IV pilus involved in twitching motility is conserved in most of the sequenced *S. sanguinis* genomes (39), suggesting biological importance.

Overall, *S. sanguinis* does not rely on a single mechanism to bind and establish itself within the acquired enamel pellicle. Rather, the process is elaborate and ensures the role of *S. sanguinis* as a pioneer colonizer. This correlates with the observation that signal peptidase I is required for biofilm development (40). In general, signal peptidases are membrane-bound endo-proteases that cleave the signal peptide portion from the majority of secreted proteins (41). *S. sanguinis* encodes two signal peptidases, SSA_0849 and SSA_0351, which are crucial for biofilm formation. Deletion of SSA_0351 abolishes biofilm formation but does not affect planktonic growth. Although the substrates for signal peptidase processing are not experimentally verified, *in silico* prediction identified 168 potential candidates, including several adhesins (40). Further characterization of signal peptidase-processed surface proteins will most likely identify new proteins involved in the adhesion process.

S. SANGUINIS IN BIOFILM FORMATION

The initial step in biofilm development is attachment, followed by microcolony formation of newly attached cells through growth expansion. This process then leads to a series of ordered and temporal events, in which coadhesion predominates, ultimately resulting in formation of a mature biofilm. The production of extracellular matrix material is a defining step in biofilm development and maturation. Matrix materials include polymers such as carbohydrates, proteins, extracellular DNA (eDNA), and lipids and are collectively referred to as extracellular polymeric substance (EPS) (42). Since EPS is produced by the biofilm inhabitants themselves, specific enzymatic functions and cellular processes are associated with its formation.

Exploiting the intake of dietary sugars, many oral *Streptococcus* species have evolved glucosyltransferases (Gtfs) that hydrolyze sucrose and polymerize the glucose into glucans. These, in turn, promote biofilm development. A single Gtf, GtfP, is carried on the *S. sanguinis* genome, which synthesizes mainly water-soluble α-1,6-linked glucans that branch at α-3,6-linked glucose residues (43). The TetR family regulator BrpT was recently identified as a repressor of *gtfP* expression. While a *gtfP* mutant formed only a fragile biofilm, the biofilm formed by the *brpT* mutant was thicker, more robust, and had a higher glucan content (44). By modulating the levels of glucan synthesis, BrpT may control the switching of *S. sanguinis* biofilms from an adherent to a dissemination state. *S. gordonii* also carries a single *gtf* gene, *gtf*G, encoding an enzyme that synthesizes both α-1,3- and α-1,6-linked glucans. This activity was found to promote mixed biofilm formation with *Candida albicans* (45), and a *gtf*G mutant was unable to persist on the tooth surface in rats (46). Expression of GtfG is under the positive regulation of Rgg (47), a homolog of which is present in *S. sanguinis*. As for other oral streptococci, it is likely that expression of Gtfs and thus the glucan content of biofilms is a tightly controlled process, affected by multiple factors and transcriptional regulators.

Compared to carbohydrates, the presence of eDNA within EPS is a relatively recent discovery. Nonetheless, growing evidence suggests that eDNA is a critical contributor to cell-to-cell adherence and overall biofilm stability (48). Courtesy of its negative charge, eDNA may facilitate association with the acquired salivary pellicle (49), and cell aggregation was shown to be promoted by eDNA for *S. sanguinis*, although not for *S. gordonii* (50). Visualization of "yarn" and "sweater" structures of eDNA that wrap around cells within *Enterococcus faecalis* biofilms (51) provides compelling evidence for how eDNA may contribute to the

structural integrity of biofilms, and similar structures have been seen for biofilms of *S. gordonii* (A.H. Nobbs, unpublished data). Moreover, eDNA regulates the viscoelastic properties of biofilms that allow them to withstand mechanical stress (52), a property that is particularly pertinent to the oral cavity environment. In line with this, the presence of DNABII proteins within the EPS of *S. gordonii* and other oral bacterial biofilms was recently found to be essential for eDNA integrity and biofilm structure (53). The regulation of eDNA release is not fully understood, and both lytic and active mechanisms have been reported. For *S. sanguinis* and *S. gordonii*, the autolysins LytF and AtlS play significant roles via mechanisms closely linked to H_2O_2 production and competence development. These are discussed in more detail below.

Multicellular entities such as biofilms require a high level of coordination, and quorum sensing (QS) circuits and two-component signaling systems (TCS) are intimately involved in these processes. One QS system found across several bacteria is LuxS/AI-2. LuxS is an integral component of the activated methyl cycle for correct methylation of nucleic acids and proteins but as a by-product of this cycle generates autoinducer 2 (AI-2), an interspecies chemical signal. LuxS mutants in *S. gordonii* and *S. sanguinis* were altered in their ability to form biofilms, and the lack of AI-2 resulted in altered *S. gordonii* microcolony architecture (54). However, a definitive role for AI-2 has not been identified, and for *S. sanguinis*, a disrupted activated methyl cycle rather than an absence of AI-2 was found to underpin the *luxS* mutant biofilm phenotype (55). A TCS associated with regulation of biofilm formation for both *S. sanguinis* and *S. gordonii* is BfrAB (56). This TCS modulates expression of two ABC transporters (BfrCD and BfrEFG) and a putative membrane-bound metalloprotease (BfrH). Given such functions, it is postulated that this system transports and processes proteins or peptides across the cell membrane that promote biofilm development, although the precise targets have yet to be identified. More recently, defects in the TCS SptRS have been found to promote biofilm formation by *S. sanguinis*, which is associated with elevated levels of H_2O_2 and eDNA (57), while stand-alone ArcR was identified as a key regulator of *S. gordonii* biofilm development, perhaps via modulation of the phosphotransferase system (58).

A final aspect of streptococcal biology that is closely associated with biofilm formation is competence development. This is a QS system that controls transformation, i.e., the capacity for bacteria to actively take up exogenous DNA, and in species such as *S. sanguinis* and *S. gordonii*, this is regulated via the *comCDE* operon (59, 60). The gene *comC* encodes a precursor molecule that is cleaved and exported via the ABC transporter ComAB, releasing the mature competence-stimulating peptide (CSP) into the local environment. For *S. gordonii* this is a 19-amino acid peptide, while the CSP of *S. sanguinis* has 17-amino acid residues, thereby minimizing interspecies cross-talk. The CSP is sensed by the TCS ComDE. Once the CSP pheromone exceeds a threshold concentration, ComD phosphorylates ComE, which upregulates expression of early competence genes, including *comCDE* and *comAB*, establishing a positive feedback loop, and *comX*. ComX then drives expression of the late competence genes required for DNA binding, uptake, and recombination. The coordination of competence and biofilm development contributes to the adaptability of bacteria such as *S. sanguinis* to changing environmental conditions via horizontal gene transfer. This is explored in more detail below.

S. SANGUINIS IN COMMUNITY DEVELOPMENT

S. sanguinis and *S. gordonii* can form monospecies biofilms, but within the host the biofilm communities are typically polymicrobial in nature. As pioneer colonizers, these streptococci can have profound consequences for niche occupation and subsequent colonization by incoming species and thus significantly influence whether a community is predisposed to health or disease. Such interactions do not occur at random but, rather, are directed in an ordered and temporal manner as a consequence of direct physical engagement (coadhesion), metabolic relationships, and interspecies communication.

Alongside streptococci, *Actinomyces* species constitute the predominant, health-associated early colonizers of the oral cavity, and both *S. sanguinis* and *S. gordonii* are able to coadhere with *Actinomyces oris*. This is mediated by recognition of the streptococcal receptor polysaccharide (RPS)-containing linkages GalNAcβ1-3Gal or Galβ1-3GalNAc by the FimA subunit of *A. oris* type 2 fimbriae (61, 62), with variations in the genetic loci for synthesis of RPS (*rps*) and RPS precursors (*rml*, *galE1*, *galE2*) subtly altering the coadhesion profile with different streptococcal species (63). In addition, the *S. gordonii* antigen I/II family protein SspB targets an extracellular polysaccharide produced by *A. oris*, although the precise composition and structure of this polysaccharide has yet to be determined (64). Once bound, *A. oris* may then promote *S. gordonii* survival under low arginine conditions by stabilization of arginine biosynthesis (65). Similarly, *S. gordonii* adhesin Hsa binds surface receptor Hag1 of early colonizer *Veillonella* species (66), but this interaction is also underpinned by a strong metabolic dependency. Lacking a fully functional glycolytic pathway, veillonellae must utilize hydroxyl acids for growth. These are provided by streptococci as the excreted metabolic waste product lactate, and utilization of lactate, in turn, protects streptococci from low pH (67). Once established, this community of pioneer colonizers then supports the incorporation of secondary or late colonizers, with *Fusobacterium nucleatum* serving as an important "bridging" organism due to its promiscuous coadhesion capabilities. *S. sanguinis* supports this engagement via interaction with the arginine-inhibitable adhesin RadD of *F. nucleatum* (68), while a second fusobacterial outer membrane protein, coaggregation-mediating protein A (CmpA), has recently been shown to promote biofilm formation with *S. gordonii* (69).

These community interactions with compatible species illustrate how *sanguinis*-group bacteria are able to promote development of a health-associated microbiota. Nonetheless, the social life of these bacteria is not exclusively beneficial, and other microbial partnerships may facilitate a more disease-prone state. Such examples have been described largely for *S. gordonii* rather than for *S. sanguinis*, leading to the designation of *S. gordonii* as an "accessory pathogen." Some of the best-characterized interactions are with the periodontopathogens *Porphyromonas gingivalis* (70, 71) and *Aggregatibacter actinomycetemcomitans* (72) and with the fungal pathogen *C. albicans* (73). Evidence from *in vitro* studies and animal models shows that these relationships can enhance both the persistence and virulence potentials of the microbes involved (74).

Chemical communication in modulation of the oral microbial community is exemplified by the complex effects of the interspecies signaling molecule AI-2. This molecule promotes dual-species biofilm formation between *S. gordonii* and *S. oralis* but can also modulate the relative proportions of these species in a concentration-dependent manner (75).

Likewise, while AI-2 from *F. nucleatum* promotes biofilm development with *S. gordonii*, it has the opposite effect on *S. oralis* (76). AI-2 from *S. gordonii* is essential for mutualistic biofilm growth with *A. oris* (77) but may also promote biofilm formation with *P. gingivalis* (78) and *C. albicans* (79). Ultimately, QS molecules and peptide pheromones work together with the molecular mechanisms described above to exquisitely coordinate biofilm development. The result is a community optimized to survive and persist under the prevailing environmental conditions in a manner that exceeds the capabilities of the individual component species.

COMPETITIVE BEHAVIOR: INHIBITION BY *S. SANGUINIS* H_2O_2 AND BACTERIOCIN PRODUCTION

Addressed above are examples of synergistic interactions with *sanguinis*-group streptococci that promote incorporation and retention of the partner microbes within the biofilm community. Nonetheless, within a defined ecological niche, resources are limited, and thus, competitive forces also work to shape the developing biofilm. One of the best-investigated competitive measures of *S. sanguinis* (and the vast majority of oral streptococci) is the production of H_2O_2 (80). The enzyme responsible for the production of H_2O_2 is pyruvate oxidase, SpxB (81, 82). SpxB is encoded by the majority of commensal oral streptococci, with an unusually high degree of conservation of over 96% amino acid identity compared to SpxB of *S. sanguinis* strain SK36. SpxB catalyzes the conversion of pyruvate to acetyl phosphate, CO_2, H_2O_2, and ATP. Therefore, besides generating inhibitory amounts of H_2O_2, SpxB confers a growth advantage on the producer via ATP generation during biofilm development (81, 82).

The overall importance of H_2O_2 production is further indicated by the fact that neither *S. sanguinis* nor *spxB*-encoding oral streptococci seem to encode for the H_2O_2 detoxifying enzyme catalase. Consequently, these bacteria are able to produce considerable amounts of H_2O_2 that can influence the surrounding environment and inhibit susceptible species. H_2O_2-dependent competitive behavior faces two challenges. First, SpxB requires oxygen for its activity (83, 84). Its production therefore declines once biofilm formation reaches a certain density resulting in an anaerobic environment. Second, released H_2O_2 is a substrate for detoxifying enzymes such as salivary lacto-peroxidase (85). Therefore, the effect of H_2O_2 production on biofilm development is confined to the immediate vicinity of the producer and most likely does not result in active killing of competitors. Rather, H_2O_2 affects susceptible species just enough to gain a growth advantage. For *S. sanguinis*, the oxygen-dependent production of H_2O_2 makes perfect sense from an ecological point of view. As the initial colonizer, *S. sanguinis* finds a sparsely inhabited environment with enough salivary oxygen tension to promote H_2O_2 production (86). However, once biofilm growth through proliferation and integration of compatible species is sufficient to result in a decline in oxygen tension, *S. sanguinis* is already an established member of the community, so H_2O_2 production is no longer required (80). The inhibitory spectrum of H_2O_2 as evaluated *in vitro* with deferred antagonism plate assays includes cariogenic *S. mutans*, as well as the periodontopathogens *A. actinomycetemcomitans*, *Prevotella intermedia*, and *P. gingivalis* (83, 87).

The genetic regulation of *spxB* expression holds a mystery. A clear repressive function of the carbon catabolite repressor CcpA has been shown since deletion of CcpA in *S. sanguinis* strain SK36 lifts *spxB* repression (88). Further, two *cre* (carbon responsive element) sites for the binding of CcpA have been verified experimentally (89), yet no glucose effect on *spxB* expression and H_2O_2 production can be observed. This is in contrast to other species such as *S. gordonii*, which follows classic carbon catabolite repression in the presence of glucose (90). Why CcpA in *S. sanguinis* does not respond to the presence of glucose, and if any environmental factor influences *spxB* expression, has yet to be determined. Compared to *S. gordonii* and other oral streptococci, *S. sanguinis* H_2O_2 production in general seems to be lower (89, 91), and a clue to the consequences of low H_2O_2 production and tight control by CcpA might be the increased susceptibility of a *S. sanguinis* CcpA knockout mutant toward its own H_2O_2 production (88). However, whether or not this is a direct effect of H_2O_2 or the result of altered gene expression from other CcpA-controlled genes is not known. From an ecological standpoint, the numerical abundance of *S. sanguinis* over other species might not require high production of H_2O_2, while other species such as *S. gordonii*, which is known to be a less prominent member of the oral biofilm, might require more aggressive H_2O_2 production to establish themselves within the oral community. Taking into account that oral streptococci intermingle during biofilm formation and can be found at the same location (92), the sum of H_2O_2 production could be more important than the quantity produced by individual species. Nevertheless, competitive H_2O_2 production and its role in community development is important and can be used to study biofilm dynamics.

Interestingly, *S. sanguinis* is also able to produce antimicrobial activity via bacteriocins. Several reports describe the antimicrobial activity of sanguicins (93, 94). Initial characterization showed bacteriostatic activity against a number of oral species, including *Actinomyces naeslundii*, but not against the periodontopathogens *P. gingivalis*, *P. intermedia*, and *F. nucleatum* (53). However, a more recent study using purified sanguicin demonstrated antimicrobial activity against such pathogens (93). Since both studies used a different strain of *S. sanguinis* and reported different molecular weights (65,000 Da versus 280,000 Da) for the purified peptide, it is most likely that different sanguicins were characterized. It is also worth mentioning that none of the studies determining the effect of H_2O_2 on periodontopathogens or *S. mutans* reported an inhibitory effect when catalase was added to the deferred antagonism assay (87, 95). Therefore, either strain-specific antagonistic activity exists or the culture conditions used in the studies were selective for specific production of bacteriocins or H_2O_2.

S. sanguinis bacteriocins are also reported to exhibit antifungal activity (96, 97). As part of the normal microbiota, *C. albicans* is commonly isolated from subjects but can also cause problems such as oral candidiasis (98). *S. sanguinis* produces a bacteriocin that can cause changes in the cell surface hydrophobicity of several *Candida* spp., a factor that influences the initial adhesion of *Candida* to oral epithelium. Furthermore, the bacteriocin can impair fungal cell membrane permeability and general cell structure (96, 97). How this ultimately affects survival of the fungal cell *in vivo* is not known, but analogous to the effect of H_2O_2 production, it might provide a competitive advantage to *S. sanguinis* by impairing the growth of competing oral fungi.

HORIZONTAL GENE TRANSFER AND THE ANTIBIOTIC RESISTANCE RESERVOIR

An important feature of oral streptococci is the ability to take up eDNA when developing competence, as discussed above.

While the process of competence development is well characterized at the molecular level (99), the origin of DNA in the environment and the molecular mechanisms of DNA release from bacterial cells are less well understood. As a vital part of the oral biofilm matrix, the eDNA available for uptake by competent bacteria is quite abundant (100, 101). In general, cell lysis can contribute to the release of DNA from bacterial cells. This process can be an active autolysis process involving murein hydrolases that weaken or completely lyse the cell wall, consequently expelling DNA into the environment (102). Interestingly, both *S. sanguinis* and *S. gordonii* release DNA in an H_2O_2-dependent manner under aerobic conditions (83). The eDNA is largely intact, high-molecular-weight DNA of chromosomal origin. Release of eDNA peaks when *S. sanguinis* grows aerobically under optimal H_2O_2-producing conditions, and release declines when cells are grown under oxygen-limiting conditions, when no H_2O_2 is produced. Furthermore, deletion of *spxB* severely impacts the release (83). However, eDNA release can be induced even under anaerobic conditions with the addition of H_2O_2, as shown for *S. gordonii*, but only when cells are metabolically active (103). The addition of H_2O_2 to cells suspended in buffer does not release DNA, indicating the requirement for active metabolism, gene expression, or protein synthesis. This is also consistent with the observation of a time delay between the production of H_2O_2 and the appearance of the released DNA and with the evidence that the addition of chloramphenicol, known to block synthesis of new proteins, also blocks release of DNA (103). This is relevant in the context of the oral biofilm, where SpxB-positive streptococci that have access to oxygen can produce H_2O_2 that might then diffuse through the oral biofilm with limited or no oxygen. Remarkably, the H_2O_2-dependent release of DNA is not the result of obvious cell lysis (50), as reported for other streptococci such as *S. pneumoniae* (104). Although the exact molecular mechanism involved in the release is not known at this moment, *S. sanguinis* might encode a dedicated system for eDNA release. This could involve partial lysis and/or active transport across the membrane. In a recent study, the transport of eDNA in *Haemophilus influenzae* was found to be dependent on the competence-related protein ComE (105), the transporter involved in the uptake of DNA. *S. sanguinis* encodes for ComE, and intriguingly, expression of competence genes seems to increase under aerobic conditions ideal for H_2O_2 production in streptococci (83, 103). However, experimental evidence that this mechanism is conserved in *S. sanguinis* is not available. Under anaerobic conditions, eDNA release is not completely absent, suggesting another mechanism involved in the release (50). One autolytic enzyme involved in this process in *S. sanguinis* is LytF, which is also under the control of the competence system as one of the early competence genes (106). LytF is a secreted autolysin and can be recovered from the environment in its active form. LytF is a fratricin but also acts on neighboring cells, causing release of eDNA not only from *S. sanguinis* but also from other streptococci (106). In general, streptococci seem to control or connect competence development with the release of eDNA (107), exemplifying their role as masters of efficacy. Utilizing this approach increases the chance that DNA is available for uptake and transformation.

Uptake of eDNA has two pronounced functions; first, it serves in horizontal gene transfer during bacterial transformation and therefore plays a pivotal role in the promotion of diversity among oral bacterial species, and is an important mechanism of evolution allowing the acquisition of new genetic traits stored in the genomic information contained in the multispecies biofilm (108). Second, eDNA in the oral cavity can serve as a reservoir for diverse antibiotic resistance mechanisms (109). A recent comparison of *S. sanguinis* and *S. gordonii* genomes revealed the presence of several genes potentially associated with antibiotic resistance determinants, including GCN5-related *N*-acetyltransferases, *parE*, and TetR family regulators (110). Combined, they potentially provide resistance to diverse antibiotics such as aminoglycosides, fluoroquinolones, and many more. Additionally, several genes were identified that encoded anion channels in *S. sanguinis* that confer resistance to fluoride (111), which is particularly important since fluoride is successfully used to prevent caries. Although the direct transfer of antibiotic resistance determinants via eDNA from other species to *S. sanguinis* has not been confirmed, evidence exists that, in general, the acquisition of new genetic traits occurs. For example, the pathway for vitamin B_{12} biosynthesis as well as the degradation of ethanolamine and propanediol, which is encoded on a large genomic region, has been acquired through horizontal gene transfer (112), although it is unknown if this was mediated through conjugation, transduction, or transformation. The best evidence for the potential of H_2O_2-induced transfer of antibiotic resistance was shown with *S. gordonii* using engineered strains carrying antibiotic resistance cassettes. Coincubation of strains encoding distinct antibiotic cassettes under ideal H_2O_2-producing conditions increased the occurrence of intraspecies genetic exchange by 300-fold compared to nonpermissive conditions (103). Overall, antibiotic resistance in the oral biofilm seems to be mainly acquired through horizontal gene transfer as suggested by a recent review (113). The dental biofilm is an ideal environment for the development and transfer of antibiotic resistance, even under conditions where no external pressure through antibiotic administration is present. This is supported by the finding that biofilm evolution and selective pressure through competitive bacterial interactions mediated by bacteriocins alone gave rise to antibiotic resistance (114). The oral microbiome is able to elicit this evolutionary pressure due to the abundance of bacteriocins (115).

S. SANGUINIS AS A MODULATOR OF THE HOST

While the predominant ecological niche of *S. sanguinis* is the tooth surface, dental plaque formed at the gingival margin brings the oral biofilm into contact with the oral epithelium and associated immune defenses. The host-microbe interplay that occurs at these sites represents a critical step in determining progression of the biofilm community below the gum line and potential transition from oral health to the onset of gingivitis, periodontitis, or other disease manifestations. Another facet of *S. sanguinis* as a coordinator of the microbial community is therefore its interactions with host tissues.

Under conditions of oral health, an equilibrium exists between microbiota and host, representing a delicate balance of antimicrobial factors from immune cells, together with pro- and anti-inflammatory molecules released from the host in response to the sustained microbial challenge. In contrast, disruption of this homeostasis is the hallmark of chronic inflammatory periodontal disease and resultant tissue damage. In keeping with this, *S. sanguinis* biofilms were found to be a poor stimulant of the proinflammatory cytokines interleukin-1α (IL-1α), IL-6, and IL-8 from OKF4 oral epithelial cells compared to biofilms of *F. nucleatum* (116). Likewise, in contrast to cell wall extracts of *F. nucleatum* or

P. gingivalis, those of *S. sanguinis* failed to induce significant upregulation by gingival keratinocytes of genes encoding human β defensin peptides, proinflammatory cytokines (e.g., IL-8), or matrix metalloproteinase-9. These keratinocyte responses were mediated by Toll-like receptor 2, with differences in acylation patterns of bacterial lipopeptides purported to underpin the differential outcomes of Toll-like receptor 2 stimulation by the bacterial species (117). Moreover, while only a weak stimulant of host responses itself, *S. sanguinis* is also able to suppress the effects of other microbes. In mixed culture, *S. sanguinis* impaired induction of IL-8 release from gingival HOK-18A epithelial cells by *A. actinomycetemcomitans*. Such effects were also seen with *S. sanguinis* spent culture medium alone, suggesting a secreted molecule as the mediator (118). Similarly, through blocking lipopolysaccharide engagement with the monocyte receptors lipopolysaccharide-binding protein and CD14, peptidoglycan from *S. sanguinis* was able to inhibit induction of genes encoding tumor necrosis factor-α, IL-6, and IL-8 by the periodontopathogens *P. gingivalis*, *A. actinomycetemcomitans*, and *Tannerella forsythia* (119). This mechanism correlates well with the observation that Gram-positive bacteria release large quantities of peptidoglycan fragments, muropeptides, during cell division (120). Such coordination of both host responses and the oral microbiota is likely critical to the role of *S. sanguinis* as a health-associated member of the oral biofilm community.

S. SANGUINIS AS AN ETIOLOGICAL AGENT OF EXTRAORAL DISEASES

Despite its main role as a benign oral commensal, the name *S. sanguinis* derives from its role in cardiovascular disease infective endocarditis (IE). In a note to the *Journal of Bacteriology*, Niven and White described a new species isolated from approximately 100 cases of subacute bacterial endocarditis (121). About one-third of the isolates failed characterization as previously described streptococci and were referred to as *Streptococcus* s.b.e. (for subacute bacterial endocarditis) (121). Overall, the group was quite homogeneous in its physiological characteristics (122). Further serological characterization confirmed the isolation of a new species since no cross-reactivity was observed between rabbit serum from *Streptococcus* s.b.e. and other identified streptococci belonging to various Lancefield groups (123). Interestingly, isolation of *Streptococcus* s.b.e. from the human throat was unsuccessful at that time, despite testing over 800 streptococcal isolates. The only other positive culture came from an extracted tooth, which we now know coincides with the preferred colonization site. However, in the original publication, the natural habitat was not identified, and the only source was from the blood of endocarditis patients; hence the species name *sanguis*, Latin for "blood" (122, 124). This has been changed fairly recently to the grammatically correct version, *S. sanguinis* (125).

IE is a relatively rare but potentially fatal disease and can affect the heart valves or endocardium. The annual incidence ranges from 3 to 7 cases per 100,000 people and has been relatively constant, whereas the etiology of IE has changed over time (126, 127). A major concern with this disease is that mortality rates remain high; the in-hospital mortality rate ranges from 15 to 22%, with a 5-year mortality rate of around 40%. Currently, *Staphylococcus aureus* is the most common pathogen associated with IE. However, oral streptococci are responsible for an estimated 35 to 40% of cases, with *sanguinis*-group species being the most common isolates (128).

Our understanding of the molecular mechanisms that might contribute to the capacity for *S. sanguinis* to cause IE has benefited from the availability of an excellent animal model for IE. New Zealand white rabbits can be catheterized at specific sites of the heart, causing injury-induced IE after bacterial blood inoculation (129). The injury provides exposed extracellular matrix components, fibrin, and platelets for attachment of the bacterial cells and subsequent aberrant clot formation, which leads to infective vegetations forming on the heart valves. Todd Kitten's group at Virginia Commonwealth University has used this model to decipher molecular determinants expressed by *S. sanguinis* during the infection process. Using a random signature-tagged mutagenesis approach, six chromosomal loci were identified from an initial screen of 800 mutants. The mutants carried transposons in an intergenic region and in genes encoding undecaprenol kinase, homoserine kinase, anaerobic ribonucleotide reductase, adenylosuccinate lyase, and a hypothetical protein (130). The screening method is elegant but has some technical limitations, since important determinants such as surface-exposed proteins, which have been shown to contribute to the infection process (131), were missed. Nonetheless, the identification of determinants regarded as housekeeping genes involved in cell wall (undecaprenol kinase), amino acid (homoserine kinase), and nucleic acid (ribonucleotide reductase) synthesis suggested a potential role for these genes in pathogenesis that had not previously been appreciated. Furthermore, since these genes are not found in humans, they may represent potential targets for drug development. However, a functional analysis of the clonal structure of *S. sanguinis* strains isolated from the oral cavity and from subjects with IE demonstrated that housekeeping and virulence genes are subject to considerable intraspecies recombination events. Thus, potential drug targets in such genes may correlate with a high potential for the selection of resistant mutants (132). Interestingly, the same study also concluded that the endocarditis strains did not form a distinct subcluster. This supports the notion that *S. sanguinis* strains are human pathobionts, and thus all strains have the potential to cause IE (132).

Following from this study, a targeted signature-tagged mutagenesis approach was employed to identify surface proteins important in IE. A total of 33 proteins were classified as cell wall associated, and of these, mutants in 31 were tested in the aforementioned rabbit model of IE, alongside mutants in 3 sortase genes (133). Interestingly, no single cell wall-associated protein was found to be essential for the development of IE (133). It may be concluded from this that *S. sanguinis* does not require any specific virulence determinants to cause IE. Rather, what is expressed and present during colonization of the oral cavity may be sufficient to colonize the endocardium. In support of this, the surface adhesins Hsa, PadA, and SspA/B from *S. gordonii* have been implicated in IE through their engagement with platelets but also contribute to the capacity for *S. gordonii* to bind salivary pellicle and other oral microbes (134–137). Such highly optimized genomes might explain the success of these bacteria as early colonizers, with their ability to cause IE on rare occasions coincident in their ubiquitous presence and abundance within the oral cavity.

Mutations in the genes encoding lipoprotein SsaB (a putative manganese transport protein) (38), *spxA1* (encoding a global regulator involved in H_2O_2 production) (138), and *nox* (encoding an NADH oxidase that also influences H_2O_2 production) (139), together with the anaerobic ribonucleotide reductase already mentioned, have all been

shown to impair the capacity of *S. sanguinis* to cause IE. This suggests that the ability of *S. sanguinis* to adapt to differences in oxygen tension and the production of and resistance to reactive oxygen species are important in the development of IE, although molecular details have yet to be explained. A surface-bound nuclease designated SWAN (streptococcal wall-anchored nuclease) has also been proposed to enable *S. sanguinis* to evade killing by neutrophil extracellular traps and thus to promote survival both in the bloodstream and within infective vegetations (140).

Surviving within the bloodstream to access extraoral sites and inducing thrombosis are key steps in IE, but these capabilities also associate *S. sanguinis* with other systemic diseases. These include meningitis, following infection of the lining of the spinal cord or brain, and disseminated intravascular coagulation, in which aberrant activation of the coagulation cascade leads to the formation of small clots that can occlude blood flow to major organs and tissues (141, 142). It is also widely recognized that oral streptococci such as *S. sanguinis* exist in biofilm communities with *Pseudomonas aeruginosa* in the lungs of cystic fibrosis patients. However, with evidence that H_2O_2 production by these streptococci can impair *P. aeruginosa* growth (143), the impact of *S. sanguinis* on cystic fibrosis disease progression remains to be fully understood.

CONCLUSION AND OUTLOOK

Considering the impact on the individual, it is easy to understand why disease outcomes have historically dominated microbiological research. Nonetheless, technological advances are providing a growing appreciation for the importance of our resident microbiota. Within the oral cavity, bacteria such as *S. sanguinis* are ubiquitous and abundant, reflecting their evolution to be exquisitely adapted to colonization of their ecological niche. As a consequence, *S. sanguinis* is able to orchestrate accretion of the dental plaque biofilm, promoting the acquisition of beneficial microbes while serving as an imposing competitor to others and ultimately providing the foundation of a health-associated biofilm community. Complex molecular mechanisms regulating physical interactions and communication networks underpin these capabilities. If these can be understood at both the molecular and ecological levels, they offer immense potential for exploitation in the development of novel strategies to combat infections from a point of health as opposed to disease.

Genetics of Lactococci

PHILIPPE GAUDU, YUJI YAMAMOTO, PETER RUHDAL JENSEN, KARIN HAMMER, DELPHINE LECHARDEUR AND ALEXANDRA GRUSS

29

INTRODUCTION

Lactococci have been used for centuries in dairy fermentation. These Gram-positive, generally nonpathogenic, nonmotile, and nonsporulating bacteria are members of the *Streptococcaceae* family, which includes food, commensal, and virulent species (Fig. 1). *Lactococcus lactis* is a relatively simple bacterium, with a 2.4-Mbp genome. Many of its functions of interest are nonredundant, which facilitates functional genetic studies of nonessential genes. Lactococci are presumed to be devoid of virulence factors (although isolated cases of *L. lactis* as the infectious agent in human and bovine infections have been reported [1, 2]). The goal of this article is to confront previous and current information in different areas of lactococcal genetics, keeping in mind the relevance of findings to related bacteria, especially pathogens. Work on pathogens has long focused on surface and secreted virulence factors, while work on lactococci has gone deeper in characterizing basic metabolic properties, nutrient uptake, and survival. Genes in basic metabolic pathways (e.g., respiration, metal homeostasis, amino acid metabolism) are now known to be essential not only for fitness but also for virulence. Numerous *Lactococcus* researchers who shifted their focus to pathogens have contributed to this understanding. The overall nonvirulence of lactococci has also been useful in determining how metabolic and virulence factors participate in bacterial "everyday life" outside the animal host. Our deep knowledge of *L. lactis* physiology has led to new concepts and general findings, for example by (i) establishing the bases for dialog between *Firmicutes*, (ii) providing concrete *in vivo* data on the biomedical or probiotic potential of recombinant and wild-type lactic acid bacteria (LAB) (3, 4), and (iii) establishing the existence of an inverse correlation between bacterial mRNA concentration and stability (5).

This article, organized in five sections, highlights major work in lactococci, including metabolic capacities, physiology, stress response, interbacterial effects, and studies leading to novel uses of lactococci for protein delivery or as probiotics. Prophages have a primordial role in fermentation processes, genetic diversity, expression, and cell lysis; this important area of research, including abortive infection mechanisms, is not a focus of this review (see 6–12). Comparative *L. lactis* genome organization analyses are considered in references 13 and 14 and references therein.

The first section, "Basic Features of Lactococci," presents a primary description of *L. lactis* and its relationship to other *Streptococcaceae*. The next section is "Metabolic Options for Lactococci." Because lactococci are industrial bacteria, the study of them has focused on optimizing growth and flavor production during fermentation. Lactococci shift to a respiration metabolism when provided with an exogenous heme source. Metabolic flexibility provides a valuable prototype for the lifestyle of other LAB and certain streptococcal pathogens, which respire when supplied with heme and menaquinones. Nitrogen metabolism is extensively studied in *L. lactis*, because it determines the capacity to grow in dairy medium for food fermentation. Remarkably, nucleotide metabolism coordinates intracellular pools with the envelope state. The third section is "Lactococcal Stress Responses." Lactococci, though largely consumed through fermented foods, have been considered noncolonizers of the animal host. Lactococci express numerous and diverse factors that allow bacteria to respond and survive in a crowded or hostile environment and were identified by simple selective systems. Unique structures discovered on the lactococcal envelope (pellicles and pili) may extend survival in harsh environments, notably the gut, and narrow the divide between food bacteria and pathogens. The fourth section, "*L. lactis* and Interbacterial Dialogue" discusses how lactococci impact expression and/or development of other bacteria in their biotopes, including pathogens. Several findings may prove valuable when considering the roles of cognate functions in pathogens. The last section is "Applications and Tools of Lactococci." Lactococci are useful bacterial vectors for biomolecule delivery. Protein expression systems were developed in lactococci for applications in biotechnology and have been used for expression in related low-GC-content Gram-positive bacteria, including pathogens; remarkably, some of them have stayed in use for over 25 years. As a simple nonpathogen, *L. lactis* is a useful host for separating potential virulence factors from pathogenic bacteria and analyzing their roles. While medical applications have not been marketed, numerous proof of concept studies show the feasibility

doi:10.1128/microbiolspec.GPP3-0035-2018

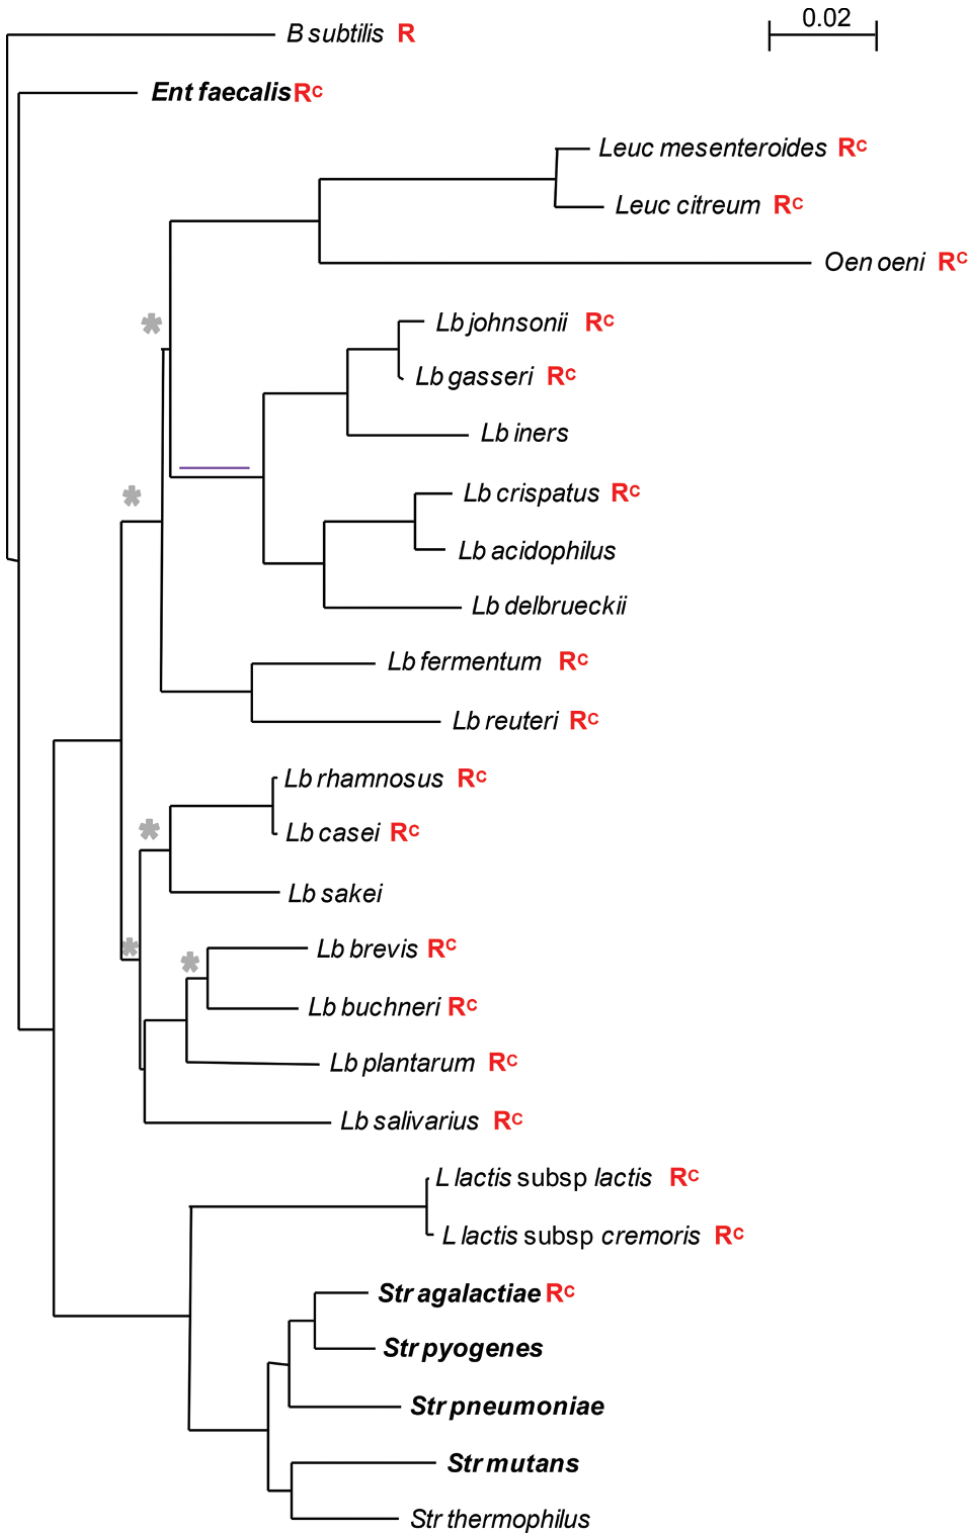

FIGURE 1 The phylogenetic tree reveals similarities between lactococci and streptococcal pathogens. A phylogenetic tree built on 16S sequences was constructed directly on the Ribosomal Database interface (210). Branches with a bootstrap value below 60% are indicated with an asterisk. Respiration capacity (see text) is indicated by a red R. R^c indicates conditional respiration: for *L. lactis*, *E. faecalis*, and *Leuconostoc* spp., aerobic respiration is activated by exogenous heme. For all *Lactobacillus* spp. and *S. agalactiae*, respiration is activated by exogenous heme and menaquinone. Opportunist pathogens are indicated in bold. *B subtilis*, *Bacillus subtilis*; *Ent*, *Enterococcus*; *Leuc*, *Leuconostoc*; *Oen*, *Oenococcus*; *Lb*, *Lactobacillus*; *Str*, *Streptococcus*. This figure is based on reference 155.

of using *L. lactis* or other LAB as biomolecule delivery vectors (see 15 and 16 for reviews).

BASIC FEATURES OF LACTOCOCCI

What Is *L. lactis*?

LAB are named for their ability to produce lactic acid via fermentation metabolism. *L. lactis* is a mesophilic LAB with an optimal growth temperature of ~30°C. It is the most extensively characterized of the LAB, which comprise a highly diverse group (Table 1, Fig. 1), including various cocci and bacilli. However, the term "LAB" is misleading, because although "LAB" generally refers to bacteria used in food fermentation, lactic acid producers also include opportunists and pathogens, including streptococci and enterococci; of note, *Enterococcus faecalis*, despite its reported beneficial effects for fermentation, has now clearly emerged as an important clinical antibiotic-resistant opportunist pathogen that may lead to intestinal dysbiosis after antibiotic treatments (17–19). Among sequenced relatives, *L. lactis* is related to *Streptococcus mutans* (Fig. 1). The 2.4-Mb genome of *L. lactis* strain IL1403 is intermediate in size between streptococcal pathogens such as *Streptococcus pneumoniae* and *Streptococcus pyogenes* (reported as 2.1 and 1.9 Mb, respectively) and *E. faecalis* (3.4 Mb). Although described as "cocci," *L. lactis* subpopulations may differentiate to a rod shape, possibly reflecting a change in the proportions of wall and division enzymes (20).

L. lactis is classified within the *Streptococcaceae* family, and it appears that *L. lactis* and the pathogenic streptococci may have a common origin. In addition to high genetic relatedness, DNA motifs called Chi, which are required for chromosomal integrity and are overrepresented in *L. lactis*, are identical to Chi sites present in both pathogenic and food-derived *Streptococcaceae*, providing evidence that a common core genome organization preceded divergence of streptococcal pathogens and food bacteria (21). Relatedness between *L. lactis* and streptococci surpasses by far that with many other LAB (including *Lactobacillus* species; Fig. 1). Streptococci also produce lactic acid and thus may be considered a branch of LAB. The *Streptococcaceae* family diverged as the result of unknown selective pressures to generate groups of pathogens, colonizers, and food bacteria, which seem to have diversified to adapt to their preferred biotopes.

Varied Lifestyle of LAB

L. lactis and LAB in general seem to have a varied lifestyle. Lactococci are isolated from plants and are likely to be ingested by grazing animals, together with milk in the case of calves. Coingestion could explain how lactococci ended up in milk. The need for several plasmid- or transposon-encoded characteristics for growth in milk (e.g., enzymes for sugar and protein metabolism, DNA restriction and abortive phage infection functions, and bacteriocins) supports the hypothesis that milk is not the original habitat of LAB.

Genome Plasticity

Studies of lactococci have focused on two organisms, IL1403, an *L. lactis* subsp. *lactis* strain, and MG1363, an *L. lactis* subsp. *cremoris* strain. Despite ~80% sequence identity between these genomes, they differ by a large chromosomal inversion (22). Even closely related isolates of MG1363 show considerable polymorphism, corresponding to large rearrangements (23) that might be mediated by mobile elements. Studies of artificial chromosomal rearrangements suggest that lactococci tolerate certain large genomic inversions if the origin and terminus regions are not disturbed (24).

Genome transfer and rearrangements may occur in lactococci via conjugation, transposition or insertion sequences, and phage transduction, as suggested by the identification of the required elements in different species, or by experimental systems in which natural DNA transfer occurs (see 25–28 for examples). DNA transfer occurs in streptococci by natural competence, as first discovered and then characterized in *S. pneumoniae* (29). Since then, competence among LABs was shown for *Leuconostoc mesenteroides* and *Streptococcus thermophilus* (30–33). *L. lactis* strains encode homologs of all late competence genes that are regulated by ComX; *com*X overexpression led to the induction of several genes linked to late competence (e.g., *com*GA, *GB*, *GC*, *GD*, *EA*, *EC*, *FA*, *FC*, *C*, *dprA*, and *coiA*), but these bacteria seemed to be defective for competence (34). Nevertheless, overexpression of ComX did lead to competence in a subgroup of lactococci (35, 36) but not in *L. lactis* model strains IL1403 and MG1363. In *L. lactis* strains KW2 and KF147, *com*X overexpression led to a transformation rate of 10^{-5} to 10^{-7} transformants/total cell number/μg of plasmid. These rates are similar to those obtained by electroporation in glycine-treated cells (37).

TABLE 1 Characteristics of *L. lactis*

Characteristic	Description
Classification	Gram-positive 38% GC content 2.4 Mb Nonpathogenic food microorganism (referred to as a lactic acid bacterium)
Close neighbors	Streptococci (food, commensal, pathogen)
Optimal growth temperature	30°C
Growth media	Plants, milk, food silage, farm animals, and human gut constituents
Environmental contacts	Plants (environmental niche) Farm animals Milk and other foods (environmental niche may rely on plasmid-encoded factors) Gastrointestinal tract
Metabolism	Fermentation Respiration in aerobic, heme-containing medium
Survival	Usually poor after fermentation growth Good long-term survival after growth by respiration

L. lactis IL1403 contains 40 putative insertion elements, 14 of which correspond to an insertion sequence element similar to IS*1070* from *Leuconostoc lactis*, and at least 4 prophage elements (38, 39). *L. lactis* and *S. thermophilus* share common integrative conjugative elements, as well as highly conserved regions coding, for example, exopolysaccharide synthesis enzymes (26). The existence of functional genes that have been transferred to *L. lactis* is suggested by the presence of atypical regions, i.e., those containing DNA that differs structurally from its context, or unexpected open reading frames (Orfs), e.g., a hemolysin-like protein. Similarly, an *S. thermophilus* isolate was shown to encode a pigment that was suspected to be transferred from pathogens and usually lost in milk bacteria (40).

Close interactions between microorganisms, e.g., in the gastrointestinal or vaginal mucosa of animals, or in industrial milk fermentation processes, could lead to horizontal genetic exchange. Contact between these bacteria is also suggested by the existence of nearly identical genes, e.g., in lactococci and *S. thermophilus* (26). Close physical contact, visualized microscopically between *S. thermophilus* and *Lactobacillus bulgaricus*, may facilitate genetic exchange (41).

METABOLIC OPTIONS FOR LACTOCOCCI

Lactococcal metabolism has been intensively studied because of its industrial importance in fermentation processes, with a focus on metabolic pathways and their engineering (42). Importantly, basic metabolic functions may have far-reaching effects, and as described below, metabolic shifts can result in dramatic changes in *L. lactis* growth characteristics and survival.

A remarkable metabolic process in lactococci, respiration, was essentially overlooked with the focus on dairy fermentation (43). Researchers confirmed and developed a 1970 study showing that lactococci not only ferment sugars but are also capable of forming an active electron transport chain to generate respiration metabolism (44–47). *L. lactis* respiration requires an external heme source due to an incomplete biosynthetic pathway (48). The respiration process and relevance for certain pathogenic streptococci and numerous lactobacilli is discussed below.

The two energy metabolism options, fermentation and aerobic/anaerobic respiration, are presented in the following sections. Pathways for nucleotide metabolism are also described, including a link established between nucleotide homeostasis and cell wall regulation.

Energy Option 1: Fermentation in *L. lactis*

Simplistically, lactococci use sugars to provide energy and amino acids to synthesize proteins (Fig. 2). Dairy lactococci have multiple nutritional requirements for amino acids and vitamins, probably resulting from their adaptation to a life in milk. Lactose is the major sugar source in milk, and through its uptake and degradation, lactococci generate energy in glycolysis. Casein, the major protein component in milk, is degraded to provide the major carbon source for anabolism. The flow of carbon for energy production is therefore almost separable from the flow of carbon for anabolism in these bacteria, making them ideally suited for metabolic studies.

All species belonging to the genus *Lactococcus* produce acid from glucose, fructose, mannose, and *N*-acetylglucosamine. *L. lactis* species used for dairy fermentation undergo mainly homolactic fermentation of lactose and other sugars. *L. lactis* subsp. *lactis* strains are more versatile than *L. lactis* subsp. *cremoris* in their use of diverse sugar sources, including maltose, ribose, and trehalose (reviewed in 49). Sugars may be transported by a plasmid-encoded phosphotransferase system in dairy strains or at a slower rate by a permease in nondairy strains (50).

Carbohydrate fermentation may be shifted from homolactic (lactate production) to mixed acid fermentation (acetic acid, formic acid, CO_2, acetoin, and ethanol produced in addition to lactate; Fig. 2). Two sets of conditions accompany this change, namely, (i) an altered redox state created by increased aeration during growth or (ii) reduced entry of sugar that is used for energy production.

Under the first set of conditions, oxygen appears to be involved in maintaining the NADH/NAD ratio, which itself seems to regulate the switch between homolactic and mixed acid fermentation (50); aerobic conditions result in oxidation of NADH to NAD^+ (catalyzed by NADH oxidases), thereby reducing the NADH/NAD^+ ratio in the cell. Lactate dehydrogenase (Ldh) is active at high NADH/NAD^+ ratios (i.e., low oxygen), while glyceraldehyde-3-phosphate dehydrogenase (GAPDH) is inhibited. Increasing the amounts of water-forming NADH oxidase from a nisin-inducible promoter was shown to decrease the NADH/NAD ratio and to decrease *in vivo* activity of Ldh. The increased pyruvate pool was directed to acetoin and the flavor compound diacetyl. Other types of engineering (e.g., through mutations which block specific pathways) can also result in altered flavor properties in lactococcal fermentation (reviewed in 42, with descriptions of applications in 51–54). Note that Ldh is essential in *S. mutans* but not in *L. lactis*, possibly because *S. mutans* lacks alternative pathways for reoxidation of NADH that are present in *L. lactis*. Among the three Ldh-like Orfs potentially present on the *L. lactis* IL1403 genome, studies suggest that at least two genes encoding functional Ldh are potentially expressed (55).

Under the first set of conditions, sugar entry may be decreased if galactose is used as an energy source or when lactose is transported by a permease (56). All sugar-carbon utilization produces pyruvate regardless of the growth conditions and the pathway; the activity of enzymes using pyruvate as a substrate determines if fermentation is homolactic or mixed acid. Decreased sugar flow thus favors the activity of enzymes giving rise to mixed fermentation products. One hypothesis is that when carbon fluxes are high, GAPDH is a bottleneck in glycolysis, resulting in high pools of upstream intermediates. These pools would then inhibit pyruvate formate-lyase in one of the fermentation pathways from pyruvate, resulting in homolactic fermentation under anaerobic conditions. The extent to which GAPDH is a bottleneck in lactococci was examined by constructing strains with GAPDH activities ranging from 13 to 210% of the normal activity and measuring metabolic fluxes (57, 58). Surprisingly, GAPDH was in large excess even when carbon fluxes were high; in terms of flux control, GAPDH would thus not be the controlling factor. Moreover, the fermentation pattern remains homolactic even after 4-fold reduction of GAPDH activity, which shows that GAPDH has no control over mixed acid flux either. Similar studies were carried out to determine the importance of other glycolytic enzymes on the fermentation pattern. Phosphofructokinase had no control over glycolytic flux or on mixed acid flux (59), despite the presence of this enzyme in excess (60). Ldh had no control over glycolytic flux either but did exert a strong negative control over mixed acid flux (61). An intriguing possibility is that the excess glycolytic enzymes are somehow shuttled to the surface, where they could play other roles in bacterial dis-

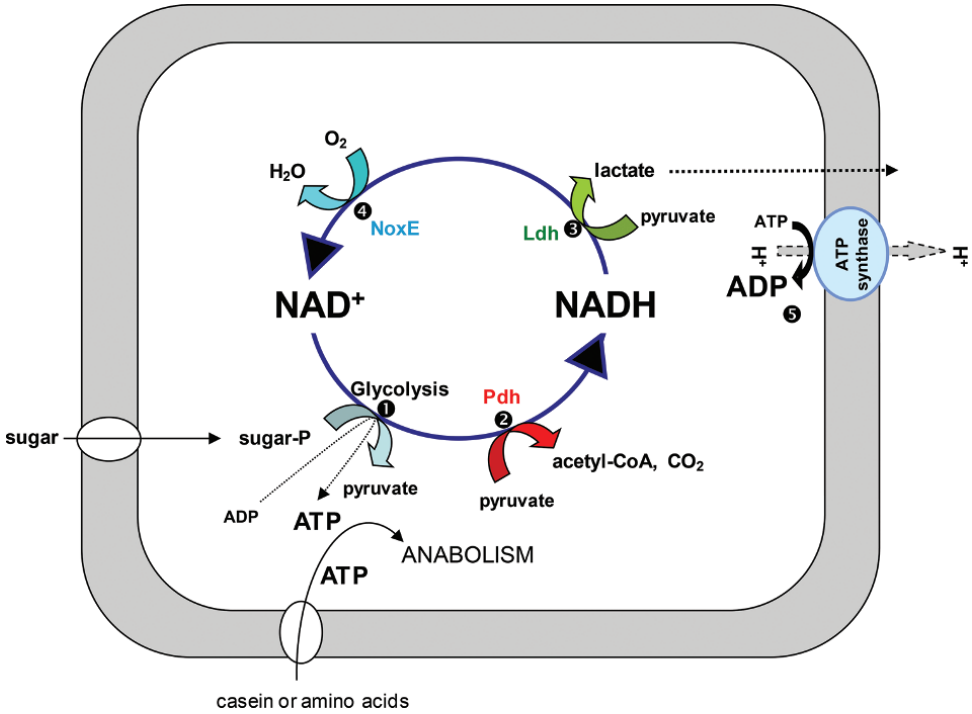

FIGURE 2 Basics of *L. lactis* fermentation. The NADH/NAD^+ ratio is placed as a central determinant of carbon metabolic choice in *L. lactis* (56). (1) Sugar fermentation generates ATP, which is used for amino acid anabolism. In anaerobic conditions and rapid sugar flux, essentially all sugar is converted to lactate (homolactic fermentation) from pyruvate (glycolysis). When sugar flux is slower, in the presence of sugars other than glucose or lactose or in aerobic growth, mixed acid fermentation may occur. The latter conditions are characterized by lower NADH/NAD^+ ratios than those found during homolactic fermentations. Besides NADH, glycolysis generates ATP and pyruvate from sugar degradation. (2) Pyruvate dehydrogenase (Pdh) provides extra NADH from pyruvate when oxygen is present. (3) Lactate dehydrogenase (Ldh) oxidizes NADH into NAD^+ by conversion of pyruvate into lactate, thus maintaining glycolytic activity during fermentation. (4) When oxygen is present, NADH can be oxidized by the cytoplasmic H_2O-forming NADH oxidase (NoxE), generating NAD^+. (5) The ATPase expulses H^+ at the expense of ATP to avoid acidification due to glycolysis. Pyruvate build-up leads to synthesis of acetate or the neutral acetoin and diacetyl (also see Fig. 4). This figure is modified from reference 155.

semination; glycolytic enzymes, like GAPDH, have been reported to be present on the surface of numerous *Streptococcaceae* (62–64).

The genetic organization of enzymes involved in sugar utilization may reveal regulation at the transcriptional level. *L. lactis* appears to coordinate the expression of three genes, each involved in key but distinct steps in fermentation, *pfk*, *pyk* (encoding phosphofructokinase and pyruvate kinase, respectively) and *ldh* genes, by having them present in one operon (called *las*). The operon organization may prevent unwanted accumulation of glycolytic intermediates. In *S. pyogenes* and *S. pneumoniae*, the *ldh* gene is not within this operon, suggesting that a common regulation of the three genes may be unique to lactococci. The *las* operon is induced in the presence of glucose via the catabolite control protein CcpA (65). Expression of the entire *las* operon was modulated to determine its importance for metabolic flux; flux was highest when expression was at its normal level and decreased rapidly when expression was reduced or increased (59).

In *Escherichia coli*, glycolytic metabolic flux is controlled almost exclusively by the demand for ATP. In *L. lactis*, the ATP demand also controls flux in slow- or nongrowing cells but not in fast-growing cells (59, 66–68).

The importance of individual enzymes for system properties such as fluxes, metabolite concentrations, frequencies of infection, survival rates, etc., can be accessed by modulating the activities of the respective components. Using synthetic promoters has proven useful for obtaining accurate tuning of gene expression and optimizing metabolic fluxes (57, 58). Moreover, this technique allows numerous genes to be modulated simultaneously and at differential levels in a cell; in one example an *L. lactis* strain was constructed in which all 10 genes encoding the enzymes of the glycolytic pathways were upregulated using synthetic promoter libraries (69).

Energy Option 2: Respiration in *L. lactis*

Components of the electron transport chain

An active respiration chain comprises three elements: (i) an electron donor, supplied by NADH dehydrogenases, (ii) menaquinones (including demethylmenaquinones or DMK), which are non-protein components of the respiration chain that deliver electrons to the terminal oxidoreductases, and (iii) terminal oxidoreductases, which contain heme as an essential cofactor and use oxygen as the final electron

acceptor (70, 71). Although *L. lactis* undergoes fermentation in a rich medium, addition of a heme source to an aerated medium activated respiration metabolism in *L. lactis* (44, 46). Demonstration of the existence of an electron transport chain and heme-dependent membrane NADH oxidase activity, and identification of factors implicated in respiration, all point to the major impact of this metabolic mode on bacterial growth and survival (Fig. 3) (45–47, 72–75). Heme-stimulated growth leads to an approximate doubling of cell biomass (in keeping with greater energy production by respiration activity), increased pH, and massive production of acetoin rather than lactic acid (46, 76). In combination with sugar-limiting conditions, as occurs during growth on maltose, the biomass yield increased further and indicated a reversal of the function of the H^+-ATPase toward the direction of ATP synthesis (77). An important feature of respiration metabolism is decreased oxidation in the cell, due to respiration-dependent oxygen elimination. This leads to a more reduced intracellular environment and consequently less oxygen-induced damage. This feature, together with increased pH, may explain the extraordinary increase in bacterial survival during respiration growth (46, 72).

Like other Gram-positive bacteria that grow via respiratory metabolism, *L. lactis* utilizes only menaquinones as electron carriers to the terminal oxidoreductase. Inactivation of *menB*, which encodes a menaquinone biosynthesis enzyme (dihydroxy naphthonic acid synthase), totally abolished both quinone production and respiration in *L. lactis* (78). However, while other respiring bacteria have several oxidoreductases that ensure respiration under different conditions, *L. lactis* uses a single enzyme, the cytochrome *bd* quinol oxidase (encoded by *cydAB*) (45, 46). This kind of oxidase has a high affinity for oxygen (79). Moreover, as shown for *Streptococcus agalactiae*, cytochrome *bd* quinol oxidase contributes to both virulence and colonization (80, 81; Y. Yamamoto, A. Gruss, and P. Gaudu, unpublished data).

Respiration in *L. lactis* requires uptake of heme (iron is insufficient), possibly suggesting the presence of a heme transporter. Genetic studies suggested that the *fhu* operon mediates heme uptake (75). However, more recent studies suggest that heme might diffuse into *L. lactis* membranes and then be recovered by cytoplasmic heme-binding factors. Heme reduction by menaquinones appears to favor membrane incorporation (82). Other factors that facilitate heme entry via diffusion are being investigated.

Based on the dramatic differences in growth, survival, and metabolite production, we had anticipated that respiration growth would induce massive changes in gene expression compared to fermentation. Surprisingly, the expression of very few genes was specifically altered by respiration as evaluated by proteomic (21 proteins) and transcriptomic (11 transcripts) analyses of late exponential phase cells (73, 83). These studies led to the hypothesis that NADH/NAD balance, which is shifted toward NAD by respiration chain activity, is responsible for modulating enzyme activities that accompany respiration growth (Fig. 3). Significant changes in expression were observed for a single operon, as discussed below (see section on heme homeostasis) (73).

Role of CcpA in respiration

The regulator CcpA, which controls catabolite carbon repression, imposes a hierarchical use of carbohydrates (84). CcpA controls carbohydrate catabolism (glycolysis) and positively controls production of Ldh (65), which converts pyruvate to lactate. CcpA also seems to coordinate respiration metabolism at different levels. The first control concerns sugar uptake, because *L. lactis* does not use amino acids or glycerol as a carbon source (85). CcpA also controls the transporter *fhu*, which appears to contribute to heme uptake (75). Third, CcpA regulates expression of genes encoding protein components of the respiratory chain.

In *L. lactis*, *ndh* (encoding NADH dehydrogenase [Ndh]) and *cydAB* are present on distinct operons (85, 86), while in other LAB they appear to be organized in a single operon (80, 87). The latter organization suggests coordinated expression of *ndh* and *cydAB* and may indicate that the respiratory chain is fueled by just one NADH dehydrogenase. In *L. lactis*, two putative NADH dehydrogenase genes (*noxA llmg_1735* and *noxB*, *llmg_1734*) are present in the genome, and both enzymes could drive electrons to menaquinones. Though *noxA* is adjacent to *noxB*, transcriptome analyses indicated that they are not in an operon (86). In the case of *noxB*, direct control by CcpA is suggested by the presence of a CcpA binding motif *cre* (catabolite response element) in the promoter region. Altogether, *noxB* seems to be repressed by CcpA, while *noxA* and *cydAB* are induced (88). Deletion of *noxA* abolished respiration activity on glucose growth, while the role of *noxB* is unknown (89). Because *noxB* is likely induced late in growth (when CcpA is less active), it may drive electrons to menaquinone, as does NoxA, but in late growth.

Interestingly, CcpA does not control respiration-induced acetoin production, because gene expression of this pathway was not affected by *ccpA* deletion (88). A challenging question concerns regulation of the pyruvate-acetoin pathway, which is functional late in respiration growth, as evidenced by acetoin accumulation in stationary phase cells; ~70% of the pyruvate pool is converted to acetoin (46, 73, 76) (Fig. 3). Interestingly, this pathway produces not only acetoin, but also carbon dioxide, which may contribute to lowering medium acidification in respiration growth (pH 6, compared to pH 4.5 in fermentation; both media contain 1% glucose as an energy source) (212). The search for regulators and/or cofactors of the pyruvate-acetoin pathway and for regulatory checkpoints of *L. lactis* respiration is ongoing.

Although *L. lactis* is only equipped for aerobic respiration, other LAB can also perform anaerobic respiration. In *Lactobacillus plantarum*, nitrate can be used as an electron acceptor instead of oxygen. Reduction of nitrate into nitrite is performed by a quinone-nitrate reductase (NarG). Nitrate respiration is repressed by glucose, suggesting potential participation of CcpA in anaerobic metabolism in this organism (89).

Heme homeostasis is a key to *L. lactis* respiration

Transcriptome studies of *L. lactis* in respiration versus fermentation conditions during exponential growth revealed strong upregulation of components of a single operon, *ygfCBA*, encoding a putative transcriptional regulator (YgfC; also detected by proteomics [83]), a predicted permease (YgfB), and an ATPase (YgfA) (73). YgfB and YgfA are HrtB and HrtA orthologs (*hrtBA* for heme-regulated transporter") encoding HrtBA, an ABC transporter that was found in parallel in *Staphylococcus aureus* (90). Its function was subsequently clarified as a dedicated heme-efflux pump, which was necessary and sufficient to maintain intracellular heme concentrations at subtoxic levels while allowing sufficient intracellular amounts for functional respiration (Fig. 4). The predicted TetR family repressor YgfC, renamed HrtR, regulates expression of *hrtBA* in *L. lactis*. HrtR shows high affinity for heme through a noncovalent hexacoordinated interaction with heme iron (74). HrtR binds a 15-nucleotide palindromic sequence in the *hrtRBA* promoter region, which is needed for repression (74). Heme binding to HrtR modifies its conformation, releasing it from its target promoter and alleviating transcriptional repression of *hrtRBA* (74, 91).

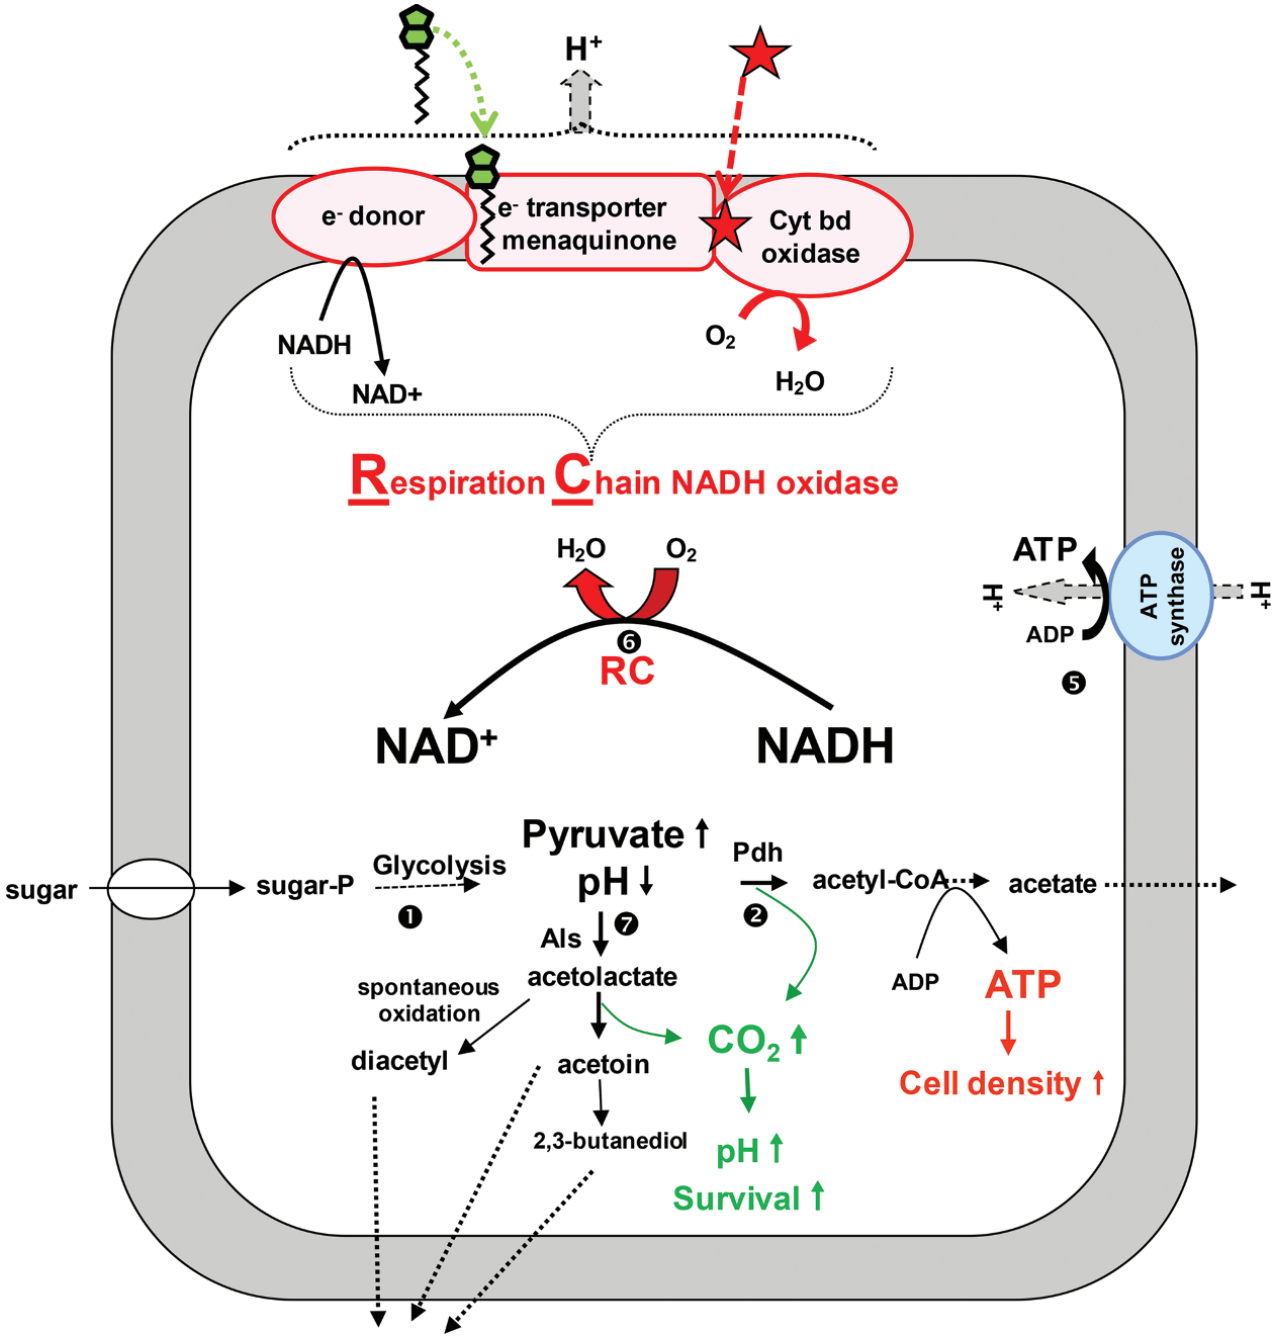

FIGURE 3 Basics of *L. lactis* respiration. Refer to Fig. 2 for reactions 1, 2, and 5, which are common to fermentation and respiration (numbering is the same). (6) The membrane respiration chain (RC) comprises an electron donor (putatively encoded by *noxAnoxB* [45, 89]), menaquinones (encoded by *men* operon genes or provided exogenously [80]), and a terminal electron acceptor (the cytochrome oxidase encoded by *cydAcydB* [46, 211]). Heme (red star) must be added exogenously (red arrow) to activate cytochrome oxidase. *S. agalactiae* and lactobacilli with respiration capacity (see Fig. 1 legend) require menaquinones (schematic molecule with green center) and heme to activate respiration. Respiration chain activity results in H^+ expulsion. (5) The ATPase might import H^+, which generates ATP but with low efficiency (47, 77). *L. lactis* lacks a complete Krebs cycle. Thus, NADH, which is needed for the respiratory chain, is produced by carbon catabolism. (1) Once phosphorylated, sugar is catabolized to pyruvate via glycolysis with production of ATP and NADH. As the respiration chain consumes NADH, Ldh activity decreases and pyruvic acid accumulates. Pyruvic acid dissociates to pyruvate and a proton, decreasing the internal pH. (7) To avoid acidification, pyruvate/pyruvic acid is converted to acetolactate via acetolactate synthase (Als) and then to the neutral compound acetoin with production of CO_2. Diacetyl is produced by spontaneous oxidation of acetolactate. This pathway raises the pH and improves cell survival. Some LAB convert acetoin to 2,3-butanediol. (2) Pyruvate may also be converted to acetyl-CoA via pyruvate dehydrogenase (Pdh), providing extra NADH and CO_2. Acetyl-CoA is further converted to acetate with production of ATP, promoting higher cell density. Acetate, acetoin, diacetyl, and 2,3-butanediol diffuse or are secreted into the medium. This figure is modified from reference 155.

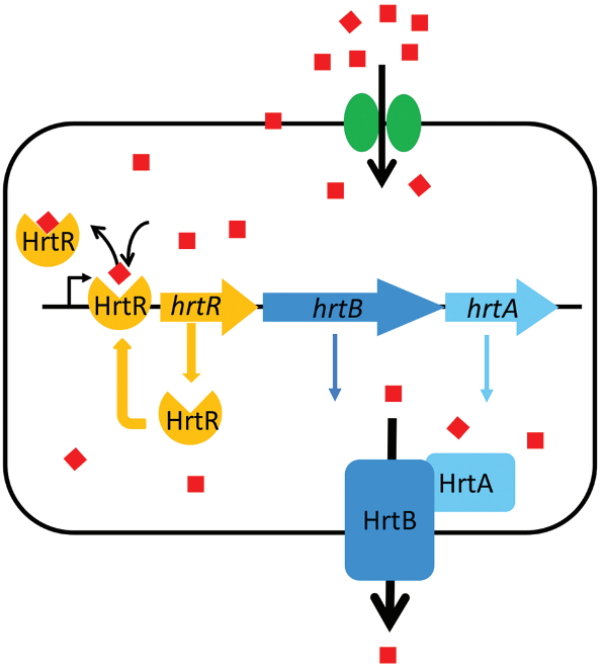

FIGURE 4 Schematic representation of *L. lactis* heme-sensing and HrtBA-mediated efflux, which regulate heme homeostasis. In *L. lactis* and numerous commensal bacteria, heme is suggested to be taken up by *fhuDBA* gene products (green ovals) and/or by diffusion through membranes (75, 82). Internalized heme binds to the HrtR repressor, which releases binding to the *hrtRBA* operon. Consequent activation of *hrtBA* results in heme efflux (74). Red squares, heme.

The use of HrtR as an intracellular heme sensor and *hrtBA* regulator appears to be conserved among commensal bacteria. In contrast, numerous Gram-positive pathogens use an extracellular two-component system, *hssRS*, to regulate *hrtBA* (92). These findings point to an essential role of efflux for heme homeostasis in *L. lactis*. In contrast, heme import mechanisms remain elusive, despite a partial role for *fhu* (75). Membrane-associated menaquinones were shown to favor the accumulation of reduced heme in membranes (82). An oxidative environment, provided by oxygen, prevents and reverses hemin reduction by menaquinone and thus limits heme accumulation in membranes (82). HrtBA counteracts menaquinone-dependent membrane retention of excess heme in membrane, suggesting direct efflux from this compartment. Moreover, both HrtBA and menaquinone-mediated reduction have a strong impact on heme intracellular pools, detected as induction of an HrtR heme sensor. This indicates that intracellular heme acquisition is controlled at the membrane level without the need for dedicated import systems, at least at high heme concentrations (82). While pathogens may have access to blood heme during infection, the existence of heme-responsive genes in lactococci and other commensal bacteria raises questions concerning the nature of heme sources in their natural ecosystems (48).

Roles of respiratory chain components in nonrespiration processes

Milk, one of the main industrial media for food fermentation, lacks heme and thus cannot support *L. lactis* respiration metabolism. However, respiration chain activity does affect fermentation by decreasing the milk redox potential of *L. lactis*, which is one of most reducing LAB, providing a very negative redox potential value in milk. To establish a low redox potential, oxygen must be removed and oxidized compounds should be reduced. During fermentation, water-forming NADH oxidase (NoxE) eliminates oxygen, and respiration chain components (NoxAB and MenC) provide a lower redox potential by reducing oxidants in milk. The redox potential of milk is known to affect the microbiota and sensorial quality of fermented dairy products. Thus, although the *L. lactis* respiration chain is incomplete in milk due to the absence of a heme source, its reducing ability plays a significant role during fermentation (93).

L. lactis is a respiration prototype

Lactococci, unlike *E. coli* and *Bacillus subtilis*, respire using a restricted electron transport chain, and only if heme is provided. Comparative studies revealed that certain, but not all, *Streptococcaceae* and certain other *Firmicutes* have the capacity to respire when provided with heme, or heme plus a menaquinone source (45) (Fig. 1). They include *S. agalactiae* (80, 94), *E. faecalis* (95, 96), and *Lc. plantarum* (89). Since the first characterization of *L. lactis*, a far wider group of LAB have been revealed to adopt respiration metabolism when provided with heme, or heme plus a menaquinone source, is added (see 48 for review).

Nitrogen Metabolism

In a milk medium, lactococci derive amino acids from casein via hydrolysis by the extracellular protease PrtP, transport of the generated peptides, and further degradation by a multitude of intracellular and envelope proteases and peptidases (97, 98). Amino acids readily available in milk are used both directly as amino acid building blocks and as a general carbon supply for other forms of anabolism in lactococci. Extracellular proteases plus at least 14 intracellular peptidases are of key importance for amino acid utilization. Lactococci grow poorly or die in milk fermentation conditions in mutants that are devoid of different combinations of these peptidases (99).

Dairy lactococci differ from plant lactococci in that they require several amino acids for growth. Surprisingly, strains of both origins appear to have the necessary genes for biosynthesis. Nevertheless, dairy lactococci require Ile, Leu, Val, and His, and sometimes Arg, Met, Pro, and/or Glu (100). These amino acid requirements in dairy strains appear to result from multiple mutations rather than deletions in the structural genes (39). This may suggest that mutations accumulated as an economic measure in strains maintained in a dairy environment. Similar results have been reported for *S. thermophilus*, a dairy bacterium related to *S. pyogenes*.

Nucleotide Metabolism

Nucleotides are not only substrates for DNA and RNA polymerases but are also substrates or allosteric effectors for many enzymes, and furthermore they constitute parts of different coenzymes. Thus, mutants in nucleotide metabolism may display numerous phenotypes. Cell nucleotide pools are also influenced by the presence of exogenous nucleobases or nucleosides in the medium. Pathways of uptake and utilization of these compounds (the so-called salvage pathways, which vary among organisms) are key contributors to bacterial responses to changes in the medium and to increased intracellular degradation of nucleic acids as illustrated below.

As seen above for operons involved in carbon metabolism, gene organization has unique characteristics in

lactococci, which may impact regulation. For example, genes encoding the pyrimidine (thymine, cytosine, and uracil) biosynthesis pathway leading to the formation of UMP are organized in five different operons in *L. lactis* and in a single operon in most investigated Gram-positive bacteria. Similarly, purine (adenosine, guanine, and xanthine) biosynthesis genes involved in the first 10 steps leading to IMP production are located in 5 separate operons in *L. lactis* and in a single operon in *B. subtilis*.

Pyrimidine biosynthesis is regulated by attenuation and antitermination by PyrR. The PyrR protein binds to PyrR "boxes" (5′-UCCAGAGAGGCUNGCAAG-3′) present on the 5′ ends of the untranslated mRNAs on four of the identified pyrimidine biosynthetic operons (101, 102). Mutation of the *pyrR* gene results in constitutively increased levels of the pyrimidine biosynthetic enzymes (101). The active RNA binding form of PyrR in *Bacillus* is a dimer which is formed when UMP, UTP, or PRPP (5-phosphoribosyl-1-pyrophosphate) is bound to PyrR; GTP counteracts UTP binding and thus promotes transcriptional read-through (103). The regulatory mechanisms seem to be the same in *L. lactis* (104). Interestingly, several *pyr* operons in *Mycobacterium smegmatis* have been found to be regulated by PyrR by translational repression (105).

Purine biosynthesis in *L. lactis* is positively controlled by PurR, and *purR* mutants are purine auxotrophs. PurR binds to a Pur box consensus sequence (5′-ANNNCCGAACAAT-3′) (106–108) to activate transcription of the *pur*C and *purD* operons. Data show that the PurR activating effector is PRPP. Because PRPP synthetase is inhibited by ADP and the addition of purine leads to increased purine pools (104), the addition of purine may indirectly decrease gene expression (108, 109). Interestingly, riboswitch control of the PurR-regulated *xpt* operon is modulated by purine pools (104). In operons activated by PurR, the distance between the Pur box and the −10 region was 57 to 58 bp. Mutational studies of pur boxes supported the importance of the central CCGAAC sequence. Interestingly, while *L. lactis* PurR often acts as an activator, the homologous PurR in *B. subtilis* usually works as a repressor. In addition to the importance of PurR binding sites, the two PurR proteins also differ in their PRPP binding properties. The two types of PurR proteins are related, and the *Bacillus* type seems to have evolved early from the activator type of PurR (109).

The PurR regulon includes purine biosynthetic genes but also genes involved in purine uptake and conversion into purine monophosphates. Genes involved in C1 carbon metabolism, guanosine tetraphosphate (ppGpp) metabolism, phosphonate transport, and pyrophosphatase activity were also identified. Interestingly, a Pur box was also identified upstream of two ribosomal RNA operons, which could imply an interconnection between the purine pathway and translation, but this link needs to be confirmed (104, 106).

L. lactis can utilize the exogenous nucleobases or nucleosides present in the medium or formed from intracellular degradation of nucleic acids via the salvage pathways. The nucleobases uracil, guanine, and adenine, as well as hypoxanthine and xanthine, are taken up and converted to nucleotide monophosphates, while cytosine is not utilized by lactococci (110). Orotate may be incorporated in plasmid-bearing *L. lactis* strains that express an orotate transporter and may be used for UMP biosynthesis, since orotidine.5′-monophosphate (OMP) is a normal intermediate (111, 112). Thymine may be incorporated via pyrimidine phosphorylase to thymidine and further phosphorylated by thymidine kinase (*tdk*) to the corresponding monophosphate (110). Thus, all common nucleobases except cytosine can be transported and incorporated into nucleotides. The ability of *L. lactis* to scavenge nucleobases or nucleosides can confer a survival advantage in stress conditions.

In *L. lactis*, all nucleosides except cytidine can be degraded to the corresponding nucleobase. However, cytidine may first be deaminated to uridine and then further to uracil. Pyrimidine nucleosides may also be directly converted to nucleotides since the corresponding nucleoside kinases (*udk* and *tdk*) are functional in lactococci. Two high-affinity nucleoside transport systems were identified: UriP is specific for uridine and deoxyuridine, while BmpA-NupABC takes up cytidine and purine nucleosides and the corresponding deoxyribonucleosides (113).

LACTOCOCCAL STRESS RESPONSES

Stress response is the adaptation to homeostatic changes due to the environment and is generally modulated by sensors and regulators that sense the state and respond to signals. Major signals for *L. lactis* include metabolites such as nucleotides, acid (self-induced), oxygen, salt, metals such as heme (natural or industrially provoked), and toxic products (e.g., disinfectants). We refer readers to recent reviews on LAB stress responses (114) and on regulatory signals in *L. lactis* (115). Here, we focus on specific effectors and responses that were not previously considered, i.e., nucleotides, Spx, cyclic-di-AMP, and heme and respiration stress responses.

Regulation by Nucleotide Pools

Low nucleotide pool sizes may serve as internal stress signals that provoke expression of stress response genes in *L. lactis* (116, 117). An important link between nucleotide pools and cell wall synthesis was uncovered: as part of the uridine synthesis pathway, PyrB converts L-aspartate (L-Asp) to N-carbamoyl-L-Asp. PyrB competes with cell wall enzymes for L-Asp; thus, L-Asp consumption during rapid growth favors cell wall flexibility, while its accumulation in the stationary phase may lead to a more rigid cell envelope (118). Additionally, high UTP pools in the human pathogen *S. pneumoniae* correlated with more capsule formation and lower biomass yield (119). These examples suggest that nucleotide pools connect nucleotide metabolism to the cell envelope structure.

The Spx Family of Regulators

A hot spot for *L. lactis* mutants that compensated for the stress sensitivity of a *rec*A mutant, thermosensitivity of a *clpP* mutant, metal toxicity, and oxidative stress mapped to the *spx* gene (117, 120, 121). Spx is conserved in numerous *Firmicutes* and was shown in *B. subtilis* to be involved in oxidative stress regulation via thioredoxin gene expression (122). Seven *spx* homologues exist in *L. lactis* MG1363, five of which contain redox-reactive CXXC regions (121). Exploration of other Spx proteins revealed that SpxB, a non-redox-sensitive Spx, is a key regulator of cell wall resistance to lysozyme by activating *O*-acetylation of peptidoglycan (PG) (123). The Spx family is intrinsic to cell responses to oxidative stress and cell wall damage conditions.

Cyclic-di-AMP as a Second Messenger in Bacterial Adaptation and Its Potential Role in Heme Sensitivity

Nucleotide pools are required for DNA synthesis but are also involved in numerous stress responses, including amino acid

starvation and acid stress (e.g., via ppGpp) (124). More recently, cyclic-di-AMP was identified as a second messenger in stress adaptation (125). In *L. lactis*, cyclic-di-AMP homeostasis is a balance between synthesis via the adenylate cyclase enzyme CdaA (Llmg_0448) and degradation by the cyclic-di-AMP phosphodiesterase enzyme (GdpP, Llmg_1816). Increasing the cyclic-di-AMP pool by deletion of *gdpP* increased heat resistance and salt hypersensitivity in *L. lactis* (126). These phenotypes might be due to a change in PG synthesis (127), because (i) salt sensibility in the *gdpP* mutant is suppressed by deletion of *cdaA* or *glmM* encoding a phosphoglutaminase enzyme involved in PG integrity, (ii) *cdaA* is in an operon with *glmM*, (iii) GlmM interacts with CdaA to modulate its activity, and (iv) *L. lactis* cells spontaneously lyse when cyclic-di-AMP pools are decreased. The exact role of cyclic-di-AMP in PG synthesis in *L. lactis*, though unknown, may be to modulate enzymatic activity to control cell wall plasticity. In contrast to CdaA, small molecules might interact with GdpP to modulate its activity. In *B. subtilis*, the GdpP homolog (YybT) harbors a PAS domain, which contains a heme binding site (128). Interestingly, *L. lactis* GdpP also harbors this domain, and deletion of the *L. lactis gdpP* gene increased the sensitivity of cells to heme (128). These observations suggest a dialogue/link between heme homeostasis and the cyclic-di-AMP pool enabling bacteria to adapt their physiology in response to exogenous heme.

In addition to its involvement in PG synthesis, cyclic-di-AMP changed pyruvate carboxylase (*pycA*) activity in *L. lactis* (129). PycA is required for aspartate synthesis. Milk acidification is delayed in a *pycA* mutant compared to the wild-type strain, indicating that cyclic-di-AMP might modulate the fermentation process in some conditions.

Strategies for Survival in Stress Conditions

L. lactis is equipped to deal with several stress conditions confronted in nature or in industrial settings, as summarized below. Salt and acid induce expression of GadB and GadC, which are putatively involved in glutamate transport by an antiporter; glutamate transport presumably involves efflux of H^+, thereby maintaining intracellular pH (130, 131).

Toxic products such as bile, quaternary compounds, and antibiotics may be actively pumped out of the cell by specialized transport functions. Among the numerous transport systems that shuttle metabolites in and out of the cell, some mediate drug expulsion and, consequentially, can confer drug tolerance (132). In *L. lactis*, LmrA is a multidrug pump that effluxes a wide range of amphiphilic, cationic drugs (including potentially toxic antibiotics, quaternary ammonium compounds, aromatic dyes, and phosphonium ions) in exchange for H^+ influx. LmrA (590 amino acids) is similar to the human multidrug resistance P-glycoprotein, thus raising questions about the origins of the pump. Judging from sequence analyses, an LmrA dimer would be the functional equivalent of the P-glycoprotein (LmrA is 32% identical to half of the P-glycoprotein, particularly within known functional domains). Remarkably, LmrA is functional in eukaryotic cells and is able to replace P-glycoprotein defects, thus making *L. lactis* an excellent model to study drug extrusion (132). Note that sequence comparisons predict an LmrA homologue in *S. pneumoniae* (an Orf with ~30% identity over 539 amino acids is present). The CmbT transporter (Llmg_1104), described initially as a cysteine and methionine biosynthesis transporter, was subsequently identified as a multidrug efflux pump that effluxes a wide range of antibiotics and toxic drugs (133).

Other efflux systems protect *L. lactis* from toxic metabolites: the dedicated heme-specific HrtBA efflux pump (see above) protects cells from heme toxicity. *L. lactis* homologs of heme and protoporphyrin IX efflux pumps identified in *S. agalactiae* may suggest that backup systems are available (134).

A series of exciting reports reveal that there is more to the envelope than was previously thought: first, pili discovered in *L. lactis* led to the idea that these bacteria might persist in the gut upon ingestion of fermented food products (135, 136). Second, a pellicle-like carbohydrate structure was visualized on the *L. lactis* MG1363 surface and characterized biochemically (137). A third structure, described as trapped within the PG, corresponds to another pellicle-like carbohydrate thin outer layer surrounding *L. lactis* strain MG1363 (138).

Finally, basic cell metabolism can determine how well the bacterium copes with oxidative conditions. Respiration metabolism presents a clear advantage to lactococci in an aerobic environment for both growth and long-term survival (Fig. 5) (46, 72).

Selections Leading to Improved Adaptation to Environmental Stress Situations

Oxygen is a ubiquitous stress. If not eliminated, reactive oxygen derivatives provoke cell damage that can be lethal. One means of reducing oxygen-related damage is by removing oxygen. In fermenting cells, H_2O-forming NADH oxidases do eliminate oxygen during growth (139), although cells are sensitive to oxygen-related damage in the stationary phase (140). Overproduction of H_2O-forming NADH oxidase could not only change metabolic end products (139) but also might improve survival in an oxidizing environment due to oxygen removal. An alternative means of creating a more reducing environment is by adding glutathione, a redox peptide (141), or dithiothreitol, a reducing agent (75), to the medium. Lactococci lack catalase, which eliminates hydrogen peroxide in many aerobic bacteria. Hydrogen peroxide has been effectively removed by cloning catalase in *L. lactis* (142). Respiration metabolism in lactococci is a "natural" and efficient means of eliminating oxygen compared to fermentation, leading to good survival in the stationary phase (46, 72).

L. lactis generates an acidic environment during fermentation growth, which might compromise its survival (143). Significantly, acidification may be more severe if cells are immobilized, because acid diffusion may be slower. This situation may provide a natural selection for strains to escape from a constrained environment, and it was shown experimentally to generate multistress-resistant mutants (116). Interestingly, acid-resistant mutants evoked changes linking nucleotide pools (ppGpp) and cell wall alterations (116, 118). Studies using a semiliquid medium have been used to impose a natural selection for mutants that can more readily escape a constraining environment (144). In one case, bacteria that make chains diffused more slowly than single cells (Fig. 6). "Dechaining" mutants, affected in penicillin binding protein and cell wall-synthesis enzyme PBP1A were isolated; the mutants no longer formed chains and were able to disperse more readily in the semiliquid medium; these mutants display greater permeability, probably due to increased cell wall breaks (144). In *S. agalactiae*, interruption of *ponA* results in reduced virulence that was linked to host antimicrobial peptide susceptibility (145, 146). In view of the identified role of PBP1A in lactococci, it is tempting to speculate that the *ponA S. agalactiae* mutant may also be defective in cell wall permeability and its chain-forming ability, thus

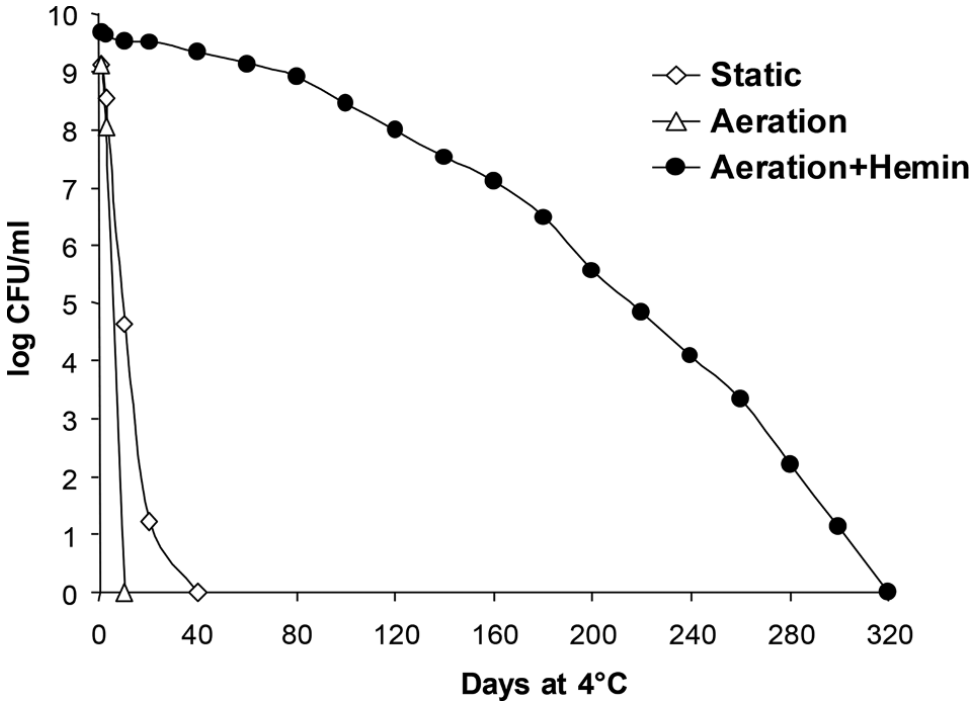

FIGURE 5 Respiration metabolism increases the survival capacity of lactococci. When supplemented with hemin, aerobically grown lactococci can undergo respiration metabolism. As a result, cells stored at 4°C show markedly better survival compared to cells grown aerobically in the absence of heme or in static conditions. Improved survival was also observed when cells were maintained at 30°C. The experiment shown was performed by Karin Vido in the authors' laboratory.

impacting its *in vivo* localization. Use of semiliquid medium for selections might prove effective in examining factors that are at work when bacteria are immobilized in their host and has also proven useful in other types of selections in which surface properties are altered (137).

Transposon insertional mutagenesis was also used to select for stress-resistant strains of lactococci. Three examples are given. (i) A combination of stress conditions is lethal for lactococci (and possibly for other organisms), although each condition alone may be nonlethal. Simultaneous high temperature (37°C), oxygen, and either low pH (i.e., similar to conditions in the stomach) or a *recA* background give rise to mutants, many of which seem to affect intracellular metabolic pools of guanosine-phosphate and phosphate in stress response (116, 117). Low intracellular levels of these metabolite pools in the mutants may constitute a starvation signal to induce a stress response. These mutant strains show better long-term survival than their nonmutated parents. It thus appears that a general stress response is induced in *L. lactis* when intracellular guanosine-phosphate and phosphate pools are low. In accordance with this, *L. lactis* showed resistance to acid and heat stress when grown in milk or a synthetic medium without purines (147). (ii) Hydrogen peroxide is toxic to lactococci. An H_2O_2-resistant mutant was isolated at high temperature (37°C), and although its resistance was 1,000-fold greater than the parental strain, it displayed no other stress resistance phenotypes (148). H_2O_2-resistant mutants might have a survival advantage in coculture with strains producing mM amounts of H_2O_2, e.g., some lactobacilli (149) and streptococci (150). In the former case, use of H_2O_2-resistant lactococci could lead to development of new fermented products; in the latter, more efficient growth of lactococci could improve the hygiene of food products. (iii) Mutants were selected for increased resistance to dithiothreitol (DTT), a reducing agent, at elevated temperature. By preventing the formation of disulfide bonds, DTT disables a part of the oxidative stress response pathway (numerous lactococcal stress-response proteins contain one or more CXXC motifs). All 18 DTT-resistant mutants mapped within a single operon, *pst*, involved in phosphate transport. Greater oxidative stress tolerance of *pst* was linked to its effects on copper and zinc homeostasis (151).

Stress-resistant lactococci have several potential uses. First, such strains are potentially valuable in dairy fermentation. Their greater resistance to stress may overcome survival variability as seen in conventional strains. The specifically acid-resistant strains may provide resistance to extreme acid pH conditions or may be better at maintaining a neutral internal pH. Stress-resistant strains may survive longer in fermentation and may also be more resistant to harsh storage conditions (such as freezing and lyophilization). Second, because such strains may survive the harsh environments in the gut better, they may be attractive for probiotic uses. A proof of concept mouse inflammatory gut model provided evidence that antioxidant superoxide dismutase produced by wild-type *L. lactis* may improve gut integrity (4, 152, 153). Third, LAB are potentially valuable candidates for the production of molecules with medical or biotechnological uses; Lactococci are nontoxic and have documented potential for expressing and exporting proteins or other molecules of interest, either for industrial production or in the gut.

L. LACTIS AND INTERBACTERIAL DIALOGUE

Lactococci have long been known to inhibit the growth of coexisting bacteria, including pathogens, via acid production

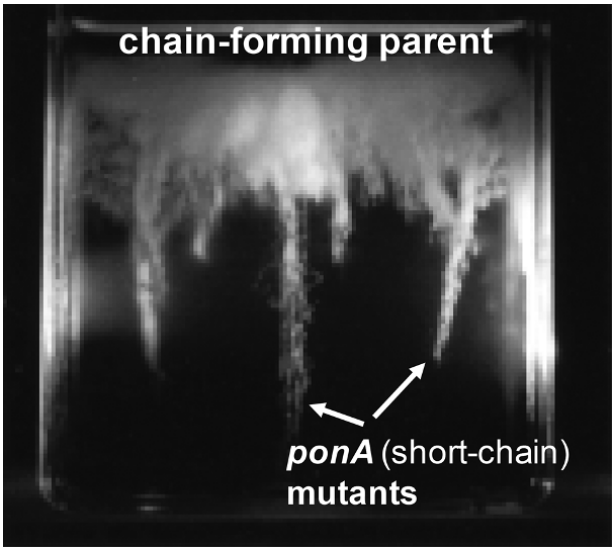

FIGURE 6 Bacterial root formation in semiliquid medium. Bacterial chains (here, an *acmA* mutant of *L. lactis*; parental strain) diffuse slowly in a semiliquid (0.035% agar) medium. Bacterial dechained mutants diffuse more quickly to form roots. In this experiment, all the roots corresponded to independent mutants in the same gene, *ponA*, encoding PBP1A (reproduced from Kulakauskas and coworkers [144]). Note that a similar strategy of semiliquid medium selection was used to uncover the existence of a cell-surface carbohydrate pellicle in *L. lactis*; the system is readily applied to other bacteria (137).

and are an important feature of fermented foods. This property has led to broader potential applications in the probiotic field, e.g., with respect to cholera infections (154). Recent studies also uncovered novel *in trans* effects of *L. lactis* and led to the identification of similar "public contributions" by other bacteria. Some examples are described in the following subsections.

Interbacterial Cross-Feeding

Via menaquinones

Other than *Lactococcus*, *Leuconostoc*, and *Enterococcus* species, most known LAB (pathogenic or not) lack a complete menaquinone biosynthesis pathway and require exogenous menaquinone or a precursor, in addition to heme, for respiration growth (48, 89, 155, 156). Unexpectedly, menaquinone-deficient strains can overcome this deficiency via contacts with menaquinone producer species. For example, respiration of *S. agalactiae*, an opportunistic pathogen, is activated in the presence of *L. lactis via* menaquinone donation and a heme source (78) (Fig. 7). Remarkably, *E. coli* expulses dihydroxynapthoate acid (DHNA), which is used by *S. agalactiae* to synthesize its own menaquinone (in this case a DMK) (156). DHNA is coupled to an isoprenyl chain by menaquinone prenyltransferase, encoded by *menA*. In *Lb. plantarum*, a *menA* ortholog is adjacent to the *cydAB* locus, suggesting that this organism can also use DHNA to synthesize menaquinones. Free menaquinones and DHNA are likely present in host ecosystems and can be used to activate metabolic pathways in commensal and pathogenic bacteria as well. Thus, environmental nonpathogens might contribute to the fitness, and potentially virulence, of neighboring pathogens.

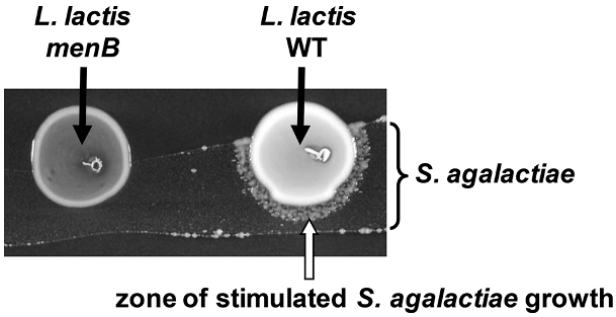

FIGURE 7 *L. lactis* produces menaquinones that cross-feed the opportunist pathogen *S. agalactiae*. Heme is present in the solid medium. A broad horizontal streak of an *S. agalactiae* strain (NEM316) is shown. Spots of cultures of *L. lactis* wild type (left) or *menB* that is defective for menaquinone synthesis (right) are deposited directly over the streaks. A stimulated growth zone is observed directly surrounding the wild-type *L. lactis* strain but not the *menB* mutant. From *Molecular Microbiology* (78).

Via respiration

Respiration growth leads to higher pH and efficient oxygen consumption. The presence of a respiration-positive *L. lactis* strain (grown aerobically with heme) rescued growth and survival of a respiration-negative mutant strain (tested with *cydA*) (Fig. 8).

Interbacterial Cross-Inhibition

Via secreted products

Lactococci, like other *Streptococcaceae*, produce toxic hydrogen peroxide under aerobic fermentation conditions, which may inhibit growth of peroxide-sensitive bacteria (72). Numerous LAB produce bacteriocins, which have widely different host spectra (see 157 for review); lysis of heterologous bacteria by bacteriocins may provide needed

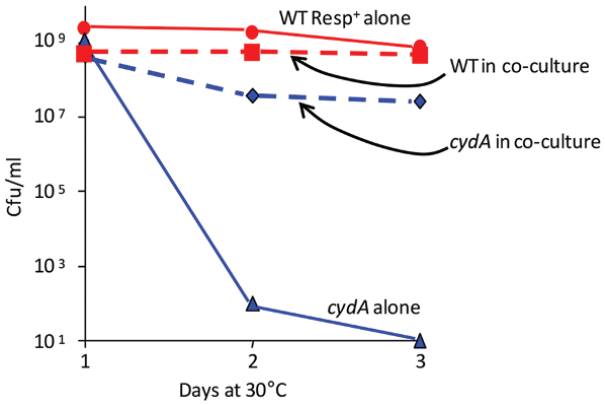

FIGURE 8 Respiring *L. lactis* can improve survival of nonrespiring bacteria in coculture. Differentially marked wild-type and *cydA* (nonrespiring mutant) *L. lactis* strains were grown separately or together in coculture. Nonrespiring *cydA* grew less well and showed poor survival when maintained in an aerobic medium with heme over a 3-day period. However, the respiring wild-type strain thrived. In contrast, the *cydA* strain fared much better when grown in coculture with the wild-type strain, as determined by cell count determinations. From *Molecular Microbiology* (72).

nutrients for the producer cells. Production of lysins may act to regulate bacterial cell wall properties *in trans* (158).

Via regulation of expression *in trans*

Studies of mixed cultures provide evidence for inhibitory effects of *L. lactis* on *S. aureus* growth and/or virulence gene expression. Tests conducted in either food or mammary gland cell lines indicate that (i) *L. lactis* reducing activity contributes to inhibition of a major virulence gene regulator (*agr*) and (ii) *L. lactis* at high bacterial concentrations inhibits *S. aureus* internalization in a mammary epithelial cell line (159, 160). These findings open prospects for antibiotic alternatives for prevention of infection, although their applicability to food industry and *in vivo* situations remains to be confirmed.

APPLICATIONS AND TOOLS OF LACTOCOCCI

The use of lactococci in "bioprotein" delivery, i.e., for antigen or enzyme delivery *in vivo*, is based on the idea that *L. lactis* can act as an effective nonpathogenic carrier, which can be administered orally or nasally without provoking a reaction other than that induced by the bioprotein of interest. Prior to this update, numerous reports described encouraging results of using lactococci for (i) prophylaxis to prevent bacterial infection (161), (ii) treatment of inflammatory bowel disease (3), (iii) prophylaxis and/or treatment of virally induced tumors (162), and (iv) allergy prevention (163, 164). Other properties of lactococci, including the expression of pili that might mediate bacterial adhesion *in situ* (135, 136), and novel applications have since been reported (165) which support their uses in biomolecule delivery. Despite a strong start, pharmaceutical drug development using *L. lactis* has not been reported, possibly due to the cost of development and the existence of industrially backed alternatives. Reported success with bioactive molecules might change this picture in the future.

Numerous applications using lactococci resulted from the development of genetic tools. Interestingly, a thermosensitive plasmid developed in *L. lactis* over 20 years ago, pG^+host, is still the gene replacement and transposition tool of choice in numerous *Firmicutes*, including pathogenic bacteria (166, 167). pG^+host is a derivative of the broad-host-range plasmid pWV01 and is nonreplicative in *L. lactis*, streptococci, staphylococci, and some lactobacilli at temperatures of 37.5°C or above. The thermosensitive replication protein has been retooled to produce numerous derivatives. Furthermore, pG^+host is replicative in *E. coli*. The existence of an *E. coli* strain bearing a chromosomal copy of the nontemperature-sensitive *rep* gene (168) facilitates gene cloning, as well as characterization of pG^+host insertions.

Another tool that has withstood time is the nisin-inducible expression system. Nisin is a bacteriocin encoded by a conjugative transposon (169–171). The promoter for the nisin biosynthesis gene, *nisA*, is regulated by *nisR* and *nisK* gene products. In the absence of nisin, or of *nisR* and *nisK* genes, promoter activity is very low. Addition of sublethal amounts of nisin results in strong induction of promoter activity, as demonstrated in innumerable applications of this system. This system has been shown to be functional in other *Firmicutes* (see 172 for review). Expression systems have also been developed for wider use among *Firmicutes* and in some cases may be advantageous over the nisin system. Controlled expression systems have arisen from studies of pH, salt, metal, heme, chloride, and sugar-regulated promoters (see 115 for review); some systems may overcome two potentially important limitations of the nisin system: (i) the requirement for either a specific host strain or a second plasmid (to provide *nisR* and *nisK* genes) and (ii) effects of nisin on the membrane, which may be particularly undesirable in studies of membrane proteins.

Highly regulated promoters can also be turned around for use as specific sensors. An interesting example concerns the HrtR repressor, which regulates heme efflux (Fig. 4). This and other heme-responsive promoters have been developed as sensitive heme sensors, with proof of activity *in vivo* (81; D. Lechardeur, unpublished data).

Constitutive expression of promoters at fixed levels can be valuable for quantitative physiological studies or for fine-tuning of gene expression in biotechnology. The *L. lactis* promoters P45 and P32 are commonly used, and strong constitutive promoters have been described (173). A set of synthetic promoters that differ by the sequence and length of spacers between the consensus sequences allows a broad range of constitutive activities (57, 174). A high-expression promoter based on the phosphotransferase system is further enhanced by cellobiose and was shown to be active in *B. subtilis* (175).

Site-Specific Single-Copy Integration

Lactococcal bacteriophages were initially studied with the goal of controlling starter culture lysis during fermentation. These phage studies led to the characterization of numerous bacterial strategies to abort phage activity. Phage studies have also been exploited to develop a site-specific integration system. Integration of temperate phages uses a phage-specified integrase that catalyzes insertion of the phage at a specific bacterial target, which is often localized at or near a tRNA gene. Using elements of lactococcal bacteriophage TP901-1, a site-specific integrative vector was designed to obtain chromosomal single-copy integration (176). This system should allow stable insertion and expression of foreign genes and can also be used to study the expression of genes in single copies under different growth conditions. The TP901-1 integration system has also been used in human cells (177). Another integration system based on a lactococcal intron led to efficient and stable insertion of genes without the need for selection (178).

Immune System against Phages: the CRISPR-Cas System

Chromosomal manipulation was upstaged by a mechanistic breakthrough made in *S. thermophilus* on phage resistance via the clustered regularly interspaced short palindromic repeat (CRISPR)-CRISPR-associated (Cas) system, which makes up a natural immune system against phage infections (179). During phage DNA infection, a bacteriophage DNA fragment is integrated in a specific chromosomal CRISPR locus. During a second attack with the same bacteriophage, small RNA expressed from the CRISPR system directs adjacently expressed Cas nuclease to cleave phage DNA, which prevents new infection. CRISPR-Cas is present in various LAB, including *S. thermophilus* and lactobacilli, but is uncommon in lactococci (180), although applications of the system are seen as ubiquitous (181).

Protein Export and Display Systems

Protein export reporters were developed to probe the membrane protein structure and identify export signals (182–184). One such reporter, the nuclease of *S. aureus*, is a stable,

well-characterized protein which is active when present as an amino- or carboxy-terminal fusion to other peptides and is faithful in reporting export events and in determining membrane protein topology. It is used in *L. lactis* and other *Firmicutes* to follow expression of exported proteins under different environmental conditions. The major advantages of using the nuclease over previously described export reporters are that it rapidly assumes its conformation and thus avoids degradation, and as few as ~300 nuclease molecules per cell can be detected in colony assays (183–186).

The use of *L. lactis* as a bacterial factory has been developed to deliver proteins of interest in the extracellular medium or on the bacterial surface. The export signal of Usp45, a secreted *L. lactis* protein, or signals from identified secreted native or heterologous proteins, is routinely used. Secretion efficiency can be improved by introducing (if necessary) an overall negative charge at the N-terminal end of the mature, translocated secreted protein (185). Advantages of using LAB other than *L. lactis* concern transit time in the intestinal tract; systems are thus being transposed to lactobacilli, such as *L. plantarum*, to improve efficacy (see 165 for review).

Anchoring of exported proteins via C-terminal LPXTG motifs is widely documented, particularly with respect to virulence factors such as *S. pyogenes* M-protein (187–189). *L. lactis* encodes several anchored proteins and at least two sortase-like proteins (190). Expression of the anchoring motif of the *S. pyogenes* M6 protein has been adopted to express recombinant proteins on the lactococcal surface (191). The AcmA autolysin is also cell wall associated, due to the presence of a three-times-repeated LysM motif (192). Anchoring via the AcmA binding motif was found to effectively present antigens at the lactococcal surface; a spacer between the anchoring domain and the protein of interest (a fimbrial protein) facilitates its access to target epithelial cells (193).

Expression Strains

Lactococci are remarkable for their simple genomes compared to complex bacterial models such as *B. subtilis* or *E. coli*. An interesting example is HtrA, which is the only surface protease in *L. lactis*. In contrast, *B. subtilis* and *E. coli* both encode numerous exported proteases (194). An *htrA* mutation leads to temperature sensitivity; at 30°C, exported proteins showed increased stability, although activity was not necessarily improved (194).

Cell Lysis Systems

Controlled cell lysis is a potentially powerful means of arresting cellular and metabolic activity; in fermentation, it may additionally result in a coordinated release of enzymes which could accelerate product maturation. The host autolysin, AcmA (195), or bacteriophage-encoded lysins and holins (which allow lysin release) are good candidates for this purpose. This application is potentially useful in controlling cell growth in fermented dairy products, as well as for enzyme release (196, 197). Expression of lysin and holin by a nisin-induced promoter does appear to accelerate cheese ripening (198). Lysins, derived from bacteriophage specific to several pathogens, effectively prevented or treated infections by streptococci, bacilli, and staphylococci in mice (199–201).

The cell envelope is an important barrier protecting the cell from stress situations. Cell wall damage via autolytic enzymes can render cells more sensitive to environmental conditions. Bacteria that have undergone even partial cell wall damage are permeable to small labeled probes used in standard *in situ* hybridization methods, while undamaged cells are not (202). As mentioned above, the SpxB protein mediates regulation of cell wall integrity (123). Rather than affect autolysin activity, SpxB is induced by lysozyme and/or PG digestion products, leading to PG *O*-acetylation, which renders it lysozyme resistant. Such changes could have profound effects on bacterial state, fitness, and resistance to autolysins, with applications for probiotic uses.

Containment and Food-Grade Strains

Inactivation of the *L. lactis* thymidylate synthase *thyA* gene results in a requirement for thymine or thymidine (66, 203). In *L. lactis*, a *thyA* mutant was exploited as a means of strain containment; i.e., strains can grow in a thymine-containing environment, such as the gut, but not in more limiting environments (203).

Nonsense suppressor strains are used in *E. coli* genetics to analyze phenotypes of point mutations. Plasmids carrying the suppressor genes could suppress an otherwise lethal nonsense mutation in the cell. This property of suppressors was exploited in *L. lactis* to construct and establish a food-grade plasmid (i.e., no foreign DNA) containing the suppressor genes in a suppressible purine auxotroph; this plasmid is stable in a milk media which cannot sustain growth of a purine auxotroph (204).

Higher Antigenicity

Studies have compared the effectiveness of presentation of different antigens as bacterial cytoplasmic, surface-anchored, or secreted proteins. Cell wall-associated antigens seem to induce a greater immune response than secreted or cytoplasmically expressed proteins (205, 206). Furthermore, immune response was reportedly enhanced in mutant strains with cell wall defects due to mutation of the alanine racemase (207).

CONCLUSIONS

L. lactis is likely the microorganism most eaten by humans. It belongs to a family comprised of pathogens (e.g., *S. pneumoniae*, *S. pyogenes*), commensal and opportunist microorganisms (e.g., *Streptococcus gordonii*, *S. mutans*), and food microorganisms (e.g., *S. thermophilus* and *L. lactis*). Studies of *L. lactis* reveal that differences between pathogens and nonpathogens are limited. As a bacterium that acidifies its own medium, *L. lactis* may have a high capacity for stress resistance when preadapted; stress-resistant mutants with constitutive stress resistance can be selected. Its metabolic flexibility by shifting to respiration metabolism can dispense with most acid production. As a food microorganism, *L. lactis* comes into close contact with, and may cross-feed, other bacteria in both the food environment and in the gut; as such, it may impact the behavior of other bacteria in complex ecosystems. As a nontoxic bacterium that secretes relatively few proteins in quantity, *L. lactis* may also be an organism of choice for oral vaccine or protein delivery design and biotechnological uses (see 165, 208, 209 for reviews). As a simple organism with diverse biotopes, including plants, milk products, and the gut, *L. lactis* may be a good choice for studies of the influence of environmental stress on evolution.

We are grateful to our laboratory colleagues T. Franza and B. Cesselin of the MicrobAdapt group and S. Kulakauskas (Micalis) for their insights on lactococci, which were incorporated into this chapter.

We acknowledge funding from the Agence Nationale de la Recherche, and from the Chr Hansen company, with whom we collaborated, for

research in the MicrobAdapt laboratory (P.G., D.L., and A.G.) on some of the subjects developed in this review.

During the 12 years since the second edition of Gram positive Pathogens, the staphylococci have joined the best understood, best characterized, and most productively studied of the bacteria, driven, not least, by the revolution in genome sequencing. According to Lindsay, in chapter 30, there are now at least 275 fully sequenced *S. aureus* genomes and nearly 10,000 shotgun compilations in GenBank, plus a substantial number of non-aureus genomes, many of them of species associated with animals. This information has revealed the extent and importance of horizontal gene transfer and the nature, genetic contents, and mobility of the mobile elements, which is arguably responsible for the diversification and spread of pathotypes. Regulatory molecules and networks have been deciphered, not only those that govern metabolism, but also those that govern virulence and the production of toxic exoproteins and virulence-enhancing surface proteins, all of which has greatly enhanced our understanding of how and why these bugs cause disease. We now have better understanding of the relation between colonization and disease, and of the fascinating and remarkable battle between the staphylococci and the immune system, which leads one to

envision the host animal as a walled city surrounded and besieged by an invading army with a vast armamentarium of weapons designed to infiltrate and subvert or to breach or undermine the ramparts and kill the populace and its defenders. And the city in turn with its lookout towers and solid walls surmounted by an army of archers with arrows directed against the invaders and each of the invaders weapons, plus soldiers that venture forth to attack enemy individuals and a populace ready to mobilize and fight to the last. And the invaders with shields and armor to ward off the arrows and disarm the soldiers plus the ability to tunnel under the walls and construct their own defensive ramparts. How is the outcome of this siege decided? When the city is strong and well-armed, its ramparts well-maintained, and its soldiers healthy, its populace determined, it usually (but not always) prevails — but sometimes the invaders have secret weapons against which the besieged populace is defenseless. When the city is old and its ramparts and defenses weakened by desuetude or inattention and its populace indifferent, the siege is successful unless an outside force comes to the rescue with re-enforcements in the form of its own secret weapons — weapons that the invaders are learning all too rapidly to counter.

Staphylococci: Evolving Genomes

JODIE A. LINDSAY

30

INTRODUCTION

The genome of a bacterial cell encodes all of the potential functions of that cell and how they respond to environments (1). The first staphylococcal genomes to be sequenced in full were landmark achievements in 2001 (2), allowing the first overview and predictions of the metabolic, regulatory, and virulence potential of *Staphylococcus aureus*. As more genomes were sequenced in the next few years, different regions of the genomes were discovered that were core and conserved, often including essential genes, as well as regions that were variable, nonessential, or mobile and allow the cell to adapt to new environments (3–7). Now that thousands of genomes are available, we understand the constant flux that staphylococcal genomes are under. Change occurs in small or single nucleotide variations (SNVs) or by horizontal gene transfer (HGT), and evolution occurs when these changes provide a selective advantage to the bacterial cell and become fixed in subpopulations. Particular variants adapt to evolving habitats, new environments, and stresses, leading to the spread and expansion of successful clones that continue to evolve.

Staphylococci are colonizers and common opportunistic pathogens of mammals and birds. The pathogenic importance of staphylococci ensures that they are one of the most frequently sequenced genera. *S. aureus* is the species most studied due to its virulence and antimicrobial resistance (AMR) (8, 9). *S. aureus* is a colonizer of humans, predominantly the nose, throat, axillae, and groin of healthy humans. The colonization rate of populations is approximately 25% but is dependent on geography, age, and risk factors (10). *S. aureus* colonization is a risk factor for subsequent infection (11), and most infection is caused by the colonizing isolate (12, 13). *S. aureus* is a common cause of minor skin infections that do not require antibiotic treatment due to a healthy innate immune response driven by neutrophils. In hospitalized or immunocompromised patients, particularly those with breaches in the protective skin barrier, infection risk is higher and treatment may require antibiotic therapy. *S. aureus* is one of the most common causes of hospital-associated infection (8).

Acquisition of AMR genes ensures that *S. aureus* it is a formidable pathogen in health care. Penicillin resistance due to penicillinase enzymes that digest the β-lactamase ring is almost ubiquitous in human isolates (14). The widespread introduction of second-generation β-lactamase antibiotics such as methicillin selected for a new type of penicillin-binding protein-mediated resistance encoded by the *mecA* gene. Methicillin-resistant *S. aureus* (MRSA) emerged in the 1960s and spread globally and dramatically in the 1980s to 1990s (15); it is prevalent in health care clones of *S. aureus* at varying frequency across the world (16) and increases the overall burden of *S. aureus* infection. MRSA strains are often endemic in hospitals and resistant to a range of additional antimicrobials, drastically reducing the options available for prophylaxis and empirical treatment of *S. aureus* infection, leading to more infections, economic costs, and increased morbidity and mortality (8, 17). More recently, MRSA spreading among healthy community populations (CA-MRSA) has dramatically impacted health care provision (9), and livestock-associated MRSA clones have caused concern in high-risk groups with exposure to animals (18).

Humans are also colonized by many coagulase-negative staphylococci species (19), so called because they are not *S. aureus*, which is easily differentiated in the laboratory by its ability to clot plasma via coagulase production. Coagulase-negative staphylococci are generally considered less pathogenic than *S. aureus* yet are a common cause of infection in immunocompromised patients, particularly those with indwelling medical devices such as catheters and artificial joints and valves. The ability to produce extracellular polysaccharide biofilm and toxins and to carry multiple antimicrobial resistances contributes to their pathogenesis. The most prevalent species is *S. epidermidis*, and other important pathogens include *S. hominis*, *S. capitis*, *S. haemolyticus*, *S. simulans*, *S. xylosus*, *S. warneri*, *S. cohnii*, and *S. carnosus*. Uniquely, *S. saprophyticus* is a common cause of urinary tract infection and encodes proteins for binding to human urinary tract epithelial cells (20). Recently, several new coagulase-positive or -intermediate staphylococci have been identified that are capable of causing disease equivalent in humans to *S. aureus* but are much less prevalent, including *S. lugdunensis* (21) and *S. argenteus* (22).

S. aureus is also a common cause of infection in companion and livestock animals, in particular, bovine mastitis in the dairy industry (14) and invasive infections in chickens (23). *S. pseudintermedius* is considered to be a major canine pathogen (24), while many other staphylococci have unique associations with particular hosts (25).

Adaptation of successful clones to evolving habitats, such as host and antimicrobial pressure, is increasingly being studied using genomic tools. Analyses of whole genomes, genomic variability, epidemiology, and evolution of staphylococci shed light on staphylococcal colonization of and

doi:10.1128/microbiolspec.GPP3-0071-2019

interaction with hosts, pathogenic pathways, and adaptation and spread in response to selective pressures. Ultimately, these studies identified key features of genetic, microbiological and biological phenomena as well as being applicable to preventing and treating infection in humans and animals.

GENOMES

A typical staphylococcal genome consists of a circular piece of DNA of between 2.5 and 3.0 million base pairs, which may be supplemented by additional plasmids. This equates to around 2,500 to 3,000 putative open reading frames or predicted protein coding sequences, as well as some tRNAs, rRNAs, noncoding RNAs, and pseudogenes. An example genome is shown in Fig. 1.

Signatures in the DNA sequence allow automated prediction of the start and stop of each coding sequence, and the coding sequences can be compared to genes of known function in other bacteria to predict protein function. Signaling sequences and conserved domains can identify the active sites of proteins and their physical location in the cell. Promotors can be predicted, and estimates can made of how genes are expressed and which other genes are expressed at the same time. A holistic picture of the potential of the cell emerges (1).

The first staphylococcal genomes sequenced to completion belonged to the colonizing and pathogenic species *S. aureus* (7). These early sequencing projects set the groundwork, identifying the key regions of the genome responsible for essential processes in growth, replication, and survival and identifying novel genes and pathways.

Over the next few years, another 10 *S. aureus* genomes were sequenced to completion, predominantly methicillin-resistant isolates (1) and a laboratory reference strain (5). These projects began to identify the regions of the chromosome that were conserved among strains and those that were variable. Most of the variability was due to variation in genes associated with surface proteins and regulators, as well as the presence or absence of mobile genetic elements (MGEs) and variations in their genetic content.

At the time of writing, the public database GenBank holds 272 completed *S. aureus* genomes and whole-genome shotgun genomes of another 9,065 *S. aureus* isolates (https://www.ncbi.nlm.nih.gov/genome/154). Including those genomes in the NCBI Sequence Read Archive and the European Nucleotide Archive, this number is almost 50,000 (26). This enormous increase in the amount of sequencing data is driven by increasingly inexpensive technology, particularly the Illumina sequencing platforms, which generates shotgun genomes of short reads of sequence that are unable to be resolved into a single contig of DNA but can be aligned to a reference genome of the same lineage. Similarly, other species of staphylococci are increasingly being sequenced. GenBank lists the whole genomes of at least 31 staphylococcal species, including colonizing and pathogenic coagulase-negative staphylococci, animal colonizers and pathogens, and food organisms. More than 200 staphylococci have been deposited without a designated species, indicating that the taxonomy is not completely resolved, although identifying and classifying species is increasingly accurate using whole genomes (27).

These databases are somewhat skewed by the choice of isolates for genome sequencing (26) and tend to favor those with clinical or industrial significance. Nevertheless, the extraordinary volume of data available ensures an

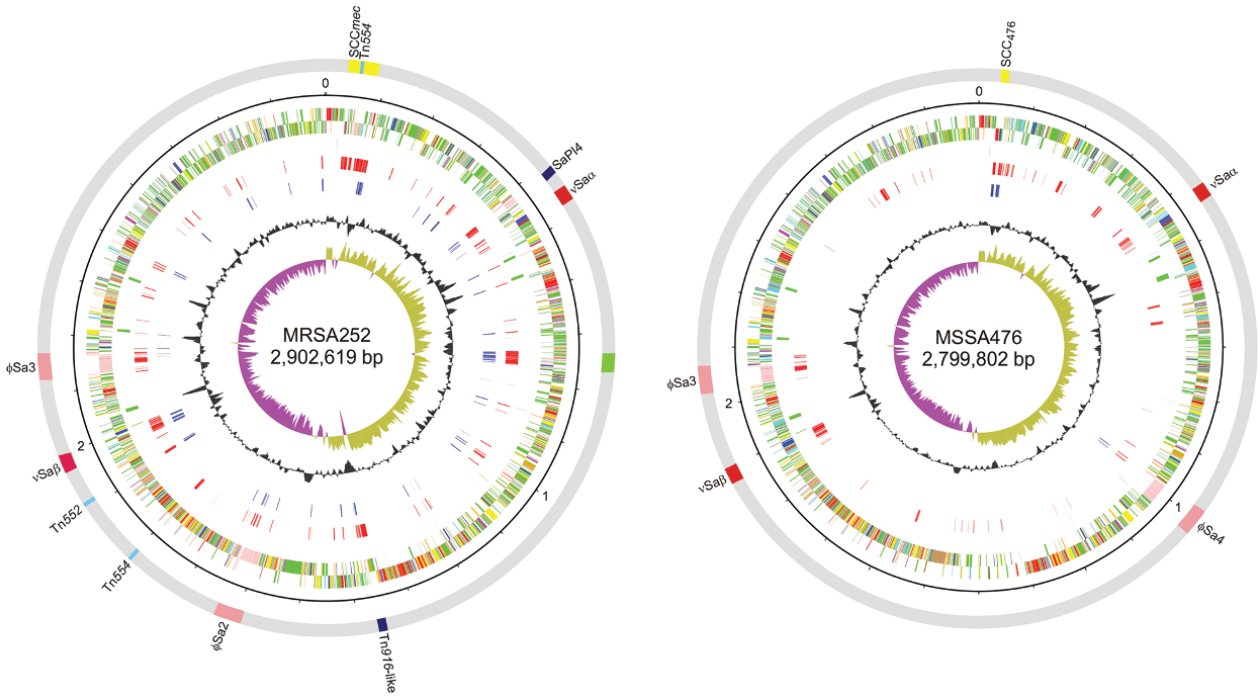

FIGURE 1 Example of *S. aureus* genomes illustrating variation in the core genome and mobile genetic elements. MRSA252, an example of a hospital-associated EMRSA16 ST36 CC30 isolate (left) and MSSA476, an example of a CC1 isolate (right). The core genome is highly conserved, with each lineage (CC) associated with specific variation. The outer gray ring indicates the location and distribution of the mobile genetic elements in these individual isolates, which can be highly variable. From reference 4 (https://www.pnas.org/content/101/26/9786/tab-figures-data).

unprecedented resource for the study of trends in the evolution, selection, and epidemiology of staphylococcal isolates.

The volume of information can be overwhelming to the nonspecialist. There are increasing numbers of tools to assist with the interpretation of genome information. For example, AureoWiki (aureowiki.med.uni-greifswald.de) is useful for searching for common genes across multiple *S. aureus* reference genomes with links to gene annotation and expression data (28). Staphopia assembles, maps, and annotates raw genome sequences (26). The Artemis Comparison Tool (ACT) is useful for aligning genomes and comparing where they vary (29). PanX can identify the distribution of accessory genes across multiple isolates (30). Regulatory RNAs can be identified using the SRD database (31). The Mykrobe predictor reads an *S. aureus* rapid shotgun sequence result and identifies up to 12 AMR markers in only 3 min (32). The Microreact project compares whole-genome sequences (WGSs) of isolates over time and geography to identify clones of public health importance (33). For laboratory researchers, an extremely useful tool is the Nebraska Transposon Library, identifying essential genes and actively distributing mutants deleted in specific genes in the reference strain JE2 (34) and tools to manipulate these strains (35).

The next generation of long-read sequence hardware technologies includes single-molecule real-time sequencers such as PacBio (155), and nanopore sequencing such as MinIon (156). Long-read technologies remove the need for alignment to reference genomes and are particularly useful for studying MGEs. Additional advantages include increased information about the epigenomes (methylation maps) of the DNA, and enhanced portability and low cost will ensure new insights into staphylococcal genomes in the future.

CORE GENOME VARIATION

The core genome is highly conserved among all isolates of a species and typically has a conserved gene order. The core genome encodes all the essential genes as well as many nonessential genes, including those involved in metabolic, housekeeping, replication, structural, regulatory, and some virulence functions (1). We might consider the genome that is not composed of MGEs as the core genome.

Multiple colonies from the same host are likely to have identical core genomes or vary in only a few single nucleotide variants (SNVs) or single nucleotide polymorphisms compared to each other (36). This type of SNV variation may be due to a swap in a base pair or an addition or deletion of a base pair or a very short sequence. From studying multiple colonies from the same host, it has been suggested that isolates are closely related if their core genomes contain 40 or fewer SNVs (37, 38). This level of variation within a colonizing population in a host is called a "cloud of diversity." Bacteria that spread between carriers or infected patients can have few SNV differences and therefore high levels of similarity, suggesting that the transmission event was recent (39).

SNVs arise as errors in replication catalyzed by the DNA polymerase enzyme as it rapidly unwinds and replicates the 3 million base pairs of staphylococcal genome in minutes during cell replication. Errors include incorporation of an incorrect base, deletion of a base, or insertion of an extra base. Bacteria have DNA error repair mechanisms, and in staphylococci these include the mismatch repair system. Occasionally, a mutation in a gene such as *mutL* or *mutS* leads to a "mutator" phenotype, where mutations accumulate at a higher frequency due to the lack of ability to repair them (40, 41).

From population studies of MRSA clonal types, the "molecular clock" of *S. aureus* is estimated to result in one SNV per genome every 5 to 10 weeks (36, 38, 42). Based on this concept, it is presumed that patients with larger clouds of diversity have been colonized for longer periods of time (43). As bacteria spread to new hosts and across nations and continents, this molecular clock of variation can reveal the transmission pathway. This was first seen in a large-scale epidemiological study of MRSA ST239 isolates from across the globe (36), which confirmed expected transmission pathways and identified unexpected ones.

It is important to note that the Illumina WGS methodology used to compare bacterial genomes and identify SNVs for transmission studies restricts analysis to the conserved regions of the genome in any given data set. This is typically the core genome only and will vary between experiments. The analysis will be most discriminatory when related isolates are compared, such as those belonging to the same lineage. Variable regions of the chromosome, such as the MGEs, are usually excluded from analysis. Nevertheless, it is an extremely powerful method for analysis of the evolutionary relationship of isolates and for predicting how recently they shared a common ancestor.

S. AUREUS LINEAGES

The *S. aureus* species has a population structure that divides into lineages, which are often referred to as clonal complexes (CCs) (44). Some of these lineages are dominant (common), while most others are rare (45). Isolates from the same lineage share a core genome that is extremely conserved and unique compared to other lineages. Each lineage is sufficiently different that WGS is rarely used to compare isolates from different lineages because the variation is too great to infer epidemiological relationships. Lineage-specific variation includes thousands of SNVs throughout the genome, as well as insertions, deletions, and variable regions. Isolates from the same lineage have extremely high levels of conservation in their core genomes across these SNVs and variable regions, indicating a close evolutionary relationship.

The naming of lineages is based on the original CCs assigned by a multilocus sequence type (MLST) system, where the sequence of seven housekeeping genes was compared. Isolates with seven identical sequences are grouped together into the same sequence type, and those with five or six identical sequences are assigned to the same CC (45). In contrast, two isolates that have four or fewer identical sequences typically belong to different CCs. Subsequent analysis of the highly conserved core genome across the species by WGS analysis confirms the lineage structure and that assignment of isolates to CCs by MLSTor to lineages by WGS correlate extremely tightly (26).

Microarray analysis across thousands of *S. aureus* genes and pan-genomes identified a broad range of genes that were present, absent, or highly variable in *S. aureus* populations but were conserved within lineages. These included many genes encoding surface-bound virulence factors and their regulators and immune evasion mechanisms (46, 47) that were predicted to play a role in host-adaptation or virulence. In some cases, the variation represents the acquisition or loss of an individual gene, such as collagen-binding protein. In other cases, one or more genes within an operon have been swapped with the corresponding genes from strains or other lineages, such as the four genes in the capsule locus that differentiate capsule type 5 from capsule type 8 or those determining the type VII secretion system. In some cases, a specific region within a gene varied, such as active sites

within the fibronectin-binding protein or the region within the *agr* regulatory locus determining the different *agr* classes (1, 46).

S. aureus genomes typically contain two "genomic island" regions of 20 to 30 kb called alpha and beta, which contain strings of duplicated but variable genes (44, 48). These islands are highly variable between unrelated lineages but very conserved within lineages. GIα typically contains 7 to 11 variant copies of staphylococcal enterotoxin-like genes that have superantigen-like (*ssl*) like properties involved in immune evasion, as well as multiple copies of related lipoprotein genes. GIβ carries multiple copies of serine proteins and different types of superantigens, as well as additional leukocidins or lantibiotic synthesis genes. Both GIα and GIβ also carry a restriction modification system with a modification and restriction specificity that is lineage specific. Such a system allows DNA to be transferred more efficiently between isolates of the same lineage than between isolates of different lineages (49, 50). The Sau1 restriction-modification (RM) variant genes (*hsdS*) are potent markers of lineage (49, 51) and likely contribute to the formation and independent evolution of the lineages.

Despite these major differences in genomes between lineages, isolates from most lineages of *S. aureus* appear to cause the same types and incidence of disease, and lineages generally have similar pathogenic potential. (The exceptions are some specific toxin-mediated diseases such as toxic shock syndrome, scalded skin syndrome, and food poisoning, where pathogenesis is dependent on the carriage of MGEs encoding relevant toxins.) Variation in the incidence of disease caused by each lineage correlates well with variation in the incidence of carriage, suggesting opportunistic infection (44, 45). Some lineages are more successfully carried in some hosts (for example, animals or humans) compared to others (14), and carriage appears to be the main risk factor for subsequent infection (12, 13). The importance of lineage-specific genomic markers in colonization and infection is still unclear, but redundancy of gene function is a common feature of staphylococcal genomes, suggesting that when one gene is missing or variable, others can compensate.

All *S. aureus* lineages share a common ancestor, but each lineage contains a unique combination of common variant genes, indicating extensive recombination. Only some of these lineages have become prevalent, including CC1, CC5, CC8, CC15, CC22, CC25, CC30, and CC45 (44, 45). This evolutionary pattern of repeated recombination of surface and host-interacting genes with expansion of only a small number of successful combinations has led to some very stable lineages. There is a surprisingly close relationship between isolates from the same lineage that can have highly conserved lineage-specific features despite very different epidemiological behavior and geography. An example is the USA400 MRSA lineage CA-MRSA represented by the MW2 isolate from the USA in 1998, which caused severe skin and soft tissue infection in children compared to the methicillin-sensitive isolate MSSA476 identified in a nasal carrier in Oxford, United Kingdom, in 1999 (4). The two isolates both belong to CC1 and have only 285 SNV differences in their core genomes within functional coding regions. In contrast, they have many differences in MGEs (4). Similarly, CC8 isolates, such as the laboratory strain 8325 (5) and MRSA USA300 FPR3757 (52), both belong to CC8 and have highly conserved core genomes despite extensive variation in MGEs and pathogenic and epidemiologic behavior. Therefore, the success of some of these lineages appears to be due to the emergence of specific clones that have acquired MGEs and resistances, allowing rapid adaptation to new habitats and environments.

MOBILE GENETIC ELEMENTS

MGEs are discrete pieces of DNA that replicate on their own or integrate into the host chromosome. They are not essential for the host but have specific mechanisms ensuring their own ability to transfer between bacterial cells and survive. They include bacteriophages (53), *S. aureus* pathogenicity islands (54) (also known as phage-inducible chromosomal islands [55]), plasmids (56), transposons, and the staphylococcal cassette chromosome (SCC) elements. MGEs are important because they carry many virulence, host-adaptation, and AMR genes, so their carriage and transferability can have a substantial impact on the success and spread of staphylococci.

MGEs are widely distributed in *S. aureus* and can make up 10 to 20% of the genome (7). There is enormous variation in MGE gene carriage and distribution, even among related bacterial isolates. Variation and recombination between MGEs appears to be common (53, 56). Having multiple MGEs per cell ensures a flexible bacterial genome that can acquire and lose a variety of virulence and resistance genes.

Bacteriophages

Virtually all natural isolates of *S. aureus* harbor one or more intact bacteriophage (or phage) genomes inserted into the chromosome (53). *S. aureus* phages are typically around 45 kb, temperate, reside quiescently within the chromosomal DNA (where they are termed prophages), and can be induced by DNA damage or stressful conditions to excise, replicate their DNA, and produce phage proteins, including those that assemble into phage particles. Phage DNA is packaged into new phage particles and released on bacterial cell lysis, and the particles bind to and inject their DNA into new host bacteria. This results in either the lytic pathway or the lysogenic pathway. The lytic life cycle induces further replication of phage DNA and protein production, lysis of the bacterial host, and release of infectious particles. The lysogenic life cycle results in the phage DNA integrating into the bacterial chromosome at the phage-specific conserved integration site. Some virulence factors, such as Panton-Valentine leucocidin, enterotoxin A, and exfoliative toxin A, are encoded on lysogenic prophages, where they may provide a benefit to the host bacterium during infection. Host-specific immune evasion pathways such as *chips*, *scin*, and *sak* are also found on the φ3 family of bacteriophages associated with human carriage and disease (14, 53).

Pathogenicity Islands and SaPIs

S. aureus pathogenicity islands (SaPIs) are related to prophages but do not carry the genes for phage particles (54). They excise, replicate, and package their DNA into phage particles, but the phage particles are supplied by a helper phage (57, 58) which also regulates induction of the SaPI and directs lysis of the bacterial cell. SaPIs carry toxic shock syndrome toxins and can also carry biofilm-associated genes, iron uptake pathways, and antibiotic resistance genes.

SCC*mec*

In terms of clinical significance, the most important MGE may be the SCCs that carry the *mecA* gene encoding methicillin resistance. SCC*mec* elements have been classified into

at least 11 types, each with different combinations of *ccr* genes that catalyze excision and integration of the element into the chromosome (http://www.sccmec.org) (59). Integration only occurs at one chromosomal site, *orfX*, and each bacterial cell has either zero or one copy, ranging in size from 3 to 70 kb (60). Early SCC*mec* types tended to be larger and carry multiple resistance genes, while the smaller and streamlined SCC*mec* type IV is probably now the most successful and widely distributed type. While SCC*mec* regions can transfer between isolates, they appear to be more stable than other MGEs in clonal MRSA. The acquisition of an SCC*mec* by a sensitive *S. aureus* strain appears to be the first step in the evolution of MRSAs with unique epidemiology (36, 61–63) and the ability of MRSA clones to subsequently spread in specific environments, particularly health care, community, and livestock, and will be discussed below in the section on AMR. Successful MRSA clones tend to have stable SCC*mec* elements (36, 61, 64).

Plasmids

Staphylococcal plasmids are circular supercoiled DNA molecules ranging in size from 1 to >60 kb. They replicate autonomously and regulate their own copy numbers. Smaller plasmids replicate by the unidirectional rolling circle mechanism (65), while larger ones utilize the bidirectional theta mechanism (66). Plasmids are common, with most isolates harboring one or more, and strains with up to four have been found. Plasmids carry a large proportion of AMR genes in *S. aureus* (56, 67).

Transposons

Transposons are MGEs that encode transposases, which are capable of catalyzing replication and/or excision of the transposon, followed by integration into a new insertion site on the genome. Insertions can be site-specific or random and can be located on the chromosome, plasmid, or another MGE. In staphylococci, transposons are particularly associated with antimicrobial gene carriage (67), especially penicillin, macrolides, tetracycline, and vancomycin.

Insertion Sequences

Insertion sequences (ISs) encode only a transposase, but two ISs can form a composite transposon and transfer the DNA between them, including resistance genes (68). ISs such as IS*256* can insert into coding or regulatory regions of the genome, altering gene function and expression. An example is IS*256* that affects biofilm expression in *S. epidermidis* (69).

HORIZONTAL GENE TRANSFER

Horizontal gene transfer (HGT) requires several steps for success. First, DNA must transfer from one cell to another, and it must find a way to replicate or integrate, evade host defense mechanisms, and not cause a fitness cost to the new cell (70). DNA can transfer between bacterial cells by transformation, conjugation, or transduction. In *S. aureus*, transformation is inefficient (71) and probably rare. While conjugation functions effectively in staphylococci, the distribution of conjugative genes necessary for transfer is relatively constrained, suggesting that conjugation is not the major driver of HGT in *S. aureus*. In contrast, bacteriophages are widespread in *S. aureus* genomes, and HGT via transduction is efficient and widespread, probably the most common mechanism (70).

Transduction involves DNA transfer via bacteriophage packaging and delivery of DNA, such as transfer of phage DNA between cells. Generalized transduction occurs when host bacterial DNA is packaged into the phage particles, which are released by lysed cells, and the noninfectious particles inject DNA into new bacterial hosts. Packaging can be dependent on *pac* sites or *cos* sites scattered through the genome (72, 73), and packaging of host DNA is not accidental but dependent on environmental conditions such as antibiotic exposure (74). Some host DNA is packaged at a higher frequency, particularly plasmids, which may be a reflection of copy number or concatemer formation (75). SaPIs are preferentially packaged into phage particles by targeting the terminase packaging proteins of the phage directly (58). Phage heads typically hold a maximum of 45 kb of DNA, yet some larger MGEs appear to have been transferred by generalized transduction, perhaps by multiple transfer events (76).

Once DNA is delivered into the recipient cell, it needs to find a way to replicate in order to survive the next round of bacterial cell division. Plasmids replicate autonomously as circular DNA. Most other MGEs have a specific mechanism for integrating into the chromosome or a plasmid, using integrases or transposases. These may be site-specific or random integration events. In contrast, a chromosomal piece of DNA that enters a recipient cell without a mechanism of replication or integration relies on homologous recombination with the chromosome (77). In *S. aureus* this is an inefficient process.

Transduction of MGEs is highly efficient in colonizing populations of bacteria. In a controlled evolution experiment in four gnotobiotic piglets, plasmids were shown to transfer between coinoculated isolates within 4 hours (78). Multiple phage and plasmid transfers occurred continuously during 16 days of colonization, resulting in heterogeneous colonizing populations that varied enormously in MGE content (78). Gene transfer appeared to be localized to the bacterial populations within each of the four piglets, despite the close physical contact of the animals and the opportunity for strains to spread (78). Similarly, in human MRSA carriers, free generalized transducing phages are detectable, and clonal colonizing populations in individual hosts often vary in MGE and AMR gene content, indicating frequent gene transfer (79). These studies also suggest that loss of MGEs occurs, although the mechanisms are not understood.

Since high-level MGE transfer occurs within the host, and MGEs are also lost within the host, it is expected that variation in MGE carriage is extensive in clonal population isolates from multiple hosts. Since epidemiological studies typically analyze only one colony or isolate from each host, only a sampling of this variability is detected in studies investigating MGE distribution. This limits our ability to make predictions about the distribution and importance of virulence and AMR genes. However, genomic trees generated to investigate the epidemiology of successful MRSA clones typically identify frequent acquisition and loss of the same or similar MGEs (44, 61, 80), suggesting that they are widespread among the population and undergo their own evolutionary adaptation.

There are several barriers to HGT that protect bacteria from phage DNA that otherwise might lyse and destroy populations. First, prophages produce regulators that prevent phage excision and replication of incoming related phages and therefore protect the cell from lysis (53). The second barrier is RM. The type I Sau1 system is widespread and lineage specific, ensuring that DNA transferred from one

bacterial cell to another of the same lineage is recognized as self due to specific modification and protection of target site sequences (49), whereas DNA transferred from one bacterium to another of a different lineage is recognized as foreign by its unprotected DNA target sites and digested with restriction enzymes (49, 53). Additional RM systems are also found, such as the type II, III, and IV systems (70), and many of these genes are encoded on MGEs themselves, protecting host bacteria as well as protecting themselves from other MGEs. Clustered regularly interspaced short palindromic repeat (CRISPR) systems were first described in *S. epidermidis* (81) but are very rare in *S. aureus* (70, 82). CRISPRs are an adaptive immunity system for bacteria, because they incorporate segments of invading DNA, which they recognize and target for digestion by CRISPR-associated (Cas) endonucleases on the next encounter (83).

Staphylococci coevolve with some MGEs, with each providing advantages and disadvantages to each other. For example, resistance to phage infection by host receptor modification prevents lysis by the phage (an advantage to the cell) but also HGT by that staphylococcal phage (a disadvantage to the cell) (84). The phage itself requires a host to replicate, driving adaptation to respond to altered host receptors. Plasmids and phages can also evolve to expand their host range. Plasmid immunity (incompatibility) occurs when two plasmids share the same replication mechanism, ensuring that after several rounds of cell division, one plasmid tends to be lost (85). Plasmids have therefore recombined extensively so that related genes are carried on plasmids with different replication genes (56). Interestingly, some large conjugative plasmids have overcome type I RM barriers by removing restriction target sites from their genomes, freeing their transfer between certain lineages (50).

The high efficiency of MGE HGT, the inefficiency of transformation and homologous recombination, and the distribution of barriers to gene transfer markedly shape the genome of *S. aureus* and the population structure compared to other species. As a result of these mechanisms, the *S. aureus* lineages are distinct and stable, while the MGEs encode most of the adaptive traits and can be highly mobile and unstable, and those MGEs that maintain stability in successful clones are likely to be important and continuously selected.

SELECTION AND ADAPTATION

Evolution occurs when changes in the genome are selected for and variants outcompete established populations and may move into new niches. MGEs that encode host-adaptive or AMR markers are particularly involved in the evolution of successful clones that can then expand and spread. Considering how rapidly MGEs can be transferred between isolates and lost, the stable presence of an MGE is taken as an indicator that it plays an important role in adaptation.

Virulence and Pathogenicity

S. aureus produces dozens of known and putative virulence factors, including toxins, immune evasion proteins, and adhesins. Regulation of these virulence processes is controlled by a multitude of gene regulators that respond to environmental conditions and ensure efficient expression at the appropriate time and place. Despite many virulence factors being encoded on MGEs, there are few cases where the presence of a single virulence factor has been associated with evolution and adaptation. Since the normal niche of staphylococci is not the diseased host but the normal skin and mucous membranes, we can imagine that the ability to cause disease may not necessarily provide the bacteria with a selective advantage during colonization. Early studies suggested that the presence or absence of virulence factor genes on MGEs was similar in both colonizing and infecting isolates (44). For example, the role of the immune evasion cluster genes on φ3 phages appears to be associated with successful human clones but is also common in colonizing isolates rather than being specifically selected in infection-causing isolates. Another interesting example is the Panton-Valentine leukocidin, which is associated with severe skin and soft tissue infection, where the toxin may play a role in disease but is also relatively stable in colonizing populations (86), where perhaps it reduces clearance by neutrophils in the nose. A third example is the *sasX* gene which is carried on the φSPb-like prophage in the successful ST239 health care-associated MRSA (HA-MRSA) clone and encodes a surface protein for adherence to nasal epithelial cells (36, 87).

More recently, single nucleotide polymorphisms in genes associated with virulence were detected with a 3.1-fold enrichment in infecting versus nose-colonizing bacteria from the same host (88). This suggests that these mutations arose and were beneficial to the bacteria during the pathogenic process. In particular, genes associated with the regulation of virulence were variable, such as the accessory gene regulator, *agr* (88, 89). While these regulators control virulence in mouse models of infection (90, 91), they are lacking in some human clinical isolates, and in others they may play a role in adaptation of colonizing isolates as the infection develops (92, 93). In contrast, no differences were detected between isolates causing bacteremia and those causing endocarditis (94). Bacteremia isolates were shown to be less toxic to eukaryotic cells *in vitro* than nonbacteremia isolates, and genome-wide association studies suggested that multiple loci could be involved (95).

Surprisingly, successful clones can maintain mutations in common virulence factors. The successful CA-MRSA USA300 does not produce capsular polysaccharide, due to multiple mutations in the capsular operon (96). The HA-MRSA strains have mutations in the alpha hemolysin gene and *agr* (157). Extensive redundancy in the staphylococcal genomes, where multiple genes can encode for similar functions, may account for the lack of a virulence Achille's heel. Unfortunately, this reduces options for therapeutics targeting a single virulence factor (97).

Antimicrobial Resistance

Genomic analysis demonstrates that AMR is the most important evolutionary adaptation of staphylococcal populations. In particular, MRSA strains carry SCC*mec* elements which encode the genes necessary to resist nearly all types of β-lactam antibiotics. MRSA strains do not just replace sensitive *S. aureus* populations, but cause an additional burden of disease (98).

Since β-lactam antibiotics are the most successful antibiotic class—effective, inexpensive, easy to tolerate, and with limited side effects—pharmaceutical companies have continually developed new β-lactam antibiotic variants to evade bacterial resistance mechanisms (9). MRSA is only susceptible to ceftaroline and ceftobiprole, which dramatically reduces the types of antibiotics that can be effectively used for prophylaxis (prevention) and empirical therapy (treatment prior to diagnosis). The *mecA* gene carried on the SCC*mec* encodes an alternative penicillin-binding protein, PBP2A, allowing synthesis of cell wall peptidoglycan in the presence of

β-lactams that block a crucial enzyme, PBP2 (99). β-lactams are widely used in humans and in agriculture, and hosts exposed to β-lactams provide an advantageous niche for MRSA over other methicillin-susceptible colonizing microbes. Once colonizing successfully, MRSA acts as an opportunistic pathogen. Since there are only a relatively small number of successful MRSA clones and they cause significant concern in health care, they are often screened for and reported and their epidemiology and spread investigated. Therefore, we investigate the evolution of these clones more than any other staphylococci (47).

In epidemiological terms, there are three main types of MRSA, each evolving on multiple occasions and each with unique features of their genome (100). They are health care associated (HA-MRSA), community associated (CA-MRSA), and livestock associated. Each type has emerged in multiple lineages, demonstrating that lineage is not the major factor responsible for the unique epidemiology. Instead, there are common MGEs associated with each MRSA type, and these MGEs are relatively stable in the clonal population, indicating repeated selection for the MGEs for survival in the respective epidemiological niche (47). In each geographical location and niche, only one or two MRSA clones tend to dominate.

HA-MRSA has emerged in lineages CC5, CC8, CC22, CC30, CC45, CC59, CC80, and ST239. Each lineage carries an SCC*mec* type, usually type II, III, or IV. Interestingly, ST239 evolved by a large recombination event between CC8 and CC30, where a large region of the genome containing the SCC*mec* region of HA-MRSA CC30 swapped into a CC8 lineage (101, 102). HA-MRSA clones also carry the ϕ3 human host-adapted bacteriophage, thought to be important for human colonization. Successful HA-MRSA strains are often multidrug resistant, and a particular association between HA-MRSA and fluoroquinolones has been identified. In the CC22 HA-MRSA clone, mutations in the *gyrA* and *par*C genes seem to have been essential for successful dissemination (61). In the United Kingdom, usage of fluoroquinolones appeared to select for HA-MRSA, and a decrease in usage correlated with a decrease in hospital infection incidence with HA-MRSA (98). This is consistent with exposure to fluoroquinolones being associated with increased HA-MRSA colonization in Europe, Asia, and the United States (103–106). Resistance to aminoglycosides, macrolides, and others is also associated with HA-MRSA, but resistance rates are variable within and between geographical locations (100), possibly due to different selective pressures.

CA-MRSA strains have evolved in lineages CC1, CC8, CC30, and CC59. CA-MRSA causes severe skin and soft tissue infection in healthy patients, often children, military members, athletes, prisoners, and those in close contact with others. Successful clones carry both an SCC*mec* and the φ3 human-adapted bacteriophage with genes for evading the host immune response. Uniquely, they also carry the φ2 bacteriophage encoding Panton-Valentine leucocidin. While the importance of this toxin was initially controversial in models of skin infection, it is now clear that Panton-Valentine leucocidin is host specific and targets human and rabbit neutrophils (107). Successful clones include the USA400 (CC1) clone, initially identified in the United States but now less prevalent, the successful USA300 (CC8) clone in the United States, which is spreading globally, the original Southwest-Pacific clone (CC30), the Asian clone (CC59) (108), and the Australian clone (CC93) (42). Antimicrobial resistance levels appear to be increasing (109), and fluoroquinolone resistance may play a role in the spread (86).

Livestock-associated MRSA strains have evolved in lineages CC398 and CC9 and are associated with pig and veal-calf agriculture. The isolates do not cause significant disease in these animals but can colonize the humans that come into contact with the farms, and the organisms can cause subsequent opportunistic infection. Interestingly, the isolates do not spread in hospitals as effectively as HA-MRSA (110), and colonization of farmers requires repeated exposure (111). CC398 isolates were originally considered untypable due to a modification of the SmaI restriction site that is lineage specific (51, 112). These successful clones are prevalent in mainland Europe and are spreading to the United States and South America and have acquired SCC*mec* elements but not φ3 with human host-specific immune evasion genes. While the reasons for their adaptation to pigs is unclear, they typically encode resistance to tetracycline antibiotics (113). Tetracyclines are widely used in agriculture but are used much less frequently in hospitals, and tetracycline resistance is relatively uncommon in hospital-acquired *S. aureus*. CC398 tetracycline resistance is due to genes carried on plasmids and/or transposons, and up to three distinct mechanisms in a single isolate have been identified (113). CC9 isolates in Asia have been reported to be multidrug resistant (114, 115). A recent increase in CC398 MRSA infection in humans with no contact with livestock has been attributed to higher carriage of this clone in the community and the acquisition of φ3 host-adaptation genes (116).

Genomic analysis has also revealed that other resistances can be selective. For example, in New Zealand, high usage of fusidic acid in the community has driven the evolution and selection of three MRSA clones that carry the *fus*C resistance gene (117). However, not all resistances are selective. Vancomycin and other glycopeptides are widely used to prevent and treat MRSA infection, yet resistance is still rare. Only 14 cases of fully vancomycin-resistant *S. aureus* (VRSA) have been described in the United States. They have evolved independently of each other due to the acquisition of the *van*A operon on a transposon from vancomycin-resistant enterococci (118). VRSA is unfit compared to its MRSA parents and is susceptible to both antibiotics in combination (119). VRSA has been reported in India, Brazil, Portugal, Turkey, and Iran (120–124) but is still rare, and there is little evidence of patient to patient spread. In contrast, intermediate-level vancomycin resistance in MRSA (vancomycin-intermediate *S. aureus* [VISA]) is more widely reported, and these bacteria have thickened cell walls that absorb excess antibiotic, slightly reducing susceptibility. Populations are often hetero-resistant with only a small subpopulation showing the VISA phenotype (125). These isolates probably have limited ability to resist vancomycin in the clinic, and associations between laboratory susceptibility and response to therapy are unclear (126). VISA does not appear to be a clonal trait associated with successfully spreading clones. Instead, VISA organisms are generally isolated from patients with chronic infection who have been exposed to long-term antibiotic therapy, and they arise due to SNV variation (125, 126). It can be concluded that despite substantial selective pressure, *S. aureus* has not yet been able to develop resistance to vancomycin that allows maintenance of fitness in its normal habitats and spread to new hosts.

Host

Genomic analyses of isolates from different hosts, particularly animal versus human, have identified key pathways that are

associated with adaptation to these hosts. Evasion of host innate immune responses is central to the survival of *S. aureus*, particularly escape from complement and neutrophil killing (48). Particular lineages are often associated with specific hosts, with each lineage carrying different combinations or variants of immune evasion genes, particularly on the genomic islands, such as inhibitors of complement cascade or antibodies, neutrophil signaling, migration and recognition, and cytolytic toxins (48).

In addition, host specificity can be strongly associated with MGEs. Human isolates typically carry the φ3 prophage with at least two or three genes at one end that are associated with evasion of the human immune response, while animal isolates are usually missing the phage (14, 127). These genes are the staphylococcal complement inhibitor (*scin*), which blocks activation of the human complement system (128), the chemotaxis inhibitory protein (*chips*), which prevents human neutrophil recruitment (129), and staphylokinase (*sak*), which activates human plasminogen and local spreading (130). Interestingly, the enterotoxin A (*sea*) gene, encoding the most common cause of staphylococcal food poisoning, is also carried on the φ3 phage adjacent to the immune evasion genes but is missing in many human isolates, suggesting that there is frequent recombination of this phage region and that *sea* is not required for host adaptation (14). The specific role of the φ3 phage in selection is most likely to be a requirement for survival in the normal colonizing habitat of the human nose, suggesting an active neutrophil response targeting *S. aureus* during colonization. It is unclear why only about 25% of humans are continuously colonized with *S. aureus* while others are colonized intermittently or not at all.

Leukocidins are two-component pore-forming toxins and function by binding to host-specific receptors on the surface of target cells (131, 132). One of these, Panton-Valentine leucocidin, targets human neutrophils (107) and is carried on a φ2 phage. While only a small proportion of human *S. aureus* bacteria carry Panton-Valentine leucocidin toxin, it has been implicated in rare lethal necrotizing pneumonia (133), as well as severe skin and soft tissue infection and the success of CA-MRSA clones (107).

S. aureus is a common cause of bovine mastitis, causing economic losses in the dairy industry. Unique lineages are associated with bovine isolates (14). A novel SaPI found in bovine isolates coagulates ruminant plasma only (23). The leukocidin toxin LukMF is carried on a φ1 phage in ruminant isolates only (48) and targets bovine neutrophils and immune cells (131).

In horses, a specific phage, φSaeq1, encodes a novel inhibitor of complement from horses, humans, and pigs, eqSCIN (134). Isolates from chickens often carry avian-adapted phages and plasmids, putatively involved in lysing chicken heterophils (135). In both wild mice and laboratory mice, *S. aureus* colonizing isolates have lost φ3 and immune evasion cluster genes (136).

A unique situation occurs in rabbit *S. aureus*, because host specificity can be conferred by a single naturally occurring nucleotide mutation in the *dltB* gene altering teichoic acid and lipoteichoic acid charge (137), a receptor commonly used by bacteriophages and for HGT (138).

Microbiome and Competing Bacteria

The normal habitat of staphylococci is the skin and mucous membranes of animals and birds, and this is the reservoir of infecting isolates. During colonization, a variety of adapted bacteria compete for space and nutrients (139). Competition and coevolution of these bacteria can result in direct inhibition, synergistic cooperation, and/or gene exchange. Environments can also change in nutrient availability, humidity, immune responses, infection with viruses, or antibiotic exposure (139). The microbiome is constantly adapting, and the ability of staphylococci to adapt to these environments is vital for their survival.

In the absence of a microbiome, such as a gnotobiotic animal model, *S. aureus* inoculated onto a single skin site can colonize the whole host within hours (78), presumably due to the lack of competing bacteria. However, once colonized, hosts in close contact exchange strains infrequently (78). Antimicrobials can also deplete microbiomes. In a mouse model of colonization, those treated with streptomycin were more likely to be colonized and colonized with greater numbers of bacteria (140). Humans exposed to antimicrobials that *S. aureus* is resistant to are more likely to be colonized (141).

Nutrients are also important. *S. aureus* survives better on the nutrients available in the human nose than coagulase-negative staphylococci (142), accounting for their different niches.

During evolution, a staphylococcal cell that has altered its genome by SNV or MGE acquisition must compete with not only the microbiome, but with its peers that have not altered their genome. The relative fitness of an evolving isolate can be compared to its peers, but its ability to survive depends on environmental factors.

Competition between microbiome species can be for nutrients and space or can be targeted. *S. lugdunensis* colonizing the human nose produces lugdunin, a peptide antibiotic that inhibits *S. aureus* colonization (143). Some *S. aureus* isolates also produce lantibiotics that target other *S. aureus* isolates, staphylococcal species such as *S. epidermidis*, and lactococci (144, 145), and staphylococcal species and lactococci, in turn, are capable of producing inhibitory lantibiotics against *S. aureus* (146, 147). *Corynebacterium* spp., *Haemophilus* spp., and streptococci also inhibit *S. aureus* colonization (148–150).

In the cystic fibrosis lung, *S. aureus* has a negative correlation with *Pseudomonas aeruginosa*, which eventually displaces it. *P. aeruginosa* produces a range of antistaphylococcal factors, but most interestingly, may also activate the host to clear *S. aureus* specifically by inducing a phospholipase (151, 152). Within a *Caenorhabditis elegans* worm model, coinfection with *Enterococcus faecalis* caused *S. aureus* to evolve to produce less siderophore for iron scavenging (153), while *E. faecalis* evolved to produce more superoxide antimicrobial to combat *S. aureus* (154).

SUMMARY

Staphylococci live on the skin and mucous membranes of mammals and birds and have adapted to this environment. They are formidable opportunistic pathogens, carrying multiple colonization and virulence factors that are often variable, redundant, and highly mobile. This genetic variability contributes to their ability to adapt to changing hosts, antimicrobial exposure, and bacterial competitors, expanding their niches and ability to cause opportunistic infection. New and successful clones with unique epidemiology teach us about genetic adaptability and the selective pressures in different environments. As we improve our understanding, we improve our ability to predict the next wave of multidrug-resistant staphylococci in new host populations and identify opportunities to reduce their impact on health, wealth, and welfare.

Staphylococcal Plasmids, Transposable and Integrative Elements

NEVILLE FIRTH, SLADE O. JENSEN, STEPHEN M. KWONG,
RONALD A. SKURRAY AND JOSHUA P. RAMSAY

31

As has been the case for other bacterial genera, studies of the genetic basis of staphylococcal pathogenicity and antimicrobial resistance highlighted the presence of determinants not uniformly represented in the genomes of all staphylococcal strains. Although not a fundamental requirement for survival *per se*, such accessory DNA usually encodes functions that are advantageous in a particular environmental niche. The extent of the accessory component of the genome has been revealed by comparative analysis of whole *Staphylococcus aureus* genome sequences, which indicate that it can constitute in excess of 20% of a strain's genetic makeup (1–5). It is clear that the acquisition, maintenance, and dissemination of accessory functions have been central to the ongoing success of staphylococci as pathogens. These processes are underpinned by interactions between mobile genetic elements, such as insertion sequences and transposons that mediate intracellular movement of DNA, and plasmids, bacteriophage and integrative and conjugative elements (ICEs) that facilitate intercellular DNA mobility.

MECHANISMS OF GENETIC EXCHANGE

DNA can be introduced into staphylococci by each of the three classical bacterial gene transfer mechanisms of transformation, transduction, and conjugation. Transformation is thought to be limited by extracellular nucleases and is usually very inefficient (6, 7). However, homologs of competence genes from other Gram-positive species are evident in the *S. aureus* chromosome, leading to the suggestion that natural competence might arise under suitable growth conditions and/or in subpopulations of cells (8). Staphylococci usually possess one or more prophages integrated within their genomes, and generalized transduction is likely to be a frequent mechanism of genetic exchange between strains (9, 10). Staphylococcal conjugative plasmids not only mediate their own self-transfer, but also facilitate the exchange of other coresident nonconjugative plasmids, either by mobilization if the other plasmid carries a relaxation system (11) or more generally via cointegrate formation, and potentially subsequent resolution, in a process termed "conduction" (12, 13). Conjugation is also thought to represent the most likely basis for the apparent transmission of large DNA segments that correspond to approximately 10 to 20% of the chromosome (14). In addition to their own transfer, chromosomally located ICEs in staphylococcal strains (15) might also mediate transmission of plasmid and chromosomal DNA (16). A novel but poorly understood mechanism of staphylococcal genetic exchange, termed mixed-culture transfer or phage-mediated conjugation, was described in the 1980s (6, 17, 18). Although phage, or perhaps components of phage, play a role, the process has been shown to be mechanistically distinct from transduction. More recently, another phage-mediated mechanism, termed autotransduction, has been defined (19), which like mixed-culture transfer, requires the DNA recipient to be lysogenic for specific prophage. It is possible that mixed-culture transfer and autotransduction are actually different perspectives on the same phenomenon. There have been several reports that describe enhanced DNA transfer between staphylococci, by conjugation and transduction, in response to subinhibitory levels of some antibiotics; however, in most cases the basis of this stimulation is yet to be delineated (10, 20–22). Notably, genetic exchange has also been observed to occur more efficiently *in vivo* than *in vitro* (23).

Identical or nearly identical accessory genes, elements, and plasmids have been detected in different staphylococcal species and other bacterial genera, such as enterococci and streptococci (24–28). Such observations suggest that, directly and/or indirectly, the gene transfer mechanisms operating in staphylococci facilitate not only intraspecific transfer, but also interspecific and intergeneric exchange and hence access to an extended and shared reservoir of determinants.

STAPHYLOCOCCAL PLASMIDS

One or more plasmids are usually found in clinical isolates of *S. aureus* and coagulase-negative staphylococci (7, 29). Historically, staphylococcal plasmids can be categorized into one of three main classes based on physical/genetic organization and functional characteristics (24, 25, 30). These correspond to small plasmids that utilize a rolling circle (RC) replication mechanism and usually carry a single resistance gene or are cryptic, larger multiresistance plasmids that often carry several resistance genes and conjugative plasmids that usually also contain multiple resistance determinants and are typically larger, again due to the conjugation-associated genes they contain; theta-mode replication is used by multiresistance and conjugative plasmids. However, categorization

doi:10.1128/microbiolspec.GPP3-0030-2018

based on resistance genes is parochial and does not necessarily reflect relatedness between plasmids, since resistance determinants can be readily lost from, or acquired by, plasmid backbones. For example, there are plasmids closely related to multiresistance and conjugative plasmids that lack any recognized resistance genes. Toxins are also encoded by some plasmids (29, 31–34), and the functions of many genes carried by larger plasmids have not been investigated, let alone elucidated.

Analysis of fully sequenced *S. aureus* plasmids in the databases has illustrated that plasmid size correlates strongly with the mode of replication used and hence with the replication initiation gene possessed. Plasmids smaller than 10 kb use the RC mechanism, whereas those larger than 14.5 kb utilize theta-mode replication, with plasmids in the intermediate 10 to 14.5-kb size range using either of these mechanisms (35). Fifteen plasmid incompatibility groups (Inc1 to Inc15) were established for staphylococcal plasmids, incorporating both RC replicating (RCR) and theta replicating plasmids (24, 36). However, the rate of plasmid discovery through genome sequencing has rendered incompatibility testing impractical. A plasmid typing system for plasmids from Gram-positive bacteria (including staphylococci) based on replication region DNA sequence has been established (37) and incorporated into the PlasmidFinder database (38). Unfortunately, coincident identification of additional replicon types (39, 40) has subsequently resulted in discordant classification of some staphylococcal plasmids.

Small RCR Plasmids

The most thoroughly characterized staphylococcal plasmids are those that utilize asymmetric RC replication via a single-stranded DNA intermediate (for detailed reviews of RC plasmid replication, see Khan [41] and Ruiz-Maso et al. [44]). Probably reflecting constraints imposed by this replication strategy, RCR (sometimes alternatively called just RC or single-stranded DNA) plasmids are usually less than 5 kb in size and are rarely found to contain transposable elements (24). This restriction in RCR plasmid size probably reflects elevated production of high-molecular-weight DNA with increasing plasmid size, which impairs cell growth, leading to counterselection against host cells and hence the plasmid itself (42). RCR plasmids are frequently found cointegrated within larger theta replicating plasmids, commonly flanked by insertion sequences such as IS*257*; in such cases the replication system of the integrated RCR plasmid is often inactivated in some way (28, 43).

Staphylococcal RCR plasmids can be subdivided into four families, exemplified by pT181, pC194, pE194, and pSN2, based on replication region sequence similarity (24); representative plasmids are shown in Fig. 1. These families contain plasmids found in different staphylococcal species and are related to plasmids of other bacterial genera, such as *Bacillus*, *Lactobacillus*, and *Streptococcus*, attesting to the horizontal transmission of RCR plasmids (42). Plasmids belonging to each of these four families encode evolutionarily distinct replication initiator (Rep) proteins that possess the conserved domains Rep_trans, Rep_1, Rep_2, and RepL, respectively (35). However, despite the Rep proteins having unique evolutionary origins, they perform a remarkably similar role in recognizing, binding, and nicking specific DNA sequences in the double-strand origin (*dso*). In the RCR plasmids examined so far, the Rep proteins also perform cleavage and ligation reactions at the termination of leading strand synthesis (44). pT181 family Rep proteins recruit the host-encoded helicase, PcrA, which is essential for synthesis of the new, and displacement of the parental, leading strands (45, 46). The leading strand contains a single-strand origin of replication (*sso*) that, upon displacement, is recognized and primed for replication by host-encoded RNA polymerase (47). The inability of host RNA polymerase to recognize and prime the *sso* limits the host range of RCR plasmids. For example, the *sso*A carried by pT181 only functions efficiently in staphylococci, whereas the *sso*U carried by pE194 family plasmids allows stable replication in a broader range of Gram-positive hosts (48).

RCR plasmids are usually maintained at 10 to 60 copies per cell (7), and copy number control is achieved via an antisense RNA that is transcribed divergently to the replication initiation gene (35). In the case of pT181, binding of the antisense RNA causes transcriptional attenuation of *rep*C mRNA (49), whereas for pC194 family plasmids antisense binding is believed to block translation of the Rep protein (50, 51). Antisense inhibition of Rep translation is also thought to occur in pE194 family plasmids, but transcriptional regulation mediated by a repressor protein may also play a role (35), as has been shown for the streptococcal RCR plasmid pMV158 (52, 53).

Some staphylococcal RCR plasmids contain mobilization systems that facilitate their horizontal transmission when coresident with a conjugative plasmid. Plasmids such as pC221 possess a multigene mobilization system (*mob*CAB and origin of transfer [*oriT*]) (Fig. 1) (11). The pC221 MobA relaxase and MobC relaxase accessory proteins are both required for nicking at *oriT* (54, 55). Other RCR plasmids possess a different mobilization locus that is homologous to the *mob*M relaxase gene and *oriT* of pMV158 (56, 57). This locus was originally identified as a site-specific recombination function on staphylococcal plasmids such as pT181 and pE194 (Fig. 1) (24), where the constituent sequences were named *pre* and RS_A (corresponding to mob_{pre} and $oriT_{RSa}$, respectively) (Fig. 1). Additionally, the replication initiation protein and *dso* of several RCR plasmids have been shown to "moonlight" as a relaxase and *oriT* for mobilization mediated by the ICE Tn*916* (see below) (58).

RCR plasmids, including those in different families, often share highly similar DNA segments, such that they appear to be mosaic structures consisting of discrete functional cassettes encoding replication, resistance, and sometimes recombination/mobilization functions (24, 59). Exchange of these segments between plasmids is thought to be promoted by the single-stranded intermediates generated by the RC replication strategy, which enhance the frequency of homologous recombination events between regions of flanking sequence similarity (60). DNA processing at replication and transfer origins also promotes the swapping of such cassettes (24, 61).

Theta Replicating Plasmids

Most staphylococcal plasmids larger than 10 kb employ theta-mode replication and are maintained at low copy numbers (7, 35, 62–65). The majority encode a replication initiation protein containing an N-terminal conserved RepA_N domain (29, 35, 66), which corresponds to a winged helix-turn-helix DNA binding domain that binds to origin Rep box repeat sequences characteristically located centrally within the *rep* gene coding sequence (67–69); the C-terminal domain of the Rep protein from the *S. aureus* conjugative plasmid pSK41 (see below) has been shown to interact with the host encoded DnaG primase (70). An interesting variation is seen in the plasmid pTZ2162, where the RepA_N-type initiation protein has been split into two smaller distinct polypeptides, expressed from two partially overlapping *rep*

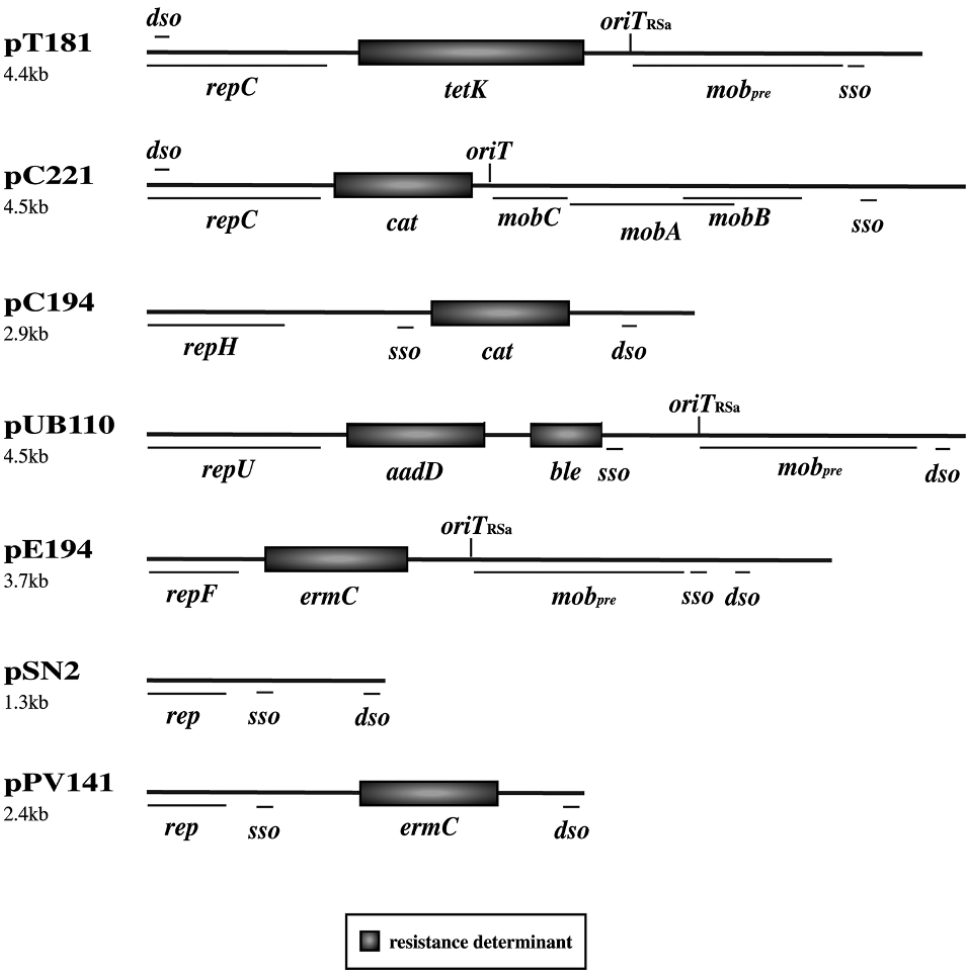

FIGURE 1 Maps of representative RCR plasmids: pT181, pC221, pC194, pUB110, pE194, pSN2, and pPV141 (25, 231); see text for additional references. Plasmid sizes are shown on the left. Resistance and plasmid maintenance genes/loci are shown: *rep*/*repC*/*repF*/*repH*/*repU*, initiation of replication; *dso*, double-stranded origin of DNA replication; *sso*, single-stranded origin of DNA replication; *mobA*/*mobB*/*mobC*/mob_{pre}, mobilization; *oriT*/$oriT_{RSa}$, origin of DNA transfer; *cat*, chloramphenicol resistance. Refer to Tables 1 and 2 for the antimicrobial resistance(s) conferred by other resistance determinants.

genes that have likely arisen from a frameshift (71). In staphylococcal plasmids encoding RepA_N type initiators, copy number is thought to be controlled by a small antisense RNA that binds to the leader region of the *rep* mRNA to block its translation (68, 72, 73).

Two groups of nonconjugative multiresistance plasmids were described previously in staphylococci: the β-lactamase/heavy-metal resistance plasmids and the pSK1 family plasmids; both utilize RepA_N initiation proteins (74). *S. aureus* strains from the 1960s and 1970s commonly contained plasmids that conferred resistance to β-lactam antibiotics and heavy metals or other inorganic ions. These plasmids characteristically carried a Tn*552*-like β-lactamase-encoding transposon or a derivative thereof (75, 76) and frequently possessed a composite structure designated Tn*4004* conferring resistance to mercuric ions and operons encoding resistance to arsenical and/or cadmium ions (Fig. 2) (6, 77). Additionally, some β-lactamase/heavy-metal resistance plasmids carry the transposon Tn*4001* or Tn*551* conferring resistance to aminoglycosides (6, 78) and macrolide-lincosamide-streptogramin type B (MLS) antibiotics (79), respectively, and/or a *qacA* or *qacB* gene mediating multidrug resistance to antiseptics and disinfectants (Fig. 2) (6).

Plasmids related to the prototype, pSK1 (Fig. 2), were first identified in epidemic *S. aureus* and coagulase-negative staphylococcal strains isolated in Australia during the 1980s and later in isolates from Europe (25). In addition to a *qacA* gene mediating multidrug resistance to antiseptics/disinfectants carried ubiquitously by pSK1 family plasmids (80, 81), members of this family variously encode Tn*4001*, which confers resistance to gentamicin and other aminoglycosides (82), a Tn*552*-like β-lactamase transposon, Tn*4002* (83), and/or a composite structure designated Tn*4003* that mediates trimethoprim resistance (84). Tn*4003* represents a vestige of a cointegrated pSK639-like plasmid (see below (26, 85).

As more plasmid sequences have accumulated through genome sequencing it has become clear that there is a broad diversity of plasmids with a *repA_N*-type initiation gene, including plasmids lacking resistance genes and/or containing

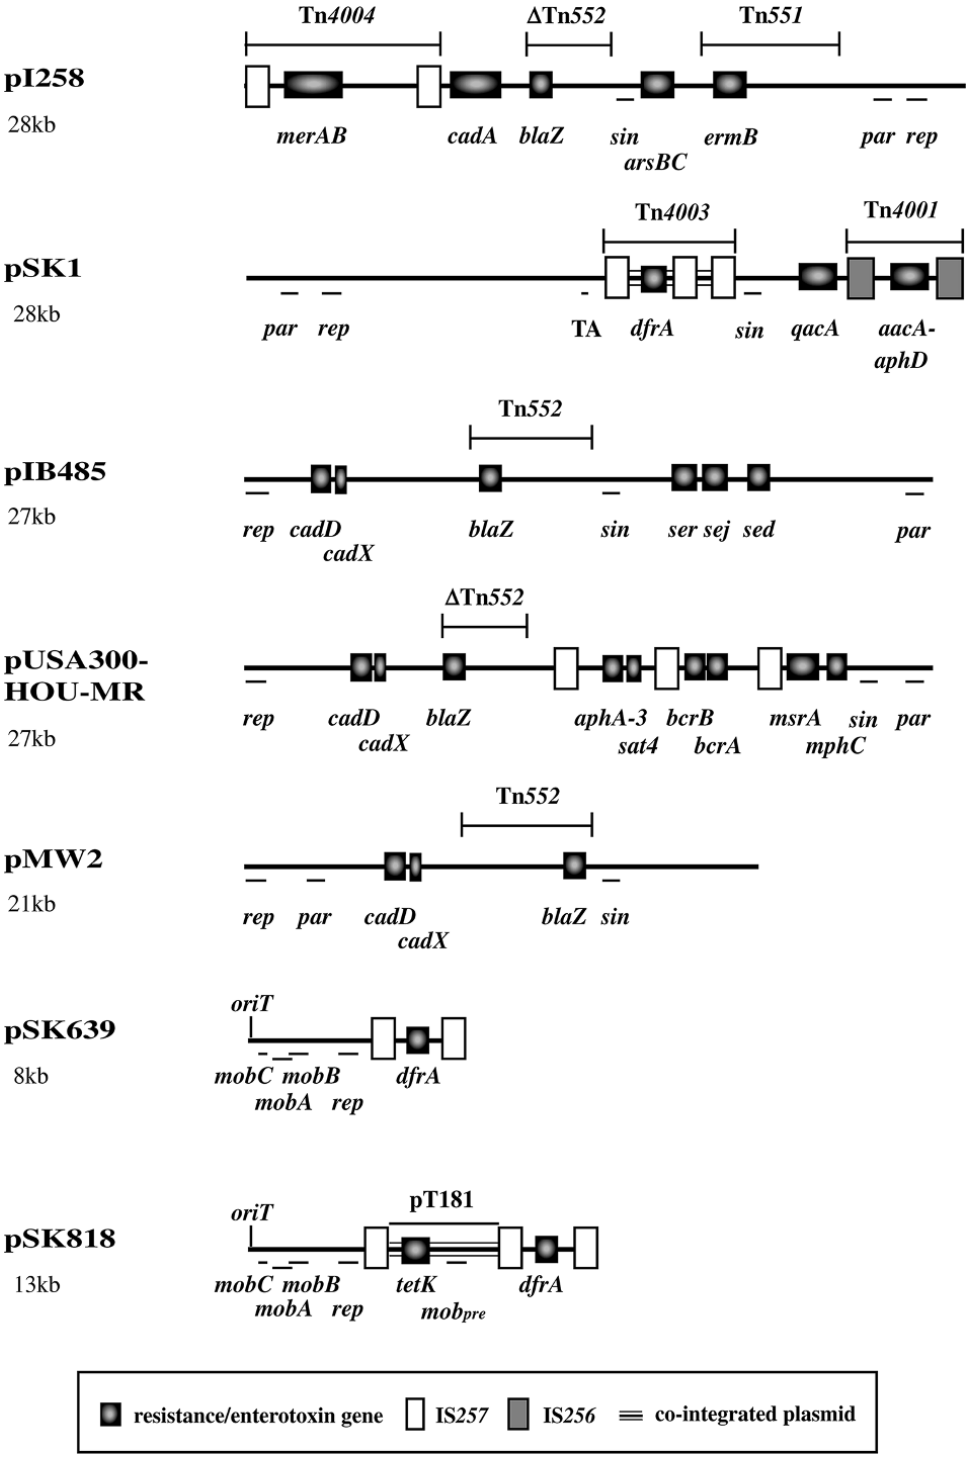

FIGURE 2 Maps of representative nonconjugative theta-replicating plasmids: pI258, pSK1, pIB485, pUSA300-HOU-MR, pMW2, pSK639, and pSK818 (3, 25, 29, 65, 85, 89, 232); see text for additional references. Resistance/enterotoxin genes, transposons, insertion sequences, and cointegrated plasmids are shown: *ars*BC, arsenic resistance; *cad*A, cadmium resistance; *mph*C, macrolide resistance; *msr*A, macrolide/streptogramin B resistance; *qac*A, antiseptic/disinfectant resistance; *ser*, *sej*, and *sed*, enterotoxins. Refer to Tables 1 and 2 for the antimicrobial resistance(s) conferred by other resistance determinants. Plasmid maintenance genes/loci are also shown: *par*, novel partitioning system; *rep*, initiation of replication; *sin*, multimer resolution; TA, Fst-like toxin-antitoxin system; *mobA*/*mobB*/*mobC*/mob_{pre}, mobilization.

toxin genes, such as pIB485 (Fig. 2) and related plasmids that have been isolated from strains of wide geographic distribution (29). Two other loci are nearly ubiquitous on RepA_N-encoding plasmids, suggesting that they are important for plasmid survival (29). The first is a multimer resolution system that includes a gene coding for a serine recombinase, which is usually annotated as *sin* or *bin3* (86, 87). The second is homologous to the pSK1 *par* (formerly *orf245*) gene, which is usually located upstream of, and transcribed divergently from, the *rep* gene. This locus increases plasmid segregational stability and is thought to constitute a novel single-protein partitioning system (64, 88). In contrast, type I and II partitioning systems, comprising two protein-encoding genes, are found only occasionally on these plasmids (29). Finally, an Fst-like type I toxin-antitoxin system, which might contribute to plasmid segregational stability, is carried by pSK1 (89), and related loci have been identified on numerous other theta replicating staphylococcal plasmids (90, 91).

A minority of theta replicating staphylococcal plasmids code for a Rep protein containing a Rep_3 conserved domain (35); initiation proteins of this type from Gram-negative bacteria, encoded by iteron plasmids such as F, pPS10, and R6K, contain tandem winged helix-turn-helix domains (92). This type of replication system was first detected in the genus in plasmids from *Staphylococcus epidermidis* related to the 8-kb trimethoprim resistance plasmid pSK639 (Fig. 2), which also contains a mobilization system related to that of the RCR plasmid pC221 (65). More recently, *rep_3*-type genes have been found in addition to the usual *repA_N*-type gene on larger β-lactamase/heavy-metal resistance plasmids such as pN315 (1), whereas in the case of pMW2 (3) (Fig. 2), only a remnant of the *repA_N* gene remains. Finally, plasmids employing an initiation protein containing a PriCT_1 conserved domain, such as pETB, which encodes exfoliative toxin B (32), have also been found in staphylococci but appear to be quite rare; some also encode a RepA_N or Rep_3 type initiator (35).

Conjugative Plasmids

The largest staphylococcal plasmids (>30 kb) are those that encode their own conjugative transfer (7, 25). Three distinct families of conjugative plasmids have been identified in staphylococci: the well-known pSK41/pGO1-like plasmids and the recently characterized pWBG4 and pWBG749 families.

S. aureus plasmids such as pSK41 (43, 93, 94) (Fig. 3), pGO1 (95, 96), and pJE1 (20) were first identified in association with gentamicin resistance in the mid 1970s (13, 25). Structurally related conjugative plasmids were found in coagulase-negative staphylococci (97, 98), and interspecific transfer has been demonstrated (99, 100). In pSK41 and many relatives, the plasmid backbone consists of two IS*257*-flanked segments, termed the transfer (*tra*) region and region I (Fig. 3) (94). However, in other family members (e.g., pPR9) these segments are contiguous, and this likely represents the ancestral configuration prior to the incorporation of additional DNA segments (43, 101, 102).

Multiple copies of IS*257*, mostly in the same orientation, are a feature of many pSK41-like plasmids (Fig. 3). These usually delimit segments that carry resistance genes and often correspond to cointegrated copies of smaller plasmids (43, 103). Such determinants include the aminoglycoside and bleomycin resistance genes *aadD* and *ble*, respectively, on a copy of pUB110 and the small multidrug resistance determinant *qac*C on another RCR plasmid (Fig. 3). Plasmids such as pJE1 and pGO1 also contain a Tn*4003*-like structure derived from a pSK639-like trimethoprim-resistance plasmid (see above). The *aacA-aphD* gene encoded by Tn*4001*-IS*257* hybrid structures is responsible for resistance to gentamicin and other aminoglycosides (104). Members of the family have also been found that contain IS*257*-flanked genes encoding resistance to tetracycline (*tetK*) (29), MLS antibiotics (*erm*C) (105), mupirocin (*mupA*/*ileS2*) (102, 106), and most recently, multidrug resistance to phenicols, lincosamides, oxazolidinones (e.g., linezolid), pleuromutilins, and streptogramin A compounds ($PhLOPS_A$ phenotype; *cfr*) (107). Plasmids of this type can also carry unit transposons, such as Tn*552* (*blaZ*) (43) and the *vanA* glycopeptide resistance transposon Tn*1546* (27). The pSK41-like plasmid pLW1043 (Fig. 3) was responsible for the first reported high-level vancomycin-resistant *S. aureus* strain, isolated in Michigan in 2002 (27), and resulted from the transposition of Tn*1546* into a copy of IS*257* within the pSK41-like plasmid pAM829 (27, 108). A Tn*1546*-containing Inc18 broad-host-range conjugative plasmid, pAM830, carried by a coisolated *Enterococcus faecalis* strain, is thought to have mediated the intergeneric transfer event (27, 109). Such enterococcal Inc18 *vanA* plasmids themselves have subsequently been detected in some vancomycin-resistant *S. aureus* strains, but their scarcity in *S. aureus* suggests some limitation on their establishment in this species, possibly inefficient replication, an incompatibility with staphylococcal cell wall biosynthesis, a restriction barrier, and/or high metabolic burden associated with *vanA* carriage (108). Cointegrates composed of Inc18 and pSK41-like plasmids are also thought to occur (110), and it has been suggested that carriage of pSK41-like plasmids might enhance the recipient ability of *S. aureus* cells for enterococcal donors containing Inc18 plasmids, but the mechanism has not been determined (111).

Conjugative transfer of pSK41 family plasmids occurs only on solid surfaces and does so at comparatively low frequencies, in the range of 10^{-5} to 10^{-7} transconjugants per donor cell (13). The majority of genes thought to be responsible for conjugative transfer are located in the *tra* region (Fig. 3) (93, 95). The *tra* genes are most similar to the transfer genes of the *Lactococcus lactis* plasmid pMRC01 (112) and the broad host range plasmid pIP501 (43), originally identified in *Streptococcus agalactiae*, exhibiting both synteny and product amino acid sequence similarity (43, 113, 114). Several deduced products show homology to proteins from the type IV secretion system superfamily, including to coupling proteins, peptidoglycan hydrolases, and several other core mating pair formation-type proteins (115, 116). Thus, the basic conjugative process is likely to resemble that of more extensively characterized Gram-negative counterparts, *viz.*, transfer of a single strand of plasmid DNA via direct cell-cell contact. However, no pilus-like structure seems to be associated with Gram-positive conjugation (114), perhaps reflecting the distinction in the cell envelope organizations and accounting for the solid surface requirement for conjugative transfer. The origin of transfer, *oriT*, and the relaxase, Nes, that acts upon it, are encoded in region I (117, 118), as are a number of genes of unknown function that might also play a role in conjugative transfer (20, 43, 113).

As mentioned above, pSK41-like conjugative plasmids encode a RepA_N type replication initiation protein, whose translation is regulated by an antisense RNA called RNAI (67, 70, 72, 73). However, several members of the family, such as pPR9 and pUSA03, possess a novel chimeric *rep* gene where the sequences that usually encode the N-terminal RepA_N DNA-binding domain, and the origin Rep box

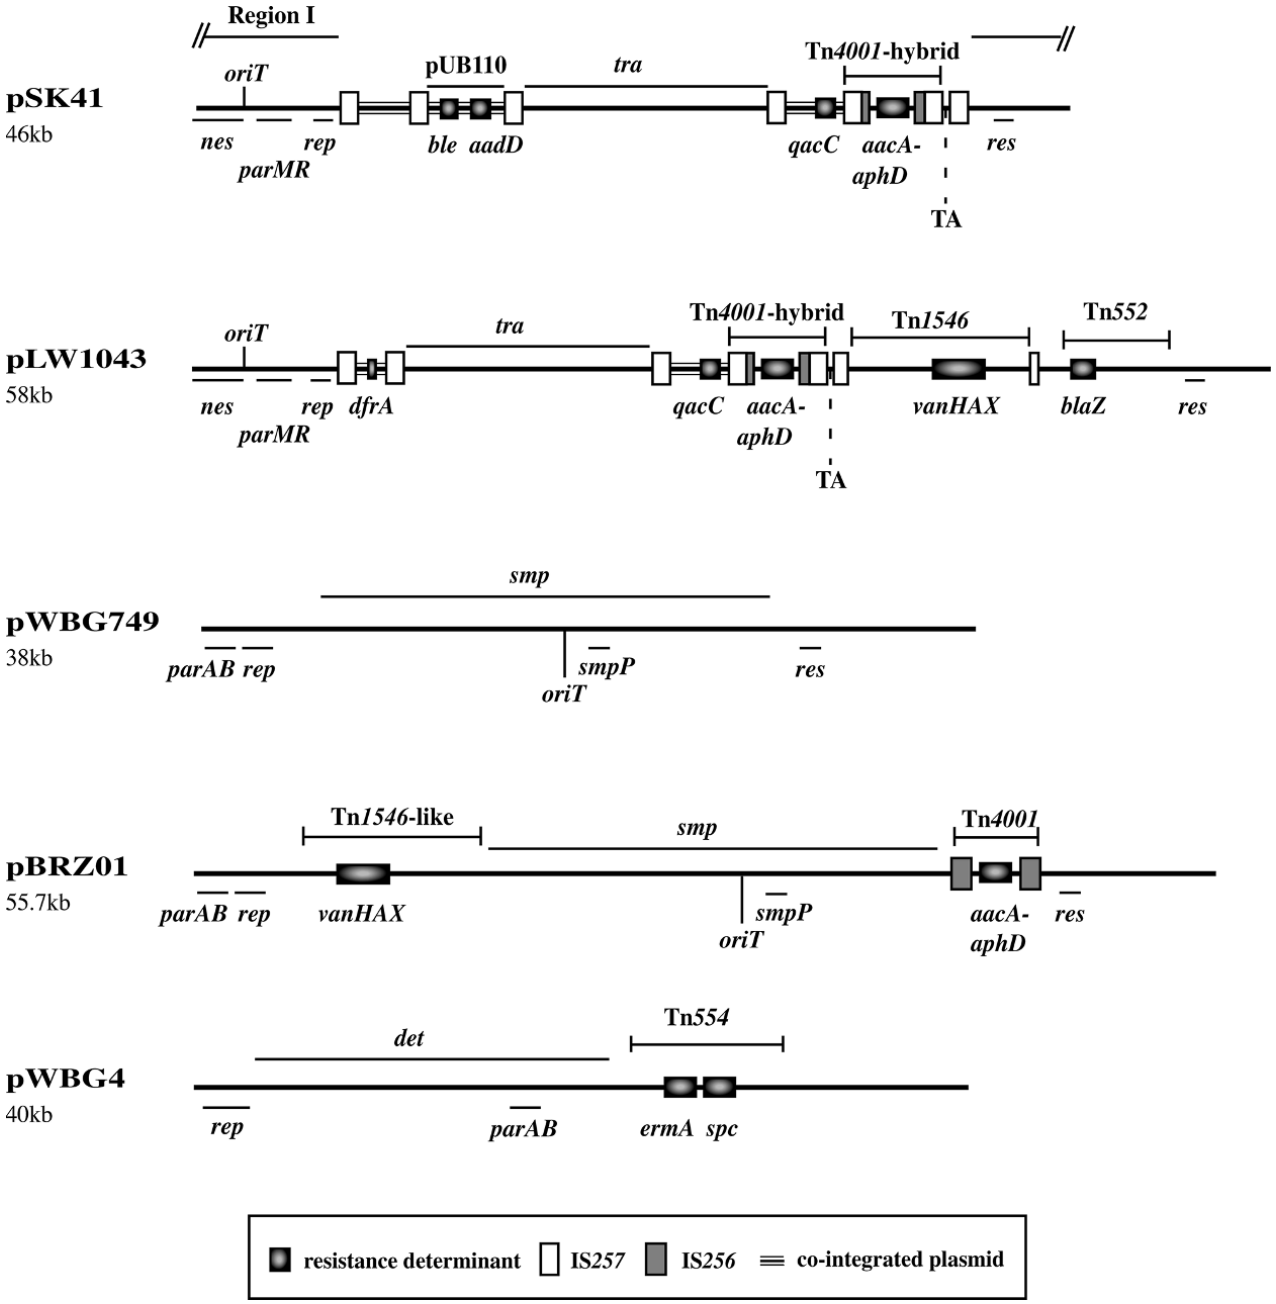

FIGURE 3 Maps of representative conjugative theta-replicating plasmids: pSK41, pLW1043, pWBG749, pBRZ01, and pWBG4 (27, 43, 128, 136, 137); see text for additional references. Resistance genes, transposons, insertion sequences, and cointegrated plasmids are shown: refer to Tables 1 and 2 for the antimicrobial resistance(s) conferred by the resistance determinants. Plasmid maintenance genes/loci (if known) are also shown: *parAB*, type I partitioning system; *par*MR, type II partitioning system; *rep*, initiation of replication; *res*, multimer resolution; TA, Fst-like toxin-antitoxin system; *tra*/*smp*/*det* genes, conjugative transfer; *nes*/*smpP* genes, relaxases; *oriT*, origin of transfer. Note that pLW1043 and pBRZ01 are members of the pSK41 and pWBG749 families, respectively.

repeats to which it binds, appear to have been replaced by sequences encoding a helix-turn-helix protein sequence related to phage replication proteins and distinct DNA sequence repeats (35, 102). The usual upstream antisense RNA control region and downstream in-frame end of the *rep* gene, encoding the conserved C-terminal end of the Rep protein that interacts with host DnaG primase (70), remain intact in these plasmids, but the variation is sufficient to allow compatibility with the pSK41 replication system (102).

All known pSK41 family plasmids encode a serine recombinase and a type II active partitioning system, the latter representing a significant difference from *rep*A_*N* replicating nonconjugative staphylococcal plasmids, which usually contain an unusual *par* gene or occasionally a type I partitioning system (see above). The pSK41 *res* locus is functional, facilitating the conversion of plasmid multimers into monomers, with the Res protein shown to bind to a resolution site, comprising three subsites, located in the intergenic

region upstream of the *res* gene; Res binding also autoregulates transcription of its own promoter (119). Functionality of the pSK41 partitioning system has also been demonstrated (120). It comprises a centromere-like site, *par*C, and two genes in an operon, *par*M and *par*R. The ParM protein is an actin-like motor protein that forms single-stranded helical filaments (121). ParC is a ribbon-helix-helix protein that binds to DNA repeat sequences within *par*C (120) and interacts with ParM to modulate its activity (122). ParR also autoregulates transcription from the partitioning operon promoter, which is also controlled by the plasmid-encoded ArtA protein (see below). Some pSK41-like plasmids encode an additional potential plasmid maintenance determinant in the form of an Fst-like toxin-antitoxin system, which is located on a small IS*257*-flanked DNA segment adjacent to Tn*4001*-hybrid elements in plasmids conferring gentamicin resistance (94).

In pSK41, transcription of the majority (21 out of 30) of the plasmid backbone genes is controlled by the product of the conserved *art*A gene (corresponding to *trsN* on pGO1) (101, 123). The ArtA protein is a ribbon-helix-helix DNA-binding protein that represses five promoters in addition to its own—including two operon promoters in the *tra* region and two more operon promoters in region 1 (Fig. 3). ArtA is therefore thought to coordinate basal-level transcription of most of the plasmid's backbone genes (101).

The pWBG4 family of conjugative plasmids, also called diffusible pigment (DiP) plasmids, were first identified as a distinct family of *S. aureus* conjugative plasmids in the 1980s by the Grubb laboratory (124–127), but the complete sequence of pWBG4 (Fig. 3) was only reported in 2016 (128). The first example of this family, pWBG14, was isolated in Western Australia in 1968 and conferred resistance to MLS antibiotics (*erm*A) and spectinomycin (*spc*) and production of a diffusible orange pigment. Related plasmids were subsequently identified carrying resistance to aminoglycosides and trimethoprim (*dfrD*), and more recently several pWBG4-related plasmids were implicated in the conjugative transfer of linezolid and phenicol resistance (*cfr* and *fex*A) (128, 129) in America, China, and Germany (128, 129). pWBG4 family plasmids carry an ~18-kb conjugation-gene cluster *detA-detV* which is distinct from that of pSK41/pGO1 family plasmids and uniquely includes a MobC-like conjugative relaxase (DetB) and T4CP (DetA) related to those of the mobilizable *Enterobacter cloacae* plasmid CloDF13 (128, 129). pWBG4 plasmids also encode a PriCT_1-domain replication-initiation protein common to enterococcal Inc18 plasmids (35). pWBG4 family plasmids have been isolated from both *S. aureus* and *S. epidermidis*, and transfer between and within these species has been demonstrated (125).

The pWBG749 family was also only recently sequenced and identified as being a distinct family of *S. aureus* conjugative plasmids. pWBG749 (Fig. 3) was originally isolated in 1995 (29, 125, 130, 131) from colonizing *S. aureus* present in remote indigenous communities in Western Australia, but more recent sequencing has identified variants isolated as early as 1985 (36, 128, 132–135). pWBG749 encodes a RepA_N initiation protein, possesses a type IB partitioning system (29), and carries an ~23-kb conjugation gene cluster *smpA-X* (136) (Fig. 3). While most identified pWBG749 family plasmids lack antimicrobial-resistance determinants, members carrying resistance to penicillin (*blaZ*), aminoglycosides (*aacA-aphD*), and vancomycin (*vanA*) have been isolated (130–133, 137). Despite their frequent cryptic nature, pWBG749 family plasmids likely have an extensive impact on antimicrobial resistance dissemination through their so-far unique ability to horizontally mobilize large multiresistance plasmids in addition to smaller plasmids (131).

The mechanism by which pWBG749 mobilizes nonconjugative plasmids was only recently recognized as a naturally occurring phenomenon, potentially explaining why it was previously overlooked (128, 136). Most characterized plasmid mobilization systems described require a mobilizable plasmid to carry its own relaxase gene (138). Plasmids capable of being mobilized by pWBG749 need only carry a short "mimic" of the pWBG749 origin-of-transfer sequence (136). The conjugative relaxase of pWBG749, SmpP, along with an *oriT* specificity factor, SmpO, acts *in trans* on the *oriT* to pilot it to the mating apparatus. Approximately 50% of unique nonconjugative staphylococcal plasmids carry a pWBG749 family *oriT* mimic (136). Most common mimics are near-identical to those on pWBG749 or the closely related conjugative plasmid pWBG745 and its vancomycin resistance-encoding derivative pBRZ01 (Fig. 3) (137). Bioinformatic inspection of 397 sequenced clinical *S. aureus* isolates from the MRSA Orange County initiative of the Broad Institute (broadinstitute.org) identified just 24 contigs matching pWBG749 or pWBG745, but astonishingly, 736 *oriT* mimics were identified among the sequence contigs. This abundance is likely explained by the presence of up to three *oriT* mimic variants per plasmid on common large multidrug resistance plasmids such as pIB485, pMW2, and pUSA300-HOU-MR (Fig. 2) and on small RCR plasmids (128, 136, 138).

Analogous to pWBG749-like *oriT* mimics, multiple mimic types that resemble the pSK41 *oriT* sequence were also detected recently on numerous staphylococcal plasmids (139). Although pSK41 could not mobilize the variants tested, it would seem likely that other pSK41 family plasmids encoding relaxation systems with appropriate specificity might also mediate relaxase-*in trans* mobilization. Recent bioinformatic analyses have revealed that nearly all theta replicating *S. aureus* plasmids carry at least one *oriT* mimic sequence, with many possessing both pWBG749 and pSK41 types, suggesting that the capacity for conjugative mobilization via the relaxase *in trans* mechanism is widespread (138).

TRANSPOSABLE ELEMENTS

Insertion sequences and composite transposons detected in staphylococci are listed in Table 1, and unit transposons are presented in Table 2. For many, designation as a transposable element is based on possession of diagnostic characteristics, such as terminal inverted repeats, flanking insertion sequences and/or target duplications, presence of an open reading frame encoding a transposase homolog, and/or detection in varied genetic contexts, rather than formal demonstration of mobility in a *rec*A recombination-defective host. As outlined for specific elements below, in addition to facilitating the translocation of genes between replicons, insertion sequence elements are increasingly being shown to play more subtle roles in phenotypic expression and genome evolution.

Inverted copies of IS*256* flank the composite transposon Tn*4001* (Figs. 2 and 3; Table 1) (82). Tn*4001* and elements related to it are responsible for the emergence of linked resistance to the aminoglycosides, gentamicin, tobramycin, and kanamycin in staphylococci, having been found on the chromosome and theta replicating plasmids (Figs. 2 and 3) in clinical *S. aureus* and coagulase-negative staphylococcal isolates from around the world (6, 25). Indeed, some of the earliest reported gentamicin-resistant strains, dating from 1975, have been shown to carry a Tn*4001*-like structure on

[d]Tn*3853* is likely to be similar or identical to Tn*554*.

the chromosome (140). Resistance is mediated by the gene *aacA-aphD*, which encodes a bifunctional enzyme possessing both aminoglycoside acetyltransferase and phosphotransferase activities (75). Transposons closely related to Tn*4001* are also evident in enterococci (141) and streptococci (142). In enterococci, IS*256* and related insertion sequences are also associated with elements encoding resistance to vancomycin (143) and erythromycin (144). IS*256* also appears to be contributing to the spread of the *cfr* multiresistance gene, forming a composite-like structure with a copy of the related enterococcal element IS*Enfa4* (145, 146).

Roles in gene expression and regulation have been attributed to IS*256* via both transcriptional promotion and insertional inactivation. Transcription of the *aacA-aphD* resistance gene of Tn*4001* is directed by a complete promoter located within the end of the upstream copy of IS*256*, and it has also been found that a small flanking deletion can result in a −35-like sequence at the terminus of that element forming part of a hybrid promoter which mediates a higher level of aminoglycoside resistance (147). Additionally, roles for IS*256* hybrid promoters have been demonstrated in the expression of methicillin resistance (148, 149). Insertional inactivation of genes by IS*256* has been shown to modulate expression of several phenotypes, including virulence and glycopeptide resistance. Alternating IS*256* insertions and excisions in the *ica* operon responsible for the synthesis of the polysaccharide intercellular adhesin mediate phase-variable biofilm formation in *S. epidermidis* strains responsible for indwelling device infections (150). Notably, biofilm phase variation has also been attributed to IS*256* insertions that affect global regulatory circuits, including the *sarA* global regulator, the quorum-sensing *agr* system, and *rsbU* which positively regulates the σ^B stress response factor (151, 152). IS*256* inactivation of the *tcaA* locus was found to increase the teicoplanin resistance of a glycopeptide intermediate-resistant *S. aureus* strain (153), and IS*256* insertion into the promoter region of the *walKR* two-component regulator system similarly resulted in decreased glycopeptide susceptibility (154, 155). Insertion into the promoter repressor of toxins gene, *rot*, was also found to enhance the virulence of a USA500 strain (156).

IS*256* utilizes a "copy-out-paste-in" transposition mechanism via an excised circular double-stranded DNA intermediate (157–159). Its transposase contains an N-terminal helix-turn-helix domain that mediates binding to the element's terminal inverted repeats (160). The capacity of IS*256* to mediate phase variability has been linked to a capacity for precise excision of the element and the target duplication generated during insertion (150). Interestingly, this excision behavior occurs independently of the element's transposase and is instead thought to involve host-mediated illegitimate recombination acting on the flanking target duplications (161).

IS*257* (also known as IS*431*) has been found in diverse genetic contexts in staphylococci, variously associated with a number of determinants (Table 1). The prevalence of resistance genes flanked by copies of this element resulted in the designation of several such composite structures as transposons, *viz.*, Tn*4003* and Tn*4004*. Although the possibility that these structures can behave as traditional composite transposons cannot be excluded, such an organization is probably a consequence of the transposition mechanism of IS*257*. This insertion sequence element is thought to undergo nonresolved replicative transposition (26, 103). The expected outcome of such an event involving two replicons is cointegration, so that the replicons become fused with a directly repeated copy of IS*257* at each junction, as has been experimentally demonstrated by Needham et al. (162). The IS*257*-like element IS*Sau10* is also found in such configurations (163, 164). Many IS*257*-flanked segments represent plasmids cointegrated into larger plasmids (Figs. 2 and 3) or the chromosome (26, 103). Frequently observed deletion events adjacent to IS*257* may result from intramolecular transposition of IS*257*. However, replicon fusions and

sequence deletions have also been shown to have resulted from homologous recombination between pre-existing copies of IS*257* (43).

IS*257* is a member of the IS6 family of insertion sequences (159). Another member of this family, IS*26*, which is found flanking resistance genes with increasing prevalence in Gram-negative bacteria, has recently been shown to undergo a second "conservative" mode of transpositional movement (165, 166); the process was IS*26* transposase dependent and *recA* independent in *Escherichia coli*. It involves the insertion of a single copy of the element and a flanking DNA fragment (often containing a resistance gene), termed a translocatable unit (TU), adjacent to an existing copy of IS*26* in another replicon. The resulting composite structure can be equivalent to an IS*26*-mediated cointegration event into an "IS*26*-less" replicon, but importantly, movement of an IS*26* TU was found to occur at a much higher frequency than cointegrate formation mediated by transposition of just an IS*26* copy. As a consequence, the presence of IS*26* in a replicon predisposes it to the acquisition of IS*26* TUs. The capacity of IS*257* to promote movement via comparable TUs is yet to be investigated, but the similar properties of these elements in their distinct hosts, particularly their prevalence in gene arrays punctuated by directly repeated insertion sequence copies, suggests it is a distinct possibility (165, 166).

The activities of IS*257* are illustrated by the pSK41 family plasmids (Fig. 3). It would seem that IS*257*-mediated cointegration has enabled these conjugative plasmids to collect functions, in the form of smaller plasmids, as they move horizontally through bacterial populations. Insertions and flanking deletions mediated by this element provide a mechanism for the inactivation or removal of deleterious sequences, such as redundant replication function.

Interestingly, short (148-149 bp) elements, named ISLE39 and ISLE49, that lack any transposase coding sequence but possess terminal inverted repeats similar to those of IS*257*, have been identified in several staphylococcal species (167). These presumably represent non-autonomous miniature inverted repeat transposable elements (MITEs) that could be rendered mobile by transposase encoded by IS*257* copies present in the same cell.

A central role for IS*257* has been suggested in the evolution of staphylococcal trimethoprim resistance, including the probable capture of the resistance gene, *dfrA*, from the chromosome of an *S. epidermidis* strain (26, 103). Furthermore, an IS*257*-hybrid promoter is responsible for transcription of this determinant (103, 168). In some plasmids, the high-level trimethoprim resistance typically conferred by this determinant has been moderated as a consequence of IS*257*-associated flanking deletions. An analogous IS*257*-hybrid promoter transcribes the *tetA*(K) tetracycline resistance gene of a cointegrated copy of pT181 within type III SCC*mec* elements (see below), and several other resistance genes are likely to be similarly promoted (102, 169).

One or more copies of IS*257* are carried by most types of staphylococcal cassette chromosome *mec* (SCC*mec*) elements (where it is commonly denoted IS*431*; see below). As well as flanking various resistance determinants within these elements, in several *SCCmec* types an IS*257* copy has mediated deletion of the *mecI* and part of the *mecR1* regulatory genes, resulting in derepressed transcription of the *mecA* methicillin resistance gene (170). Equivalent *mecI-mecR1* deletions are associated with another insertion sequence in some other SCC*mec* types, which instead contain a remnant of IS*1272*, ψIS*1272* (see below) (171–173). Multiple intact copies of IS*1272* have been found on the chromosomes of *S. aureus* and coagulase-negative staphylococcal strains, and it is particularly prevalent in *Staphylococcus haemolyticus* (4, 172, 174). IS*1272* is also associated with the elements Tn*Sha1* and Tn*Sha2*, which encode the *fabI* determinant responsible for resistance to the biocide triclosan (175); these elements are believed to target palindromic sequences and not generate target duplications during transposition.

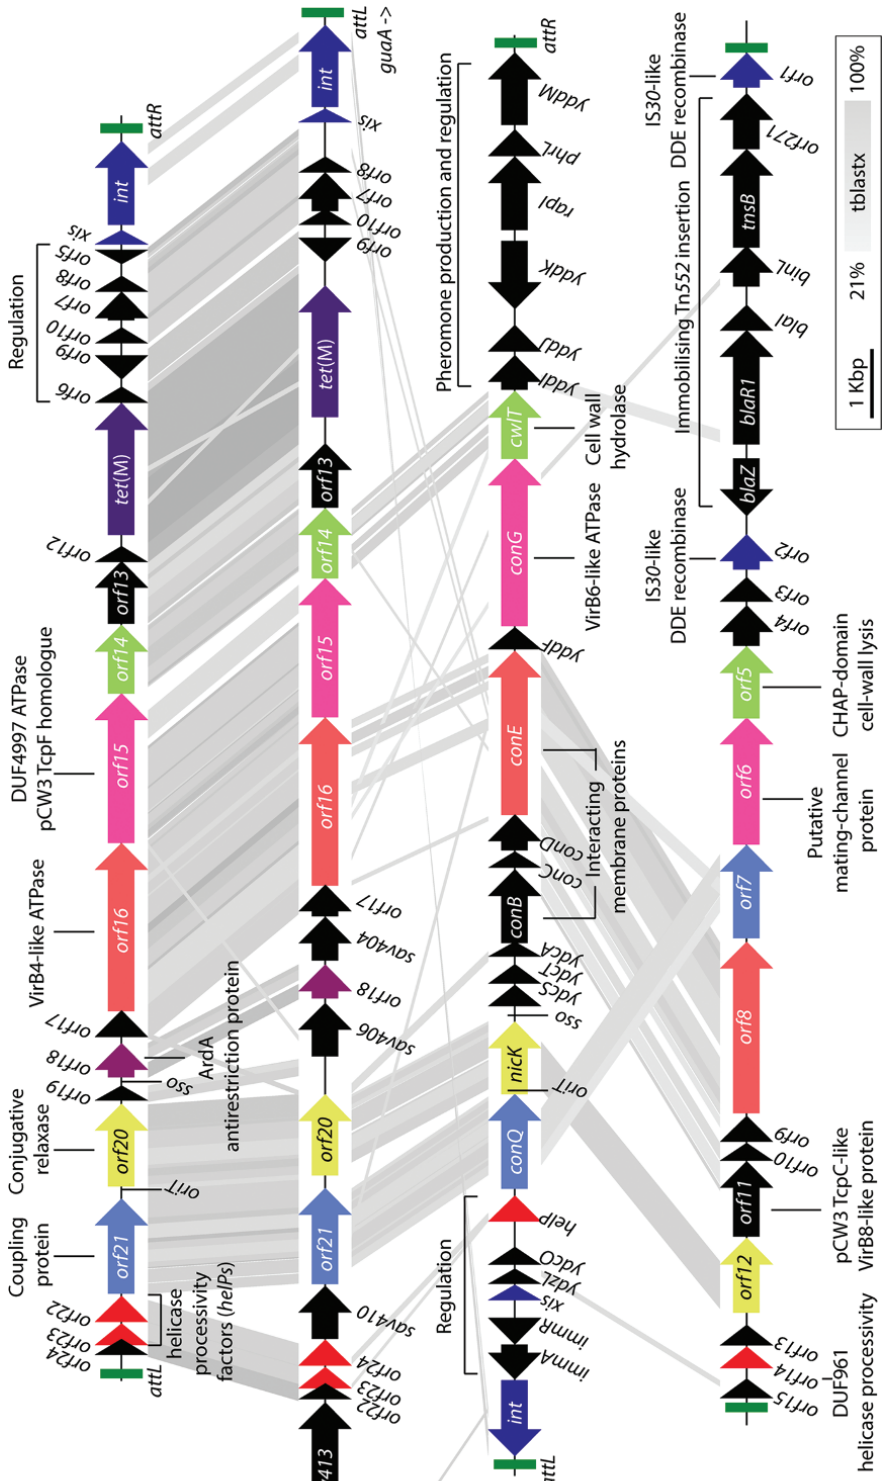
IS*21-558* (also called IS*Sau9*) and derivatives thereof have been linked with the *cfr* multiresistance gene in a range of contexts and hosts (145). Its name reflects the fact that it is a member of the IS*21* family of insertion sequence elements and that it was initially detected within a variant of Tn*558* (176), which itself carries a *fexA* determinant that mediates chloramphenicol and florfenicol efflux (177). Within the Tn*558* variant, two directly repeated IS*21-558* copies formed a composite configuration flanking both *cfr* and the *lsa*(B) lincosamide resistance gene (176).

In addition to the high-level glycopeptide resistance VanA element Tn*1546* of enterococcal origin (27) described above, one other Tn*3*-type transposon, Tn*551*, has been detected in staphylococci. This MLS (*ermB*) transposon is closely related to Tn*917* from *E. faecalis* but confers constitutive rather than inducible MLS resistance (7). Tn*551* was originally identified on the β-lactamase/heavy-metal resistance plasmid, pI258 (Fig. 2) but has subsequently been shown to transpose to numerous sites in other large plasmids and the chromosome. Despite a tendency to "hot-spot," it has served as a valuable tool for mapping and mutagenesis studies (7, 178).

Tn*552* and Tn*5404* are Tn*7* family unit transposons. Tn*552* appears to be restricted to a very limited set of insertion sites on the chromosome and in plasmids (25). In theta replicating plasmids (Figs. 2 and 3), the insertion sequence sites of Tn*552* and Tn*552*-like elements are normally located within resolution sites upstream of resolvase (recombinase) genes encoded by the plasmids (43, 86, 87, 179). An invertible segment can be formed between resolution sites that are present in both the plasmid and transposon (180). In some ICE*6013* elements (see below) Tn*552* is also found proximal to the probable recombinase genes (181). This property is shared with Tn*5035*-like elements from Gram-negative bacteria, which are termed "*res* site hunters" (182). Despite such insertional specificity, Tn*552*-type transposons are thought to represent the source of all staphylococcal β-lactamase genes (76). However, in many plasmids, only remnants of such transposons remain, presumably as a consequence of multiple insertion events and/or rearrangements mediated by the recombinase systems present on both the transposon and plasmids.

Tn*5404* is thought to have resulted from the transposition of a chromosomal element to a plasmid in a clinical *S. aureus* strain (183). This transposon shares an invertible segment (between resolution sites) with an adjacent copy of Tn*552*, such that an entire copy of one or the other of these elements is generated depending on the orientation of the segment (183). Another invertible segment within Tn*5404* represents a composite structure designated Tn*5405* (183), which encodes resistance to aminoglycosides (*aadE*, *aph*A) and streptothricin (*sat4*) (184). Tn*5405* is bounded by copies of IS*1182*, an element related to IS*1272* (see above) (185). Moreover, one of the IS*1182* elements flanking Tn*5405* is interrupted by a copy of IS*1181*, which is both prevalent and active in *S. aureus* (1, 185, 186).

An incomplete vestige of an element related to IS*1181* has been detected on the plasmid pACK1 from *Staphylococcus simulans* biovar *staphylolyticus* ATCC1362. This element,



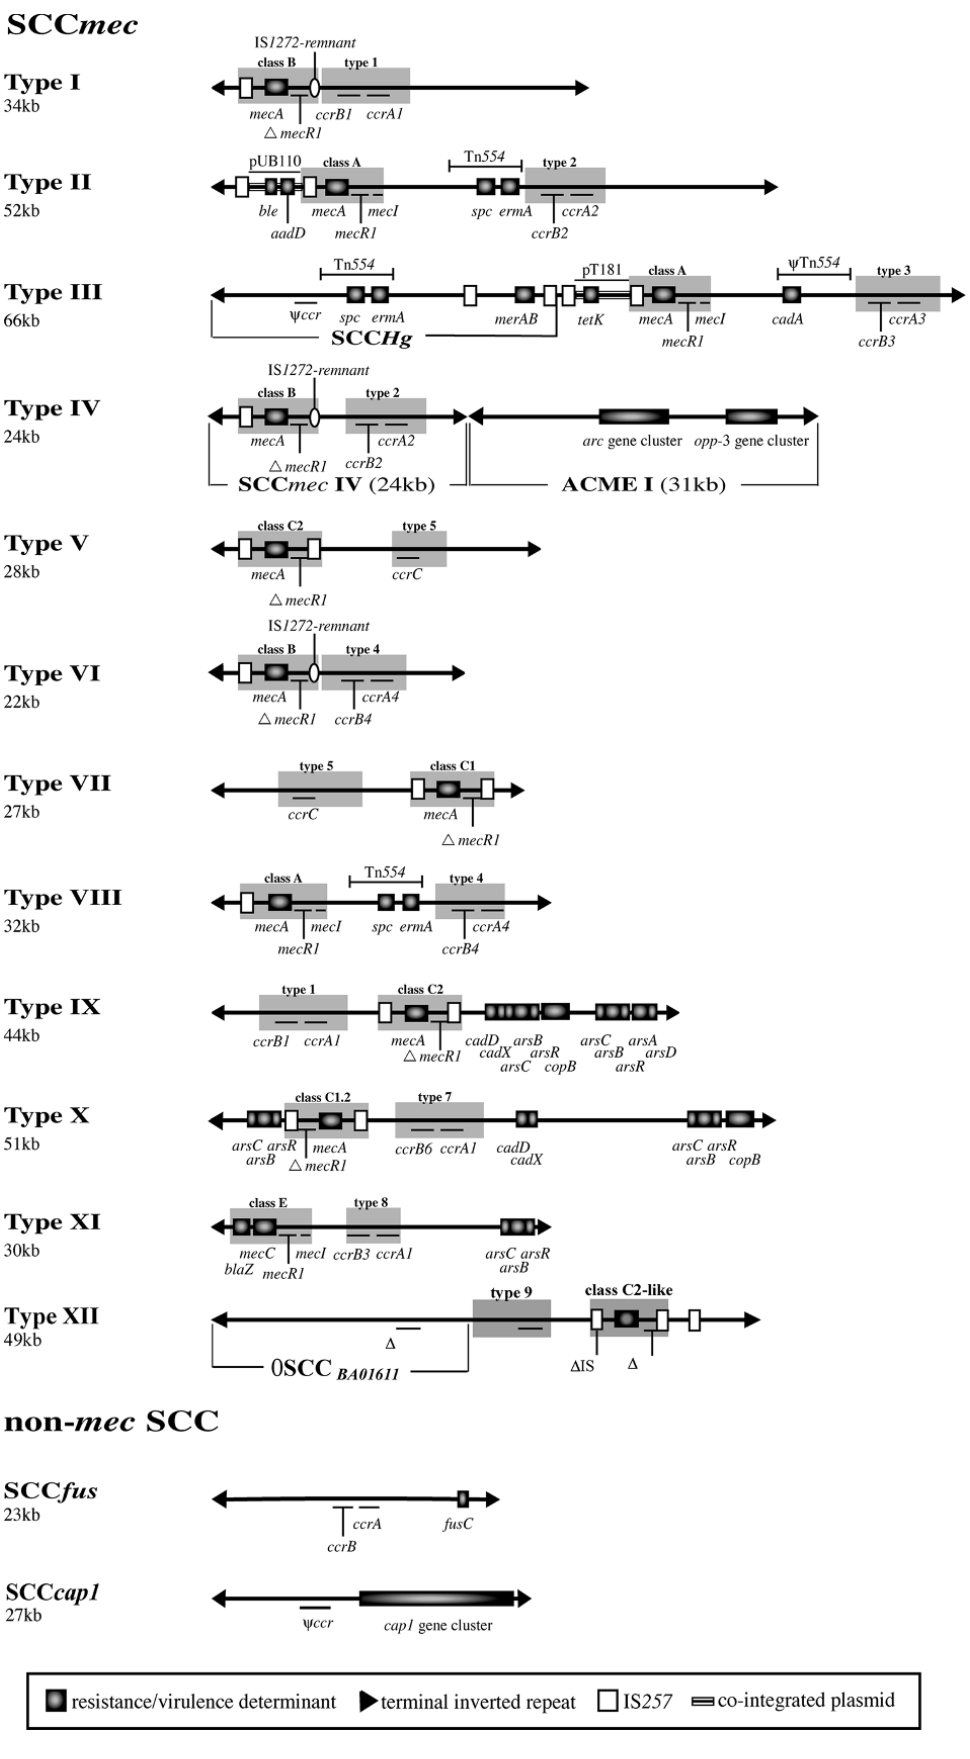


FIGURE 4 Genetic organization of Tn*916*, Tn*5801*, ICE*Bs1*, and ICE*6013*. A comparison of Tn*916*, Tn*5801*, ICE*Bs1*, and ICE*6013* constructed using EasyFig (233). Amino acid similarity comparisons (20% lower cutoff) using tblastx and are shown as gray shading between regions on each ICE. Genes with likely common functions—regardless of sequence similarity—are similarly colored. Positions of the conjugative origin of transfer (*oriT*) and single-strand origin of replication (*sso*) are indicated if known. Recombinase attachment/target sites are indicated by green rectangles. Annotations were collated from previously published figures for each ICE (15, 181, 197, 204, 206, 234, 235).

IS257
co-integrated plasmid

designated IS*1293*, is located at one end of a segment that contains the genes encoding preprolysostaphin (*lss*) and lysostaphin immunity factor (*lif*) (187). It is likely that the *lss-lif* segment of this plasmid, which possesses a truncated remnant of IS*257* at its other end, has been acquired through horizontal transfer (187). Numerous copies of another IS*1181*-like element, IS*Sha1*, have been found in *S. haemolyticus* strains (188).

The MLS- and spectinomycin-resistance element Tn*554* is unusual in that it lacks terminal inverted repeats and generates no target sequence duplications upon insertion (189). It inserts at an efficiency approaching 100% into a unique site in the *S. aureus* and *S. epidermidis* chromosomes, termed *att554* (189), within the *radC* gene (190), with a preference for one orientation. Secondary insertions can be generated in the chromosome or plasmids, albeit at much lower frequency, if *att554* is absent or occupied by a preexisting copy of Tn*554*. However, natural isolates have been identified that carry this or related elements, such as ψTn*554* encoding cadmium resistance, at different secondary sites, including some located in SCC*mec* regions (see below) (1, 179). Insertion of Tn*554* is dependent on two tyrosine-based site-specific recombinases encoded by the *tnpA* and *tnpB* genes and the product of a third, *tnpC*, that influences efficiency and orientation specificity (191, 192). The recombinases of Tn*554* are related to integrases of bacteriophage and ICEs such as Tn*916* (see below). The Tn*554*-like elements, Tn*558* (177), Tn*559* (190), Tn*5406* (193), and Tn*6133* (194) exhibit equivalent insertion site specificity but encode additional or alternative resistance determinants.

INTEGRATIVE AND CONJUGATIVE ELEMENTS

ICEs are mobile genetic elements that share characteristics of both conjugative plasmids and chromosomally integrating elements such as transposons and prophage. ICEs primarily exist within the host chromosome but can excise, circularize, and transfer via conjugation. ICEs encode all genes necessary for mating-pair formation and DNA transfer. The broad impact of ICEs on an organism's capacity for horizontal gene transfer and dissemination of antimicrobial resistance and virulence factors is significant. However, perhaps due to the often-changing classification of ICEs as genomic islands, transposons, or conjugative transposons and the evolving differences in naming conventions (195, 196), the roles of ICEs in *S. aureus* gene transfer are not yet as widely recognized as those of their plasmid and bacteriophage counterparts.

Identified *S. aureus* ICEs can be grouped into two families: those identical or closely related to the Tn*916* ICE and those related to the distinct ICE*6013* family (16). The conjugation gene clusters of Tn*916* and ICE*6013* family elements both carry conjugation genes related to those of *Bacillus subtilis* ICE*Bs1* (Fig. 4) and more distantly, plasmids such as *Clostridium perfringens* pCW3 and *Enterococcus* spp. pIP501 (197). *S. aureus* Tn*916* and ICE*6013* family elements vary in their integration mechanism, insertion site preference, and antimicrobial-resistance gene cargo.

Tn*916* elements are extremely promiscuous in Gram-positive organisms, and those identified in *S. aureus* are often identical to those in other Gram-positive genera. Tn*916* transfer from *E. faecalis* to *S. aureus* and transfer between *S. aureus* strains has been experimentally demonstrated (15, 198). The 18-kb Tn*916* element carries genes for conjugation, integration, excision, and the tetracycline-minocycline-resistance gene *tetM*. Tn*916* integration is mediated by the tyrosine recombinase Int, and excision is stimulated by Int and the excisionase Xis. Int preferentially targets pairs of poly-A and poly-T tracts separated by a 6-bp spacer for Tn*916* insertion (199). Tn*916* excision is stimulated in the presence of tetracycline and other ribosome-targeting antibiotics through an antiattenuation mechanism resulting in the derepression of *xis*; therefore, antibiotic exposure directly drives the spread of Tn*916*-mediated resistance (200–202).

Various distinct Tn*916*-like elements have been described in *S. aureus*, but the most well-documented example is the Tn*5801* subfamily. Tn*5801* (Fig. 4) was originally identified in *S. aureus* strain Mu50 (1) and carries conjugation and resistance genes (*tetM*) closely related to those of Tn*916* in both sequence and organization. Tn*5801* is larger (25 kb) than Tn*916* and harbors several Tn*5801*-specific genes within the conjugation-gene cluster. *int* and *xis* genes of Tn*5801* are distinct from those of Tn*916*, as is the integration preference for the 3′ end of the conserved GMP-synthase gene, *guaA*. Tn*5801* transfer between *S. aureus* strains has also been demonstrated (15). Like Tn*916* elements, Tn*5801* elements have been identified in human and animal-associated *S. aureus* and are particularly prevalent in *S. aureus* clonal complex CC398 (15, 203, 204). Both elements are also abundant in other animal-associated *Staphylococcus* spp. (204, 205), suggesting that agricultural and companion animals may be reservoirs of Tn*916* and Tn*5801*-carrying staphylococci.

ICE*6013* is the most recently identified family of *S. aureus* ICEs, and although it is also related to Tn*916* and Tn*5801*, it is more closely related to *B. subtillis* ICE*Bs1* than any other *S. aureus* element (206) (Fig. 4). Unlike Tn*916* and Tn*5801*, ICE*6013* family members generally lack antimicrobial-resistance determinants, although the first discovered ICE*6013* element in *S. aureus* HDG2 carries a Tn*552* insertion conferring penicillin resistance, and the insertion has immobilized this copy of ICE*6013* (181, 206) (Fig. 4). As well as being one of the smallest known families of ICE, with a minimum size of 12.7 kb, ICE*6013* is the only known ICE to utilize a DDE family transposase for its integration and excision and has an insertion preference for the sequence 5′-TTTTTANNNTAAAAA-3′ (181). ICE*6013* was originally identified in the ST239 *S. aureus* strain HDG2, and related elements have been identified in 44% of distinct *S. aureus* sequence types, including the dominant American community-associated lineage USA300. Conjugation frequencies of ICE*6013* approach rates similar to that of the conjugative

FIGURE 5 Maps of representative SCC elements (4, 216); see text for additional references. Resistance/virulence genes, transposons, insertion sequences, and cointegrated plasmids are shown: *arsBC*, arsenic resistance; *cadA*, cadmium resistance; *cap1* genes, capsular polysaccharide (220); *fusC* (previously known as *far*), fusidic acid resistance (236); *mecA*/*mecC*, β-lactam resistance. Refer to Table 1 for the antimicrobial resistance(s) conferred by other resistance determinants. Cassette recombinase genes (*ccrA*, *ccrB*, and *ccrC*), *mecA*/*mecC* regulatory genes (*mecI* and *mecR1*), and an arginine catabolic mobile element (ACME I [227]) are also shown; *mec* classes and *ccr* types are denoted by gray shading. Note that *cch* genes, *polA*, and SAUGI are not shown and that IS*257* is also known as IS*431*.

plasmid pSK41/pG01. Some strains harbor various combinations of up to four unique ICE*6013*, Tn*916*, and Tn*5801* family ICEs simultaneously (23, 181). The Tn*916*/Tn*5801* *orf18* gene encodes the ArdA antirestriction protein (Fig. 4), which inhibits type I restriction modification systems ubiquitous in *S. aureus*, so capture of Tn*916*/Tn*5801* ICE may increase the propensity for horizontal acquisition of additional mobile elements (207–209).

In addition to their own conjugative transfer, ICEs can mobilize the transfer of compatible nonconjugative plasmids or other integrative elements (16, 210). ICE*Bs1* is able to mobilize the transfer of RCR plasmids encoding RepU replication initiators through an interaction dependent on RepU and the ICE*Bs1* T4CP, ConQ (58, 197). ICE*6013*, Tn*916*, and Tn*5801*-family ICEs share closely related ConQ homologs (Fig. 4), so it is plausible that *S. aureus* ICEs may facilitate mobilization of RCR plasmids. Indeed, ICE*Bs1*- and Tn*916*-mediated mobilization of *S. aureus* antimicrobial-resistance plasmids pC194 and pUB110 has already been demonstrated, albeit in a *B. subtilis* host (58, 211). The impact of *S. aureus* ICEs on the capacity to facilitate horizontal gene transfer of other mobile genetic elements warrants further investigation (16, 138).

STAPHYLOCOCCAL CASSETTE CHROMOSOME

Most methicillin-resistant *S. aureus* isolates contain a 20- to 70-kb DNA segment, generically termed the *mec* region, that is not present in methicillin-sensitive strains. These segments are a type of genomic island (i.e., are bounded by terminal inverted repeats and subject to horizontal transfer) called staphylococcal cassette chromosome *mec* (SCC*mec*) (179). Methicillin resistance is mediated, at least in part, by the *mecA* gene or the more recently identified *mecC* gene (212, 213), both of which encode a related low-affinity penicillin-binding protein, termed PBP2a. Two regulatory loci, *mecI* and *mecR1*, are commonly found upstream of, and transcribed divergently to, *mecA*/*mecC* (however, see discussion of IS*1272*/IS*257*, above). In combination, the *mecA*/*mecC*, *mecI*, and *mecR1* genes and associated insertion sequence(s) are referred to as the *mec* gene complex, of which several classes have been defined (A, B, C1, C2, D, and E) on the basis of structural diversity (http://www.sccmec.org).

Additionally, SCC*mec* contains the *ccr* gene complex, which comprises either a combination of *ccrA* and *ccrB* genes (one of each) or a single *ccrC* gene; different allotypes for these genes also exist, and several types of the *ccr* gene complex have been defined (http://www.sccmec.org) (214). Each *ccr* gene encodes a recombinase that mediates the excision and circularization of the cassette and its site- and orientation-specific insertion into the $attB_{SCC}$ site of the *S. aureus* chromosome and homologous sites in other staphylococcal species (179). Recently, a conserved gene located upstream of the *ccr* gene(s) has been shown to encode a DNA helicase (215) referred to as *cch* or *cch2*, and the latter is also preceded by a putative primase (*pol*A). This implies that SCC elements might be able to replicate (postexcision), and multiple copies would likely facilitate the horizontal transfer process. Moreover, a gene located downstream of the *ccr* gene(s) encodes a uracil-DNA glycosylase inhibitor (SAUGI). *S. aureus* pathogenicity islands, which are specifically induced to excise and be packaged by invading bacteriophage, carry homologs of *cch*, and regulate their excision in response to phage-induced changes in uracil metabolism. These commonalities suggest that phage may also have a role in stimulating and/or facilitating SCC*mec* transfer (128, 215).

At present, SCC*mec* has been classified into 12 allotypes based on the organization of the *mec* and *ccr* gene complexes (Fig. 5) (216); subtypes also exist and are defined by the structure of the three joining (J) regions (previously called junkyard regions) located between these gene complexes and the chromosomal regions flanking SCC*mec*. The J regions also act as a chromosomal hot-spot for the insertion of additional antimicrobial resistance determinants, often in association with transposable elements (173). These include Tn*554* or related elements encoding resistance to erythromycin and spectinomycin, or cadmium, and IS*257*-flanked segments conferring resistance to mercury, tetracycline, and/or aminoglycosides and bleomycin; the latter two segments are known to be cointegrated copies of the plasmids pT181 and pUB110, respectively (Fig. 5) (26, 103). Based on this classification system, an online tool, SCC*mec*Finder, has recently been developed for rapid whole-genome sequence-based SCC*mec* typing (217).

It is important to note that SCC*mec* elements are not exclusive to *S. aureus* and are frequently carried by coagulase-negative staphylococci. Moreover, the ubiquitous carriage of a *mecA* homolog by *Staphylococcus sciuri* has led to the suggestion that this or closely related species represent the origin of the *mec* determinants found in other species (218). In this regard, a recent study by Rolo et al. (219) indicates that *Staphylococcus vitulinus* and *Staphylococcus fleurettii* contributed to the evolution of the *mec* complex and that *S. sciuri* likely provided the mobile element into which this complex was later incorporated. In any case, it is clear that coagulase-negative staphylococci act as a reservoir from which methicillin-sensitive *S. aureus* can acquire SCC*mec*, contributing to the emergence of new methicillin-resistant *S. aureus* clones.

However, not all SCC elements encode resistance to methicillin, because related structures have also been identified (179, 220, 221). These include SCC*cap1*, which encodes a type I capsular polysaccharide (220), and SCC*fur* (also known as SCC_{476}) and SCC*Hg* (also known as SCC*mercury*), which encode resistance to fusidic acid and mercuric chloride, respectively (4, 222) (Fig. 5). Additionally, the arginine catabolic mobile element, which is broadly associated with certain coagulase-negative staphylococci (223–225), has also been identified in association with SCC*mec* allotypes, largely type IV (226). This element is a virulence/colonization determinant that utilizes SCC*mec*-encoded cassette recombinases and integrates into the $attB_{SCC}$ site (223, 227, 228) (Fig. 5). Arginine catabolic mobile element allotypes are defined by the presence or absence of the *opp*-3 and *arc* gene clusters, the latter of which encode a complete arginine deiminase pathway, and carriage of this element has been shown to enhance fitness and skin colonization (228–230).

PERSPECTIVES

Mobile genetic elements and the mechanisms of genetic exchange they facilitate/exploit act in concert to catalyze rapid microbial adaptation by providing access to an extended reservoir of niche-adaptive functions. Clinical staphylococci represent a salient illustration of the evolutionary potential this affords. Genomic technologies have greatly expanded our understanding of variability between strains (clinical and nonclinical) and the relationships between them and revealed a growing repertoire of mobile genetic elements, thereby illustrating the significance of horizontal genetic exchange. There is little doubt that the ongoing acceleration of genomics will yield further insights in the future.

Our research on staphylococcal genetics is supported by National Health and Medical Research Council (Australia) project grants APP1081412 (to N.F., S.O.J., and S.M.K.) and APP1145697 (to N.F. and J.P.R.).

Temperate Phages of *Staphylococcus aureus*

HANNE INGMER, DAVID GERLACH AND CHRISTIANE WOLZ

32

INTRODUCTION

The diversity of the *Staphylococcus aureus* species is mainly determined by mobile genetic elements, many of which are prophages or phage-related genomic islands. Strain evolution as a result of short- and long-term adaptation to diverse environments is tightly linked to phages. Many phages carry accessory genes coding for staphylococcal virulence factors, which are important for the success of certain *S. aureus* clonal complexes (CCs). Second, phages support the induction, packaging, and transfer of genomic islands (1, 2). This topic is reviewed elsewhere. Third, phage-mediated transduction is an efficient way to transfer not only extrachromosomal mobile elements, such as plasmids, but also chromosomal markers (albeit with lower efficiency). *S. aureus* is thought not to be naturally competent, so that recombination and horizontal gene transfer are mostly phage mediated and, to a lesser extent, conjugative. Here, we will first give a brief overview of previously used methods to classify *S. aureus* phages. Then we will mainly focus on the impact of temperate phages on the evolution of the bacterial host.

CLASSIFICATION OF *S. AUREUS* PHAGES

All known *S. aureus* phages belong to the order *Caudovirales* (tailed phages) and are composed of an icosahedral capsid filled with double-stranded DNA and a thin filamentous tail. Based on the complete genomes of 27 phages (3), *S. aureus* phages were assigned to three size classes: siphoviruses, with a genome size of 39 to 43 kb, podoviruses, with a smaller genome size of 16 to 18 kb, and myoviruses, with a genome size of 120 to 140 kb. This capsid and genome size-based classification correlates with the tail morphology as observed by electron microscopy: *Podoviridae* have a very short tail, *Siphoviridae*, a long noncontractile tail, and *Myoviridae*, a long contractile, double-sheathed tail (for recent reviews, see 4–6). All of the known temperate staphylococcal phages belong to the *Siphoviridae*, which are the primary focus of this chapter.

The siphovirus genomes are usually organized into six functional modules: lysogeny, DNA replication, packaging, head, tail, and lysis (7–9). The evolution of phage lineages was driven by the lateral gene transfer of interchangeable genetic elements (modules), which consist of functionally related genes. A functional module found in one phage can be replaced in another phage by a sequence-unrelated module that fulfils the same or related functions; often, genes within such modules travel together (10). Thus, multiple alignments of *S. aureus* phage genomes reveal a chimeric and mosaic structure resulting from horizontal transfer and recombination (3, 5, 9, 11–13).

Due to this modular structure, phage nomenclature and classification of the *Siphoviridae* are challenging and are a matter of debate. In Table 1 the different designations and properties of a representative set of *S. aureus Siphoviridae* are illustrated. In one approach phages were classified based on protein repertoire relatedness (5, 7). Thereby, *Siphoviridae* from *S. aureus* were clustered into six major clades. Clades 4 to 6 (Sfi21-like phages) share characteristic features with the capsid region of *Escherichia coli* HK97 phage and use the cos-site strategy for DNA packaging. Clades 1 to 3 (Sfi11-like pac-type phages) are related to the *Bacillus subtilis* SPP1 phage (7). The Sfi11/Sfi21-like grouping of *Siphoviridae* is based on genome analysis of lactococcal phages. Gene clusters extending from the DNA packaging genes to the tail genes were found to be represented by two unrelated configurations: one is characteristic of cos-site phages (prototype: phage Sfi21), and the other is characteristic of pac-site phages (prototype: phage Sfi11).

In another approach, *S. aureus Siphoviridae* were classified according to polymorphism of the *int* gene and the modular composition of lysogeny, regulation, replication, structural, and lytic modules (9, 12) (Table 1). The modules can be defined by multiplex PCR or sequence analyses of selected genes within the modules. *S. aureus* prophages were primarily classified on the basis of *int* gene homology (9, 12, 13). By including information on the allelic variation of other modules, a further meaningful subdivision can be achieved. A similar approach to the general classification of bacteriophages has been proposed previously (14, 15). Kahánková *et al.* (9) established a mulitplex PCR assay to distinguish between different types of integrase (10 types), antirepressor (five types), replication proteins (four types), dUTPase (four types), portal protein (eight types), tail appendices (four types), and endolysin (four types). The proposed extended typing scheme covering seven major genomic modules enables not only the differentiation of phages but also the design of a classification system. For the basic description and rapid differentiation of a phage strain, the serological group type, the *int* type, and the endolysin type are the most relevant (located at the left side, the middle, and the right side of the prophage genomes). Using a simplified scheme, e.g., phage φ11 can be classified as Sa5int-Ba-ami1 or phage φ13 as Sa3int-Fb-ami3 (9). Despite the multiple mosaic variants, there are close links between particular modules; e.g., all phages using *polA* for replication are serogroup A.

[a]Classification based on reference 5.
[b]Classification based on reference 12.
[c]Location of the native phage or the attB site in the genome of reference strain 8325 (GenBank accession number NC_007795.1).
[d]virulence genes
[e]Abbreviations: ND, Not determined; tmRNA, transfer messenger RNA.

There are several reasons to classify *S. aureus* prophages primarily based on *int* polymorphism. First, nucleotide sequences are well conserved within *int* groups, making the gene an ideal target for PCR amplification. The *int* grouping has good discriminatory power, reflecting the diversity of the *S. aureus* phage population. Recombination and exchange of certain modules seem to occur more often between phages of the same *Sa-int* group than between phages of different *Sa-int* groups (16). Second, the *int* typing allows for prediction of the chromosomal location of the prophage. Last, the *int* type is closely linked to the virulence gene content of the prophage and can therefore convey information about the pathogenic potential of the bacterial lysogen (12). Most of the *S. aureus* phages can be assigned to one of the major *Sa-int* types 1 to 8.

PHAGE INTEGRATION/EXCISION

All prophages integrate to position the *int* gene in close proximity to the bidirectional origin of chromosome replication. Based on amino acid sequence homology and catalytic residues, most integrases belong to the tyrosine recombinase type family. Only the integrases of Sa7int phages were found to belong to the serine recombinase type family (12). Despite the usually strong association of the *int* type with the integration site, there are also events where a phage may integrate in an illegitimate attachment site. This phenomenon was described to occur for Sa3int phages during chronic lung infections of cystic fibrosis patients (17). Under these conditions, the reconstitution of the phage-interrupted *hlb* gene may be an advantage. When these mislocated phages were induced and used to reinfect *S. aureus in vitro*, the phages reintegrated at their dedicated attachment site within *hlb*. Sa3 phages are only rarely found in livestock-associated *S. aureus* strains of CC398. In these strains the canonical attB site within *hlb* is altered, and therefore Sa3int phages integrate at diverse alternative attB sites (18, 19). The mechanism for excision of *S. aureus Siphoviridae* is much less well understood. Excision followed by replication may result not only in bacterial lysis and phage release but also in a process termed "active lysogeny." This term was recently introduced to describe instances where prophages temporally and reversibly excise from the chromosome without lysing the bacterial host (20). This might be seen as a form of bacterial gene regulation that possibly improves bacterial fitness. Evidence for active lysogeny in *S. aureus* comes from a recent sequencing approach to detect extrachromosomal phages in *S. aureus* (21). Furthermore, it could be demonstrated that phages are readily induced under infectious conditions (17, 22–25). Analysis of isolates from cystic fibrosis patients revealed that translocation of the Sa3int phages often leads to a splitting of the bacterial population (17) into Hlb-positive (phage-cured) and phage-positive fractions. Both the phage-encoded virulence factors and Hlb are secreted factors; thus, functional complementation can be assumed.

PHAGE-BACTERIAL RECOGNITION

Adsorption to the bacterial host is the first critical step within the phage life cycle. Interaction of the receptor-binding protein (RBP) of the phage and its receptor initiates the infection cycle and, importantly, determines the host range and specificity (26). Phage receptors have to satisfy the following distinct requirements to be suitable for viral attachment. (i) Accessibility: phage receptors have to be accessible to the phage by random Brownian motion, flow, or diffusion. (ii) Abundance: with attachment being a stochastic process, the abundance of the receptor must be high enough to permit a sufficient probability of RBP-receptor contact. (iii) Constancy: the chemical composition of the receptor must be stable enough to allow evolutionary adaption of the phage to possible changes in the receptor appearance. Wall teichoic acid (WTA) of *S. aureus* fulfills all three requirements imposed on a proper phage receptor and was shown to act as the primary phage receptor. It is a major component of the cell wall and is expressed by all *S. aureus* strains. Most *S. aureus* strains produce WTA comprised of ribitol-phosphate (RboP) repeats. The complex biosynthesis of WTA is reviewed elsewhere (27, 28). WTA is covalently attached to the peptidoglycan of the cell wall (29, 30). Further derivatization of WTA is achieved in two ways. Attachment of *N*-acetyl-glucosamine residues (GlcNAc) occurs at the C4-position of the RboP unit by two glycosyltransferases, TarS and TarM, which attach GlcNAc in the β-position and α-position, respectively (31, 32). Recently, a third prophage-encoded glycosyltransferase, named TarP, was identified (33). Unlike TarS, TarP catalyzes the attachment of GlcNAc in the β-1,3-position.

The second modification of WTA is attachment of D-alanine residues at the C2-position by the Dlt-machinery (34). In contrast, a completely different type of WTA, composed of a glycerol-phosphate (GroP) repeating unit modified with α-*N*-acetyl-galactosamine (GalNAc) residues is found in *S. aureus* strains belonging to CC395 (35). This GroP WTA resembles the WTA structure found in many coagulase-negative staphylococci (36). Early studies identified *B. subtilis* mutants lacking WTA or WTA glycosylation. Those mutants appeared to be resistant against certain *B. subtilis* bacteriophages (37, 38). It was subsequently shown that the sugar moiety of WTA is also important for *S. aureus* phage interaction. Treatment of *S. aureus* with exo-β-acetylglucosaminidase or use of WTA glycosylation mutants leads to a decrease in phage binding (39, 40).

Although a majority of publications describe only carbohydrate-based phage interactions (WTA in combination with peptidoglycan structures), work by Nordström *et al.* (41) suggested that additional proteinaceous factors, prominent among them, surface protein A, interfere with phage adsorption. To our knowledge, this is the only account of surface protein phage interactions reported for *S. aureus*. Interestingly, a secondary protein receptor besides the primary receptor WTA has been described for the Gram-positive model organism *B. subtilis*. The lytic phage Spp1 adsorbs first in a reversible manner to WTA, which accelerates an irreversible interaction with the membrane receptor YueB and injection of viral DNA (42). A similar phenomenon was described for the membrane protein PIP, which serves in lactococcal species as a secondary phage receptor (43). However, PIP homologues in *S. aureus* have not been shown to be necessary for phage adsorption (44). Thus, so far, there is no clear evidence for a secondary proteinaceous receptor in *S. aureus*.

The advent of bacterial genetics allowed further insights into the molecular basis of bacteria-phage interactions. An early study suggested that besides WTA, a different anionic polymer of the *S. aureus* cell envelope, lipoteichoic acid, might serve as a receptor for the tail protein ORF636 of *S. aureus* phage ΦSLT (45). Lipoteichoic acids (LTA) consist of D-alanylated glycerol phosphate repeating units attached to the cell membrane of *S. aureus* (46). However, using an LTA-deficient mutant strain of RN4220, no difference in the infectivity of phages expressing homologues of

the tail protein of ΦSLT could be observed (47). In contrast to the LTA-deficient mutant, gene deletion of *tag*O, the first gene of the WTA biosynthesis pathway, leads to a phage-resistant phenotype (47, 48). By creating a transposon mutant library, Xia *et al.* (32) were able to isolate the RN4220 mutant K6, which is deficient in WTA glycosylation. K6 carries a transposon interrupting the gene coding for the α-glycosyltransferase TarM. K6 additionally carries a premature stop codon in *tar*S coding for the β-glycosyltransferase (31). K6 was resistant to a wide range of siphoviruses (47). Interestingly, as reviewed later, lytic myoviruses (Φ812 and φK) were able to infect K6 despite the lack of WTA glycosylation.

By using defined knockouts of the two identified ribitol-phosphate glycosyltransferases, *tar*M and *tar*S, it could be demonstrated that siphoviruses of serogroup B do not seem to differentiate between α- or β-GlcNAcylation at the ribitol C4 position (31, 44) (Fig. 1A). The receptor promiscuity of siphoviruses might reflect their role as the main vectors of horizontal gene transfer. Of note, Winstel *et al.* (49) demonstrated that *S. aureus* pathogenicity islands (SaPIs) can be transferred between strains expressing α- or β-GlcNAcylated WTA. Notably, β-1,3-GlcNAcylation by TarP seemed to reduce the infection and SaPI-transfer capacity of serogroup B siphoviruses (33) (Fig. 1A). More importantly, the Winstel and coworkers publication established the compatibility of phage and host receptors as a key driver of cross-species horizontal gene transfer (49). Even distantly related bacterial species such as *Listeria monocytogenes* can engage in horizontal gene transfer with *S. aureus* (49, 50), as long as they express a compatible phage receptor. In contrast, lack of RboP-GlcNAc WTA excludes bacteria from the exchange of genetic information. For instance, *S. aureus* PS187 (CC395), equipped with GroP-type WTA, is cut off from horizontal gene transfer with RboP-WTA-expressing *S. aureus*, but is able to engage in exchange with coagulase-negative species that share a similar GroP-type WTA (35, 49). Interestingly, ectopic expression of RboP-type biosynthesis genes in coagulase-negative staphylococci with GroP-WTA rendered them susceptible to *S. aureus* phages (49). Hence, it can be speculated that RBP-receptor incompatibility is a major hindrance for horizontal gene transfer between *S. aureus* and coagulase-negative staphylococci. The other two described classes of morphological groups, namely *Myoviridae* and *Podoviridae*, show more diverse receptor specificities, that are discussed later in the article.

Returning to the postulated requirements for a phage receptor (accessibility, abundance, and constancy), one can audit whether they hold true for WTA as the phage receptor of *S. aureus*. WTA is an exposed cell surface molecule attached to the peptidoglycan (51), which would allow easy access to phages. The negative charge of WTA, conferred by phosphate residues, might allow polar or ionic interaction

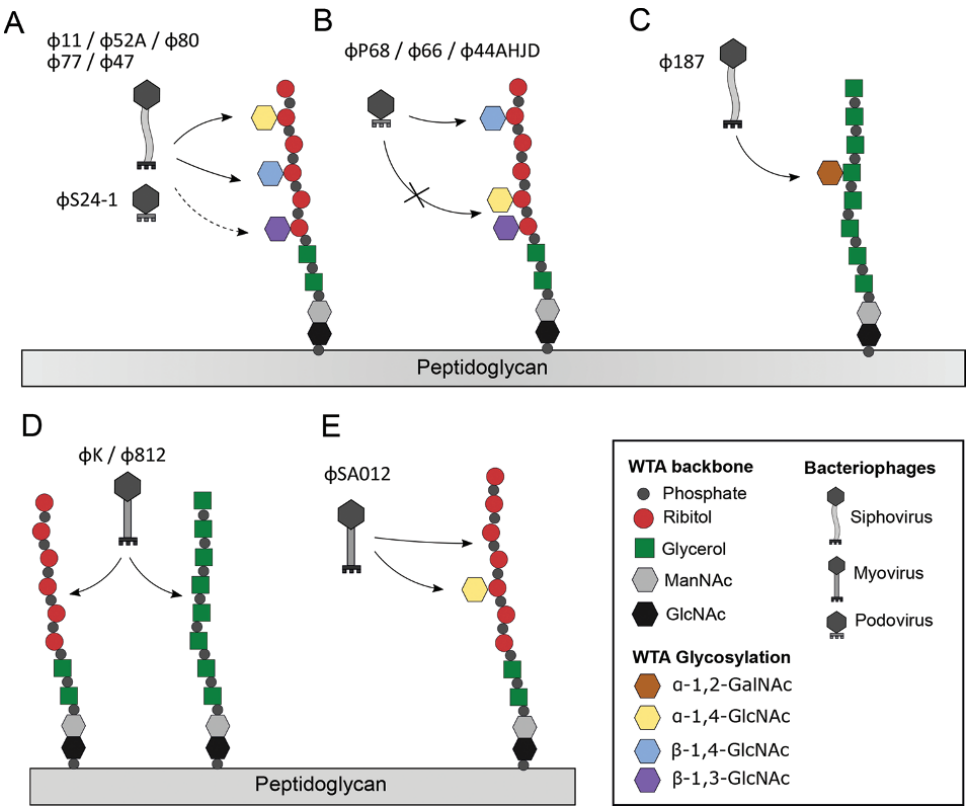

FIGURE 1 Receptor specificity of *S. aureus* phages. (A) Siphoviruses Φ11, Φ80, Φ52A, Φ47, and Φ77 and podovirus SA24-1 recognize α-or β-1,4-GlcNAc-RboP WTA. β-1,3-GlcNAc-WTA is adsorbed to less strongly by Φ80, Φ52A, and Φ11. (B) Podoviruses ΦP68, Φ44AHJD, and Φ66 bind to β-1,4-GlcNAc-RboP WTA and are blocked by β-1,3-GlcNAc or α-1,4-GlcNAc modifications. (C) Siphovirus Φ187 binds to α-GalNAC-GroP. (D) Myovirus ΦK, Φ812, attache to the backbone of GroP and/or RboP. (E) ΦSA012 recognizes both the RboP WTA backbone and α-1,4-GlcNAc-RboP by two different RBPs.

with RBPs. LTA, due to its presence in the more internal cell membrane of *S. aureus*, might therefore be of less utility as a receptor for bacteriophages. Additionally, WTA is a highly abundant glycopolymer that constitutes up to 60% of the cell wall mass in many Gram-positive bacteria. It is a key component of the cell wall, and no natural isolates of *S. aureus* without WTA have been reported so far. The indispensability and abundance of WTA ensure a high probability of phage-receptor contact, which is crucial for the adsorption process. Coagulase-negative bacteria, especially *Staphylococcus epidermidis*, show an increased diversity of WTA glycosylation patterns (36, 52). *S. aureus* appears to encode only one housekeeping glycosyltransferase, TarS. The *tarS* gene is found in almost all *S. aureus* genomes (53). The second glycosyltransferase, TarM, appears to have been acquired very early in *S. aureus* evolution (54). However, certain clonal lineages, such as CC5 and CC398, seem to have deleted *tarM* during their emergence or may have acquired phage-encoded *tarP*. The introduction of more sophisticated WTA glycosylation patterns might lead to less phage interaction and therefore to a decrease in the ability to participate in horizontal gene transfer. The described receptor constancy of WTA together with the widespread absence of clustered regularly interspaced short palindromic repeat (CRISPR)/Cas systems allows rapid acquisition and exchange of genetic elements by phages or phage-like particles (SaPIs), which ensures the role of *S. aureus* as a major human pathogen.

OCCURRENCE AND ROLE OF ACCESSORY PHAGE GENES

Although phages may be regarded as selfish elements, bacteria have learned to use them for their own purposes, and lysogeny can be regarded as a motor for short-term evolution. In many pathogens, phages provide the bacteria with additional genes that enable them to establish a new lifestyle. In *S. aureus*, several such phage-encoded virulence factors have been described, an observation originally described as phage conversion. Genes coding for Panton-Valentine leukocidin (*lukSF*) exfoliative toxin A (*eta*) (55), the cell-wall anchored protein SasX (56), and the immune evasion cluster (IEC) composed of enterotoxin S (*sea*), staphylokinase (*sak*), the chemotaxis inhibitory protein (*chp*), and the staphylococcal complement inhibitor (*scn*) (57) are the best-characterized phage-encoded virulence factors in *S. aureus*. A transposon mutant library was screened for virulence genes, and phage-encoded virulence genes were detected on all four prophages from strain Newman (58). Moreover, small RNAs involved in gene regulation (SprD = teg14) (59) or coding for the type I toxin-antitoxin system (SprF1/SprG1) (60) are encoded on Sa3int phages. With the availability of new phage and *S. aureus* genomes, new putative phage-encoded virulence genes (e.g., those coding for putative Clp protease or phospholipase) are being discovered and are awaiting functional analysis (18, 61–63).

Interestingly, accessory genes are strongly associated with phages of certain *int* groups and are localized at the left or (more frequently) right ends of the phage. There is a link between the encoded virulence factors, the *int* module, and the lytic module (holin and amidase genes), which are localized at the opposite end of the prophages (9). One may assume that it is evolutionarily beneficial to interchange this whole unit. Of note, these modules are in close proximity after phage excision in the circular and/or concatamer form of the phage. The close link of the lytic module and the inserted virulence factors is perhaps favored to optimize the phage control of the expression of the virulence genes (64). For instance, the expression of the virulence genes becomes cotranscribed with the late phage genes upon phage induction (64–66).

Sa1int Phages Carrying *eta*

The exfoliative toxins are virulence factors of *S. aureus* that cause bullous impetigo and its disseminated form, staphylococcal scalded-skin syndrome. The clinical symptoms vary from blisters anywhere on the body to multiple lesions complicated by conjunctivitis and staphylococcal scalded-skin syndrome (67). The exfoliative toxin A gene (*eta*) is carried in the genomes of Sa1int phages (9, 12, 13). An *eta* homolog is also carried by SaPI2 but is not known to be functional (1). However, these phages can be differentiated into at least six types due to variation in different modules (68). These *eta*-phages were associated with outbreaks of methicillin-resistant *S. aureus* (MRSA) and methicillin-susceptible *S. aureus* strains of various CCs in Japan and the Czech Republic (67, 69, 70) and are also present in a subpopulation of CC121 strains associated with superficial infections (25, 71).

Sa2int Phages Carrying *lukSF*

lukSF encodes the bi-component leucotoxin PVL, which targets human phagocytes through interaction with the complement receptors C5aR1 and C5aR2 (72). *lukSF*-encoding phages are strongly associated with skin and soft tissue infection and necrotizing pneumonia, which can also affect young, immunocompetent people (73–76). The majority of *lukSF*-carrying phages are Sa2int phages (66, 77–82). These phages are integrated within a conserved ORF which is surrounded by a cluster of tandemly repeated genes. In CC80 strains, phage induction led to the acquisition of host DNA into the phage genome probably due to a homologous recombination event between direct repeats of the two paralogous genes adjacent to the phage integration site (83). Phage excision was accompanied by an additional chromosomal deletion in this region. PCR-based typing schemes were established and modified to further subtype the *lukSF*-encoding phages (78, 84, 85). These studies confirm the high mosaicism of phage genomes and show that different *S. aureus* lineages have acquired a diverse set of *lukSF* phages. The combination of *lukSF* phages with methicillin resistance is characteristic of community-associated MRSA strains that are spreading in various continents. Strains of the most prominent USA300 lineage (CC8 isolates) are mainly spreading in North America, whereas in Europe CC80 strains are spreading, in Asia, CC59 strains, in the Asia Pacific region, CC30 strains, and in Australia, CC93 strains are more prevalent. The global spread of different *S. aureus* clones containing different *lukSF*-carrying phages supports the idea that PVL provides some fitness advantage to the bacterial host. The most common feature of all these strains is the strong association of *lukSF* phages and superficial, recurrent skin infections (75).

Sa3int Phages Carrying the IEC

Sa3int phages are by far the most prevalent *S. aureus* phages. Up to 96% of human nasal isolates were found to carry Sa3int phages integrated into the *hlb* gene (17, 86). Hlb can modify endothelial cells and platelets by both toxin sphingomyelinase and biofilm ligase activities, thereby increasing infection severity (87). The *hlb*-converting phages carry genes representing the IEC (*sea*, *sak*, *chp*, and *scn*) (57), coding for highly human-specific virulence genes. SEA has been

described to modulate the function of chemokine receptors such as CCR1, CCR2, and CCR5 (76). CHIPS blocks two G-protein coupled receptors involved in chemotaxis and phagocyte activation (C5a and the formylated peptide receptor) (88). SAK is a potent plasminogen activator with pleiotropic function including fibrinolysis and antiopsonic activity. The latter occurs through degradation of immunoglobulin G and C3b/C3bi on the surface of staphylococci (89). SCIN is a specific inhibitor of the C3 convertase of the complement system (90). Seven IEC variants were discovered, carrying different combinations *of sea* (or *sep*), *sak*, *chp*, and *scn*. The genes' order was conserved and always in the same 5′ to 3′ orientation. *Scn* was the only gene present in all IECs analyzed, whereas, e.g., *sea* was detectable in only 27% of the IECs (57). Interestingly, genes coding for a type I toxin-antitoxin system (SprF1/SprG1) are also localized within the IEC gene cluster (60).

Sa7int Phages Carrying *sak*

As an exception to the rule, *sak* could be detected not only on Sa3int phages but also occasionally on Sa7int phages. Curiously, such a *sak*-encoding Sa7int phage is found in derivatives of the laboratory strain 8325-4 (17). The widely used phage-cured strain 8325-4 was somehow lysogenized with such a phage and has since been distributed to laboratories worldwide (designated strain RN6390 or ISP479C). A similar phage was detected in most of the prevalent hospital-associated MRSA clones (belonging to the ST5 lineage) isolated in southern Germany (91). These strains were highly successful over the years and were quickly diversifying, as illustrated by differences in pulsed-field gel electrophoresis patterns and antibiotic susceptibility. Notably, these isolates can be clearly discriminated from other CC5 isolates (ST225, a single-locus variant of ST5) circulating in Germany, which are characterized by the high prevalence of a typical Sa1int phage (91, 92).

SasX-Carrying Phage in MRSA

The assumption that mobile genetic elements promote the spread of bacterial clones was emphasized by the emergence of highly epidemic MRSA strains carrying a phage harboring a newly identified cell wall-anchored virulence factor, SasX (56). SasX promotes nasal colonization, bacterial aggregation, and virulence. *sasX*, similar to other phage-carried virulence genes, is located as an accessory gene at the right end of a phiSPβ-like prophage. The genome size of 127 kb is significantly larger than that of a typical *S. aureus* siphovirus and highly similar to a prophage found in *S. epidermidis* strain RP62A (93), indicating that the phage and thus a new virulence trait was acquired from *S. epidermidis*. This phage is spreading between *S. aureus* strains and is also found in MRSA strains of the CC5 lineage (56). It is unclear whether this phage and other genetic elements managed to cross the species barrier and, if so, how.

TarP-Carrying Phages

Recently, the phage-associated WTA-glycosyltransferase TarP was found to glycosylate the WTA in an alternative way (33). The *tarP* gene is located in the lysogenic module of three different *S. aureus* prophages with integrase groups, Sa1int, Sa3int, and Sa9int. The *tarP*-Sa3int phage, ΦN315, additionally encodes the IEC discussed above. *tarP*-encoding phages can be found in clonal lineages CC5 (hospital-associated clones with Sa3int TarP-phages) and CC398 (livestock-associated clones with Sa1int and Sa9int TarP-phages). Modification of WTA by TarP lead to reduced opsonization by IgG in human sera. The immune evasion capabilities of TarP were reflected by lower immunogenicity of TarP-modified WTA in comparison with TarS-modified WTA.

ROLE OF PHAGES IN HUMAN ADAPTATION OF ANIMAL ISOLATES

S. aureus colonizes a variety of animal species and adapts to particular species through changes in the core genome as well as potential phage-encoded virulence genes (94). However, transmission of strains between human and animal reservoirs also occurs. Since the early 2000s MRSA strains with the sequence type ST398 were described as colonizing pigs and also causing infections in humans living in close contact with livestock (95, 96). Strains belonging to the CC398 lineage are commonly found in livestock and are resistant to multiple antibiotics but lack several important virulence factors (97–99). More recently, human to human transmission of CC398 strains was reported. Critical in this jump are Sa3int phages that generally are absent in CC398 strains but are present in most livestock strains infecting humans without livestock contact (61, 100). The importance of Sa3int for virulence of CC398 strains to humans has also been demonstrated more directly, because the presence of Sa3int decreased phagocytosis by human but not by pig polymorphonuclear neutrophils, while β-hemolysin production was abolished due to integration of the phage in the *hlb* gene (101).

Interestingly, the livestock-associated MRSA CC398 strains originated in humans as a methicillin-susceptible *S. aureus* strain, and upon introduction into livestock they lost Sa3int and acquired methicillin resistance and resistance to tetracycline, which is commonly used in livestock production (102, 103). The recent reintroduction of Sa3int into the livestock-associated MRSA strain population appears to be restricted by mutations in the 14-base pair phage attachment site of many CC398 strains (104) that leave the *hlb* reading frame intact but reduce integration of Sa3int (18, 19, 105). In these strains Sa3int integrates elsewhere in the chromosome, and the majority of those integration sites contain a 4-nucleotide sequence (5′-CTGG-3′) that is shared with the bona fide integration site in *hlb* (19). Importantly, the location of the integration appears to influence the stability of the Sa3int prophage in the livestock strains (18, 19), indicating that the success of the livestock MRSA strains in humans may depend on the location of the prophage. Interestingly, Sa3int also can promote animal adaptation, because some of the avian isolates carry a Sa3int-like phage with two putative avian-niche-specific genes (102).

The loss of Sa3int in the original jump of methicillin-susceptible *S. aureus* strains to livestock and the observation that the *hlb* gene of livestock-associated CC398 strains is mutated such that the phage integration site is eliminated but the *hlb* gene is kept intact underscores the role of the phages in lysogenic conversion. It also underscores the probability that Hlb is important for livestock but not for human pathogenesis. Also, the human to bovine jump of CC8 strains has been associated with the loss of Sa3int, similar to the human to livestock jump of CC398 (102, 106).

Phages other than Sa3int have also been associated with the human adaptation of CC398. Several studies document the presence of a phiMR11-like phage in these strains, and further analysis suggested that it is a defective phage that may act as a helper phage which interacts with a coresiding Sa3int phage to promote the expression of phage gene products (61, 107, 108). In another subset of CC398 strains associated with

human to human transmission, Sa7int phages were detected (103). Little is known about this phage, but its association with strains being transmitted between humans suggests that it may be important for human adaptation.

DUAL CONTROL OF PHAGE-ENCODED VIRULENCE GENES: LINK TO HOST REGULATORY SYSTEMS AND PHAGE LIFE CYCLE

Phage-encoded virulence genes are integrated into the regulatory mechanism of the bacterial host and modulated in a manner surprisingly similar to bacterial chromosome-encoded virulence factors. The alternative sigma factor B seems to inhibit the expression of most, if not all, of the currently analyzed phage-encoded virulence factors (109–111). Furthermore, the two-component regulatory system *saeRS* and, to a lesser extent, the quorum-sensing system *agr* (66, 109, 110, 112) are required for the activation of most of the phage-encoded virulence factors, such as *eta*, *pvl*, *scn*, and *chp*. Interestingly, as an exception to this observation, *sak* was not, or was only marginally, influenced by *sae* and/or *agr* (66, 110). Both the *sae* and *agr* regulatory systems are essential for the coordinated expression of many bacterial chromosome-encoded virulence factors, and mutants deficient in these factors are clearly less virulent as shown in different animal models of infection. Thus, the phage-encoded virulence factors are integrated into different regulatory circuits employed by the bacteria. It is likely that the prophages acquired these virulence genes along with their pre-existing chromosomally determined regulatory features. Moreover, the expression of phage-encoded virulence genes is also influenced by subinhibitory concentrations of certain antibiotics. β-Lactam antibiotics, for instance, enhance PVL production presumably via the transcriptional factors SarA and Rot (112).

The expression of these virulence factors is also tightly linked to the phage life cycle. Prophages are induced by environmental conditions that lead to DNA damage, including exposure to reactive oxygen species generated by leukocytes or exposure to exogenous agents such as antibiotics (65, 113, 114). It has been demonstrated that under such phage-inducing conditions, the transcription of the virulence factors that are localized in close proximity to the lysis module of the phage genome is increased (64–66). This phenomenon is partially due to a multicopy effect caused by phage replication. However, it has also been shown that transcription becomes intimately linked to the phage genes through cotranscription with the now derepressed lysis genes (65, 66). In this regard, the use of antibiotics that induce the SOS response, such as quinolones or β-lactam antibiotics, is a special concern. Antibiotic-induced expression of phage-encoded toxin genes is well documented for *E. coli* prophages harboring Shiga-toxin-encoding genes (*stx*). Quinolones enhance *stx* transcription, Stx production, and toxin release from the bacterial cells via phage-mediated lysis and death in mice (115).

MYOIRIDAE AND *PODOVIRIDAE*

Although more is known about the siphoviruses, the phages belonging to the *Myoviridae* and *Podoviridae* are receiving increasing attention because of their therapeutic potential in combating *S. aureus* infections. In this context, their nontemperate and lytic nature does not carry the risk of enabling the spread of virulence or antibiotic-resistance genes upon phage treatment (116).

The receptor interaction of *Myoviridae* and *Podoviridae* demonstrates more diversity in comparison with the discussed *Siphoviridae*. The well-described Myovirus ΦK and Φ812 only require either a GroP or RboP backbone of WTA (Fig. 1D) (35, 47). Structural elucidation of the RBP of Myovirus φ812 demonstrates a sophisticated conformational change of the double-layered baseplate upon binding of the bacterial cell wall (116). Hence, their high receptor promiscuity allows infection of many coagulase-negative staphylococci expressing GroP-WTA (49, 117). Alternatively, Twortlikevirus ΦSA012 appears to distinguish between α- and β-GlcNAcylation (118). At least two RBPs are encoded by ΦSA012: one interacting with the RboP backbone and the other, with α-1,4-GlcNAc residues (Fig. 1E). Interestingly, Podovirus ΦP68, Φ44AHJD, and Φ66, requiring β-1,4-GlcNAcylated WTA, fail to adsorb and infect strains carrying WTA modified with α-GlcNAc or β-1,3-GlcNAc residues in a dominant manner (33, 54). This finding demonstrates that certain WTA glycosylation patterns are able to protect *S. aureus* from viral predation by preventing proper phage adsorption. Furthermore, it shows that the alternative WTA glycosyltransferase, TarM and TarP, play an antiviral role. Obtaining phage resistance by blocking the host receptor is an often-observed feature (119, 120). However, TarM-mediated glycosylation does not block all *S. aureus* podoviruses from infection. Certain podoviruses, such as S24-1, appear to have evolved an RBP that allows adsorption to α- or β-GlcNAcylated WTA (121). Noticeably, this RBP shares key amino acids with the RBP of siphovirus φ11, GP45, also shown to facilitate binding to α- or β-GlcNAcylated WTAs (44).

The application of phages to limit *S. aureus* both *in vitro* and *in vivo* has been tested extensively, and there seems to be some therapeutic potential (122, 123). In the following, we mention just a few examples of how phages may be used to combat *S. aureus*. Additionally, the therapeutic use of phage lytic proteins in *S. aureus* is yielding promising results, showing good efficacy without apparent side effects (124). During dairy production a phage cocktail consisting of *Myoviridae* and *Podoviridae* as well as lytic *Siphoviridae* eradiated a 10^6 CFU/g *S. aureus* population after 14 days in Cheddar cheese curd during ripening at 4°C (125). Also, in biofilms, phages appear to reduce *S. aureus* numbers as exemplified in two studies using members of the *Myoviridae* family (126, 127). However, if present in sublethal doses, the action of the lytic phages may promote DNA release and collectively enhance biofilm formation, suggesting that caution should be used when considering phage therapy for eradication of *S. aureus* biofilms (128). The potency of phage therapy *in vivo* has also been evaluated. In a mouse model of bovine mastitis a phage cocktail significantly reduced infection with a clinical bovine mastitis when applied 4 h post-inoculation as demonstrated by improved pathology and decreased bacterial counts. Importantly, phage quantification indicated that the phage cocktail maintained high intramammary phage titers without spreading systemically (129). Future studies are likely to further address the therapeutic potential of targeting *S. aureus* with phages.

PHAGE DYNAMICS: MOVEMENT OF THE PHAGE WITHIN AND BETWEEN STAPHYLOCOCCAL SPECIES

Whereas most *S. aureus* isolates harbor multiple phages, less is known about the prevalence and nature of phages in coagulase-negative staphylococci. Analyses of available

phage genome sequences of coagulase-negative staphylococci revealed a modular structure similar to that of *S. aureus* phages. The transfer of phages between different staphylococci is also supported by cluster analyses of phages from different staphylococcal species (130). CRISPR/Cas loci are present in some *S. epidermidis* strains but are lacking in most *S. aureus* isolates. These loci are involved in the recognition and cleavage of foreign DNA. Therefore, it was postulated that the gene flow is uni-directional (131), as indicated by several instances in which genetic material was presumably transferred from *S. epidermidis* to the more pathogenic *S. aureus* species. For example, the staphylococcal cassette chromosome expressing methicillin resistance (SCC*mec*) genomic islands that carry the *mec*A gene conferring resistance to methicillin at least occasionally originate from *S. epidermidis* (132). Genetic exchange might be possible between different staphylococcal species because they live in similar environments, such as on the skin or in the nose. Additionally, phages might persist in a specific environment even though the bacterial host is already eliminated through the action of the immune system or antibiotics. Such phages or transducing particles may then infect coinhabitants, providing them with new properties.

PHAGES MEDIATE HORIZONTAL GENE TRANSFER

Horizontal gene transfer is commonly observed in *S. aureus*, and phages are believed to be major contributors (6, 16). In 1959, transduction was described for a staphylococcal phage (133), and soon thereafter, several phages were shown to be transducing (134), particularly those belonging to serological group B (135), such as Φ11, Φ80a, and Φ80 (136, 137). Transduction is the process by which bacterial DNA, during lytic replication of the phage, is mis-packaged into phage capsids forming transducing particles and upon release can be taken up by bacterial cells. In generalized transduction, the phage machinery recognizes pseudo *pac*-sites that mimic the sequence from where phage DNA packaging is initiated during lytic growth, and thus, in principle, any bacterial DNA can be transferred by this process. Normally, it is thought that the recipient strain should be susceptible to the transducing phage, but this appears not to be the case, because plasmid DNA is effectively transduced into recipient *S. aureus* strains by φ29, φ52A, and φ80α as well as by prophage φ53 in spite of their insensitivity to the lytic action of the transducing phage (138). In *S. aureus*, the transfer of antibiotic resistance genes has mostly been studied, but metabolic traits have also been transduced, as have been various mobile genetic elements (139, 140). The size of the DNA transferred by a transducing particle is limited to that of the *S. aureus* siphophage genome (approximately 43 kbp) (8, 141), and molecules of smaller sizes such as plasmids are transferred as linear multimers (142). The size limitation of the phage capsid prevents transfer of larger chromosomal elements such as the SCC*mec*. The SCC*mec* cassettes vary in size from 20 kbp to 60 kbp, so only the smaller SCC*mec*s are expected to transfer through generalized transduction, as demonstrated for SCC*mec* type IV and SCC*mec* type I (143, 144). Even then, transfer of methicillin resistance is a rare event, and other factors are likely required, such as lysogeny prior to transduction and the presence of a penicillinase in the recipient strain (145). The need for penicillinase activity was confirmed and explained by the transcriptional regulation of the *mec* gene by the plasmid-borne *blaR1-blaI* regulatory genes (143). Thus, transduction is possibly responsible for the transfer of SCC*mec* elements, although additional factors are required.

In the laboratory, the phages Φ11 and Φ80a in particular have been used extensively for genetic manipulations of *S. aureus* (146). However, outside of the lab a diverse range of transducing phages are being reported (49, 147, 148). One example is Φ187, which only binds and transduces ST395 strains expressing an unusual WTA (Fig. 1C) that, surprisingly, is also present in *S. epidermidis* and *L. monocytogenes*, which are also transducible (49). Another phage, S6, isolated from sewage, proved to be a giant myophage that is able to transduce plasmid and methicillin resistance between *S. aureus* and non-*aureus* staphylococcal species, including *S. epidermidis*, *S. felis*, *S. sciuri*, and *S. pseudintermedius* (148).

Although some phages are able to readily transduce between staphylococcal species, horizontal gene transfer appears generally limited within the species through restriction-modification (R-M) systems. The principle function of these R-M systems is to protect the cell by degrading foreign DNA. If the phage is derived from a host with the same R-M system, the phage DNA becomes methylated at the cognate restriction site and thus is protected. Strains of the major CCs were shown to differ in their R-M specificity genes (149). Thus, mobile genetic elements present in one strain move to a strain of the same lineage at a higher frequency than to strains of other lineages. Consequently, *S. aureus* lineages carry a unique combination of core variable genes, suggesting only vertical transmission of these genes (149). It has also been shown that prophage prevalence is associated with the clonal background of *S. aureus*, indicating that the spread of the phages in the bacterial population is at least partially restricted (12, 13). In certain CCs, some phage groups are completely absent, whereas others are significantly less or significantly more frequent. The most prominent disequilibrium was the finding that CC15 strains do not carry Sa3int phages, although this is the most common phage group found in *S. aureus*, with a prevalence of up to 90% (17, 57, 150). In addition, many isolates from the CC15 complex carried none of the seven prophage groups, suggesting that this lineage is particularly restrictive to the uptake of foreign DNA. From these studies, it is clear that restriction barriers are important in limiting phage transmission and likely also transduction. Other barriers may also be present, such as the CRISPR/Cas system, but their biological importance is unknown because the system has only been reported for a few *S. aureus* strains (151).

Although it is well accepted that transduction is central for horizontal gene transfer in staphylococci, surprisingly little is known of the process under biologically relevant conditions. Recently, we observed that phages spontaneously released from a subpopulation of lysogenic cells can infect, lyse, and efficiently transfer DNA from a phage-susceptible bacterial population back to the intact lysogenic population, which itself survives because of immunity to phage killing (152). The process, which we termed "auto-transduction," is driven by the spontaneous release of phages from the lysogenic population. Upon infection of susceptible cells, phages are formed together with transducing particles containing bacterial DNA and mobile genetic elements such as plasmids or SaPIs. These elements are effectively introduced in the original population, which due to lysogeny resists phage killing (152). Even though the phenomenon of transducing particles entering lysogens was observed in the first transduction experiments (153), we still do not know the extent to which it has biological impact. What, for example, remains to be studied are the conditions that promote the spontaneous

release of prophages and those that influence the formation of transducing particles. A recent study showed that the ratio of transducing particles to phages is affected by antibiotics (154), thus stressing the need for *in vivo* studies that assess the potential impact of antimicrobial therapy on transduction.

Recently, another study investigated transduction and found that packaging of bacterial DNA in transducing particles differs depending on whether they arise from an induced, temperate phage or from an infection (155). Interestingly, while infection with a transducing phage leads even to packaging of the bacterial chromosome in transducing particles, the induction of a temperate transducing phage leads to preferential packaging of bacterial DNA downstream of the integration site in a process termed "lateral transduction." By lateral transduction, several hundred kilobases of *S. aureus* DNA is packaged with high frequency, leading to hypermobility of this chromosomal region (155). With these findings in mind, we are beginning to understand how bacteriophages can be the main vehicle of staphylococcal horizontal gene transfer.

We thank the Deutsche Forschungsgemeinschaft (DFG) and Danish National Research Foundation, grant DNRF120, for funding.

We thank Carina Rohmer for help gathering the information summarized in Table 1. Part of this chapter is based on a previous review (6).

Pathogenicity Islands and Their Role in Staphylococcal Biology

RICHARD P. NOVICK

33

INTRODUCTION

Once upon a time, bacteria, like other organisms, were considered to have stable genomes with essentially constant overall composition that unequivocally defined each species. The bacterial genome was initially seen to consist of a single very large circular DNA molecule (chromosome) containing all of the organism's genes (1). In retrospect, the proof that prophages were physically integrated into the chromosomal DNA provided the first inkling that this view was incorrect: discrete, variable, and mobile genetic units could exist within the bacterial chromosome. The profundity of this observation, however, was not immediately realized, since phages were seen as parasitic invaders that had found integration as a way to achieve stable intracellular inheritance. It was soon realized, however, that not only temperate phages but also the F plasmid and, as it was then thought, the ColE1 plasmid could reversibly integrate into the host cell's chromosome and that there were also short DNA segments (insertion sequences) that could be found in various locations (2). These observations led to the idea of discrete elements of genomic variability superimposed on the overall constancy of the chromosomal genophore; indeed, by 1996 the intergeneric transfer of mobile genetic elements had been documented so widely that David Summers was led to suggest, a bit whimsically, that all bacteria are but a single megaspecies, cohered by a vast marketplace of exchangeable genetic units (3).

Within this overarching firmament of genetic mobility are the genomic islands (GIs)—elements that were first realized to be members of this universe when several reports described DNA segments that carried genes involved in pathogenicity, lacked genes belonging to the core chromosome, and were present in some strains of a species but absent from others (4). Termed "pathogenicity islands," they launched the concept of the GI, which is now the generic term for all inserted DNA segments in bacteria (5). However, despite the clarity of this concept, it has often been misapplied and therefore deserves a very clear and exclusive definition: "a genomic island (GI) is a discrete segment of DNA with defined ends, that has a limited phylogenetic distribution" (6); because a GI lacks genes belonging to the core chromosome, it is dispensable. Membership in the island family involves acquisition by horizontal transfer; although extant islands may not be or may no longer be mobile, most possess stigmata of their horizontal acquisition, including flanking direct repeats, mobility genes such as *int* and *xis*, transfer origins, *tra* genes, replication-related genes, and transposition genes. It is generally possible to distinguish a GI from an indel by these criteria. Included in the island family are insertion elements and other transposons, integrating conjugative elements, pathogenicity islands, resistance islands, symbiosis islands, integrating plasmids, and prophages (see Table 1). With the exception of symbiosis islands, all of these occur in staphylococci, where they have a major role in the biology of the organism.

This article focuses on a critically important group of staphylococcal GIs, the *Staphylococcus aureus* pathogenicity islands (SaPIs). They are a coherent family of phage-inducible, highly mobile GIs of 12 to 18 kb that are widely distributed among *S. aureus* strains. Although the SaPIs have a modular organization, reminiscent of prophages, and encode several prophage-like functions, they are not defective phages but distinct genetic elements with a characteristic life cycle, novel functions, and unique cargo. They play a significant role in the pathogenesis, evolution, and biology of the organism.

SaPI Encapsulated

Like prophages, the SaPIs reside quiescently in the *S. aureus* chromosome under the control of a SaPI-coded master repressor (Stl) and replicate along with the chromosomal DNA. However, unlike most prophage repressors, the SaPI repressors are not SOS-inducible but are derepressed by specific (helper) phage-coded proteins. When helper phages infect the cell or undergo induction as prophages, they produce antirepressors that counteract Stl, initiating expression of the overall SaPI genome, which leads to excision and replication. Postreplicative SaPI DNA is packaged in phage-like particles composed of phage virion proteins, which are released by helper phage-induced cellular lysis. SaPI particle titers are commensurate with helper phage titers, resulting in extremely high transfer frequencies. The SaPIs frequently carry and disseminate staphylococcal signature toxin genes and therefore play an important role in pathogenesis. Like *pac* phages, most SaPIs are capable of mediating generalized transduction (GT) and therefore play a role in the adaptability and evolution of the organism. However, the SaPI's actual *raison d'etre* may, ironically, be to protect the staph cell from its most formidable foe, the

TABLE 1 GIs in staphylococci[a]

Island	Size (kb)	Accessory genes	GI stigmata
Insertion sequences	1–2	None	Flanking DRs, transposase
Transposons	>5	Ab resistance genes	Flanking DRs, transposase
SCC elements	20–60	*mec*A, other Ab resistances	Flanking DRs, *ccr* genes
Prophages	40–50	Toxin and other converting genes	Flanking DRs, *int*/*xis*, replicon, virion genes, autonomous replication, mobility, etc.
SaPIs	12–27	Sag genes, other virulence and resistance genes	Flanking DRs, *int*/*xis*, replicon, *terS*, autonomous replication, mobility
Integrated plasmids	4–40	Ab and heavy metal resistance	Typical plasmid genes, replicon
Conjugative transposons	15–50	Ab resistance	Flanking DRs, *tra* genes, oriTs, *int*/*xis*, mobility
ICE elements	15–50	Ab resistance	Flanking DRs, *tra* genes, oriTs *int*/*xis*, mobility

[a]Abbreviations: Ab, antibiotic (not antibody); DR, direct repeats; ccr, cassette chromosome recombinae; Sag, superantigen; SCC, staphylococcal cassette chromosome; tra, transfer; oriT, transfer origin; ICE, integrative and conjugtive element.

bacteriophage. Although the SaPIs are derived from and dependent on phages, all SaPIs code multiple mechanisms for interfering with phage reproduction.

A Brief History of SaPIs

Some 20 years ago, the Novick lab cloned *tst*, the gene for toxic shock toxin-1 (TSST-1) and confirmed that it was a variable gene, present in only about 10% of clinical *S. aureus* isolates. Strains lacking the gene were also missing about 14 kb of flanking sequences, and when the gene was transferred by GT to a new strain, using an inserted tetracycline resistance gene to enable genetic selection, the flanking 14 kb were also transferred, and the transfer occurred at an extremely high frequency. Examination of different TSS strains revealed that the gene was in more than one location, suggesting that the 15-kb unit was a transposon. Analysis of a *tst* element in a different location revealed that the flanking sequences were different, ruling out a transposon and prompting us to consider it a pathogenicity island (7). We named the first one SaPI1 and the second, SaPI2. Though it was assumed that pathogenicity islands were mobile, this was the first demonstration. Several others were soon characterized, including one from a bovine isolate (SaPIbov1) (8). Later, when large numbers of *S. aureus* genome sequences became available, we observed that SaPIs made up a huge family, with an average of one per strain, with those having two, three, or more balanced by those with none. At least two major families were discerned, of which the prototypes are SaPI1 (7) and SaPIbov5 (9) (Fig. 1). Five SaPI attachment (*att*) sites were identified in *S. aureus*, in which only SaPIs but no other mobile genetic elements were located, nor were SaPIs found at any other location. These sites are utilized by members of both SaPI subsets.

SaPI-like elements are also found in non-*aureus* staphylococci, but much less frequently. Although the SaPIs were initially designated pathogenicity islands and are the only known source of TSST-1 (7), many of them do not carry identifiable virulence genes, so the "SaPI" designation is something of a historical accident. Although the term "SaPI" is too well established to consider modifying it, similar elements, with which other Gram-positive cocci are replete and which have yet to be found carrying virulence genes, are called phage-inducible chromosomal islands (PICIs) (10, 11).

The SaPI Genome

The SaPIs and their relatives in other Gram-positive bacteria were, almost certainly, derived from a bacteriophage or protophage in the very distant past by a deletion eliminating the phage morphogenesis and lysis modules, as illustrated in Fig. 1. The resulting SaPI genome contains three types of genes: life-cycle genes, interference genes, and accessory genes. It has, however, retained its prophage-like modular organization in which the life cycle genes are organized as follows: there is an integrase gene (*int*) at one end followed by a key site of transcriptional divergence flanked by two key regulatory genes, a *c1*-like master repressor (*stl*) and a *cro*-like activator (*str*) (see reference 12 for a review). In some SaPIs, the region between *int* and *stl* contains accessory genes. The integrase is always accompanied by an *xis* function; a *pri-rep/ori* complex defines the SaPI replicon, which is organized similarly to typical prophage replicons in which the replication origin (*ori*) is directly downstream of the replication initiator (*rep*) gene; upstream of *rep* is a primase homolog (*pri*), which is fused to *rep* in some SaPIs; the *ori* consists of two sets of GC-rich short repeats flanking an ~80-bp AT-rich region. Downstream of the replicon is a prophage packaging inhibitor (*ppi*), one of the phage interference genes (see below). Although a detailed transcription map is not available, three main transcripts have been defined (the green arrows in Fig. 1). The SaPI genome can be readily identified by genome scanning; for example, a typical SaPI at the *groEL* (SAV2029) site in mu50, from genes SAV2008(*sec3*) to SAV2028(*int*) is shown in Fig. 2.

The SaPI1 Subset

In this group of SaPIs, *ppi* is followed by operon 1, which contains several other phage interference genes and ends at *terS* (Fig. 1). The TerS (terminase small subunit) is highly conserved among these SaPIs and is specific for the packaging of SaPI DNA; unlike in prophages, the *pac* site is separated from the *terS* gene, which enables transcomplementation of *terS* mutants and is a crossover suppressor of heterologous recombination in that region. Unlike the typical prophage *pac* sites, which are embedded within the *terS* coding sequence (13), the SaPI *pac* site is typically separate from and upstream of the SaPI $terS_S$ coding sequence (14). Beyond *terS* is a region occupied by accessory genes.

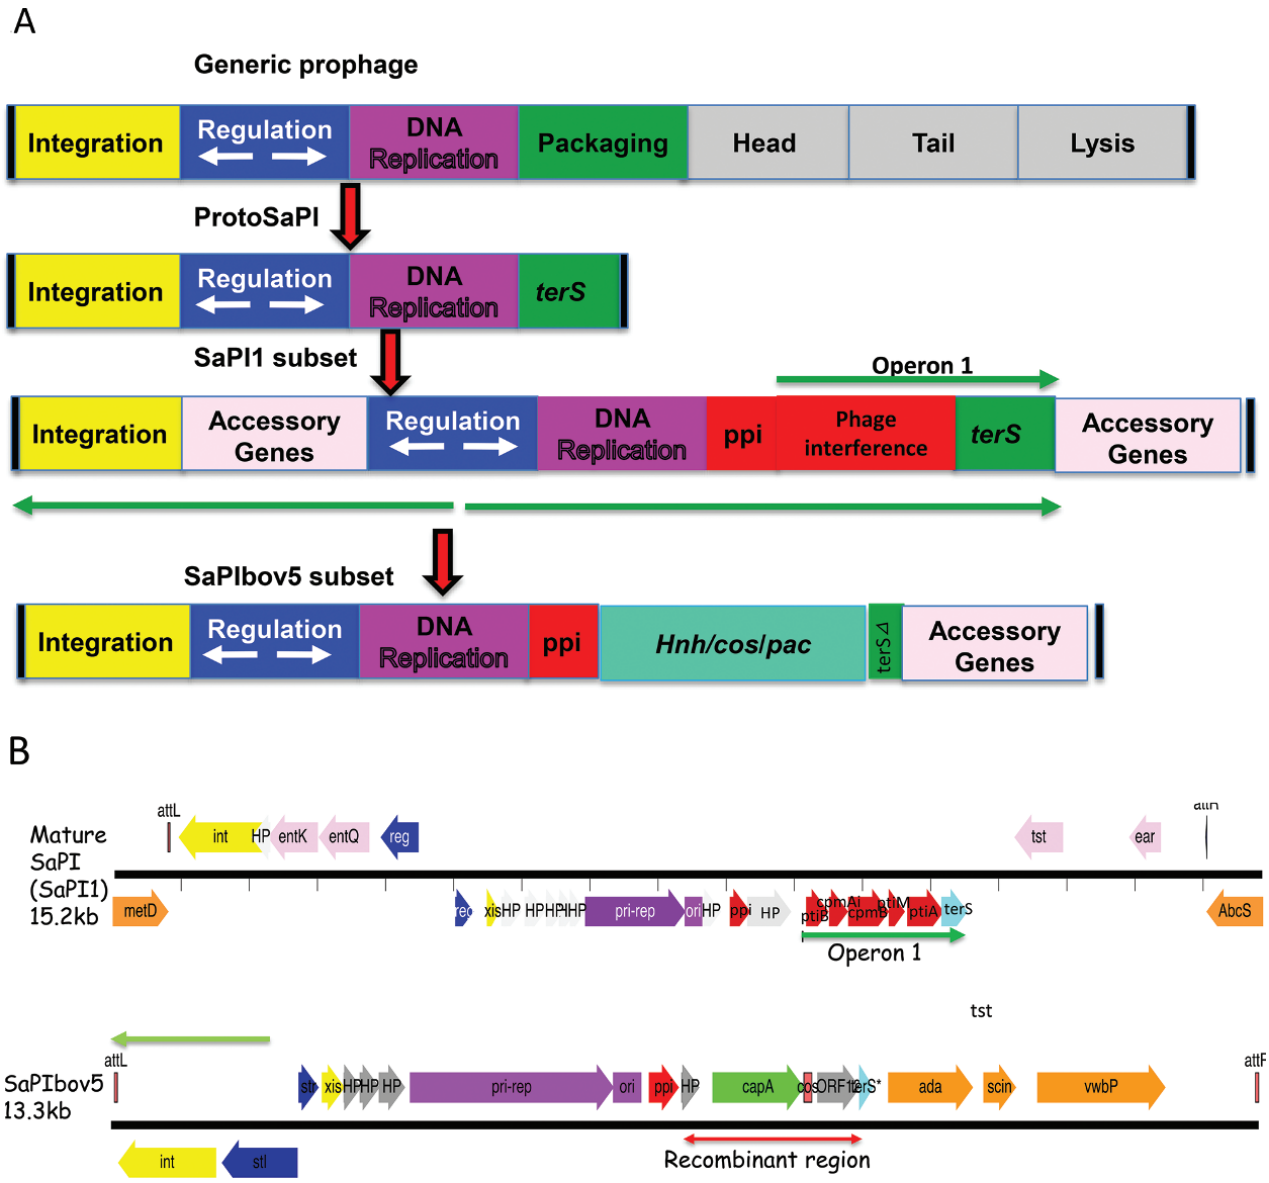

FIGURE 1 The SaPI genome and its putative origin. (A) Block diagrams. At the top is a typical prophage genome, and below that is the putative SaPI precursor, presumably the result of a major deletion. Next are two extant SaPI genomes. (B) Genetic maps of SaPI1 and SaPIbov5. Colors: red, interference genes; aqua, *terS*; orange, accessory genes; blue, regulatory genes; yellow, *int*/*xis*; gray, hypotheticals; purple, replication.

The SaPIbov5 Subset

Many *S. aureus* strains of domestic animals harbor variant SaPIs of which the prototype is SaPIbov5 (9, 15). These lack a functional *terS* but have a C-terminal remnant of a typical SaPI *terS* gene. They were probably derived from a typical SaPI by recombination with a *cos* phage. This recombination event replaced most of operon 1 by a prophage DNA segment containing a *cos* site, an *hnh* protease gene, and *ccm*, a gene encoding a homolog of the phage major capsid protein. The *terS* remnant marks one end of the putative recombinational event. It is possible that this putative recombination event occurred several times, since SaPIs of this type are found in several SaPI *att* sites (see Table 2).

THE SAPI LIFE CYCLE (FIG. 3)

Regulation

As noted above, SaPI DNA expression is controlled by a c1-like master repressor, Stl, which is countered by helper phage-encoded derepressor proteins, all of which have significant roles in the phage life cycle and are therefore moonlighting proteins (16, 17). The Stl amino acid sequence is highly variable, and different Stls are countered by different derepressors. Thus far, four derepressors have been analyzed in *S. aureus* and one in *Enterococcus faecalis*. Table 3 lists the SaPIs that encode these Stls and their respective phage-specified derepressors. Remarkably, 80α encodes four

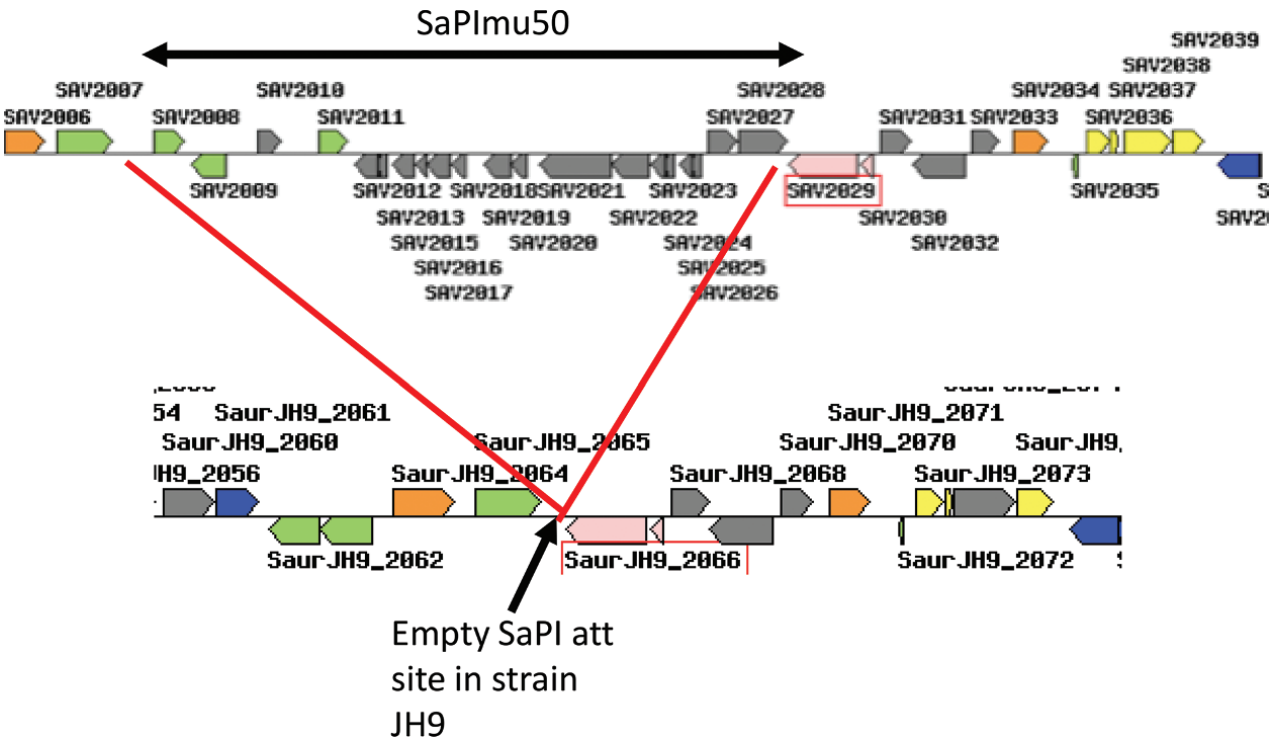

FIGURE 2 SaPI genomic pattern. At the top is the *groEL* region of *S. aureus* strain mu50, with a classical SaPI inserted at the 3′ end of *groEL*. The basic SaPI genes are in gray, and accessory genes at the left end are in green. Note the typical transcriptional divergence. Below is shown the corresponding region of strain JH9, in which the SaPI *att* site at *groEL* is empty.

independent and unrelated SaPI derepressors, and there could easily be additional ones that are as yet unrecognized. It is also highly likely that 80α is not unique among temperate staphylococcal phages in its possession of multiple SaPI derepressors.

The fascinating question arises of how these remarkable relationships could have evolved. Perhaps the SaPIs were derived from a prophage induced by a *trans*-acting derepressor protein (18) (although in the known cases, the derepressors are SOS induced). Alternatively, the SaPI followed an evolutionary pathway in which a classical SOS-induced repressor evolved to one that is bound and inactivated by an important phage-coded protein. The Stls are remarkably diverse, and the evolutionary forces driving their diversity are far from obvious. Moreover, even those that interact with a given derepressor do not seem to have any common motif that could be identified as a binding target. The most interesting of the derepressor proteins is dUTPase, which is universally conserved among temperate phages and has a significant (but nonessential) role in the phage life cycle. dUTPase is a bifunctional protein whose enzymatic and derepressor activities are genetically separable but functionally linked, in that binding of dUTP causes an allosteric shift which enables the protein to bind the Stl (19). dUTPase occurs in dimeric and trimeric forms, and both have the same derepressor specificity. In other species, the repressor-binding region has an important role in signaling and in immune modulation (20). Among the other known derepressor proteins, Sri inhibits loading of DnaB helicase and thus blocks chromosomal replication (21); Sak is a single-strand DNA binding protein that functions in recombination (22); Xis is the classical excision protein, and gp15 is a small protein of unknown function.

The SaPI-Phage War

As detailed below, all known SaPIs and similar elements from other organisms devote considerable genetic energy to interfering with the reproduction of their helper phages. The biological rationale for this is probably that the SaPIs are engaged in supporting their host cells, and one of their most potent weapons is the blocking of phage predation while at the same time commandeering phage proteins for their own life cycle. This generates a phage versus SaPI war, against which the phage's defense is for its derepressor to mutate. This idea is supported by a study demonstrating the frequent occurrence of SaPI-resistant mutations in the derepressor genes during passages of helper phages on SaPI-containing strains (23). Although this might seem to win the war for the phages, in actuality it does not. The derepressor proteins have important roles in the phage life cycle, and one of them, Sak, is evidently essential (22). The experimentally observed mutations are always detrimental to the phage and would not persist in the absence of continuous selection by the presence of a SaPI. Nevertheless, genome data suggest that many phages have actually won this war; the derepressor genes all have homologs in nonhelper phages, and these always differ considerably at the amino acid level from their derepressor cousins (23). If these proteins were once derepressors, this suggests that the development of SaPI resistance must have been a slow and arduous process. Not to be thus outdone, the SaPIs have "learned" to utilize related phage proteins as derepressors. A striking example is the utilization by SaPI2's Stl of distantly related proteins in four different phages as derepressors (22). Remarkably, the SaPI2 Stl appears to have different domains that interact with the different derepressors (22), indicating that the SaPI2 Stl is structurally rather accommodating and not so easily defeated. While this

capability does not enable the SaPI to utilize a phage whose derepressor has evolved away from SaPI sensitivity, it means that the range of phages that a given SaPI can utilize as helpers is immeasurably broad and extends *trans*-specifically and even *trans*-generically (22, 24).

Integration-Excision

SaPI integrases are of the tyrosine type, with *att* site cores of 15- to 22-bp direct repeats; the long flanking sequences generally required by tyrosine integrases have not been mapped. Early results suggested that following the entry of SaPI DNA, integration is delayed for more than an hour because the recombination event required for circularization is very slow (25). Integration is inhibited by 10- to 100-fold if the recipient's *att* site is occupied by a resident SaPI; this inhibition is not caused by the resident SaPI's repressor, but rather by the occupation of the *att* site (26), presumably because the hybrid *att* sites flanking the resident SaPI are poor substrates for the integrase. Nevertheless, integration eventually occurs at either of these hybrid *att* sites, generating a tandem double. The tandem double is highly unstable, ran-

domly losing either integrant by excision. Since the excised SaPI cannot replicate, owing to the presence of the SaPI repressor protein, it is immediately lost (26). A SaPI entering a recipient lacking its normal *att* site integrates with remarkably high efficiency (perhaps as high as 10% of the frequency of its integration into its primary site) into a secondary *att* site, of which there are at least 25 for SaPI1 (24). These secondary *att* sites generally match the primary site rather poorly, indicating that the integrases have rather loose site specificity. A remarkable unsolved mystery is that a SaPI in a secondary site is not induced by SOS induction of a resident helper prophage, although it is induced normally following superinfection of a nonlysogen by the same helper phage (24).

Replication

Replication is initiated by the Rep (or *pri-rep*) protein, which is SaPI specific; specificity is determined by a short C-terminal region of the protein, as shown by an experiment in which this region was switched between SaPIs of different specificities (27). The Rep protein is a helicase which binds to the two sets of flanking repeats that define the *ori*, causing the intervening AT-rich region to form a loop. Superhelix-driven melting of this loop exposes single-stranded regions which serve as the sites for Rep-initiated bidirectional replication (27). Following initiation, the host DNA polymerization system, modified to accommodate phage replication, takes over, and replication is completed by this system, resulting in concatenated multimers, the substrate for packaging (27).

Capsid Morphogenesis and Packaging

Most SaPIs package their DNA in small capsids commensurate with their small genomes. The precedent for phage satellite capsid modification is the *Escherichia coli* P2-P4 system, in which P4 modifies the P2 capsid to fit its 12-kb genome (28). This is accomplished by a P4-encoded scaffold protein, Sid, which forms an external shell within which the P2 capsid proteins are assembled to form the small P4 capsids (29). Many SaPIs also direct the helper phage capsid proteins to form small capsids, commensurate with their 15-kb genomes. For members of the SaPI1 subset, SaPI capsid size is determined by SaPI-coded CpmA and CpmB proteins (5), which act rather differently than the P4 Sid protein. CpmA and CpmB are both required for efficient small-capsid production (5), with CpmB modifying the internal scaffold to switch the capsid from T = 7 to T = 4 icosahedral geometry and CpmA ensuring the efficiency of size determination (5). For members of the SaPIbov5 subset, the Ccm protein (a homolog of the major phage capsid protein) is responsible for capsid size determination. In this case, the resulting small capsids have a morphology entirely different from that of the helper phage (30). In either case, deletion of the capsid morphogenesis gene(s) results in packaging of SaPI DNA in full-size phage capsids (30, 31).

Following replication, for members of the SaPI1 subset, headful packaging of SaPI DNA is initiated by a SaPI-coded terminase small subunit ($TerS_S$), which is distinct from the helper phage counterpart ($TerS_P$) and recognizes the SaPI-specific *pac* site (16, 32). $TerS_S$ complexes with the phage TerL to direct the SaPI DNA into preformed capsids composed of phage virion proteins (5, 33, 34). Packaging specificity is determined by TerS recognition specificity and is independent of procapsid size (31). Upon phage-induced lysis, SaPI particles are released in large numbers to infect other cells. Deletion of $terS_P$ eliminates phage DNA packaging but does not affect lysis, so that lysates are produced with particles of both sizes containing only SaPI DNA (21). For members of the SaPIbov5 subset, packaging is initiated by the helper phage terminase and occurs by the headful mechanism if the helper phage is a *pac* phage or by the *cos* packaging mechanism if the helper phage is a *cos* phage.

SaPIs of the bov5 type also reside quiescently under the control of a master repressor, which is countered by helper phages. Because they lack a functional *ter*S, they rely on helper phage terminases for packaging, and they use two independent packaging pathways. They can be packaged by a typical helper phage, φ11, using the φ11 terminase and by a φ11*pac* site (which has not been mapped). Alternatively, they can be packaged by φ12, which is not a helper phage for the SaPI1 family, using the φ12 terminase/HNH complex and a *cos* site derived from φ12 (or a related cos phage). The putative φ12 derepressor has yet to be identified.

Interference Mechanisms

Bacteria have developed a vast array of phage resistance mechanisms; indeed, phage-resistance mutations have been isolated affecting every stage of the phage life cycle. As noted above, a critical and highly evolved feature of SaPI biology is the presence of phage interference systems, which do not resemble known bacterial phage resistance mechanisms and utilize SaPI-specific genes, some of which have no counterparts among the phages or elsewhere. Among the well-characterized SaPIs of the SaPI1 subset, four such systems have been described (25, 35, 36) (see Table 4). The first of these to be identified (25, 35) is the capsid morphogenesis system, which catalyzes small capsid formation. Since SaPI DNA can be packaged equally well in capsids of either size, the selective value for the SaPI of small capsid formation must therefore be attributed to interference with helper phage reproduction, which amounts to over 90% in some cases (25). This system causes interference not only by diverting the phage virion proteins, but also by causing the phage to waste its DNA by packaging in small capsids, which can accommodate only one-third of the phage genome. The second interference mechanism discovered consists of a SaPI-encoded protein, Ppi, that binds to and inhibits the function of the phage small terminase ($TerS_P$) but does not affect the SaPI counterpart ($TerS_S$), sharply reducing the packaging of phage DNA (35). The third interference system involves a protein, PtiA, that blocks transcription of the late phage genes, including the virion protein and lysis modules, by binding to and inhibiting the late gene activator, LtrC (36). Unchecked, PtiA would block SaPI as well as phage particle production and would be suicidal for both; consequently, there is a second component of this inhibition system, PtiM, which binds to and moderates the inhibitory activity of PtiA (36). There is also a second *ltr*C-blocking protein, PtiB, which thus represents a fourth interference mechanism (36). Three of the phage interference systems are encoded in operon 1; the fourth, *ppi*, is not. Whether this is biologically significant or is an evolutionary "accident" is unclear. The multiplicity of unrelated interference systems, necessarily the products of convergent evolution, underlines their key role in SaPI biology. Since the interference systems are expressed only following SaPI induction, they were first identified as acting on helper phages; however, they also act with undiminished efficiency on other phages, so long as the SaPI is induced by some other agency.

As far as is known, the PICIs of other Gram-positive bacteria also interfere with phage reproduction (11). For members of the SaPIbov5 subset, the primary interference

TABLE 4 Mechanisms of SaPI-mediated phage interference

Action	Gene(s)	SaPI1	SaPI2	SaPIbov1	SaPIbov2	SaPIbov5
Diverts phage virion proteins for the formation of small capsids	*cpmAB*	++	+++	+	–	–
Blocks procapsid formation by binding to the phage capsid protein	*ccm*	–	–	–	–	+++
Binds to and blocks function of phage TerS	*ppi*	–	+++	++	+++	ND
PtiA binds to LtrC and blocks activation of late phage gene transcription; modulated by PtiM	*ptiAM*	++	++	–	ND	Absent
Blocks activation of late phage gene transcription by an unknown mechanism	*ptiB*	ND	++	ND	ND	Absent

+, Relative strength; –, inactive; ND, no data.

mechanism involves Ccm, which interferes with prohead formation by interacting with the major capsid protein (30). Here, the interference mechanism is much more stringent than that seen with members of the SaPI1 subset, resulting in a 10^6- to 10^7-fold reduction in phage titer (30). Since the SaPI capsids also utilize the major phage capsid protein (30), this interference necessarily results in lower SaPI titers than those seen with the SaPI1 subset.

There is an interesting contrast between SaPI-mediated phage interference and the powerful clustered regularly interspaced short palindromic repeat (CRISPR) antiphage system: the SaPIs not only do not totally block phage reproduction, but they also use their interference systems to aid in their own transfer and that of unlinked bacterial genes, whereas the CRISPR system destroys the phage genome and thus precludes phage-mediated gene transfer. Perhaps the high frequency of SaPIs and the rarity of CRISPRs in *S. aureus* is related to the effects of both on gene transfer. This is especially noteworthy since phage- and SaPI-mediated gene transfer are by far the most import genetic exchange mechanisms in this species.

SaPI OPERON 1, A FEATURE OF THE SaPI1 SUBSET, AND ITS KEY ROLES IN HOST CELL BIOLOGY

Host Cell Protection by Operon 1

Virtually all naturally occurring *S. aureus* organisms are lysogenic, many carrying several prophages, most of which are SOS-inducible. Although SOS induction is a stress response which counters DNA damage (37), the presence of an SOS-inducible prophage defeats this because its induction is lethal for the cell. (One must imagine that the SOS response evolved before prophages came on the scene.) SaPIs, however, counter this lethality in a remarkable way through their unique possession of an SOS-inducible operon, operon 1. The discovery of operon 1 and its SOS induction, early in the study of the SaPIs (38), was highly puzzling. Why should this element, which was not itself SOS inducible but required a phage-coded antirepressor instead, contain an SOS-inducible operon? Part of the answer, as noted below, is that SOS induction of operon 1 promotes SaPI-mediated GT. A more important rationale is that operon 1 encodes three of the four known phage interference systems (see below). Thus, DNA damage, resulting in the SOS response, induces operon 1 and is thus predicted to counter the lethal SOS induction of resident prophages, rescuing the cell and enabling the stress response. Perhaps the presence of several different interference mechanisms could be related to differential phage sensitivities. It is perhaps highly relevant in this context that most prophages are not helpers for SaPIs that happen to be coresident; instead, the presence of a SaPI would protect the cell from lethal phage induction during the SOS response. The story is slightly different if an SOS-inducible prophage happens to be a helper for a coresident SaPI. In this case, both SaPI and phage are induced, and the interference dynamics are more complicated; although the induced SaPI interferes with phage reproduction by one or more mechanisms, it blocks phage reproduction only partially because it needs the phage packaging and lysis systems for the production of infectious SaPI particles.

SaPI-Mediated Gene Transfer

In addition to their own high-frequency transfer, SaPIs mediate GT based on $TerS_S$-directed mis-packaging of genomic DNA (39), entirely analogous to phage-mediated GT. In both cases, $TerS_S$ and $TerS_P$ recognize pseudo-*pac* sites homologous to the respective SaPI and phage *pac* sites. Since $TerS_S$ is encoded in operon 1, which is SOS-induced independently of the SaPI life cycle, SOS-induced DNA damage promotes SaPI-mediated GT independently of SaPI transfer. This transfer, like phage-mediated GT, occurs with widely varying frequencies, depending on the similarity of the pseudo-*pac* site to the true SaPI *pac* site. Interestingly, SaPI-mediated GT has a strong preference for genes involved in iron metabolism and therefore impacts pathogenesis.

ACCESSORY GENES

The third class of SaPI genes is the accessory genes, mostly virulence genes—genes that have important beneficial roles for the host bacteria, aiding in their survival in the animal host, often by directly causing diseases. Unlike converting phages, which rarely carry more than one virulence gene, many SaPIs carry four or more, chiefly superantigens, though resistance genes and other accessory genes are also encountered, some of which have no obvious role in virulence. The accessory genes are located at either of two sites: between *int* and *stl* and downstream of *terS*. They are transcribed by promoters that are not under Stl control and therefore are usually expressed in the quiescent state. It is assumed that these genes were acquired from some foreign source by the intact SaPI. As is generally the case with converting phages, neither the source nor the mechanism of acquisition of most of the accessory genes by the SaPIs is known. An exception is the presence of the immune evasion gene, the staphylococcal complement interference gene, on some members of the SaPIbov5 family, a gene that also occurs on the converting prophage φSa3 (40). The observation that *tst* in SaPI1 and *seb* in SaPI3 are in the same location but in opposite orientations suggests that nonhomologous end joining may be the

mechanism of their acquisition, even though nonhomologous end joining is very hard to demonstrate and is perhaps nonexistent in most bacteria. Indeed, one of the great unsolved mysteries of bacterial genetics is how certain genes have moved between genomes, movements that cannot be accounted for by known mechanisms of recombination.

A SaPI-Carried Determinant of Animal Adaptation

Staphylococci have evolved along with their animal hosts, and particular genotypes have come to be associated with particular animals (see chapter 46), implying that there are animal-specific bacterial genes or homologs. One such gene is carried by many members of the SaPIbov5 subset. This gene encodes a homolog of the von Willebrand factor binding protein, which is a coagulase and occurs in different allelic forms associated with SaPIs carried by staphylococci that are specific for different livestock; each allele specifically coagulates the plasma of the animal with which its SaPI is associated (41), suggesting that it is an animal-specific virulence factor. A nonspecific allele is also encoded by a chromosomal gene in most staphylococcal strains (41). Many of these SaPIs also carry an adenosine deaminase and the phage-derived staphylococcal complement interference protein (42). Others carry superantigen genes including TSST-O, a nontoxic variant of TSST-1, typical of ovine strains (43). An animal ST398 strain causing human endocarditis carried a SaPI of this type and had probably jumped from animal to human. Table 2 lists examples of the two known SaPI subsets.

Virulence Gene Clusters: Pretenders to the GI Throne

S. aureus strains encode several clusters of virulence-related genes: a cluster encoding serine protease-like (*spl*) proteins, one encoding exotoxin-like (*set*) proteins, a third encoding enterotoxin-like (*egc*) proteins, and a fourth encoding lipase-like (*lpl*) proteins. These sets of gene clusters are widely regarded as pathogenicity islands (40, 44) and are considered an important feature of the staphylococcal pathogenicity mobilome. However, because they are universally conserved among the available *S. aureus* genomes, they do not satisfy the primary island criterion, limited phylogenetic distribution (6), and moreover, they lack most island stigmata. It is suggested instead that despite their genomic organization and their potential role in pathogenesis, these clusters are not GIs and are not mobile but, rather, are sets of paralogous genes that evolved *in situ* by successive gene duplications, and though transferrable like other genes, this occurs by GT only.

SaPI EVOLUTION

We have proposed (see Fig. 1) that a proto-SaPI arose from a protoprophage by deletion; this was followed by evolutionary divergence resulting in several critical modifications that led to the currently extant SaPI genome as exemplified by SaPIs 1 and 2. SaPI evolution has resulted in deep divergence of all of the phage-related genes. Although these all retain a low degree of similarity to ancestral phage genes, they are much more closely related to cognate SaPI genes (10). Some of the extant SaPI genes, however, have no counterpart among prophages and are clearly products of the independent evolution of the SaPIs following their original split. The most important of these is operon 1, which is widely conserved and, as noted above, unlike the overall SaPI life cycle, is regulated by the SOS response (38). It contains three sets of genes that are responsible for phage interference and is responsible for gene transfer (39), all unique features of the SaPI life cycle. The similarity among SaPI genes also extends dramatically to genes of unknown function, encoding hypothetical proteins (HPs) that may or may not be translated. Most of these HP genes are well conserved among the SaPIs but have no detectable similarity to phage genes (10); phages have their own HPs that are not related to those of the SaPIs. This suggests that the HPs evolved *in situ* or were acquired following SaPI-phage divergence. Most important for the SaPI lifestyle is the possession of a master repressor that is

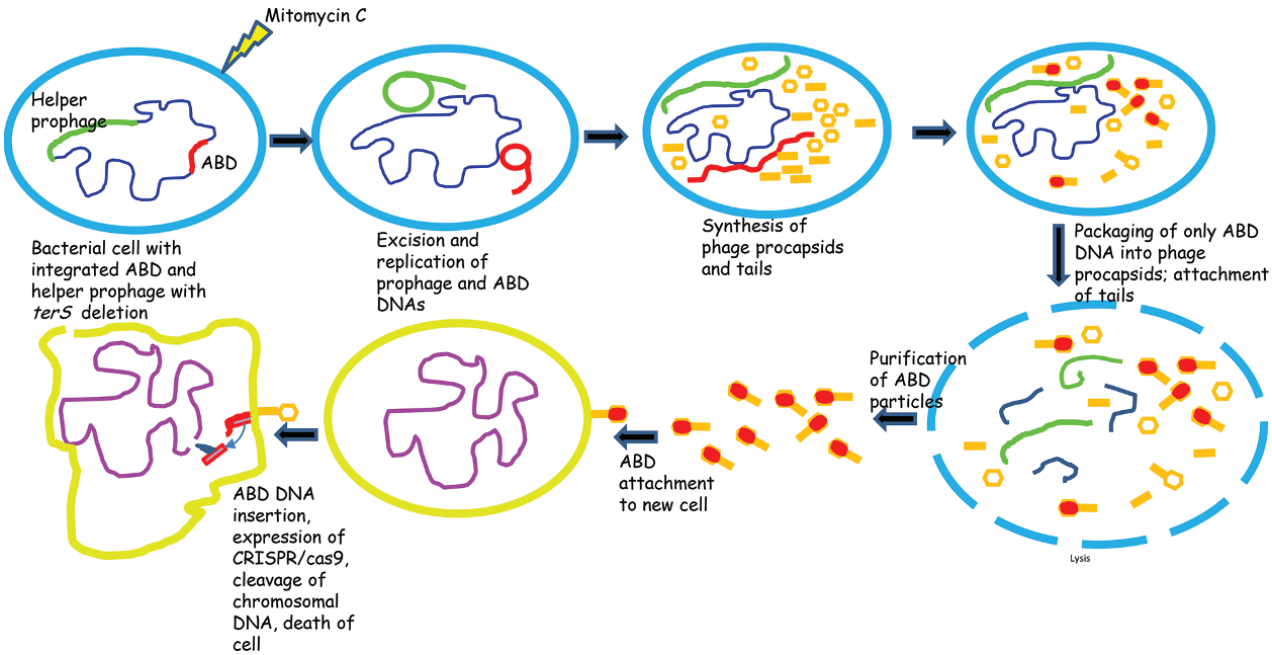

FIGURE 4 Induction, maturation, release, and cell killing by a CRISPR/cas9 ABD.

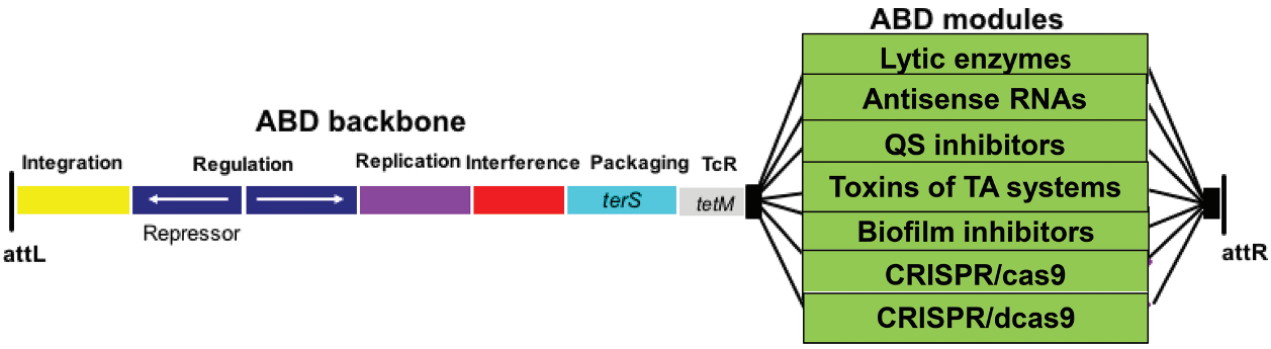

FIGURE 5 Diagrammatic representation of the ABD backbone.

counteracted by a phage-coded derepressor (17) rather than by the SOS response.

CONVERSION FROM WORKHORSE TO TROJAN HORSE: THE ABD STORY

Many years ago, Hope Ross, a research scientist in the Novick lab, realized that we could exploit the high-frequency transfer and great packaging capability of the SaPIs to create an effective delivery system and that if we added antistaphylococcal cargo to this system, we could convert the SaPIs into therapeutic islands and convert the workhorse into a Trojan horse. Accordingly, the genome of a typical SaPI1 family member, SaPI2, was modified by replacing the superantigen and other virulence and resistance genes with genes that, when expressed within a bacterial cell, would either kill the cell or block its virulence and thus cure an infection (Fig. 4). Several antibacterial cargo modules were added to this backbone vehicle (Fig. 5 and Table 5), including CRISPR-Cas9 with spacers matching either *agrA* or *fnbB*, CRISPR-dCas9 with a spacer matching the *agr* promoter region, and *lsp*, the gene for lysostaphin. This versatility was achieved by removing the capsid morphogenesis genes, causing the island to be packaged exclusively in full-sized phage particles, providing >30 kb of cloning space. Packaging in full-sized phage particles had no adverse effect on SaPI reproduction and actually increased SaPI transfer frequency (35). The *terS* gene of the helper prophage was also deleted, resulting in the production of mitomycin C-induced lysates that contained only SaPI particles, typically at titers of $\sim 10^{10}$/ml. These islands, known as antibacterial drones (ABDs), functioned as expected *in vitro* and cured mice infected subcutaneously or

Respiration and Small Colony Variants of *Staphylococcus aureus*

RICHARD PROCTOR

34

STAPHYLOCOCCAL METABOLISM AND RESPIRATION

The end point of bacterial respiration is the production of ATP as it uses oxygen, or other molecules, to accept electrons while oxidizing dinucleotides (Fig. 1). Because multiple cell wall biosynthetic enzymes require ATP (1), lowering ATP levels reduces the rate of growth of *Staphylococcus aureus*, resulting in small colonies. Some small colony variants (SCVs) have been found to be defective in respiration (2). Under glucose-rich conditions, ATP is produced via glycolysis without using oxygen, wherein glucose metabolism ends with the production of lactate (3). Under aerobic conditions, once glucose and other simple sugars are exhausted, pyruvate is further metabolized to acetate/acetyl-CoA, which enters the tricarboxylic acid (TCA) cycle (also called the Krebs cycle), and the chemical energy is fed into dinucleotides such as NADH and reduced flavin adenine dinucleotide ($FADH_2$). Under anaerobic conditions, pyruvate is mainly metabolized to lactate (3, 4). In addition to the oxidation of carbohydrates, the metabolism of amino acids and lipids also results in the production of acetyl-CoA (3). As acetyl-CoA is oxidized to CO_2 and H_2O, there is a simultaneous reduction of NAD^+ and FAD^+ to NADH and $FADH_2$, respectively. Ultimately, these reduced dinucleotides must be reoxidized because many reactions in the cell, e.g., dehydrogenases, require $NAD(P)^+$ for their activity.

Oxidation of dinucleotides can occur through multiple reactions, but the largest amount of oxidation is accomplished via the electron transport chain, wherein electrons flow from NADH and $FADH_2$ to quinones and then onto the cytochromes as terminal oxidases (5, 6). In *S. aureus*, there is only one quinone, specifically, menaquinone, which is formed from menadione. An isoprenoid tail attaches to menadione and facilitates its entry into the membrane (7) and the transfer of electrons to the cytochromes. There are three types of cytochromes in *S. aureus* (5). Cytochrome types aa_3 and bo_3 are most active when oxygen is abundant. These cytochromes are oxidized by oxygen with the formation of water. In contrast, under reduced oxygen conditions, cytochrome type *bd* is most active during and linked to the nitrate reductase complex (8, 9). The cytochromes and nitrate reductase complex both contain heme that is used in the oxidoreductase reactions. As the dinucleotides are oxidized, the protons are translocated across the membrane, creating a membrane potential.

Staphylococci use nitrate as an alternative electron acceptor during anaerobic respiration. Activation of the genes in the nitrate reductase complex involve an oxygen-sensitive two-component regulator, NreBC, wherein NreB is the sensor with an oxygen-labile iron-sulfur cluster (10). NreBC then activates the genes involved in nitrate reduction to ammonia as NADH is oxidized. The nitrate reductase complex contains both a cytochrome and menaquinone in the oxidoreductase reactions. In summary, the three major complexes that oxidize dinucleotides and create a membrane potential via transport of protons across the membrane in *S. aureus* are Ndh2 (NADH dehydrogenase), cytochromes, and the nitrate reductase complex.

The reentry of the protons through the F_0F_1 ATPase produces ATP in bacteria (11). The F_0F_1 ATPase is a large transmembrane protein complex that uses the proton gradient to release the ATP into the cytoplasm. The net amount of ATP produced by glycolysis is 2 ATPs, whereas the net quantity of ATP production per glucose molecule under aerobic conditions via the F_0F_1 ATPase is 30 to 32 ATPs. Uptake of glucose, mannitol, mannose, lactose, sucrose, maltose, and glycerol requires ATP (12), which is calculated into the net amount of ATP produced via glycolysis (3).

RESPIRATION AND TCA CYCLE ACTIVITY

ATP Levels and Control of the TCA Cycle

Low levels of ATP stimulate a stress response in *S. aureus* (13). ATP levels can be sensed by ClpC, which is a chaperone that binds stress regulators, and by a proteolytic partner, ClpP, in *S. aureus* (14). When ATP levels are high, ATP binds ClpC, and then it associates with ClpP, a protease that digests multiple proteins in the stress regulon. However, ClpC can play a dual role not only by proteolytic removal of proteins (13) but also as a chaperone to enhance the activities of other proteins (14). While this ClpC regulon spans the production of virulence factors to controlling metabolism, one particular link to respiration comes in thymidine auxotrophic *S. aureus* SCVs. ClpC is required for *citB* activation, and *thyA* mutant strains of *S. aureus* have reduced levels of

doi:10.1128/microbiolspec.GPP3-0069-2019

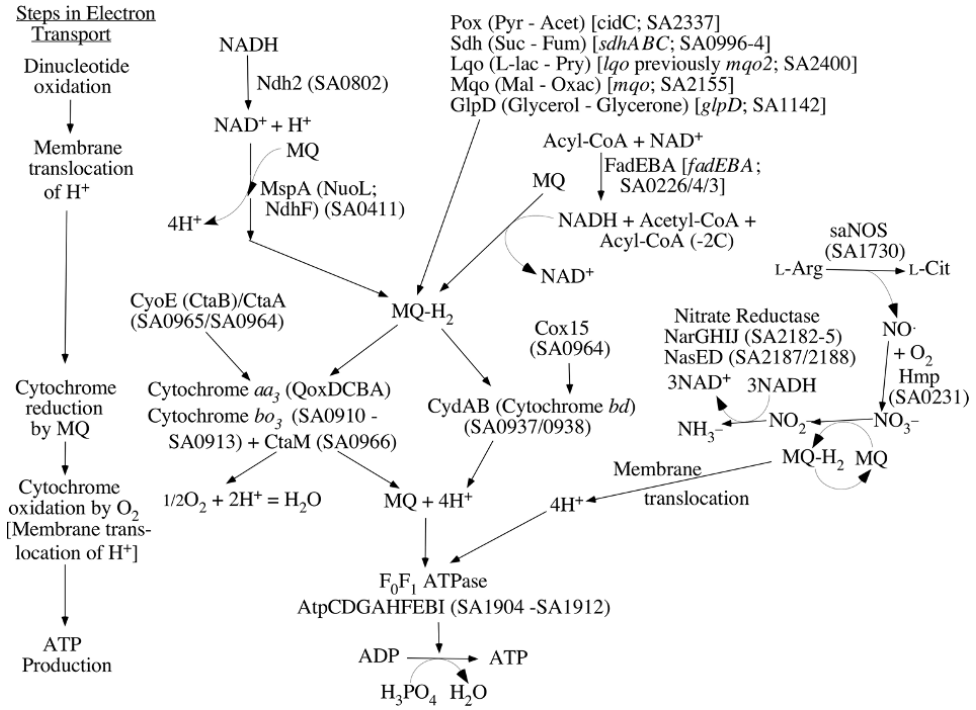

FIGURE 1 Electron Transport in *Staphylococcus aureus*.

ClpC (15–18). The exact pathway involved in *citB* activation through ClpC in *S. aureus* is not known, but it is clear that *thyA* mutants have a reduced TCA cycle because of reduced levels of aconitase. When the TCA cycle is inactive, the electron transport chain also shows reduced activity. Therefore, *thyA* mutants are respiratory deficient, giving them a very similar phenotype to menadione and hemin auxotrophic SCVs (19).

NADH Levels and Control of the TCA Cycle

Redox balance must also be maintained, as is reflected in the NADH/NAD^+ ratio. High NADH levels slow growth of respiratory-deficient bacteria because many dehydrogenases require NAD^+, thereby having a widespread impact on cellular metabolism. The TCA cycle uses the largest quantity of NAD^+ to release NADH. When NADH levels are high, several Krebs enzymes are inactivated by NADH through negative allosteric regulation of the enzymes, and TCA cycle genes are downregulated via redox-responsive regulators (3, 20). Thus, when electron transport is interrupted, levels of NADH rise, which downregulates the Krebs cycle.

Another example of the importance of redox balance comes from our observation that mannose, but not mannitol, stimulates growth of electron transport-deficient *S. aureus* (21). Both mannose and mannitol are metabolized to fructose-6-phosphate, and this leads to ATP production via glycolysis. Consequently, the difference between these compounds is due not to differences in net ATP production but, rather, to the first metabolic step in mannitol metabolism, wherein NAD^+ is reduced to NADH as mannose is produced from mannitol, thereby increasing NADH levels. This small difference makes respiratory-deficient SCVs unable to grow on mannitol salt agar, which is routinely used to identify *S. aureus* (22).

Host Nitric Oxide Redirects Metabolism, Including TCA Activity, in *S. aureus*

A fascinating interplay exists between nitric oxide (NO·) generated by the host and *S. aureus* metabolism, wherein NO· interferes with the TCA cycle, aerobic respiration, fatty acid metabolism, pyruvate metabolism, and nucleic acid synthesis. NO· causes widespread compensatory responses in *S. aureus* (9, 23–28). Overall, this disruption of respiratory metabolism results in rising levels of NADH that inactivate the transcriptional repressor, Rex, which allows derepression of lactate dehyrdogenases, *ddh*, and *ldh1* (29). Moreover, NO· stimulates SrrAB, which increases *hmp* and *qoxABCD* (Cyto aa_3) as well as other regulators such as Fur, SarA, CodY, and Rot (23–25, 29, 30). Finally, *S. aureus* makes its own NO· via nitric oxide synthase that modulates the respiratory chain (31). Taken together, these factors allow *S. aureus* to respond to a normally toxic host defense system by utilizing its regulation of its nitrogen respiratory pathways to its survival advantage.

GENES INVOLVED IN ELECTRON TRANSPORT AND SCVs

Mutations in genes that express the enzymes involved in electron transport (Fig. 1) result in the formation of respiratory-deficient SCVs (Table 1). As would be expected, mutations in genes whose protein products are involved in electron transport result in slower growth, thereby producing SCVs.

Mutation of the genes active in the first step in electron transport, dinucleotide oxidation, e.g., *ndh2* (type 1 NADH: quinone oxidoreductase) or *sdhCAB* (succinate dehydrogenase complex), results in *S. aureus* with an SCV phenotype (32, 33). While a second Ndh2 has been described in *S. aureus*, it is probably not a major Ndh in *S. aureus* (34). Deletion of *sdhCAB* in *S. aureus* produced an SCV with

TABLE 1 Metabolic pathways and mutations found in SCVs with reduced ATP[a]

Stage in electron transport	Biochemical reaction	Genes involved in electron transport pathways	Mutated genes that produce SCVs	Mutations discovered in clinical SCVs
Dinucleotide oxidation	NADH oxidation	*ndh2* (major pathway)	*ndh2*	No
		nasED	No	
		lqo, *mqo*, *glpD*	No	
	FADH oxidation	*sdh*, *fadD*	*sdhCAB*	No
Membrane translocation of protons	Makes a proton gradient	*mpsABC*	*mpsA*	No
		qoxABCD (Cyt aa_3 oxidase)		
		cydAB (Cyt *bd* oxidase)	*cydAB*	No
Transfer of electrons to cytochromes	Menaquinone transfers electrons to cytochromes	Menadione biosynthesis	*menB*, *menC*, *menE*, *menF*	Yes, yes, yes, yes
			menG, *aroD*	Yes, no
			menA, *menD*	Yes, no
		Isoprenoid tail	*ispA*, *mvaS*	No, no
Oxidation of cytochromes	Electrons move from cytochrome to oxygen (nitrate)	Heme biosynthesis	*hemB*, *hemG*	Yes, yes
			hemC, *hemD*, *hemE*, *hemH*, *hemQ*	No, no, no, no, no
		Cytochrome protein biosynthesis	*ctaA*, *ctaB*	No, no
			qoxB + *cydAB*	No, no
ATP production	Proton reentry	*atpCDGAHFEBI*	No	No
Production of NADH	Tricarboxylic acid cycle is major producer of NADH	*citB* (reduced aconitase activity turns off TCA)	*thyA* mutation suppresses *citB* activation	Yes
		odhAB (α-ketoglutarate dehydrogenase complex)	*odhA*, *odhB*	No, no

reduced pigmentation and increased aminoglycoside resistance whose phenotype is identical to clinical SCVs (2). These SCVs have been found in the laboratory but not yet in clinical isolates. Similarly, decreased translocation of protons across the cell membrane also results in SCVs. Mutations is *mps*A (33) and in the *cydAB* also interrupt electron transport and produce SCVs (5, 6). Again, no clinical isolates with these mutations have been reported. While the nitrate reductase complex also transports protons across the membrane, and mutations in the *nar*G operon slow the growth of *S. aureus* under anaerobic conditions, identifying these mutants as having an SCV phenotype is difficult because *S. aureus* grown anaerobically already demonstrates many of the features of respiratory-defective SCVs (2).

Moving down the electron transport chain, one finds that mutations in genes controlling menaquinone and cytochrome biosynthesis produce SCVs that are auxotrophic for menadione and heme, respectively (2) (Table 1). Mutations in genes for the biosynthesis of the menadione core or for the biosynthesis of the isoprenoid tail produce SCVs that are deficient in menaquinone. Point mutations in *menB*, *menC*, *menD*, and *menF* have been found in clinical isolates of *S. aureus* (35, 36). Mutations in other genes involved in (i) the menadione biosynthetic pathway, such as *men*A, *menD*, and *aroD*, and (ii) the biosynthesis of the isoprenoid tail of menaquinone, such as *isp*A (geranyltransferase) and *mva* (3-hydroxy-3-methylglutaryl CoA synthase), also produce SCVs (7, 37–42). Further support for a role of reduced menaquinone in the formation of SCVs comes from studies wherein inhibition of menaquinone reduction by diarylurea compounds also produced typical SCVs in *S. aureus* (43). Thus, the biochemical and genetic basis is well established for menaquinone-defective SCVs.

Oxidation of the reduced menaquinone is accomplished by the cytochromes (Fig. 1), which are membrane proteins that contain heme, an iron-containing porphyrin. SCVs have been identified with mutations in biosynthetic genes for the porphyrin and protein portions of the cytochrome. Clinical SCV isolates with mutations in *hemB* and *hemG* wherein these mutants reproduce the phenotype have been seen in laboratory-generated and clinical hemin auxotrophs (44, 45). Mutations in *hemE*, *hemH*, and *hemQ* produce SCVs, but these have not yet been reported in clinical specimens (37, 46, 47). In addition, mutations in genes involved in the biosynthesis of the protein portion of cytochrome aa_3 [*ctaB*(*cyoE*), *qoxDCBA*] or cytochrome *bd* (*cox15*, *cydAB*) also produced SCVs (5, 48), but again, these genes have yet to be described in clinical SCV isolates. Genes for both terminal oxidases in *S. aureus* (*cydB qoxB*) must be mutated to produce an SCV in *S. aureus*, suggesting that there is overlapping activity of these cytochromes (49).

While mutations in *atp*A, *atp*B, *atp*G, and *atpH* produce slow-growing *S. aureus*, they do not show typical SCV characteristics (50). Indeed, in an effort to generate ATP, these mutants have increased respiratory activity, thereby creating an enhanced membrane potential, which makes them more susceptible to gentamicin, whereas menadione and hemin auxotrophic SCVs are often more resistant to aminoglycosides (2, 51). Also, by reducing AtpE via *atpE* mRNA antisense, small colonies were also obtained (52). Inhibition of AtpE with diarylquinoline compounds also produces SCVs (52). Thus, while mutations in the biosynthetic genes for the F_0F_1 ATPase produce slower growth and smaller colonies, they do not produce a phenotype found in typical clinical SCVs.

Finally, as noted above, reduced activity of the TCA cycle results in decreased electron transport activity. Thus, it is not surprising to see that mutations in genes controlling the expression of TCA cycle enzymes also produce SCVs typical of the electron transport-defective phenotype. Mutations in *citB* (aconitase), *odh*A (a-ketoglutarate dehydrogenase), and *ohdB* (dihydrolipoamide succinyltransferase) have been reported to form SCVs (32).

COMPENSATORY METABOLIC PATHWAYS IN *S. AUREUS* SCVs

The loss of respiration in SCVs results in the upregulation of many compensatory pathways and the decrease in other pathways, which are summarized in Table 2. It is apparent that these variants are optimizing reactions that produce ATP and oxidize NADH by non-oxygen dependent mechanisms. In addition, because of decreased Krebs cycle activity in SCVs, large amounts of lactic acid cannot be metabolized (53); therefore, reactions that alkalinize the medium are favored, e.g., the arginine deiminase pathway. This pathway has the added benefit of producing ATP. Data that support the findings summarized in Table 2 are based upon transcriptional analysis of genes, protein expression, and isotopologue studies wherein the data using these multiple techniques strongly support one another (18, 53–57). There is upregulation of the genes involved in uptake of sugars and the enzymes in the glycolytic pathway, as this supplies ATP for *S. aureus*, which cannot produce ATP via electron transport. The metabolism of glycerol, pyruvate, butanoate/acetoin, arginine, and nitrate are all increased, because these can oxidize NADH and produce ATP. Reactions that are unfavorable produce NADH, and these are downregulated. As noted above, mannose, but not mannitol, can support growth of *menD*-defective *S. aureus* because mannitol use requires the reduction of NAD^+ to NADH (21, 58). Of note, this profile of genes and pathways up- and downregulated in *hemB* and *menD* mutant *S. aureus* is strikingly similar anaerobically that of grown *S. aureus* (18, 54–56, 59, 60). Finally, of the several reactions shown in Fig. 1 that lead to the reduction of menaquinone, the only gene showing increased expression was *glpD*, whereas the fatty acid oxidation pathway (*fadEBA*) was reduced and *ndh2*, *sdh*, *lqo*, and *mqo* were unchanged. Perhaps this is not surprising, because Ndh2 might be already maximal at baseline since it is the major pathway for oxidation of NADH, but MpsABC increases to ensure a membrane potential in the absence of the cytochrome oxidases.

RESPIRATION AND VIRULENCE FACTOR PRODUCTION IN SCVs

A connection between respiration and toxin production was established decades ago when *S. aureus* grown anaerobically on blood agar failed to cause hemolysis. This was found to be due to reduced production of α-hemolysin (Hla) (61). Similarly, the production of toxic shock syndrome toxin-1 (TSST-1) was found to be reduced under strict anaerobic conditions (62). It is now known that both Hla and TSST-1 are regulated by the *agr* operon via RNAIII (63). RNAIII levels are reduced under anaerobic conditions (64). Hence, a strong connection between respiration and expression of virulence factors has been noted for decades.

Respiration and virulence factor production have been studied in detail in staphylococcal SCVs wherein defects in electron transport and reduced production of toxins are found (2, 22). While multiple pathways can produce slow growth, hence SCVs, in *S. aureus*, only respiratory-defective

SCVs, including thymidine-auxotrophic ones, have consistently shown reduced levels of RNAIII (19). In many cases, low RNAIII leads to reduced toxin, protease, and phenol-soluble modulin (PSM) production but increased expression of adhesins and ligands for uptake by host cells (2, 22, 65). Because SCVs are often unstable, this allows the organisms to shift from a virulent to a quiescent form that can hide within host cells (2, 66). This instability can in some cases be attributed to point mutations in *men*, *hem*, and *thyA* genes (22). Thus, *S. aureus* alteration of respiration allows for populations of virulent organisms during acute infection and quiescent bacteria during chronic infections (discussed below).

REGULATORS, SCVs, AND PERSISTENCE WITHIN THE HOST

SCVs have been associated with unusually persistent, recurrent, and antibiotic-resistant infections (2, 22). Thus, it is not surprising that the reduced activity of *agr* seen in respiratory-defective SCVs is associated with persistent infections, because loss of *agr* activity has been associated with persistent infections even when there are no SCVs (67, 68). Early studies with *hla* mutants revealed that they persist within cultured endothelial cells (69) and that *S. aureus* SCVs behaved similarly because they were not producing Hla (70). Thus, the reduced *agr* activity in SCVs results in persistence because of low levels of Hla production. Of interest, during prolonged infections of cultured cells, the intracellular milieu is able to select for *S. aureus* with reduced Hla production and the SCV phenotype (66, 71, 72). Similarly, *S. aureus* strains harvested from cows with chronic bovine mastitis show lower expression of *agr* and less Hla production than strains harvested from acute mastitis (73).

In addition to Hla, PSMs are highly lytic to mammalian cells (74). The *psm* genes are strongly upregulated by RNAIII. Thus, mutations in *agr*CA or in *agrD* result in low levels of PSMs (75), which might allow persistence. Persistence of *agr*CA or *agrD* mutants requires the presence of *nanK* (ManNAc kinase gene) in the sialic acid operon (75). Of note, *S. aureus* can grow on sialic acid as an energy source (76), which may have relevance to mucosal surfaces where sialic acid is found. Hence, the low RNAIII levels in SCVs result in low levels of PSMs, which may help with intracellular persistence. Naturally, an intracellular location would facilitate persistence by protecting organisms from host defenses, and the ability to switch from rapidly growing organisms that produce large amounts of toxins to SCVs, which express fewer toxins but more adhesins, is an excellent survival strategy for *S. aureus* (2, 19, 66).

Also, suppressing Agr activity with diflunisal, which blocks AgrA, reduced the production of Hla and Psmα (77, 78) and strongly reduced osteoblast cytotoxicity caused by *S. aureus*-secreted toxins independently of effects on bacterial growth (77). This resulted in reduced damage to bone. However, isolates from patients with chronic osteomyelitis showed elevated expression of *agr* and *sarA*, yet these were more invasive into cells (high FnbA and Emp expression), had less cytotoxicity and strong hemolysis in isolates from chronic osteomyelitis, and formed a higher percentage of SCVs (79). The expression of PSM was not found to be different in the groups of isolates. In summary, *agr* plays a role in the persistence seen with SCVs, but changes in Arg activity are not the whole story.

SigB is required for formation of SCVs and establishment of chronic infection in bone (80, 81). A prominent role for SigB in persistence was provided by a study using respiratory *S. aureus* isolates from patients with cystic fibrosis (82), wherein the genes under the positive control of the alternate sigma factor SigB, were specifically upregulated and differed in that way from those seen in prototype *S. aureus* and the *hemB* mutant. These clinical SCVs persisted much more efficiently in cultured cells than the *hemB* and prototype strains, and a *sigB* mutant was a poor persister. Further support for SigB playing an important role in persistence comes from studies with 4-hydroxy-2-heptylquinoline-*N*-oxide (HQNO). Exposure of *S. aureus* to the *Pseudomonas aeruginosa* exoproduct HQNO activates SigB, inhibits cytochromes, suppresses growth, provokes the emergence of SCVs, and stimulates biofilm formation (24, 46, 86). SigB activation also increases the expression of the fibronectin-binding protein A and the biofilm-associated *sarA* genes. All of these changes enhance the persistence of *S. aureus* in the airways of patients with cystic fibrosis (83). Thus, it appears that the *agr* locus plays a minor role in the regulation of the virulon of SCVs, unlike SigB, which may have a key role in intracellular persistence.

Respiratory-defective SCVs have another mechanism for persistence. The decreased use of oxygen by these variants means they would not activate HIF-1, an oxygen-sensing protein that notifies the host of intracellular invasion. In fact, *S. aureus* SCV failed to activate HIF-1 (84). This provides a further mechanism to help them hide from host defenses.

The lower membrane potential of respiratory-defective SCVs is likely to be another factor in the intracellularly persistent SCVs (85). The intracellular milieu contains cationic molecules that kill *S. aureus*, but their association with the membrane and bactericidal action requires that the membrane has a normal membrane potential. *S. aureus* SCVs are more resistant to cationic molecules such as tPMP, protamine, spermine, lactoferrin B, hBd-2, hBD-3, LL-37, and daptomycin (which behaves as a cationic peptide when loaded with calcium). This is due in part to reduced membrane potential (86–94). Resistance to spermine has some unique features in that it is menadione auxotrophic but not hemin auxotrophic. *S. aureus* SCVs are more resistant, so the resistance is not strictly related to oxygen or nitrate respiration (88). Moreover, USA300 is different from many strains of *S. aureus* that are susceptible to spermine in that it contains SpeG, which allows this strain to metabolize (detoxify) spermine (88). However, exposure of *S. aureus* to spermine also results in reduced expression of the F_0F_1 ATPase (93). Therefore, respiration and membrane potential seem to be involved in *S. aureus* resistance to many host cationic compounds.

Some experimental compounds have been reported that treat SCVs. Persistence of SCVs within host cells can be altered by tomatidine, which is the first representative of a new group of compounds that target respiratory-defective *S. aureus* (95, 96). This unique activity against respiratory-defective *S. aureus* SCVs decreases persistence (95). Moreover, tomatidine prevents virulence gene expression (97). Of further interest is the finding that tomatidine acts in synergy with aminoglycoside and β-lactam antibiotics against multiresistant *S. aureus* (97, 98). Thus, tomatidine and its derivatives may have strong relevance in the treatment of patients with cystic fibrosis, who frequently have combined *P. aeruginosa-S. aureus* infections (22, 99). In addition, iron chelators, such as deferiprone, have activity against *S. aureus* SCVs (100). They have been tested in the *Caenorhabditis elegans* and wound models and shown to enhance the activity of antibiotics against *S. aureus* SCVs (100). Finally, NP108, a lysine polymer, is a bactericidal compound that kills

TABLE 2 Compensatory changes in redox and ATP-producing reactions in SCVs[a]

Reaction	Enzyme	Genes (N315 genome numbers)
Favorable reactions produce ATP and NAD^+ increased in SCVs

S. aureus, including SCVs, by membrane disruption and cell lysis through mechanisms found in lysine-rich cationic peptides (101).

The rationale for examining intracellular persistence comes from clinical observations. *S. aureus* SCVs produce persistent, recurrent, and antibiotic-resistant infections (2, 22). In the past 20 years, there have been over 40 studies that involve over 350 patients where persistent infections have been reported (2, 22). When referring to these clinical studies, the term "persistent" means that the organisms are found in the patient for years, which is different from the term "persister" within a broth culture. Thus, this is different from clinical practice, where the term "persistent infection" applies to the failure of apparently active antibiotics and host immunity to clear infection, and this may not be related to the definition of persistence used when defining organisms *in vitro* (102). Thus, when SCVs are found in infections that are not cleared by active antibiotics, these have strongly correlated with unusually persistent infections, and the organisms recovered from patients often do have defined genetic mutations (2, 22, 103). These studies show that patients infected with SCVs often have a history of long-term treatment with antibiotics. They may have prolonged disease-free intervals (as long as 53 years), but during recurrences, they show unusual resistance to apparently active antibiotic therapy (103).

P. AERUGINOSA-S. AUREUS SCV COOPERATION

Several studies have found that respiratory-deficient *S. aureus* and *P. aeruginosa* may actually work synergistically to make infections worse. As noted above, HQNO, which targets cytochrome *bd* (6), selects for respiratory-defective *S. aureus* SCVs (104, 105). Similarly, another exoproduct of *P. aeruginosa*, pyocyanin, selects for menadione auxotrophic SCV (39). Both menadione auxotrophic and *hemB* mutant SCVs are resistant to pyocyanin (39, 106). Genome sequencing of the isolates selected with pyocyanin identified mutations in four genes: *saeS*, *menD*, NWMN_0006, and *qsrR* (39). Mutations in *menD* and *qsrR* allow for pyocyanin resistance. QsrR is a quinone-sensing repressor of quinone detoxification genes. Inactivation of *qsrR* resulted in significant pyocyanin resistance, and additional pyocyanin resistance was achieved through combined inactivation of *qsrR* and menadione biosynthesis (39). *P. aeruginosa* selection of *S. aureus* SCVs increases *S. aureus* resistance to aminoglycosides and other antibiotics (107). Of note, not all *P. aeruginosa-S. aureus* strain pairs produce this devastating synergistic effect (108), which is welcome information, because *S. aureus* SCVs are associated with worse lung disease in children with cystic fibrosis (109). Finally, *S. aureus* SCVs can serve as a source of iron to increase the virulence of *P. aeruginosa* (110). Therefore, there are several ways that combined infections with *P. aeruginosa-S. aureus* SCVs can produce synergic virulence.

CLINICAL LABORATORY IDENTIFICATION OF *S. AUREUS* SCVS

The clinical microbiologist must be alerted to look for SCVs, because their slow growth means that they may either be missed entirely or may be overgrown by more rapidly dividing strains or revertants. Furthermore, they are easily misidentified because of their unusual colony morphology and biochemical profile. Because *S. aureus* SCVs are often very slowly catalase positive and produce little pigment and hemolysins, they may be misidentified as viridans streptococci or coagulase-negative staphylococci (2, 22). In addition, these SCVs often fail to ferment mannitol and are resistant to aminoglycoside antibiotics. All aspects of this unique phenotype can be attributed to the loss of one or another of the enzymes critical to the biosynthesis of electron transport chain components (Fig. 2). At 24 hours, the colonies can be very small and easily missed if there is a mixed culture of rapidly and slowly growing colonies (22). Slow growth may occur owing to several factors when electron transport is inoperative. One direct effect of interrupting electron transport is reduced synthesis of teichoic acid, because the biosynthesis of phosphatidyl glycerol, a teichoic acid precursor, requires electron transport (111–114). Also, ATP is required for many cellular functions and supports electron transport in the synthesis of menaquinone, such as cell wall biosynthesis and uptake of amino acids and carbohydrates; hence, organisms interrupted in electron transport have a lower capacity to produce ATP and show slower

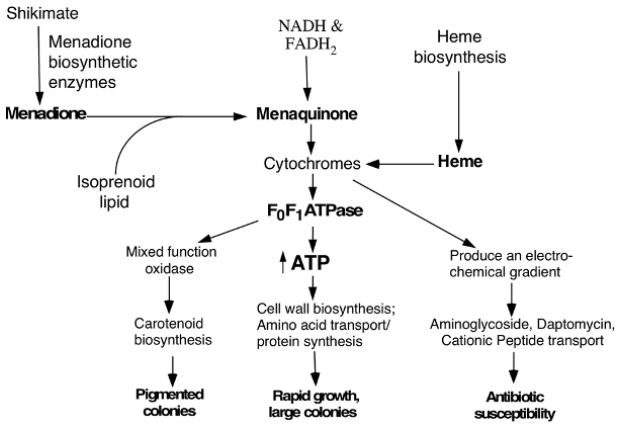

FIGURE 2 Relationship between electron transport and the small colony variant phenotype in *Staphylococcus aureus*.

growth, resulting in small colonies. We found that the interdivision time for *S. aureus* 6850, a clinical isolate (parent strain), was 20 min, compared to 180 min for *S. aureus* JB-1, a menadione auxotrophic SCV, when grown in tryptic soy broth (70). Hale (115) found similar growth rates with an *S. aureus* parent and SCV at 20 min and 120 min, respectively, in nutrient broth, and Massey and Peacock found division times of five independent strains to be 20 min, compared to 210 min in SCVs selected by gentamicin exposure (116, 117). In contrast, a hemin auxotrophic SCV had a 131- to 173-min generation time, compared to its parent's time of 53 min (113). While there are clearly differences in the growth rates of several respiratory-defective strains of *S. aureus*, all of these variants produce small colonies and fulfill the definition of an SCV, i.e., an organism that forms colonies that are 10-fold smaller than those of its parent.

The failure of SCVs to ferment carbohydrates, such as mannitol, can also be related to defects in electron transport (3). As noted above, interruption of electron transport results in the accumulation of NADH, which downregulates the citric acid cycle enzymes, thereby making the fermentation of mannitol and other such carbohydrates unfavorable.

Electron transport is also required for carotenoid biosynthesis. Electrons are shuttled through the electron transport system to the mixed function oxidase system, which is linked to pigment formation (118, 119). Hence, SCVs that are defective in electron transport form nonpigmented colonies.

Thus, *S. aureus* SCVs do not show features that are typical for wild-type *S. aureus* and can easily be missed due to the small sizes of colonies and misidentified because of atypical characteristic (22). Nevertheless, most of the phenotypic features reported for clinical and laboratory-generated *S. aureus* SCVs can be explained by the model shown in Fig. 2.

ANTIBIOTICS AND SCVs

Ever since Bigger first described the "persistence" of staphylococci in broth cultures exposed to penicillin (120), there has been interest in understanding this perplexing observation as organisms survived in broth cultures despite apparently active antibiotics. "By definition, persisters are not mutants but are regarded as phenotypic variants that are isogenic to normally growing cells within a common culture" (121). Slow growth and low ATP have been found among many types of persisters (122, 123). This provides a link to respiratory-deficient SCVs, which have low levels of ATP.

With respiratory-deficient *S. aureus*, we are able to define a number of mechanisms for *S. aureus* failing to respond to antibiotics. First, slow division of the bacterial cell wall is associated with resistance to penicillin and other β-lactams (124, 125). Second, the decreased membrane potential in respiratory-deficient *S. aureus* SCVs results in decreased uptake of aminoglycosides, cationic peptides, and daptomycin (7, 33, 86, 87, 89–92, 94, 126). These are all cationic antimicrobials, because the active form of daptomycin carries calcium. Third, alterations in membrane fluidity caused changes in the fatty acids of the membrane as seen in *fabF* mutant SCVs (127) or due to decreased carotenoid content of the membrane (128) result in daptomycin resistance. Fourth, respiratory-deficient *S. aureus* SCVs can have a hypermutator phenotype (47). This may relate to the lower levels of ATP. SOS DNA repair led by RecA only binds single-stranded DNA in the presence of ATP, and hence, mutations leading to resistance are more frequent in *S. aureus* SCVs (129). While ciprofloxacin induces the SOS response in *S. aureus* (130), development of ciprofloxacin resistance in *S. aureus* was found to occur when the organisms passed through a transient SCV phase, which was then followed by mutations that altered ciprofloxacin targets (131). Paradoxically, the SOS response may have a dual effect. Antimicrobials that reduce replication fidelity increase the formation of SCVs through activation of the SOS response and thereby potentially promote persistent infections that are difficult to treat (132). Finally, intracellular location of *S. aureus* SCVs (66, 72) provides a location where there is reduced penetration of some antibiotics (133–135). However, the intracellular location is not a benefit in all cell types, because the acidic environment of and presence of oxidant species within the phagosome greatly enhance the activity of β-lactams against *S. aureus* SCVs (133–135). In addition, SCVs release large quantities of lactic acid (53), which decreases the activity of aminoglycosides (136).

Comparing the activity of a large number of antibiotics in broth culture, within tissue-cultured cells, and *in vivo* reveals that some antibiotics may have an advantage in treating SCVs (31, 53, 54). Finafloxacin has greater activity in acidic environments where *S. aureus* SCVs may hide (137). In addition, oritavancin is especially good at killing stationary phase organisms, which also translates to the slower-growing SCVs (99, 138). Based upon tissue culture and animal studies, adding rifampin may add efficacy for killing *S. aureus* SCVs (133, 139, 141). Of the different types of respiratory-deficient *S. aureus*, *menD* was found to be the most resistant (133). Finally, a *fabF* mutant of *S. aureus* formed an SCV that was less susceptible to vancomycin and daptomycin, but this variant does not appear to be respiratory defective (127).

One solution to avoiding these antibiotic-resistant variants may be prevention of *S. aureus* SCV infection through a vaccine. This is being attempted for bovine intramammary infections (140). Also, as noted above, drugs used in combination with antibiotics may help to treat SCVs.

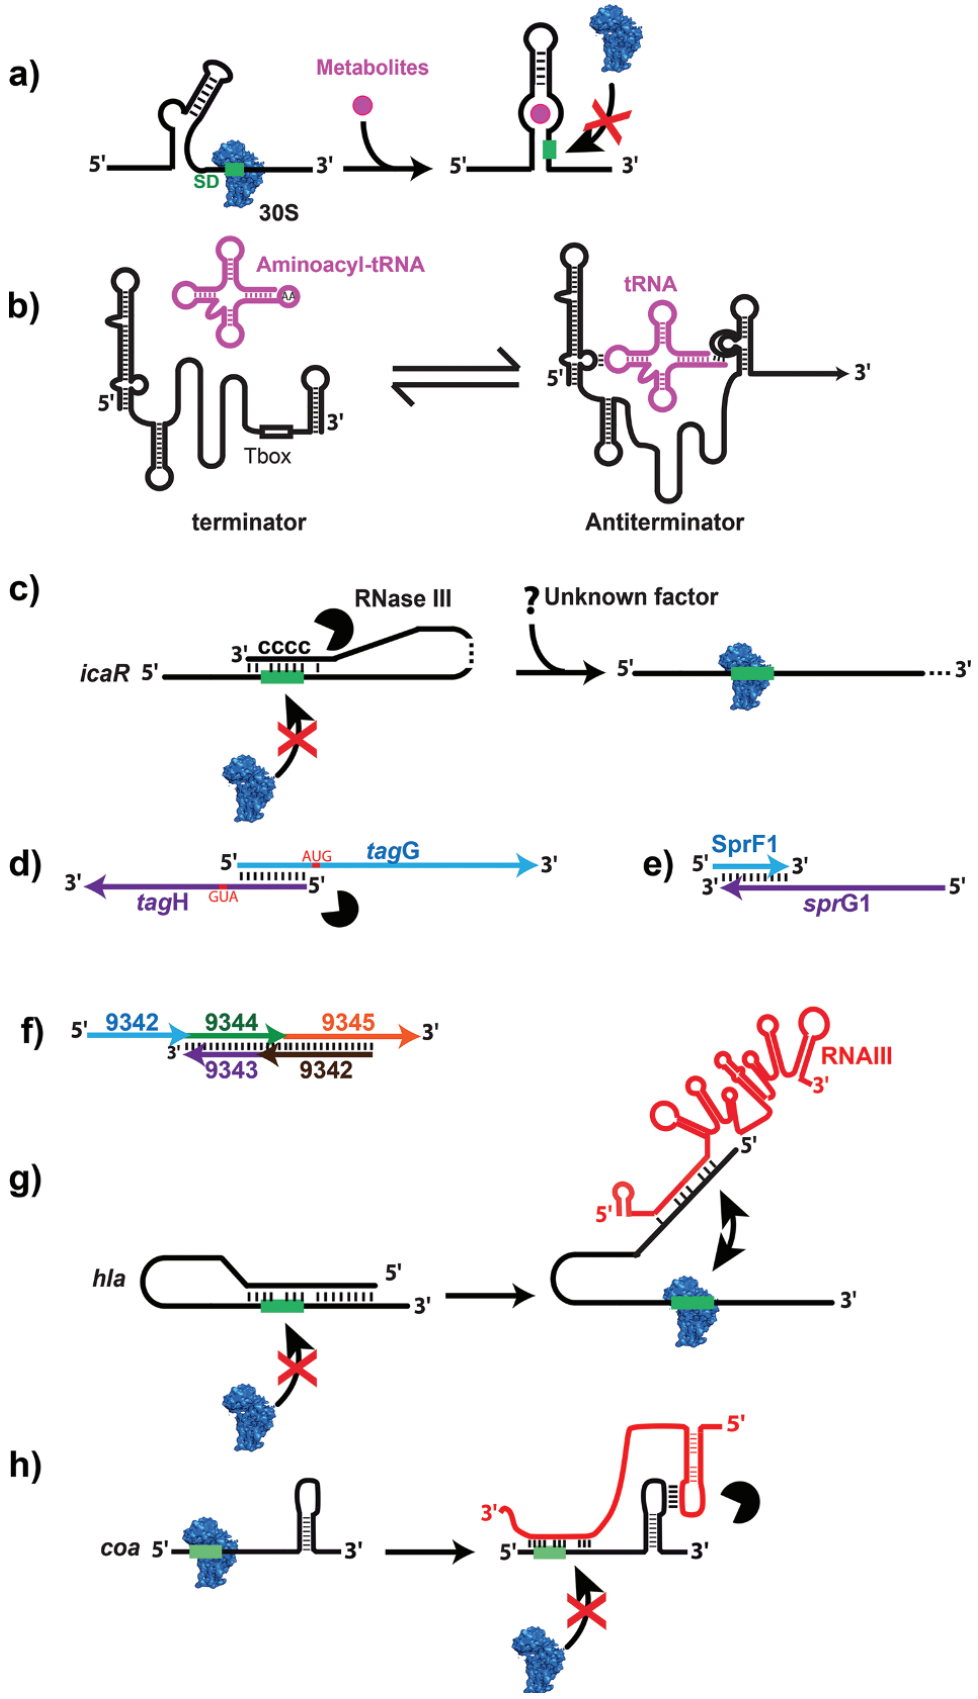
Noncoding RNA

E. DESGRANGES, S. MARZI, K. MOREAU, P. ROMBY AND I. CALDELARI

35

GENERAL INTRODUCTION



Regulatory RNAs have been identified in many bacteria and in pathogenic bacteria such as *Staphylococcus aureus*, where they play major roles in the regulation of virulence or the synthesis of metabolic proteins, besides transcriptional factors and two-component systems (1–4). Most of them are noncoding RNAs (sRNAs), but some of them express small peptides. Certain sRNAs, acting in *cis*, are situated at the 5′ untranslated regions (UTRs) of mRNAs and act as sensors of metabolites, tRNA, or environmental stimuli (e.g., temperature, pH) or are situated at the 3′ UTR. In contrast, the genes encoding sRNAs, which act *in trans*, sit on the opposite strand of the regulated mRNA or at genomic locations distant from the mRNAs they regulate. *Cis*-encoded sRNAs, also called antisense RNAs (asRNAs), are fully complementary to their targets. In contrast, *trans*-encoded sRNAs share only partial complementarity, and as a consequence, they can regulate many mRNAs. Most of them are encoded mainly in the core genome, while a few of them are localized within mobile elements, pathogenic islands, or plasmids. In this review, we will focus on the most recent mechanisms of RNA regulation discovered in *S. aureus* and how regulatory RNAs are part of sophisticated networks that allow the bacteria to adapt quickly to their environment or survive in their host.

mRNA 5′ UTRs: RIBOSWITCHES, T-BOXES, AND THERMOSENSORS

5′ UTRs of mRNAs contain riboswitches, T-boxes, or thermosensors with potential impacts for novel antibiotherapy. Riboswitches and T-boxes are found in the 5′ UTR of some mRNAs and contain highly structured domains, which recognize metabolites such as cofactors, vitamins, amino-acids, nucleotides, second messenger cyclic di-GMP, Mg^{2+}, or nonaminoacylated tRNAs (5). Binding of these metabolites induces structural changes that modify the expression of the downstream mRNA, for example, by inducing premature transcription arrest, repression/activation of translation, or cleavage (Fig. 1a). A T-box senses the aminoacylation status of tRNAs and mainly controls transcription of downstream genes that encode proteins involved in biosynthesis, transport of amino acids, or aminoacylation of tRNAs (Fig. 1b). Based on sequence and structure conservation, most of the T-boxes and riboswitches were predicted in *S. aureus* genomes (4). A large proportion of riboswitches control the expression of genes involved in metabolic pathways. Because these genes are often essential for growth, they represent interesting targets for the development of alternative antimicrobial drugs in the battle against multidrug-resistant *S. aureus*. This strategy was used with the guanine and glucosamine-6-phosphate (GlcN6P) riboswitches. Mulhbacher et al. (6) identified a pyrimidine derivative that binds to the guanine riboswitch and represses the expression of *guaA*. This compound significantly attenuated *S. aureus* infections in a mouse model. In Gram-positive bacteria, the *glmS* mRNA is both a ribozyme, which catalyzes its own cleavage, and a riboswitch responding to GlcN6P. Its product encodes an essential enzyme, which converts fructose-6-phosphate into GlcN6P, a building block of bacterial peptidoglycan. Tight regulation of *glmS* mRNA is crucial to maintain a homeostatic level of GlcN6P in the cell. At high concentrations of GlcN6P, its binding to the 5′ UTR of *glmS* leads to site-specific self-cleavage, which generates a 5′ hydroxylated end molecule rapidly degraded by the RNase J1 (7, 8). A recent study led to the design, synthesis, and characterization of a GlcN6P analogue, carba-GlcN6P, which constitutively activates the *glmS* ribozyme of vancomycin-resistant *S. aureus* and destabilizes its mRNA (7). This compound was experimentally shown to induce the efficient self-cleavage of the *glmS* mRNA in a similar fashion as the natural metabolite and thus represented an important step in the development of antibiotics with a new mode of action. Very recently, a new approach called "Term-seq" revealed that several antibiotic resistance genes are under the control of riboswitches responding to antibiotics commonly used against Gram-positive pathogenic bacteria such as *Listeria* spp. and *Enterococcus faecalis* (9). These results suggest that the same phenomenon could exist in *S. aureus* and that RNA-mediated regulation could play a broader role in antibiotic resistance mechanisms than has been envisioned.

Not surprisingly, the presence of antibiotics can also modulate the regulatory activity of T-boxes. In *S. aureus*, an unusual *glyS* T-box regulates transcription antitermination (Fig. 1b) of the unique glycyl-tRNA synthetase (glyRS) gene responsible for catalyzing the aminoacylation of the five $tRNA^{Gly}$ isoacceptors, independently of their anticodon (GCC or UCC) and with different binding affinities (10). Thereafter, the T-box senses the availability of glycine not only for its incorporation into nascent polypeptide chains during translation but also for the formation of pentaglycine bridges into the peptidoglycan molecule, linking two essential pathways. Antibiotics targeting the small ribosomal

subunit stabilized the T-box/tRNA complex and induced a read-through of transcription, while chloramphenicol and linezolid attenuated *gly*S transcription (11). The outcome depended on the binding sites of the protein synthesis inhibitors (11). Although T-boxes can be direct targets for antibiotics against *S. aureus*, it was also reported that a high concentration of the antibiotic tigecycline might induce possible off-target inhibition of the RNA polymerase (11).

RNA thermosensors are regulatory elements often localized at the 5′ UTR of mRNAs encoding heat or cold shock proteins and virulence factors (for review see 12). Briefly, at low temperatures, the mRNA cannot be translated, since the Shine and Dalgarno (SD) sequence is trapped in a hairpin structure, which melts gradually when the temperature increases. The best-studied example in Gram-positive bacteria is the thermosensor regulating the expression of the transcriptional factor *prf*A, which activates the expression of most of the virulence genes in *Listeria monocytogenes* at high temperatures (13, 14). No such example has yet been demonstrated for other Gram-positive bacteria, including *S. aureus*.

3′ UTRs OF mRNAs ACT IN *CIS* OR ARE RESERVOIRS OF sRNAs

Transcriptome analysis of the human pathogen *S. aureus* revealed that at least one-third of mRNAs carry long 3′ UTRs and thus might display multiple regulatory functions (15). Some of them have direct action on the expression of their own mRNA (15, 16). Long 3′ UTRs (>100 nucleotides) can end at an intrinsic Rho-independent terminator of transcription (TT) and can be generated from a specific RNase cleavage or from a termination read through of the RNA polymerase. Remarkably, several 3′ UTRs contain riboswitches functioning in metabolite-sensing regulation (16). Indeed, the TT of the riboswitch in an OFF conformation also serves as the TT of the gene encoded upstream of the riboswitch.

A singular example of a newly identified posttranscriptional regulatory mechanism was shown for the *icaR* mRNA (Fig. 1c), which possesses an unusually long 3′ UTR (390 bp). In this case, the expression of the mRNA is modulated through a long-distance interaction between 3′ UTR and 5′ UTR (16). Because *icaR* codes for a transcriptional repressor of the *icaADBC* operon, encoding enzymes involved in the synthesis of PIA-PNAG, the main polysaccharides of the biofilm matrix, this regulation has a direct impact on biofilm formation. Base-pairing interactions between the long 3′ UTR of *icaR* mRNA and the SD sequence of the same mRNA hindered efficient translation initiation (16). This long-range RNA duplex generated a specific site for the double-stranded endoribonuclease III (RNase III) for cleavage. As a consequence of this cleavage, PIA-PNAG synthesis increased. However, the mechanism allowing IcaR translation is not known to prevent the action of the 3′ UTR as a *cis*-acting antisense RNA (Fig. 1c).

It is also postulated that the 3′ UTR length provides other types of transcript-specific regulation. Indeed, in *Salmonella* spp., the 3′ UTRs are also reservoirs for sRNAs, which originate either by transcription from an internal promoter or by processing. In both cases, the sRNA generated from the 3′ UTR regulates trans-encoded mRNA targets. For instance, the sRNA CpxQ is generated by RNase E cleavage of the 3′ UTR of *cpxP* and represses the translation of mRNAs encoding a family of envelope proteins, whereas the sRNA DapZ is transcribed from an internal promoter within the *dapB* gene and inhibits translation of the major ABC transporters, DppA and OppA (17, 18; for review see 19). Recent work has shown that such 3′ UTR-derived sRNAs also exist in *S. aureus*, although their functions remain to be addressed (E. Desgranges, S. Marzi, P. Romby and I. Caldelari, unpublished data).

asRNAs IN PERVASIVE TRANSCRIPTION AND ACTING AS ANTITOXINS

asRNAs are transcribed from the opposite strand of the mRNAs they regulate, so that they display perfect complementarities with their targets. Short asRNAs are often encoded on mobile elements such as plasmids, transposons, and phage-like elements. Such elements can potentially be transferred horizontally to other bacterial species or be duplicated (20). In *S. aureus*, they were first described to control plasmid conjugation and replication (21). The size of asRNAs can vary from 10 to thousands of nucleotides, because these RNAs can overlap with part of a gene (3′ or 5′ ends), the entire gene, or a group of genes (Fig. 1d to f). This phenomenon is called pervasive transcription. Initially, pervasive transcription was considered a nonfunctional transcriptional noise. However, considering the large number of asRNAs expressed from the entire genome and in several bacterial species, these RNAs might play an important role in

FIGURE 1 Several mechanisms of RNA regulation in *S. aureus*. (a) Schematic drawing of the flavin mononucleotide riboswitch. The 5′ UTR adopts a particular structure recognized by the flavin mononucleotide, which in turn leads to the stabilization of a stem-loop structure sequestrating the SD sequence to inhibit translation. 30S is for the small ribosomal subunit. (b) An example of a T-box motif as found in the 5′ UTR of many mRNAs encoding aminoacyl-tRNA synthetases. Nonaminoacylated tRNA binds to the leader region at two sites and stabilizes an antiterminator structure, allowing transcription of the downstream gene. The drawing is adapted from reference 4. (c) The 3′ UTR of the biofilm repressor IcaR possesses a cytosine-rich motif, which binds to the SD sequence and hinders ribosomes from its binding site on the mRNA (see text for details). (d) Overlapping 5′ UTRs of *tag*G and *tag*H mRNAs are processed by the endoribonuclease III (Rnase III). Shorter 5′ ends might facilitate ribosome recruitment. (e) The antitoxin RNA SprF1 interacts at the 3′ end of the toxin encoded by sprG1 and triggers its degradation. (f) A cluster of five sRNAs was sequenced in the *S. aureus* Newman strain that encodes a putative toxin-antitoxin system (see text for details). (g,h) sRNAs act by an antisense mechanism. Binding of the 5′ UTR of RNAIII to the 5′ UTR of *hla* mRNA liberates its SD and activated translation (g), whereas the 3′ domain of RNAIII acts as a repressor domain, which contains C-rich motifs for base-pairing with the SD sequence of mRNA as *coa* mRNA depicted in the figure (h). Green bar, SD sequence; black circle, RNase III (for references and more details, see text).

the regulation of gene expression. Genome-wide analysis of *S. aureus* highlighted that the expression of a significant proportion (75%) of antisense transcripts to annotated open reading frames are synthesized from the complementary strand and that these sense/antisense duplexes are digested by RNase III, generating short fragments all along the genome (22). Another study using the RIP-Seq approach confirmed the involvement of RNase III in the regulation of sense/antisense transcripts and overlapping UTRs (23). The situation might be even more complex, because recent results suggested that the termination factor Rho plays a major role in preventing pervasive transcription in *Bacillus subtilis*, but also in *S. aureus* (24, 25). Although the biological outcome of pervasive transcription is not clearly understood, some of the asRNAs produced are functional and control several biological processes (15).

Type I toxin-antitoxin (TA) systems are particular cases of short asRNAs, in which the antitoxin is an asRNA regulating the translation or the fate of the toxin-encoding mRNA, whereas in the type III system, the antitoxin sequesters the toxin (reviewed in 26, 27). In *S. aureus*, several type I TA module systems have been described (reviewed in 28). One of them, called SprF1/SprG1, expresses SprF1 as the asRNA and *spr*G1 mRNA (Fig. 1e), which encodes two short secreted peptides with hemolytic and antibacterial activity (29). The antitoxin SprF1 binds to the 3′ end of *spr*G1 mRNA, which leads to mRNA degradation and inhibition of peptide synthesis to protect cells against lethality (29). The SprA1/asSprA1 pair is another intriguing and unconventional system. The asSprA1 is transcribed from the opposite strand of the *spr*A1 mRNA, producing a cytolytic peptide. Their 3′ ends overlapped by 35 nucleotides, but experimental data indicated that the functional domain of asSprA1 is outside the complementary sequence with *spr*A1 mRNA. Both RNAs were expressed concomitantly, and asSprA1 5′ base-paired with the ribosome-binding site (RBS) of *spr*A1, impairing its translation (30). Thus, asSprA1 acts as a *trans* regulator with its complementary target, suggesting that it can potentially interact with other RNA targets. Finally, a cluster of five genes encoding sRNAs specific to the *S. aureus* Newman strain contained a putative TA system (31) (Fig. 1f). Three genes were transcribed from the positive strand and two from the negative strand. Moreover, one small open reading frame was detected within one of the genes from the minus strand and coded for a secreted peptide with similarity to the RelE toxin (32). Whether these two overlapping genes corresponded to a novel TA system remains to be addressed. Interestingly, this locus was expressed in a growth-phase-dependent manner, in nutriment starvation, and in oxidative stress. Type I TA systems have been involved in many functions (e.g., membrane depolarization, plasmid maintenance), mainly in *Escherichia coli*, including the persistence phenomenon (for review see 33), but not in *S. aureus* until now (28).

TRANSCRIPTIONAL FACTORS AND sRNAs BUILD COMPLEX REGULATORY NETWORKS

The sRNAs belong to intricate networks of regulation, and their synthesis is often dependent on transcription factors or on two-component systems. In addition, sRNAs can also control transcription factors at the posttranscriptional level (Fig. 2). Typical examples will be described below. In addition, *trans*-acting sRNAs regulate mRNAs by imperfect base-pairings, which signifies that one sRNA can modulate several targets and one target can be controlled by several sRNAs. In *S. aureus*, the annealing region between sRNA and mRNAs are often longer than in *E. coli* and mostly targets the RBS of mRNAs affecting translation. In several cases, a second distinct site of interaction occurs in the coding region. Unlike Gram-negative bacteria, in which Hfq and ProQ proteins participate in sRNA regulation by stabilizing and facilitating their pairings with mRNA targets (see reviews in 34, 35), no RNA chaperones have yet been identified in *S. aureus*. Indeed, there is no identifiable *proQ* homolog, and the role of Hfq is still unclear. Recent work has shown that the rim domain of Hfq has an amino acid composition (low in arginine) incompatible with RNA annealing activity compared to *E. coli* Hfq (36).

AgrA, the response regulator of the *agr* quorum sensing system, activates the transcription of RNAIII. The bifunctional RNAIII codes for δ-hemolysin and regulates the expression of virulence genes at the posttranscriptional level (see below). It interacts with various mRNAs either to activate or to repress translation (Fig. 1g,h). The RBS of *hla* mRNA encoding α-hemolysin is embedded in a hairpin, which prevents ribosome binding and blocks the start of translation. The 5′ UTR of RNAIII possesses complementary sequences to the leader region of *hla*. Interaction between these RNAs enables the recruitment of ribosomes to initiate Hla translation. In its 3′ UTR, RNAIII carries conserved UCCC motifs that are used as the seed sequences to bind with the RBS of the target mRNAs coding for protein A, coagulase, Sbi protein, the transcription factor Rot (a repressor of exotoxins), and the endopeptidase LytM (for review see 37). Moreover, AgrA represses the sRNA ArtR, which inhibits translation of the SarA homolog SarT (38), and activates RsaE (see 39) (Fig. 2).

The staphylococcal accessory regulator SarA is synthesized from three distinct promoters (P1, P2, P3) and binds DNA or RNA (1). As a transcription factor, it regulates many genes involved in virulence, autolysis, biofilm formation, stress response, antibiotic resistance, and metabolism, but also two sRNAs, SprC and Srn_9340, located on the same pathogenicity island (40). SprC prevents ribosome binding to the SD of the *atl* mRNA coding for an autolysin. Deletion of the *spr*C gene causes enhanced phagocytosis of *S. aureus* by monocytes and macrophages, and this effect was found to be partly due to the deregulation of *atl* expression (41). SarA represses both *spr*C and *srn_9340* transcription and requires an ATTTTAT sequence in its binding site (40). However, while the SarA level remains relatively constant during bacterial growth, the expression of SprC fluctuates, which suggests that additional factors might control its synthesis and that a mechanism of derepression should coexist under specific conditions. These are the first examples of two sRNAs regulated by the same transcription factor.

In the following, we will describe an sRNA whose transcription is controlled by three independent transcription factors. The sRNA RsaE possesses two consensus sequence motifs UCCC as found in RNAIII, which interact with the RBS of several mRNAs involved in central metabolism to repress their translation (39, 42). RsaE is highly conserved between the *Staphylococcaceae* and *Bacillaceae* families. Not only is the sequence of RsaE conserved between *B. subtilis* and *S. aureus* species, but so are its regulation and functions. Recent studies have shown that its transcription is activated by AgrA (see above), the two-component system SrrAB (staphylococcal respiratory response) in response to NO, and a binding site for the redox sensing repressor Rex has been predicted (39, 43, 44). In *B. subtilis*, the Rex-repression of RsaE (also called RoxS) has been proposed to readjust

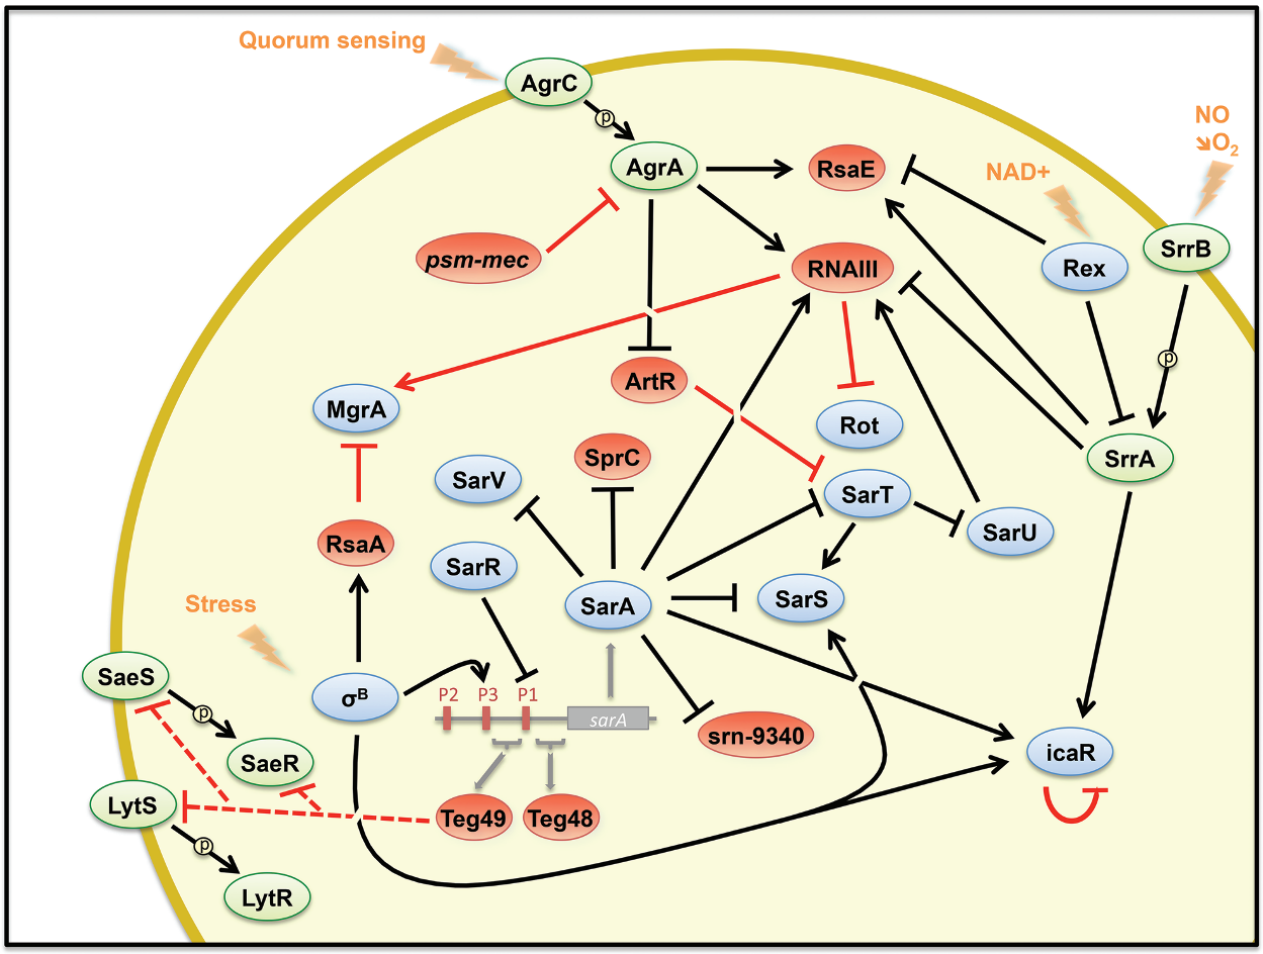

FIGURE 2 Examples of the complex network between sRNAs and transcriptional factors in *S. aureus* in response to stress. Arrows show activation and bars show repression. Blue, transcriptional regulators; green, two-component systems; red, regulatory sRNAs. Red lines corresponded to posttranscriptional regulation, and black lines, to transcriptional regulation. Dotted lines are for the target mRNAs that were not experimentally validated. Only sRNA-dependent mRNA targets encoding transcriptional factors are depicted in the figure.

the cellular balance of NAD^+/NADH on various signals (44).

The alternative sigma B factor (σ^B) together with RNA polymerase guides transcription of genes mainly in the stationary phase of growth and under stress conditions. Its regulon comprises more than 200 genes, including several virulence factors, transcription factors, and sRNAs (Fig. 2). Among the sRNAs induced by σ^B are SbrA, B, and C activated by KOH (45), and RsaA (39). The stability of RsaA depends on RNase III and the endoribonuclease RNase Y (23, 46). RsaA acts as an acute virulence attenuator in *S. aureus* (see below) by inhibiting translation of the MgrA transcription factor (Fig. 2) (47), which in turn causes the activation of the synthesis of several surface proteins (48). RsaA possesses two UCCC motifs, which in the case of *mgrA* mRNA, bind to two distant regions, involving an imperfect duplex masking the SD sequence of the mRNA and a loop-loop interaction occurring downstream in the coding region. These two distant binding sites are required for efficient repression and RNase III-dependent degradation of the repressed mRNA (47). Finally, the sRNA Teg49 is transcribed from the σ^B- dependent P3 promoter of *sar*A and is probably processed by RNase III and RNase Y with the help of the helicase CshA (49–51). Transcriptomic analyses revealed that besides genes involved in virulence and autolysis, Teg49 might posttranscriptionally affect the SaeRS and LytRS two-component systems, yet the exact mechanism is not known (51). In addition, another sRNA, Teg48, whose role is not known, is transcribed from the P1 promoter of *sar*A (Fig. 2). Even if the maturation process and the function of Teg48 and Teg49 are not clearly established, the long 5′ UTR of *sar*A mRNA encoding a master regulator of virulence in *S. aureus* represents a putative reservoir for novel sRNAs.

crRNA, tracrRNA, AND THE CRISPR-Cas ADAPTIVE IMMUNITY SYSTEMS IN *S. AUREUS*

Phages are the most abundant forms of life on earth and the natural killers of bacteria because in most cases their lytic life cycle ends with the death of the bacterial cell. Outnumbering their microbial hosts, phages impose selective pressure for the diversification of microbial defense systems. These include

various innate phage-resistance mechanisms such as restriction/modification enzymes, receptor masking, blocking DNA injection, abortive infection (52, 53), and the adaptive defense mechanism based on clustered, regularly interspaced short palindromic repeat (CRISPR) and CRISPR-associated (*cas*) genes (54, 55). The latter RNA-interference-like mechanism relies on small noncoding RNAs, CRISPR RNA (crRNA), and in some cases trans-activating crRNA (tracrRNA), through which prokaryotic hosts (bacteria and archaea) can acquire heritable resistance to genetic parasites such as phages, but also plasmids and transposons (for reviews see 53, 56). To date, CRISPR-Cas systems have been found in about 50% of bacterial genomes and 95% of archaeal genomes (57, 58). The CRISPR and the *cas* loci are often located next to each other in the genomes, sometimes organized into operons, but a significant number of genomes have also isolated *cas* loci and/or CRISPRs (59).

Despite the large diversity of the CRISPR-cas systems, they share common features. Briefly, the CRISPR loci are characterized by an array of short and palindromic repetitive sequences interspaced by sequences called "spacers" that are derived from plasmid and viral DNAs (in some cases, also RNAs). During the initial infection with a virus or plasmid, these spacers are first integrated into the CRISPR array in the host genome to provide the host with immunity (acquisition step [60, 61]). During a second infection event they are transcribed and used as guides to inactivate the viral or plasmid genome. This two-step pathway involves a variety of Cas proteins, leading to several major types of CRISPR-cas systems (reviewed in 58, 62). However, the acquisition step involves two highly conserved Cas1 and Cas2 proteins (58, 63). The Cas1-Cas2 integrase is a heterohexameric complex of four Cas1s and two Cas2s which preferentially incorporates foreign DNA at the first CRISPR repeat and participates in the discrimination against self-DNA and in the minimization of off-targeting insertions (64–66). Both proteins have been found in several *S. aureus* strains (57). During the second step, activation of transcription from a promoter located in an AT-rich leader sequence preceding the first CRISPR repeat (67, 68) leads to expression of the whole array into precursor CRISPR transcripts (pre-crRNA). The pre-crRNAs are then processed into mature crRNAs consisting of partial repeat(s) and a single spacer sequence, each complementary to a unique invader sequence (69). Different endonucleases participate in the maturation step, which might vary in different bacteria. Type I and III systems perform the function by a multisubunit Cas protein complex and are characterized by Cas6 processing (69). Type II uses another sRNA, tracrRNA, to direct RNase III-dependent maturation of the pre-crRNA in the presence of Cas9, the hallmark protein of the type II system (70). Cas9 endonuclease remains associated with the dual-tracrRNA:crRNA structure, which during the interference phase, guides the cleavage of site-specific cognate target DNA (71). Type I and II CRISPR-Cas systems target DNA (72, 73), whereas type III systems provide immunity against DNA and RNA (74).

With the completion of the genome sequences of several *S. aureus* strains, it appears that the CRISPR-Cas systems are not highly prevalent, and only a few of them have been experimentally demonstrated. A CRISPR Finder analysis (57) of the 115 sequenced *S. aureus* genomes present in the CRISPRdb (http://crispr.i2bc.paris-saclay.fr) showed that the majority of CRISPR-like loci contain only a few spacers (1 or 2), a few have between 3 and 10 spacers, and only 1 genome (from methicillin-resistant *S. aureus* [MRSA] 08BA02176, isolated from a patient) has 15 spacers. Using CRISPRone (http://omics.informatics.indiana.edu/CRISPRone), several genes belonging to the type III-A CRISPR system (including Csm2, Cas1, Cas2, and Cas6) (Fig. 3a) have been recently predicted (72) in different isolates (MSHR1132, JS395, CIG290, and 21252). Multilocus sequence typing performed on one of these isolates (MSHR1132) has shown that it belongs to a divergent clonal complex, which appears to be closely related to *Staphylococcus epidermidis* and *Staphylococcus lugdunensis* (75), and which has been renamed *Staphylococcus argenteus* (76). It has thus been hypothesized that CRISPR/cas was present in a common ancestor of *S. epidermidis*, *S. lugdunensis*, and *S. aureus* and was later lost in most conventional *S. aureus* strains. It is noteworthy that numerous repeat-spacer-like structures resemble CRISPR elements but lack spacer diversity and have been classified as false-CRISPR (72). *S. aureus* repeat-like elements (GC-rich direct repeats) belong to this class of RNAs, for which the functions remain to be addressed (77, 78).

More recently, a type II-C CRISPR-Cas system was found in an MRSA strain isolated from an Irish patient (Fig. 3b). This CRISPR element is located on a pseudo staphylococcal cassette chromosome *mec* (SCC*mec*) composite island, which was probably horizontally acquired from an *S. epidermidis* strain (79). The peculiarity of this system (SaCas9) is that it contains a shorter version of Cas9 protein. The crystal structure of a complex containing SaCas9, the sgRNA (single-guide RNA; an artificial fusion product of a crRNA and a tracrRNA [71]) and its target DNA provided a model to understand how crRNA and tracrRNA guide Cas9 on the target DNA and prepare it for double-stranded DNA cleavages (80). In this structure, the DNA duplex of the protospacer-adjacent region contains the signals recognized by the Cas9 protospacer-adjacent region-interacting (PI) domain, which discriminates the invader DNA against self-DNA and facilitates unwinding of the target DNA, leading to the formation of a heteroduplex. The beginning of the RNA-DNA heteroduplex ("seed" region) adopts a distorted structure critical for Cas9-catalyzed DNA cleavage. This conformation results from the RNA-DNA helix structure, the interactions with protein residues, and the RNA helix formed by the repeat/antirepeat regions mimicking the tracrRNA-crRNA interactions (Fig. 3c). The discovery of the smaller Cas9 protein led to recent improvements in genome editing (81). The seminal works of Jennifer Doudna and Emmanuelle Charpentier on the use of CRISPR-Cas systems for genome editing have inspired many studies showing the incredible potency of the system (82–84). Thousands of publications have reported the use of *Streptococcus pyogenes* Cas9 (85) directed by the sequence of a sgRNA for site-specific genome modifications, gene knockouts or replacements, gene expression control, and functional genome screenings in over 40 species. Interestingly, SaCas9 has been successfully used for eukaryotic genome editing since its smaller size makes it easier to be delivered via adeno-associated virus vectors to somatic tissues (81).

The fact that CRISPR-Cas has been mapped on mobile elements in MRSA confirms the importance of horizontal gene transfer from other cocolonizing bacteria in the acquisition of novel functions and in the evolution of *S. aureus* strains. Interestingly, transcription of the CRISPR-Cas genes can be highly regulated and induced upon infection (86–88) by membrane stress (89) and, in Gram-negative bacteria, by quorum sensing signaling (90, 91). Recent work has developed genetic engineering tools to apply the CRISPR/Cas9 system as an antimicrobial strategy against *S. aureus* (92).

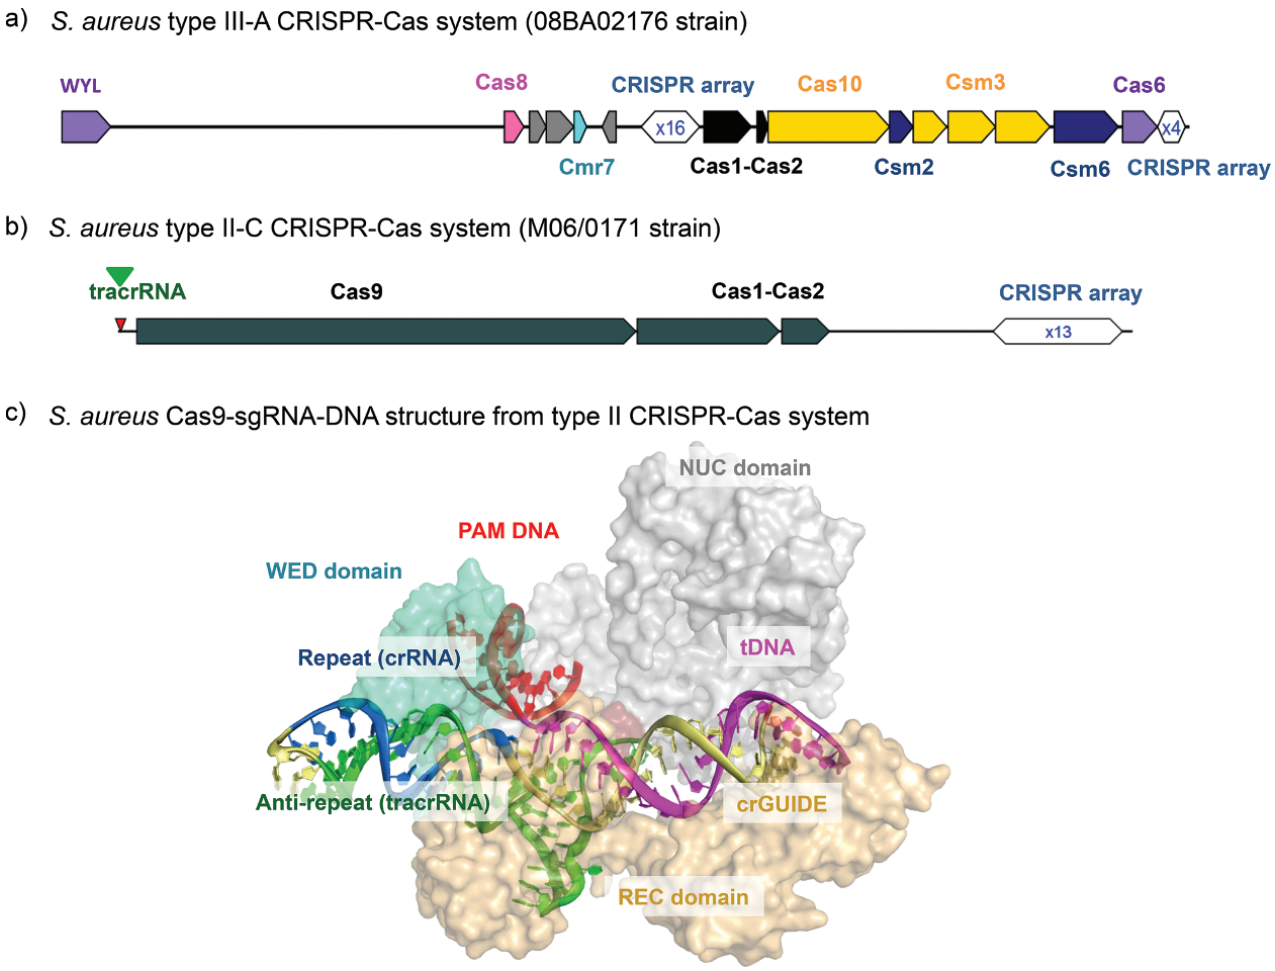

FIGURE 3 (a) Genomic organization of the loci for the type III-A CRISPR system of *S. aureus* strain 08BA02176. Type III is the typical *S. aureus* CRISPR organization. The scheme was obtained using CRISPRone (72), and the genome sequence was deposited in GenBank (accession number 08BA02176; RefSeq accession number GCF_000296595.1). (b) Genomic organization of the loci for the type II-C CRISPR system of *S. aureus* strain M06/0171. The CRISPR-Cas genes were found on an SCC*mec* inserted into the 3′ end of the chromosomally located *orfX* gene. The scheme was obtained using CRISPRone (72), and the SCCmec sequence was deposited in GenBank (GenBank accession number HE980450.1). (c) Cartoon (RNA and DNA) and surface (Cas9) representations of the SaCas9-sgRNA-target DNA complex (pdb file 5AXW) (80). The SaCas9 sgRNA consists of the crRNA guide region (crGUIDE represented in pale yellow) forming a heteroduplex with the target DNA strand (tDNA in magenta) and the repeat/antirepeat helix (blue, the repeat crRNA-derived strand, green, the antirepeat trascrRNA-derived strand). The protospacer adjacent region-containing DNA duplex is red. Cas9 domains are colored as follows: cyan, WED domain; pale orange, REC domain; gray, NUC domain. Molecular graphics images were prepared using PyMol.

Clearly, the CRISPR/Cas9 system offers an alternative therapy to conventional antibiotics.

ROLE OF sRNAs IN PHYSIOPATHOLOGY

S. aureus pathogenesis can take different forms depending on the infected tissue and the invading bacterial strain. This is often accompanied by the expression of various virulence factors involved in the colonization and the alteration of the tissue but also by the capacity to escape from the host immune response. Among key regulators of virulence, several sRNAs have been shown to modulate the synthesis of virulence factors in a dynamic manner, and some of them contribute to specific aspects of bacterial virulence in animal models of infection (1).

The most studied RNA in *S. aureus*, *agr*-RNAIII, is the main intracellular effector of the quorum sensing system *agr*. As described above, RNAIII regulates expression of virulence factors known to be associated with infectious diseases. For instance, it represses the synthesis of protein A, which triggers inflammatory signaling pathways and contributes to evasion of the immune response. Conversely, RNAIII induces the synthesis of a battery of toxins, which contribute to the degradation of tissues and subversion of host defenses, such as the pore-forming toxins, and peptides with proinflammatory and lytic activities. Recent modeling of the quorum sensing system and of its regulators has illustrated the importance of the *agr* system in promoting dissemination of the bacteria from biofilms or dense populations (93, 94). Nevertheless, despite the fact that many clinical isolates from

acute infections express RNAIII, its steady state level varies considerably among them (95, 96). In particular, a higher level of RNAIII has been observed in the community-acquired MRSA strains with increased virulence compared to other *S. aureus* lineages (97, 98). Interestingly, a recent study showed that the level of RNAIII is lower in strains isolated from patients with sepsis than in those from commensal carrier patients (99). Perhaps more surprisingly, heterogeneity has been reported in patients in which *agr*-positive and *agr*-negative strains coexisted. This has been proposed as a factor that might modulate the outcome of the infections (100, 101).

S. aureus is also frequently exposed to other microbes during colonization and infection, providing opportunities to acquire mobile genetic elements that contribute to the evolution of the genome. Some of these genomic islands play key roles in pathogenesis through their possession of new virulence factors (pathogenicity islands) or through the synthesis of novel regulators modulating the expression of genes of the core genome. As an example, SprD is an important small regulatory sRNA (142 nucleotides) expressed from a pathogenicity island, which significantly promoted *S. aureus* diseases in a mouse sepsis model of infection (102, 103). SprD interacts through base-pairings with the *sbi* mRNA, which encodes an immune evasion molecule protecting the bacteria from the host immune responses (104, 105). However, the phenotype of the Δ*sprD* mutant strain was not linked to the SprD-dependent regulation of *sbi* since the Δ*sbi* mutant strain behaved like the wild-type strain in the mouse sepsis model (102). Therefore, these data strongly suggest that SprD might regulate the expression of other proteins important for infection.

SSR42 (for small stable RNAs) is an 891-nucleotide-long sRNA whose stability is greatly enhanced in the stationary phase of growth (106, 107). It regulated the expression of approximately 80 mRNAs in 2 genetically different *S. aureus* strain backgrounds. While it increased the expression of capsule Cap5a, SSR42 downregulated the expression of protein A, α and γ hemolysin, and Panton-Valentin leukocidin (107). Because no direct binding was evidenced between SSR42 and mRNAs encoding virulence determinants, the effect was predicted to be indirect through the modulation of the expression of a transcriptional regulator. Phenotypically, the deletion of the SSR42 gene affected erythrocyte lysis, resistance to opsonization killing, and pathogenesis in a murine model of skin and soft tissue infections (107). More recently, SSR42 was identified as an important effector of intracellular virulence by screening of a transposon mutant library pool. After internalization in epithelial cells, the ΔSSR42 mutant strain was significantly enriched in the intracellular fraction, most likely due to an attenuated cytotoxicity (108).

In contrast to RNAIII, SprD, and SSR42, which contribute to enhanced virulence of *S. aureus*, other regulatory RNAs behave as attenuators of virulence. This is, for instance, the case of another encoded pathogenicity island sRNA, the so-called SprC (103). Indeed, the virulence of the isogenic strain lacking SprC was significantly and reproducibly enhanced in a mouse systemic model. Furthermore, SprC reduces *S. aureus* susceptibility to phagocytosis by human monocytes and macrophages (41). Another example is the *psm-mec* RNA, which is a bifunctional RNA located in the SCC*mec* mobile genetic element. It encodes a phenol-soluble modulin (PSMmec) cytolytic toxin and acts as a translational repressor through direct binding with *agr*A mRNA (109). The transcription of all *psm* genes is positively regulated by AgrA. This activation is linked to a specific binding of the phosphorylated form of AgrA to the promoter sequences upstream of the *psm* genes, except that this binding was not yet demonstrated for the *psm-mec* gene (reviewed in 110). The deletion of the *psm-mec* RNA increased the expression of AgrA, which resulted in an increase of toxin and PSMα production and enhanced virulence in mice (109). Interestingly, community-acquired MRSA that does not carry the *psm-mec* gene has been shown to be more virulent than the hospital-associated MRSA that harbors the gene (109, 111). Finally, a mutant strain that did not express the sRNA, RsaA, was attenuated in the severity of acute systemic infection in a mouse model (47). This deletion is linked to the deregulation of MgrA, a master regulator of capsule synthesis and clumping (112). This phenotype in pathogenesis is probably linked to the high sensitivity of the mutant strain to opsonophagocytosis by host polymorphonuclear leukocytes. Because the expression of these three sRNAs is detrimental for bacterial spreading within colonized host organisms, one may suggest that during evolution they have favored commensalism with the host.

To evaluate the impact of sRNA expression in the context of host infection, two studies explored the possible relationships between infection severity and RNA expression levels. In the first study, the expression levels of five sRNAs (RNAIII, RsaA, RsaE, RsaG, and RsaH) were analyzed in samples from acute cutaneous infection, cystic fibrosis sputum, or nasal colonization. The expression profiles did not correlate with the type of infection, but the authors noticed that the expression of these five RNAs was more homogeneous in the nasal colonization isolates than in those responsible for infection (96). More recently, the expression levels of RNAIII and SprD were measured in 40 strains cultivated from patients with sepsis or septic shock and compared to 21 strains isolated from asymptomatic colonized carriers. It appeared that strains from septic shock had significantly lower levels of RNAIII and to a lesser extent for SprD (99). It is important to note that this analysis was performed on clinical isolates cultured *in vitro* and does not necessarily reflect the expression of these RNAs during infection within the host. In fact, it is very difficult to obtain reliable data from *in vivo* studies to assess the role and importance of RNAs in the establishment or evolution of infection. The great variability of *S. aureus* strains, the difficulty in obtaining highly controlled cohorts of patients, and the reliability of sampling protocols, sample processing, and RNA expression analysis are all obstacles to be overcome. Moreover, biological variables may influence the analysis since the relationships between host immune systems and microbes seem to be particularly individualized and can influence the disease outcome (113, 114). Furthermore, interspecies interactions between bacterial pathogens and the commensal microbiota, as well as limited nutrients, play major roles in promoting or preventing *S. aureus* colonization (113). Interestingly, it was shown that the *agr* system is repressed by high concentrations of hemoglobin in the nasal fluids, leading to the expression of several cell surface proteins and favoring nasal colonization (115). Similar data were obtained when *S. aureus* was cocultivated with the nasal strain of *Corynebacterium striatum* (116). A recent study also demonstrated that the commensal *S. epidermidis* can influence the expression of one ncRNA of *S. aureus* (117).

Clearly, we are just beginning to better appreciate the roles of regulatory sRNAs during colonization and in the pathophysiology of *S. aureus* infections.

This work was supported by the Centre National de la Recherche Scientifique (CNRS) (to P.R.), by the Agence Nationale de la Recherche (ANR, ANR-16-CE11-0007-0-RIBOSTAPH) (to P.R.), and by LABEX: ANR-10-LABX-0036 NETRNA (to P.R.), funding from the state managed by the French National Research Agency as part of the investments for the future program.

The Staphylococcal Cell Wall

RITA SOBRAL AND ALEXANDER TOMASZ

36

HISTORICAL OVERVIEW

Ever since the recognition of the cell wall in the late 1940s to early 1950s as a unique anatomical component of all eubacterial cells, *Staphylococcus aureus* has often served as the Gram-positive model in wall-related studies. One of the first demonstrations that bacterial cell walls can be isolated as physical entities with the size and shape of the whole bacterium was with *S. aureus*. It was in penicillin-treated *S. aureus* that the UDP-linked amino sugar-containing wall precursor peptides were discovered, providing the first insights into the unique building blocks of cell wall biosynthesis. The history of interest in the staphylococcal cell wall also reflects the history of success and failure of the antibiotic era. The clue that eventually led to the discovery of penicillin (and later to the autolytic enzymes) was provided by the lysis of staphylococcal colonies in the vicinity of a mold contaminant on an agar plate in Fleming's laboratory. Elucidation of the mode of action of several important antibiotics in the 1960s and 1970s has been intimately linked to studies of the biosynthesis of staphylococcal cell walls. This included studies of the mode of action of penicillin and other β-lactam antibiotics as specific inhibitors (acylating agents) directed against the active site of penicillin binding proteins (PBPs)—transpeptidases with or without an additional transglycosylase function—which catalyze terminal stages in the assembly of the bacterial cell wall. It was mainly from studies of *S. aureus* and from parallel studies of *Escherichia coli* that by the early 1980s a coherent picture emerged of the biosynthetic pathway that leads to the formation of the lipid-linked disaccharide pentapeptide, which with some structural variations, is the universal building block of cell wall peptidoglycan in both Gram-positive and Gram-negative bacteria. Reviews and references summarizing various aspects of studies of the cell walls of staphylococci up to the late 1980s are available (1, 2).

Changing Image of Cell Walls

During the early antibiotic era, biochemists and microbiologists working with cell walls viewed these as more or less inert exoskeletons essential to withstand the turgor pressure of cytoplasm. However, these views are changing rapidly with the recognition of the complexity of chemical structure and biosynthetic pathways and the large number of genetic determinants involved with the synthesis of the cell wall. Cell walls are also intimately involved with host-related functions of staphylococci (see "Complex Functions of Cell Walls" below). The new image of cell walls emerging is that of a dynamic and very live structure. The assembly and replication of cell walls in dividing cells pose some of the most challenging questions of microbial cell biology, surpassing in complexity the questions of chromosome replication. How is the flow of precursor molecules and their polymerization on the outer surface of the plasma membrane controlled? What controls the unique species-specific chemical composition of peptidoglycan? What principles govern the organization of wall polymers into supermolecular sacculi which have the same size and shape as the particular bacterium? How and by what mechanism does the nascent innermost layer of this envelope mature while moving outward toward the cell surface? How and why and through what signals and by what catalysts are the outermost layers of cell wall shed into the medium during wall turnover? And how is the spatial and temporal accuracy of wall synthesis coordinated with cell division? Although large and successful efforts have been made in the past decade to provide answers to these questions, the scope of these key issues remains the roots of priority research lines.

ABOUT THIS REVIEW

In addition to the reemergence of interest in cell walls in the context of modern microbial cell biology, some approaches have been making great impact on discoveries in this field: in addition to high-resolution analytical techniques (high-performance liquid chromatography [HPLC] and mass spectrometry) and the application of molecular genetic approaches, more recently, cryo-electron microscopy, confocal fluorescence microscopy, superresolution microscopy, and nuclear magnetic resonance spectroscopy are contributing to a clearer picture of the ultrastructure of the Gram-positive cell envelope. Comprehensive coverage of all the data in a period of such rapid expansion of a field would be difficult. The purpose of an updated review may be better served by putting the interested reader "on track" of some of the most recent findings and emerging trends by quoting the relevant literature. The structure of the article will be as follows. After a brief reminder of the anatomy of staphylococcal cell walls, new information will be reviewed under four headings: –"High-Resolution Analysis of the Staphylococcal Peptidoglycan," "Variation in Peptidoglycan Composition," "Genetic Determinants and Enzymes in Cell Wall Synthesis," and "Complex Functions of Cell Walls."

doi:10.1128/microbiolspec.GPP3-0068-2019

ANATOMY OF THE *S. AUREUS* CELL WALL

Most clinical isolates of *S. aureus* express on their outermost surface one of the 13 chemically different capsular polysaccharides that have been identified so far (3, 4). The chemical subunit structures of these important and often antiphagocytic carbohydrate polymers have been elucidated, and rapid advances are being made in the identification of genetic determinants and the organization of capsular loci (5). Underneath these somewhat varied surface layers is the staphylococcal cell wall. In electron-microscopic thin sections followed by heavy metal staining, the cell wall appears as a triple layer: a diffusely staining middle layer sandwiched between two electron-dense lines (Fig. 1). The electromicrograph in Fig. 1 also shows the effect of inhibited cell wall turnover (Fig. 1B) resulting in the accumulation of large amounts of unstructured cell wall material on the cell surface of a vancomycin-resistant clinical isolate of *S. aureus* (6). The photograph of the isogenic vancomycin-susceptible parental cell recovered from the same clinical source is shown on the left side of the figure. Cell wall thickening is often the phenotype of *S. aureus* with vancomycin-intermediate *S. aureus* (VISA)-type vancomycin resistance (7).

Earlier studies established basic compositional/structural features of the *S. aureus* cell wall. It is composed of a highly cross-linked A3α-type peptidoglycan with pentaglycine oligopeptide units connecting the ε-amino group of the lysine component of one muropeptide to the penultimate D-alanine of another. This peptidoglycan, together with ribitol-type teichoic acid chains [which are attached to the 6-hydroxyl groups of some of the *N*-acetylmuramic acid residues of the glycan chain through linkage units, (glycerol phosphate)3-*N*-acetylmannosaminyl beta(1→4)N-acetylglucosamine] (8, 9), surrounds the *S. aureus* cell in the form of a multilayered envelope (Fig. 2). The peptidoglycan of *S. aureus* is typically 20 to 30 nm thick and is characterized by short glycan strands (5 to 25 disaccharide units) (10) and a high degree of cross-linking (~90%) (11), with striking specific structural characteristics that contrast not only with the peptidoglycan of Gram-negative bacteria but also with that of other Gram-positive model organisms (Fig. 3) (12). This review article only presents information on the peptidoglycan component and does not address teichoic acids.

HIGH-RESOLUTION ANALYSIS OF THE *S. AUREUS* PEPTIDOGLYCAN

Progress in the high-resolution chemistry of the *S. aureus* cell wall came from the introduction of HPLC and mass spectrometric methods (13) for the analysis of the primary structure of peptidoglycan. First, studies with gel permeation HPLC established the presence of muropeptide oligomers in lengths extending to nanometers and beyond (14). This was followed by the adaptation of the reverse-phase HPLC system in combination with mass spectrometry for the analysis of strains of *S. aureus* (11, 15). Analysis of the peptidoglycan of methicillin-resistant *S. aureus* (MRSA) provided the first high-resolution view of the complexity of cell wall structures in Gram-positive bacteria.

Enzymatic hydrolysis (with the M1 muramidase) of the staphylococcal peptidoglycan was followed by reduction and separation of the muropeptide components on a reverse-phase HPLC column. This method resolved the hydrolysate to more than 21 distinct UV-absorbing peaks plus a "hump" of unresolved material of longer retention times which made up more than 25% of the muropeptides (Fig. 4A).

Analysis of muropeptide components obtained after digestion with muramidase, or with the combination of muramidase plus lysostaphin (a bacteriolytic endopeptidase that attacks the pentaglycine bridge), revealed that the major monomeric building block is a disaccharide pentapeptide carrying D-isoglutamine in position 2, an intact D-alanyl-D-alanine carboxyterminal, most frequently with a pentaglycine substituent attached to the ε-amino group of the lysine residue (muropeptide 5) or, occasionally, without it (muropeptide 1). These monomeric units make up about 6% of all muropeptides. Another 20% consist of dimers in which

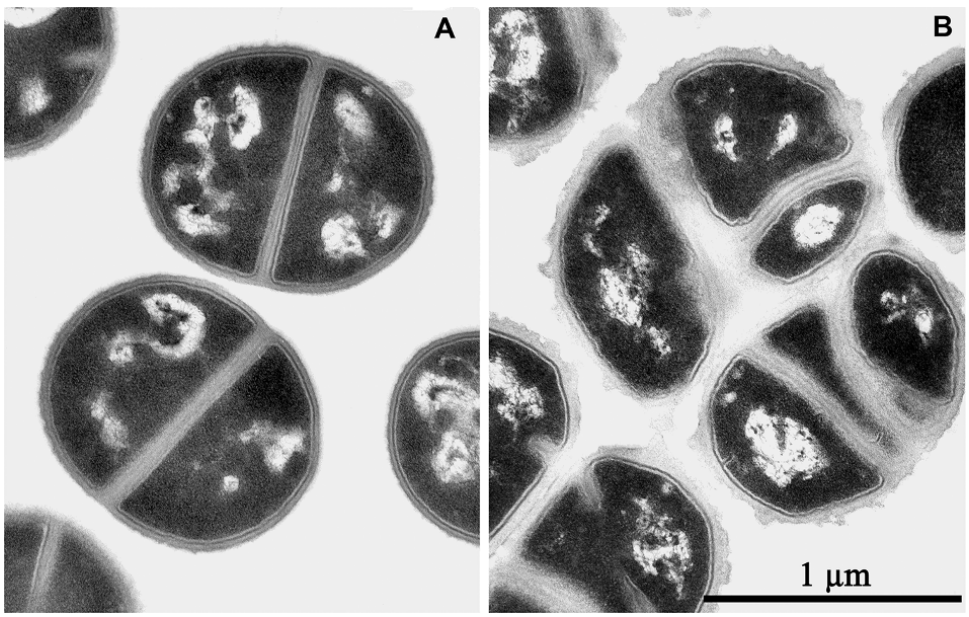

FIGURE 1 The anatomy of cell walls in normal (A) and vancomycin-resistant (B) *S. aureus*. Reproduced with permission from reference 32.

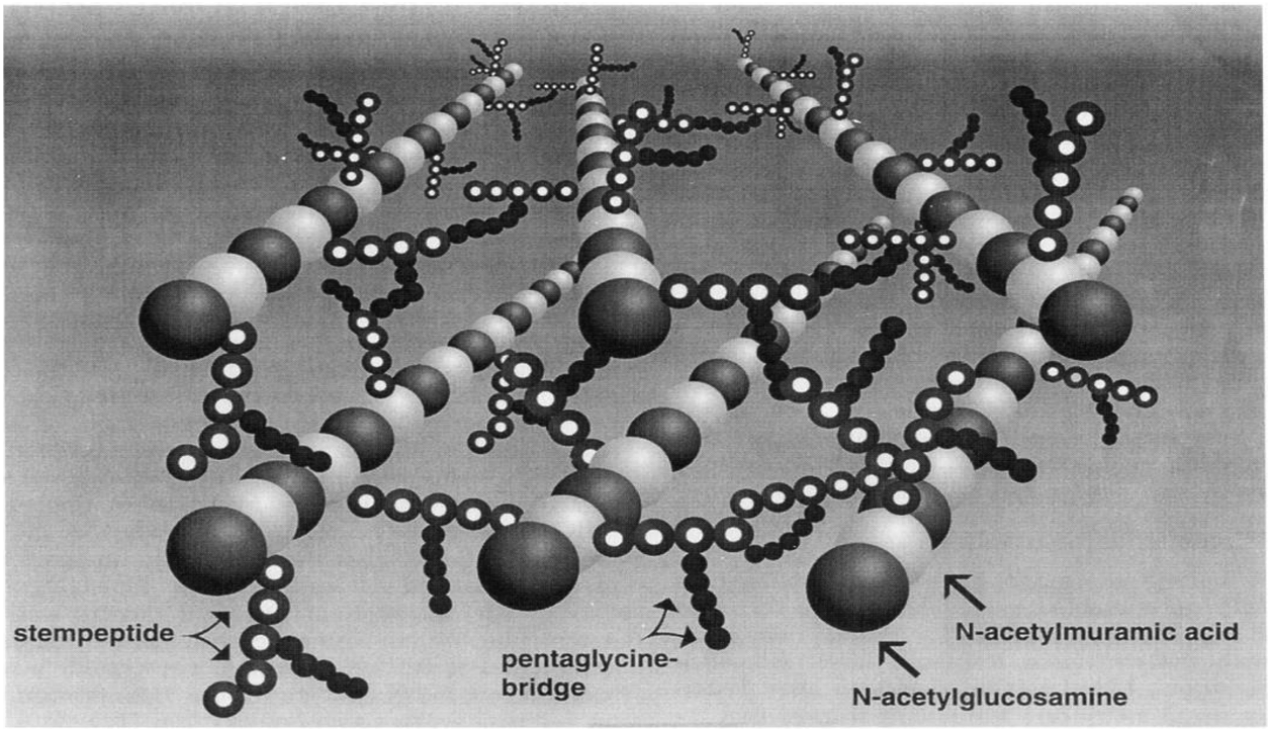

FIGURE 2 Three-dimensional structure of staphylococcal peptidoglycan. Straight lines of large globes represent sugar moieties of the peptidoglycan. Each globe in these lines symbolizes an amino sugar, *N*-acetylglucosamine (black globe), or *N*-acetylmuramic acid (white globe). Stem peptides, branching from *N*-acetylmuramic acid, are characterized by small dark globes with a white center. The connecting interpeptide bridges (pentaglycines) between the stempeptides are shown as small black globes. Schematic drawing by Peter Giesbrecht, Thomas Kersten, Heiner Maidhof, and Jorg Wecke; Robert-Koch Institute, Berlin, Germany. Reproduced with permission.

the pentaglycine substituent of one muropeptide unit is cross-linked to the penultimate D-alanine of a neighboring one (muropeptide 11). About 40% consist of higher oligomers containing 3 (muropeptide 15) to 9 muropeptide units generated by the same cross-linking principle. Still higher oligomers account for an additional 15 to 25% of the muropeptide units (the hump of unresolved components eluting with retention times longer than 110 min.).

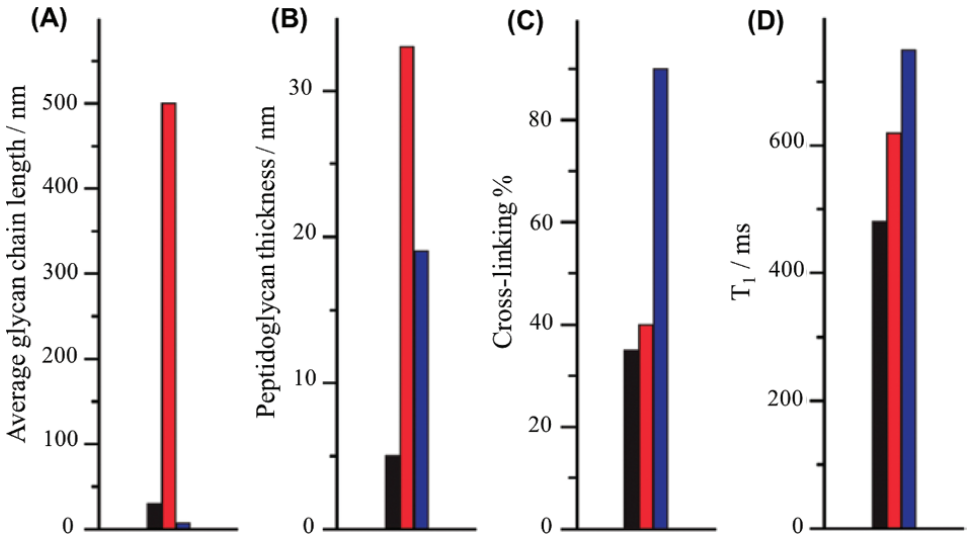

FIGURE 3 Variation of peptidoglycan global structural parameters between *S. aureus* (blue), *B. subtilis* (red), and *E. coli* (black) (164). (A) Chain length, (B) peptidoglycan thickness, (C) percentage of peptidoglycan cross-linking, and (D) relaxation time-constants, with shorter values indicating a higher peptidoglycan flexibility. Hence, the peptidoglycan of *S. aureus* is the most rigid of the three bacterial species. Reproduced with permission from reference 12.

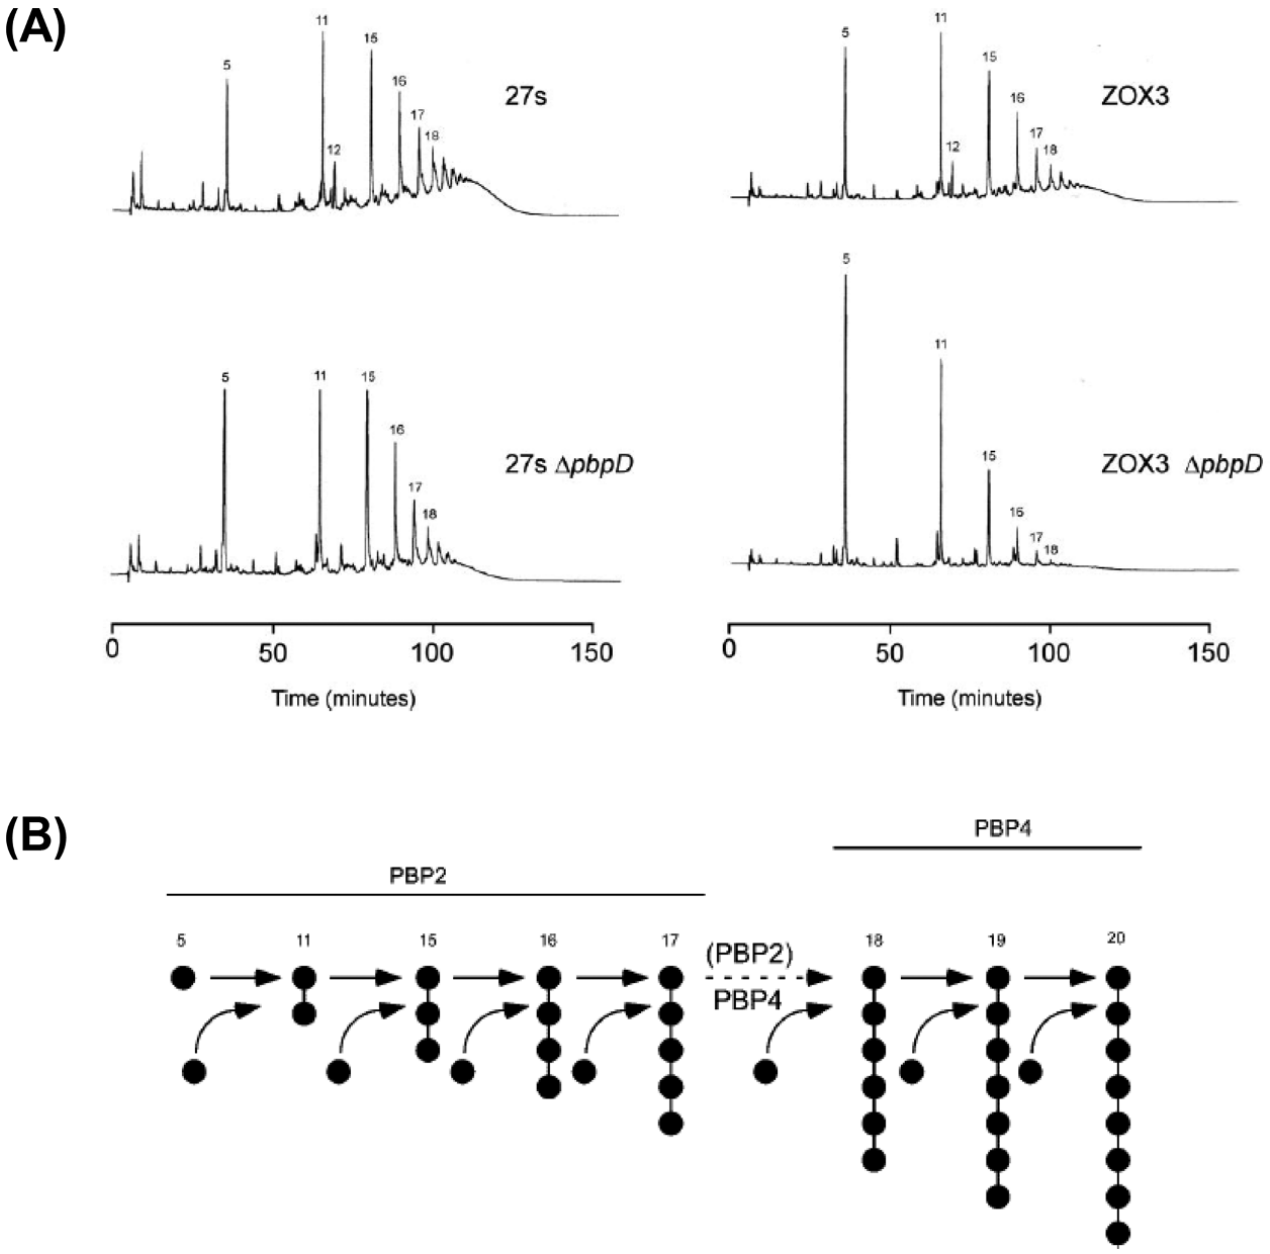

FIGURE 4 (A) Analysis of the peptidoglycan of methicillin-susceptible *S. aureus* strain 27s and its isogenic derivatives ZOX3 (PBP2 TPase point mutant), 27s*ΔpbpD* (PBP4 deletion mutant), and ZOX3 *ΔpbpD* double mutant. Numbers above the HPLC peaks identify the structure of the respective muropeptides. Peaks 5, 11, 15, 16, and 17 represent the monomeric muropeptide and its di-, tri-, tetra-, and pentameric derivatives, respectively. The poorly resolved part ("hump") of the HPLC profile eluting after peak 18 contains highly cross-linked oligomeric components. (B) Model for the cooperative functioning of PBP2 and PBP4 for the cross-linking of the *S. aureus* peptidoglycan. Muropeptides are identified by the respective peak numbers in the above HPLC chromatograms. Monomers are indicated by solid circles, and the bead diagram symbolizes the number of monomeric units cross-linked. The primary TPase activity of PBP2 is suggested to involve the cross-linking of muropeptides of lower oligomerization degree (up to pentamers), and PBP4 is suggested to catalyze the cross-linking of higher multimers. Reproduced with permission from reference 55.

A variation in the preparative technique also allows determination of the structure of the glycan chains. In this case, peptidoglycan is first hydrolyzed with lysostaphin to disrupt the pentaglycine bridges connecting neighboring muropeptides, followed by removal of stempeptides by the pneumococcal amidase (*N*-acetylmuramyl-L-alanine amidase), which hydrolyzes the covalent bond connecting the L-alanine residue to the acetyl muramic acid residue of the glycan chain. After removal of the stempeptides, the size distribution and composition of the glycan chains is determined by reverse-phase HPLC. Application of this method has resolved the glycan strands of *S. aureus* to a family of major peaks which represent oligosaccharides composed of repeating dissacharide units (*N*-acetylglucosamine beta-1,4-*N*-acetylmuramic acid) with different degrees of polymerization and terminating with *N*-acetylmuramic acid residues at the reducing ends. The method allowed separation of strands up to 23 to 26 disaccharide units. Minor satellite peaks were

also present throughout the HPLC elution profile, most likely representing products of *N*-acetylglucosaminidase activity (10).

Stability of Muropeptide Composition

Analyses of peptidoglycan prepared from a large number of *S. aureus* isolates of different clonal types, either susceptible or resistant to methicillin and grown without antibiotic challenge, all showed virtually identical HPLC muropeptide patterns (A. Ornelas-Soares, H. de Lencastre, and A. Tomasz, unpublished observations). Selective Tn*551* inactivation of the *mec*A gene did not cause any detectable change in muropeptide composition (15). These data suggest that similar to other bacteria, the muropeptide composition of *S. aureus* cell walls is specific for the species.

Ultrastructural Analysis of the *S. aureus* Peptidoglycan

Knowledge of the primary structure of peptidoglycan and other cell wall components was more recently complemented by structural data provided by high-resolution approaches. Cryo-electron microscopy has allowed a change of the previous simple concept of a thick and undifferentiated cell wall. The substitution of chemical approaches of fixation by rapid freezing as a physical method with simultaneous chemical fixation allowed observation of the cell envelope organization, namely, the identification of a low-density inner wall zone limited by the membrane and a high-density outer wall zone. The low-density region, proposed to be a periplasmic space, lacks cross-linked polymeric structures and harbors soluble components, while the high-density region consists of an intricate net of peptidoglycan and teichoic acids. Furthermore, the cell wall structure is differentiated at the septum, with two high-density zones corresponding to nascent cross walls separated by a wide low-density mid-zone, suggested to result from the activity of autolysins, separating daughter cells during cell division (16, 17).

Another step forward on the definition of the structure of the peptidoglycan of *S. aureus* was possible due to solid-state nuclear magnetic resonance (NMR) spectroscopy of fully hydrated cell wall material. First, this method showed that the peptidoglycan structure is not altered by the removal of teichoic acids, validating the established HPLC-based peptidoglycan analysis (12). Also, it corroborated the longtime notion that glycan strands are more rigid than peptide stems and that the peptidoglycan of *S. aureus* is more rigid than that of *E. coli* or even *Bacillus subtilis*. This decrease in dynamics is directly related to the higher degree of cross-linking of *S. aureus* peptidoglycan, which compensates for the shorter glycan strands and the presence of interpeptide bridges (12), that should enhance peptidoglycan flexibility. Furthermore, rotational-echo double-resonance NMR, allowed measurement of bridge-glycan distances and determined that the pentaglycyl bridge is in close proximity (5 Å) of the neighboring glycan chain, suggesting a three-dimensional model in which the peptide stems are in a plane perpendicular to the glycan chain and parallel to each other. The study was widened to include *fem* cell wall mutants affected in the glycine interpeptide bridge and VISA strain Mu50 (18). More recently, the same approach was used to study the effects of glycopeptides on the biosynthesis of peptidoglycan and teichoic acids (19).

Fluorescence microscopy and, more recently, superresolution microscopy have driven important breakthroughs on cell morphology and division patterns. In fact, *S. aureus* cells were revealed not to be spherical throughout the cell cycle and to include cell elongation steps that depend on peptidoglycan synthesis and remodeling, allowing for new models of *S. aureus* cell division to be proposed (20–23).

VARIATION IN PEPTIDOGLYCAN COMPOSITION

Effect of Antibiotics

Growth of the highly methicillin-resistant *S. aureus* strain COL in a wide range of subinhibitory concentrations of methicillin caused striking changes in muropeptide composition: the representation of trimeric plus higher oligomeric components was drastically reduced (from a combined representation of close to 50% to less than 10%), while the proportion of monomeric and dimeric components increased (from about 15% to about 50%). It was suggested that the abruptness of this change in peptidoglycan composition may represent the switching over from the normal wall biosynthetic system (the four native PBPs) to another one (PBP2A, encoded by the methicillin resistance gene *mec*A) capable of functioning in the presence of high concentrations of methicillin (11). The anomalous composition of the peptidoglycan produced under these conditions would then reflect the limited capacity of PBP2A for cross-linking more than single monomeric muropeptides. Nevertheless, similar albeit much less abrupt compositional changes were also observed when methicillin-susceptible staphylococci or an isogenic derivative of strain COL (with inactivated *mec*A) were grown in sub-MIC concentrations of methicillin.

Effect of Vancomycin and Teicoplanin Resistance

Laboratory mutants with increased MIC values for glycopeptide antibiotics have been isolated (24–26). The cell wall composition was determined in a series of isogenic laboratory mutants of the highly methicillin-resistant *S. aureus* strain COL (27). The peptidoglycan of the mutants showed distorted muropeptide composition which paralleled the increasing vancomycin MIC values, and it was suggested that some of the unusual properties of these mutants and the mechanism of resistance are related to the enrichment of the cell walls in muropeptide monomers. Muropeptides terminating in the D-alanyl-D-alanine residues are known to form the binding sites for glycopeptide antibiotics. The mechanism of resistance may then be related to trapping the glycopeptides in the mature layer of the peptidoglycan enriched for muropeptide monomers, thus preventing the antibiotic molecules from reaching sites of wall biosynthesis at the plasma membrane (26, 28). Another structural change, increased glycan chain length, was also detected in a vancomycin-resistant mutant (29). Recently, the effects of glycopeptides were analyzed by rotational-echo double-resonance NMR (19). Vancomycin subinhibitory concentrations resulted in a strong reduction of D-alanine incorporation into wall teichoic acids but no changes in the peptidoglycan stem composition, suggesting that, upon glycopeptide challenge, the cell drives the available D-alanine to peptidoglycan biosynthesis at the expense of the wall teichoic acids.

VISA Isolates

Clinical isolates of *S. aureus* with reduced susceptibility to vancomycin have been repeatedly described in the literature, and in at least some of these so-called VISA isolates,

alterations in peptidoglycan composition have been observed, including increased monomeric and decreased oligomeric components, excess of cell wall material, aberrant separation of daughter cells, and altered autolysis (6, 30–32). The genomic analysis of clinical VISA isolates, together with laboratory mutants, has contributed to the understanding of the genetic and biochemical mechanisms of intermediate-level vancomycin resistance in *S. aureus*. Isogenic groups of susceptible and resistant isolates recovered from patients with a history of vancomycin therapy or laboratory strains submitted to vancomycin selection have been studied using high-throughput whole-genome sequencing to identify the altered genes (33–36). The mutated genes were commonly identified in VISA isolates, with the most frequent mutations being in the *vraRS* (37), *graRS* (38, 39), and *walKR* (35, 40) two-component regulatory systems (detailed below). The most relevant mutated genes seem to be somehow related to cell wall metabolism and autolysis (35, 37, 38), but mutations in the RNA polymerase gene *rpoB* were also described (41). Nevertheless, the genetic alterations identified in the *in vivo* VISA isolates were not the same as the ones found in laboratory-derived VISA strains (42). For comprehensive reviews, see references 43 and 44.

Vancomycin-Resistant *S. aureus* (VRSA)

In 2002, highly vancomycin-resistant strains of *S. aureus* were recovered from clinical specimens. These bacteria acquired the vancomycin resistance gene complex through the enterococcal transposon Tn*1546*. Expression of Tn*1546* produced drastic changes in the cell wall composition: all pentapeptides were replaced by tetrapeptides, and the peptidoglycan contained at least 22 novel muropeptide species that frequently showed a deficit or complete absence of pentaglycine branches. The UDP-Mur-NAc pentapeptide, the major component of the cell wall precursor pool in vancomycin-sensitive cells, was replaced by the UPD-MurNAc depsipeptide in the resistant bacteria, and PBP2A, the product of the methicillin resistance gene *mecA*, was unable to utilize such precursors for wall synthesis. The MRSA strain COL carrying *mecA* and the *vanA* genes had extremely high MICs both for β-lactam antibiotics and for vancomycin (45). The major PBP responsible for the assembly of the abnormally structured peptidoglycan produced in the vancomycin-resistant cells was PBP2 (46).

Since 2002, the number of VRSA isolates in the United States has increased to 14 (47). Thirteen of these Tn*1546*-containing *S. aureus* isolates belong to the clonal complex 5 (CC5), an MRSA lineage that has been repeatedly isolated from clinical specimens (43, 44, 47), in contrast to VISA strains that have been associated with different genetic backgrounds, including CC5, CC8, CC30, and CC45 (48, 49). The fact that VRSA strains have not become more frequent is probably related to the specificities of the clinical scenario in which they emerge. Most VRSA isolates were retrieved from diabetic wounds of patients that carried both vancomycin-resistant enterococci and VRSA (45).

GENETIC DETERMINANTS AND ENZYMES IN CELL WALL SYNTHESIS

Penicillin Binding Proteins

Tentative roles for the four native staphylococcal PBPs in wall synthesis were originally assigned on the basis of morphological/biochemical effects of β-lactams that showed more or less selective binding to individual PBPs (50). More recent studies used genetic techniques and *in vitro* transpeptidation assays with lipid II and labeled substrates to clarify the functions of PBPs; the minimal protein composition of peptidoglycan synthesis machinery was addressed by generating a mutant strain in which seven of the nine genes encoding peptidoglycan synthesis enzymes (the five PBPs, four native and one acquired; the two MTGases, MGT and SgtA; and FmtA and FmtB, which have homology to transpeptidase [TPase] domains) were deleted. *S. aureus* was found to be able to grow and divide *in vitro* with only the PBP2 and PBP1 enzymes, without morphological changes, suggesting that the other enzymes have redundant functions. Transcriptomic analysis showed that, as could be expected, the *vraSRF* operon is upregulated and several murein hydrolases are inhibited in this mutant. However, cells with this minimal set of peptidoglycan synthetic enzymes were impaired in pathogenesis and antibiotic resistance, indicating that a complete synthetic pathway is important in natural conditions (51).

Allelic replacement approaches had already established the essential nature of PBP1 (52), and later the contribution of this PBP (a high-molecular-weight monofunctional transpeptidase) to cell division and separation was explored (53, 54). PBP1 localizes to the division septum and does not depend on other peptidoglycan synthetic enzymes for correct localization (51). A PBP1 depletion mutant rapidly loses viability but maintains a normal peptidoglycan composition (53). However, analysis of a PBP1 mutant with impaired TPase activity suggested that PBP1 plays a dual essential role, because its presence, independent of the TPase activity, is required for the formation of septa, while the TPase activity—being necessary for the mechanism of cell separation (54)—can act in a timely fashion at the end of the septal growth.

Of the four native PBPs, PBP2 is the only one composed of a TPase and a transglycosylase (TGase) domain, the former being essential for growth of the bacteria. Biochemical evidence for TPase activity was obtained through the analysis of the peptidoglycan muropeptide profile of a spontaneous ceftizoxime-resistant mutant with a point mutation in the TPase domain (55). The decreased level of highly cross-linked oligomers in the mutant suggests that the primary TPase function of PBP2 is in producing muropeptide dimers (Fig. 4A, peak 11), trimers, tetramers, and pentamers (peaks 15 through 17).

Studies of conditional mutants of *pbpB* demonstrated that this essential function of PBP2 may be replaced by PBP2A, the product of the acquired drug resistance gene *mecA* (56). The TGase domain of PBP2 was shown to cooperate functionally with PBP2A when the bacteria were growing in the presence of antibiotics (57). Critically located point mutations in *pbpB* were associated with methicillin resistance both in laboratory mutants and among some clinical isolates that did not carry the *mecA* gene but showed low-level β-lactam resistance (58). Recently, the substrate preferences of PBP2A, PBP2, and PBP4 were compared regarding the completeness of the glycine bridge. PBP2 was found to accept penta-, as well as tri- and monoglycine-associated muropeptides as substrates of transpeptidase activity, while PBP4 exhibits different enzymatic activities according to each of the three substrates, and PBP2A does not accept monoglycine muropeptides (59).

PBP3 is a class B high-molecular-weight protein with a C-terminal penicillin binding domain showing the

conserved motifs characteristic of transpeptidases and an N-terminal nonbinding domain of unknown function. Unlike in the cases of *pbpA* and *pbpB*, inactivation of *pbpC* in either methicillin-susceptible or -resistant backgrounds allowed growth of the bacteria, and there was no change in the muropeptide composition. The only observable alteration of such mutants was a reduction in autolysis rates. However, when mutants were grown in the presence of sub-MIC concentrations of methicillin, the bacteria frequently showed aberrant morphologies (60). The possible function for this PBP in cell wall synthesis and cell division is not yet described.

PBP4 is a nonessential low-molecular-weight PBP. Bacteria with inactivated PBP4 grew normally but produced a peptidoglycan in which the highly oligomeric components were substantially reduced. An extensive deletion in the promoter region was identified in β-lactam-resistant laboratory isolates which showed increased peptidoglycan cross-linking (61). Inactivation of *pbpD* was demonstrated in a highly vancomycin-resistant lab mutant which produced peptidoglycan with greatly reduced cross-linking (28). These findings confirm earlier proposals that PBP4 can act as a secondary transpeptidase. It was recently demonstrated that PBP4 not only acts preferentially as a transpeptidase, accepting both nascent peptidoglycan and lipid II as substrates but also is the main agent responsible for the incorporation of exogeneous D-amino acids into peptidoglycan. It was proposed that this PBP may be responsible for adding cross-links to partially cross-linked peptidoglycan, primarily to pentamers and higher oligomeric muropeptides (55) and to repair peptidoglycan damage (62). Furthermore, regarding the cross-linking preferences, PBP4 is much more selective than PBP2 and shows a wider range of activities; PBP4 acts exclusively as a transpeptidase for pentaglycine muropeptides and shows 90% of hydrolytic activity with triglycine muropeptides and carboxypeptidase activity for monoglycyl muropeptides (59). Initially, PBP4 was thought not to be required for β-lactam resistance as tested in hospital-acquired MRSA strains. However, in the background of community-acquired strains it was deemed to be involved in the optimal expression of resistance (63). Using atomic-force microscopy to determine the elasticity of the cell wall, the analysis of PBP4 mutants showed that *S. aureus* cells suffer an overall enhancement in elasticity upon decrease of the cross-linking level and that this effect was stronger in the community-acquired MRSA background (64).

PBP2A—the protein product of the resistance gene *mecA*–was crystallized, allowing the identification of structural features responsible for the extremely low affinity of this protein for most β-lactam antibiotics (65). The basis of the PBP2A preference for a peptidoglycan substrate is an allosteric site (distal by 60 Å from the active site) that regulates the conformation of a structural loop guarding the active site. When the allosteric site is bound to a neighboring peptidoglycan strand, the active site becomes available to its ligand, peptidoglycan. Furthermore, the catalytic serine residue changes conformation to maintain the substrate preference toward the β-lactam molecule (66–68). Such structural insights are crucial for mechanistic studies aimed to understand the mode of action of the different β-lactam molecules and the emerging PBP2A mutations. Regarding the transpeptidase activity, it was earlier proposed that PBP2A would only cross-link stem peptides with a pentaglycine branch; however, PBP2A was recently found to also accept as a substrate triglycine-containing strands but not monoglycine ones (59).

Methicillin-Conditional Mutants

The central genetic determinant of MRSA strains is the heterologous gene *mecA*. Several lines of evidence suggest that *mecA* evolved from a housekeeping gene of *Staphylococcus sciuri* (69–72). The evolution toward a resistance determinant, promoted by antibiotic use in humans and animals, involved alterations in the promoter region, structural changes in one protein domain, and the adaptation of the genetic background of bacteria (73).

Inactivation of *mecA* results in complete loss of resistance. Nevertheless, a reduction in the resistance level from a modest decrease to a virtually complete loss of resistance can also be the consequence of inactivation of a surprisingly large number of domestic genes, over 30, which have been referred to as *fem* or auxiliary genes and are not directly involved in the expression of the *mecA* gene (74–77). The transposon mutants of methicillin-resistant *S. aureus* strain COL, which led to the identification of auxiliary genes, were originally isolated to clarify some complex genetic features of staphylococcal methicillin resistance (75, 78). Biochemical analysis indicated that in several of these mutants the inactivated genes were involved with staphylococcal cell wall synthesis. This finding suggested that a reduction in the methicillin resistance level may provide a relatively easily selectable phenotype for the identification of genes in cell wall synthesis and metabolism (75). As a working model, it was proposed that the methicillin MIC value in such "methicillin-conditional" mutants may primarily reflect the success of the *mecA* gene product (PBP2A), positioned close to the end of a long and complex metabolic pathway, to continue catalyzing peptidoglycan incorporation even when this metabolic pathway is disrupted by an inhibited auxiliary gene.

Tn*551* MRSA mutants selected for reduced MIC (such as *femXA/B*, *gluM*, *murE*, *llm*, *fmtA* to C, etc.) or specifically constructed mutants (*murF*, *murT-gatD*, etc.) have led to insights into hitherto unknown or not fully characterized steps in staphylococcal cell wall precursor biosynthesis (74–76, 79–85). More recently, the list of auxiliary genes was widened by the large-scale identification, using antisense interference conditional mutants, of essential genes required for β-lactam optimal resistance (86). This study allowed the identification of essential cell division (*ftsZ* and *ftsA*) and teichoic acid biosynthesis genes (*tarL*), among others.

The Role of the Stringent Response in the β-Lactam Resistance Mechanism

Recently, the above-described model has been challenged by a sequence of studies that culminated in the identification of the stringent response as a key player in a *mecA*-dependent mechanism of homogeneous and high-level β-lactam resistance (87–89). The stringent response is a bacterial reaction to a nutrient shortage, with the aim to economize metabolic resources. Such a response involves the transcriptional regulation by RNA polymerase and the modulation of the activity of certain proteins and RNAs through the cellular level of guanosine pentaphosphate (p)ppGpp (90). A comparative study based on whole-genome sequencing of highly resistant subpopulations of early MRSA strains with different degrees of oxacillin resistance identified mutations in 27 genes of diverse functional categories. These mutations were shown to induce high-level β-lactam resistance by triggering the stringent stress response, causing increased production of PBP2A (91). Nevertheless, the mechanism of high-level resistance induced by the stringent response corroborates the

previously established model of β-lactam resistance, which considers the essentiality of the transglycosylase activity of PBP2 (87). Moreover, auxiliary mutants were shown to regain the homogeneous resistance level of the parental strain COL when challenged with mupirocin, an isoleucyl-tRNA homologue that induces stringent stress (92).

FemAX/B

The *femX* (Fmhb), *femA*, and *femB* genes are part of an operon involved with the synthesis and attachment of the pentaglycine branches to the epsilon amino group of the lysine residue of the *S. aureus* muropeptides. The synthesis of pentaglycine bridges occurs in three sequential steps catalyzed by the FemABX nonribosomal peptidyl transferases, which cannot substitute for one another. The protein product of *Fmhb* catalyzes the addition of the first glycine residue to the muropeptides. This gene is essential for bacterial survival and growth (93). The protein product of *femA* is involved with the addition of the first and second, and the protein product of *femB*, with the addition of the third and fourth, glycine residues to the cross-bridge (83, 94). In an elegant series of studies, the entire sequence of pentaglycine branch synthesis and attachment has been determined and reproduced *in vitro* using bactoprenol-linked disaccharide pentapeptide as the acceptor and t-RNA-linked glycine as the source of the amino acid residues (95, 96). Structural NMR studies of *femAB*-deletion mutants with shortened pentaglycine interpeptides showed that the pentaglycine bridge is required to reduce the average distance between the nearest-neighbor bridge and glycan and that a poorly cross-linked cell wall may not be able to resist the cell's internal turgor. To counteract the internal osmotic stress in the absence of *femAB* genes, transcriptomic studies suggested that the cell resorts to metabolic alterations, namely, of the arginine-deiminase pathway and nitrogen metabolism (18, 97). Nevertheless, viability in the absence of *femA* and *femB* suggests that one or more of the native PBPs can cross-link stem peptides with monoglycyl or triglycyl bridges.

Secondary Modifications

Secondary modifications of the glycan strands of the staphylococcal peptidoglycan, namely, *O*-acetylation and *N*-deacetylation of *N*-acetylglucosamine, have been mostly associated with evasion of the human host. *O*-acetylation occurs at the C-6 position of muramic acid residues and is catalyzed by the integral membrane *O*-acetyltransferase OatA; this modification confers resistance to lysozyme, a muramidase present in most human biological fluids and secreted by cells of the immune system (98–100). The proposed basis of resistance is that the *O*-acetyl group sterically prevents the binding of lysozyme to peptidoglycan (101), and only pathogenic species of *Staphylococcus* have *O*-acetylated peptidoglycan (98). The stem peptide of *S. aureus* also suffers modifications to the primary structure, including the addition of the pentaglycine bridge (see previous section) and amidation of the second residue D-glutamate to D-iso-glutamine. The genetic determinants of the amidation reaction, the *murT* and *gatD* genes, were described in 2012, and the protein products form a bi-enzymatic complex, with MurT being a member of the mur ligase family and GatD a glutamine amino transferase that uses glutamine as the source of the amino group (79, 102). As for *O*-acetylation, peptidoglycan amidation is involved in lysozyme resistance, but in contrast, it is not restricted to pathogenic species but, rather, is widely distributed among Gram-positive bacteria. The MurT-GatD catalyzed reaction is essential for viability and for resistance to β-lactams, showing different levels of involvement in the resistance mechanism according to the genetic background of the strain (79, 102, 103).

The pentaglycine bridge is a modification of *S. aureus* peptidoglycan and the specific target of lysostaphin, a bacteriolytic enzyme secreted by *Staphylococcus simulans*. This species is resistant to the activity of lysostaphin since it contains serine/glycine cross-bridges, a modification catalyzed by Epr (lysostaphin endopeptidase resistance) of the FemAB protein family (104).

Insights into Regulation and Contribution of Transcriptomic Studies

Upregulation of the transcription of *pbpB*, the structural gene of PBP2, by exposure of *S. aureus* cells to oxacillin, vancomycin, and other cell wall inhibitors has been reported (105), suggesting transcriptional regulatory pathways linking the cell wall structure and metabolic functions. This first observation was corroborated and widened by a large number of transcriptomic studies using state of the art DNA microarrays to study cell wall exogenous stress conditions (37, 106–110) or cell wall mutations (37, 97, 107, 111–114). Utaida et al. were the first to describe a large set of genes, the so-called cell wall stimulon (CWS), the expression of which was activated in response to cell wall-targeting antibiotics of diverse classes, suggesting the sensing of cell wall damage (110, 115). The CWS included cell wall-associated genes such as *pbpB*, *murZ*, and *sgtB*, encoding a TGase, and *fmtA*, encoding an enzyme with TPase activity. The vancomycin resistance-associated (VraSR) two-component system, identified for being activated by vancomycin challenge, was found to induce all members of the CWS (37, 116). Upregulation of the CWS is suggested to provide resistance to VraSR-inducing agents, including β-lactams.

S. aureus contains 16 sets of 2-component regulatory systems that monitor cell wall damage and activate an appropriate physiological response; among these is not only VraSR, but also GraRS and WalKR, which interestingly were all found to be implicated in the development of VISA strains (40, 117, 118).

The VraSR system autoactivates its own expression and most CWS genes, which are suggested to contribute to the repair of the sensed cell wall damage (113, 119). VraS is an intramembrane sensing kinase that undergoes autophosphorylation upon challenge with a cell wall-targeting antibiotic and subsequently phosphorylates the VraR response regulator (120), which binds to its own promoter and activates or represses the genes of the regulon (121). The molecular signal detected is not yet defined but is suggested to be a by-product of cell wall damage since a diverse class of unrelated antibiotics was shown to induce the system. The Vra system effects methicillin resistance by a still unclear mechanism, independently of *mecA* gene (116).

The glycopeptide resistance-associated (GraSR) system confers resistance to cationic antimicrobial peptides by increasing the positive charge of the cell surface, contributing to electrostatic repulsion through the modulation of the D-alanylation of teichoic acids and of lysinylation of phosphatidyl glycerol (122, 123). A transcriptomic study showed that the GraSR system is also involved in pathogenesis, stress response, and cell wall signal transduction, and its regulon overlaps the WalKR regulon (112). This system is proposed to be a five-component system composed of GraS, an

intramembrane sensing kinase, GraR, the response regulator, GraX, a regulatory cofactor, and the VraFG ABC transporter that senses the presence of cationic antimicrobial peptides and is involved in signaling transduction (112, 124).

The two-component system, WalKR, is essential for *S. aureus* viability and is primarily involved in the regulation of cell wall metabolism by positively modulating autolytic activity through the control of the expression of most of the cell wall hydrolase genes, including the direct binding of WalR to the *atl* promoter (125). LytM autolysin seems to play a particularly important role in this mechanism by reducing the degree of cross-linking in the peptidoglycan through its endopeptidase activity toward the pentaglycine bridge (126). Mutants for this system showed enhanced biofilm formation, decreased peptidoglycan biosynthesis and autolytic activity, thickened cell walls, and reduced vancomycin susceptibility (125, 126). A role in virulence was also described for this system, because WalKR was found to trigger the host inflammatory response through the release of peptidoglycan fragments as a consequence of increased autolysis (111). A mutation in WalK sensor kinase that was also found in a clinical VISA strain was responsible for deficient autophosphorylation and concomitant reduced phosphorylation of WalR, which binds less efficiently to the *atl* promoter, impairing the control of the autolytic system (118).

Two monofunctional glycosyl transferases were identified and characterized in *S. aureus* (127, 128), and genomic analysis suggested that besides PBP2, only MGT and SgtA contain TGase motifs. MGT enzyme was shown *in vitro* to catalyze glycan chain polymerization, using lipid II as a substrate, with an efficiency of 5,800 $M^{-1}s^{-1}$ (129). All three enzymes have the capacity to elongate glycan chains, and although the monofunctional glycosyl transferases are not essential, *S. aureus* cannot survive without the TGase activity of PBP2 or MGT, indicating that the activities/specificities of MGT and SgtA are different. Both MGT and SgtA were found to interact with PBP2, suggesting the existence of a cell-wall synthetic complex in *S. aureus* (127). Expression of the *mgt* gene was found to be upregulated in the presence of cell wall antibiotics (110). However, although MGT can compensate for the lack of PBP2 TGase activity in methicillin-susceptible *S. aureus* and MRSA strains, it does not replace PBP2 upon challenge with high concentrations of oxacillin (127).

Although never fully described, several pieces of evidence support the existence of a coordinated multienzyme complex responsible for cell wall assembly. One piece of evidence was provided by the analysis of the peptidoglycan of a PBP2 TPase mutant and of its corresponding double PBP4 deletion mutant (Fig. 4A). This study allowed the description of the cooperative functioning of PBP2 and PBP4 in which the TPase activity of PBP2 is suggested to produce the substrates for PBP4, dimers, trimers, and tetrameric muropeptides, which are subsequently transformed into higher oligomers by PBP4 activity (Fig. 4B). In the same study, PBP2A was proposed to directly provide "assistance" to this PBP2-PBP4 transpeptidation system through a still undescribed mechanism (55).

COMPLEX FUNCTIONS OF CELL WALLS

The peptidoglycan is a protective barrier against the host and also a scaffold for the attachment of surface proteins and polysaccharides, which are essential for cell division and pathogenesis. The carboxyterminal end of staphylococcal surface proteins (such as protein A) are covalently bound to the oligoglycine cross-bridge of peptidoglycan muropeptide units through a threonine residue in the protein (generated after cleaving of the wall sorting signal LPXTG), which is then linked to the amino terminal glycine residue of the muropeptide. Sortase-anchored surface proteins were shown to be released into the external environment together with peptidoglycan immunostimulatory fragments linked to their C-terminus by the action of murein hydrolases (130). The structure of these cross-bridges is under the control of the *fem* gene complex. Therefore, the already pleiomorphic *femA/B* mutant (showing defective wall structure, reduced methicillin resistance, and slow wall turnover) may also be affected in virulence.

The active involvement of the cell wall in complex functions is also being recognized in studies of the transport (release and uptake) of large molecules (131). Increased susceptibility of *femA/B* null mutants to some antibacterial agents other than β-lactams may be related to increased porosity of the peptidoglycan. Increased extractability of proteins (wall porosity?) was noted in a highly teicoplanin-resistant staphylococcal mutant with greatly decreased peptidoglycan cross-linking (132).

Murein Hydrolases in Cell Division and Antibiotic Resistance

Peptidoglycan is a dynamic structure, being constantly synthesized and hydrolyzed. The cell biological functions of staphylococcal murein hydrolases and their regulation have been intensively investigated, and these studies benefited greatly from zymography for profiling bacteriolytic enzymes and from genetic work. The major autolysin gene *atl* was found to encode a bifunctional protein that undergoes proteolytic processing at the cell surface into the independent *N*-acetylmuramyl-L-alanine amidase and endo-β-*N*-acetyl glucosaminidase domains (133, 134). The still "double-headed" *atl* gene product containing the fused amidase and glucosaminidase proteins was found to be localized on the plasma membrane as a circumferential ring at the future cell divisional site, and this localization precedes the appearance of centripetally growing cell wall (135) (Fig. 5). The molecular signature that directs the autolysin gene to its site of action at the cellular equator was shown to reside within the three repeat elements present in each domain (136, 137). The presence of wall teichoic acids at the septum was described to prevent the binding of Atl domains to the septal region through an avoidance strategy (138). Atl is primarily involved in the separation of daughter cells during cell division but also contributes to cell wall turnover and antibiotic-induced lysis (139, 140).

In zymograph gels, a Δ*atl* mutant showed a single lytic band that was determined to correspond to the amidase Sle1 (141), also involved in cell separation. Besides the *atl*, *sle1*, and *lytM* genes, *S. aureus* is thought to contain 10 additional genes encoding peptidoglycan hydrolases, although their products are not biochemically characterized.

Alteration of autolytic properties has been consistently seen in staphylococcal mutants isolated for changed β-lactam resistance. Increases in autolytic rates (and cell wall turnover) in parallel with the increase in resistance level were demonstrated in cefotaxime-resistant mutants (142), while reduced rates were observed in *femA*, *femB*, and *femC* mutants. Also, the downregulation of PBP2 and PBP1 expression resulted in an associated reduction in the transcription of *atl* and *sle1*, indicating a coupling of cell wall synthesis to the autolytic enzymes at the transcriptional level (54, 143).

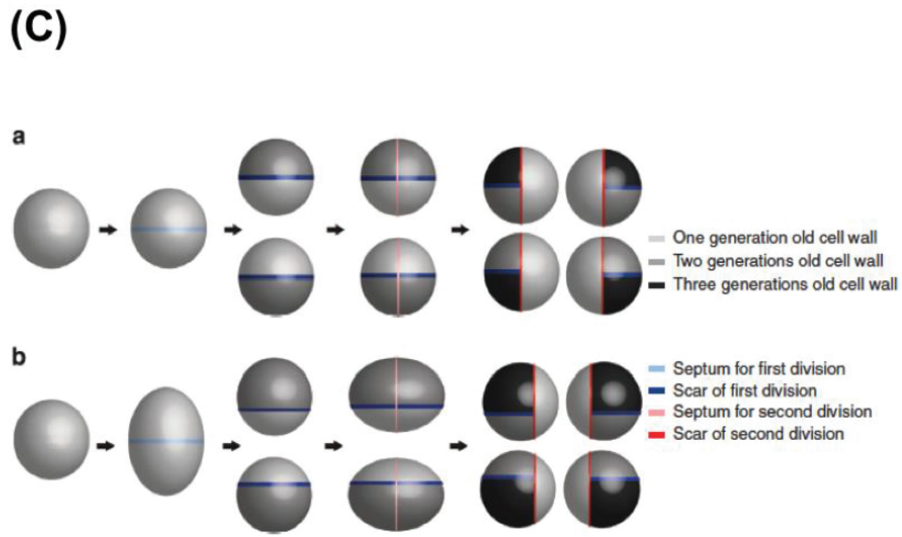
Cell Division



Recent methods allowed the identification of functional links between the peptidoglycan structure and synthesis pathway and the cell division process. Fluorescence microscopy localization studies demonstrated the essential role of FtsZ and of lipid II peptidoglycan precursor in the correct localization of PBP2 to the septum (144, 145). On the other hand, wall teichoic acids were shown to indirectly control PBP4 localization to the septum (146).

The process of cell division in *S. aureus* occurs equatorially and on consecutive orthogonal planes in three dimensions in accordance with the previous suggestion that peptidoglycan insertion only occurs at the septum (145, 147). It was possible to correlate the architecture and dynamics of peptidoglycan with the cell cycle using atomic force microscopy and fluorescence microscopy by observing a thick band of peptidoglycan, the so-called piecrust, at the division plane before the formation of the septum. After division, these structures remained as orthogonal ribs, marking the location of the previous division event, possibly to enable the cell to maintain the division plane localization sequentially orthogonal over the generations. Upon cell expansion after separation, the peptidoglycan mesh must undergo rearrangements since the area of the flat septal disc is much less than the area of half of the new cell (Fig. 6A) (21, 148). Some peptidoglycan hydrolases (Atl, SagA, ScaH, and SagB) with glucosaminidase activity have recently been shown to be required for cell enlargement, presumably by altering the mechanical properties of peptidoglycan that becomes more flexible for stretching (23).

The model of functional association between peptidoglycan synthesis and cell division still needs further work in light of new observations obtained by super-resolution microscopy. In contrast to original beliefs, *S. aureus* cells were shown to elongate before dividing, and the septum forms in a slightly unsymmetrical plane, suggesting that the peptidoglycan "piecrust" does not mark quadrants of the cell (20) (Fig. 6B and C).

Interaction with the Host

Purified insoluble peptidoglycan of *S. aureus* was shown to induce arthritic symptoms in mice and interleukin-1b expression in macrophages, indicating that live bacterial cells are not necessary to elicit an inflammatory response (149, 150). The fact that this heterogeneous polymer is ubiquitous, essential, and unique to bacteria makes it the perfect target for the innate immune system through the action of lysozyme, a muramidase that is well distributed among the animal kingdom (151).

S. aureus peptidoglycan undergoes several secondary modifications (see above), such as *O*-acetylation of MurNAc and amidation of the second position of the stem peptide, contributing to lysozyme resistance, with a Δ*oat*A mutant showing impairment in the capacity to mediate septic arthritis (152). Other surface alterations that add to such resistance in *S. aureus* by modification of the net charge include the incorporation of D-alanine in teichoic acids and L-lysine in the membrane phosphatidylglycerol (153, 154).

Peptidoglycan fragments, released by cell wall turnover, have strong proinflammatory capacity, since they are recognized by host immune receptors, including nucleotide oligomerization domain protein-2 (NOD2), which detects L-lysine-containing muropeptides and the muramyl dipeptide as the minimal recognition structure (155). Peptidoglycan is also recognized by the extracellular Toll-like receptor-2 (TLR2) (156) and by peptidoglycan recognition proteins (PGRPs) that are present in leucocytes, liver, and epithelial cells and also in insects (157). Another clever host concealment strategy of *S. aureus* was described to rely on the activity of autolysins to trim the peptidoglycan fragments that stand out from the cell wall surface and become exposed to PGRP (158). Recognition of peptidoglycan by all these receptors, and perhaps others that remain to be identified, leads to the activation of multiple host defense responses (159).

Interaction with the External Environment and Recycling

Bacteria build and remodel their peptidoglycan scaffold not only through the primary biosynthetic pathway but also by interaction with the external environment. One form of interaction is peptidoglycan recycling, which although well described in Gram-negative bacteria for which turnover products are retained in the periplasm, has been a subject of debate for Gram-positive organisms. Recently, recycling of *N*-acetylmuramic acid was described for *S. aureus*, *B. subtilis*, and *Streptomyces coelicolor*, mediated by MurNAc-6P etherase, which converts per generation about 5 to 10% of MurNac-6P to *N*-acetylglucosamine-6-phosphate and lactate intracellularly. Deletion mutants showed no growth defects during exponential phase, because recycling was shown to occur mainly upon transition to stationary phase, suggesting that this process contributes to survival in the late phase of growth (160). Another form of interaction with the environment is the peptidoglycan chemical plasticity in challenging conditions. Noncanonical D-amino acids are known to be released to the environment by a wide range of bacterial species and to be exogenously incorporated into the mature peptidoglycan structure, through the action of surface associated enzymes, as a mechanism of peptidoglycan editing (161). In fact, the effect of exogenous glycine on the structure of staphylococcal peptidoglycan was described in early studies. Growth of *S. aureus* in the presence of high concentrations of glycine, D-serine, or other D-amino acids caused dramatic distortions of the peptidoglycan scaffold with reduction in cross-linkage and replacement of the muropeptide components by abnormal structures in which the carboxyterminal D-alanine residues were replaced by glycine or the other amino acids added to the medium (11, 162). One of the best-documented roles for such peptidoglycan editing capacities is to confer resistance to glycopeptides, but other functions related to adaptation to sudden environmental stresses, presence of the host, or an aging cell population have been suggested (161, 163). Most recently, incorporation of exogenous amino acids into *S. aureus* peptidoglycan was described to occur inside the infected live organism *Caenorhabditis elegans*, revealing a process of *in vivo* cell surface remodeling, eventually as a communication platform between pathogen and host (163).

SUMMARY

Through these studies, the staphylococcal cell wall is beginning to emerge not only as a critically important exoskeleton responsible for the structural integrity of the bacterium, but also as an organelle of multiple functions: it is intimately involved with interactions with the system of innate immunity of the host; it is a dynamic scaffold undergoing permanent remodeling upon external changes; it provides covalent attachment sites for a number of host-related surface proteins; and it occupies center stage in resistance to

FIGURE 6 (A) AFM height (H) and phase (P) images of purified sacculi from exponential phase *S. aureus* and key architectural details of the piecrust, division rings, and knobbles (21). (Top panel) Sacculus showing apparent incomplete septum parallel to the plane of the image, encircled by a piecrust feature associated with the initiation of septum formation; inset shows detail of piecrust features. (Middle panel) Sacculus showing ring texture associated with nascent peptidoglycan and knobble texture associated with older peptidoglycan; insets show details of rings and knobbles. (Bottom panel) Interpretive diagram drawn from the yellow rectangle in the middle panel. Reproduced with permission from reference 148. (B) SEM images of *S. aureus* strain COL showing an asymmetric scar (blue line) corresponding to the previous division site and a fissure located in the middle of the cell (red line), presumably corresponding to the next division site. The new cell wall (light brown), resulting from septal material from the mother cell, which has a smooth surface immediately after division (first panel), occupies less than half of the total surface. Scale bars, 600 nm. (C) Comparison of two models for *S. aureus* growth and division. (a) An earlier model which assumed that *S. aureus* cells remained approximately spherical over the cell cycle and that, on division, the cell wall material from the septum of the mother cell increased in cell surface area to constitute half (one hemisphere made of new cell wall) of the cell surface of each daughter cell. As a consequence, "scars" of previous divisions were proposed to encode epigenetic information that could be used to determine orthogonal placement of division septum. (b) In the other model proposed, *S. aureus* cells are approximately spherical at the beginning of the cell cycle and elongate as the cell cycle progresses. On division, there is no increase in the surface area of the previous septum, which becomes ~33% of the surface area of each daughter cell. This asymmetry in the regions composed of new and old cell wall results in scars of previous divisions that do not divide cells in quadrants. Consequently, T-junctions of scars of two previous divisions are not located at the cell poles. Two consecutive divisions in orthogonal planes are depicted in panels a and b. Reproduced with permission from reference 20.

β-lactam and glycopeptide antibiotics. Some of these observations have also begun to throw light on how the control of degradative and synthetic activities and morphogenetic principles come together in the assembly and replication of cell walls.

We thank P. Giesbrecht and M. Sugai for allowing the reproduction of their illustrations in this review.

Staphylococcal Protein Secretion and Envelope Assembly

OLAF SCHNEEWIND AND DOMINIQUE M. MISSIAKAS

37

The cell wall envelope of *Staphylococcus aureus* is a surface organelle with anchored proteins, teichoic acids, and polysaccharides that enable bacteria to promote specific interactions with their environment (1). During colonization and invasion of their mammalian hosts, secreted and cell wall-anchored surface proteins fulfill a wide spectrum of functions, including bacterial adhesion to host cells or tissues, evasion of innate host defenses, and diversions of host adaptive immune responses (2). Secreted proteins trafficking in and out of the cell wall envelope promote both the persistent colonization of mammalian hosts and the pathogenesis of specific disease states that are characteristically associated with *S. aureus* (2).

CELL WALL SYNTHESIS AND ENVELOPE ASSEMBLY

When analyzed by electron microscopy of thin-sectioned bacteria, staphylococci are spherical cells whose envelope is composed of a plasma membrane and surrounding cell wall layer (20 to 40 nm in diameter) (3). Cell walls are isolated by physical disruption of staphylococci and chemical treatments that remove secondary polymers, including wall teichoic acids (WTAs), polysaccharides, and proteins (4). The remaining structures, designated murein sacculi, retain the spherical shape of the bacteria and are composed of peptidoglycan, including glycan strands with a repeating disaccharide, →4 (*N*-acetylmuramoyl-β-(1→4)-*N*-acetylglucosaminyl-β-(1→), abbreviated $(MurNAc\text{-}GlcNAc)_n$, and cross-linked wall peptides, L-alanyl-D-iso-glutaminyl-(pentaglycyl)L-lysyl-D-alanyl$_n$, abbreviated $[Ala\text{-}iGln\text{-}(Gly_5)Lys\text{-}Ala]_n$ (5, 6). Wall peptides are tethered to glycan chains via amide bonds formed by the amino-group of L-alanyl and the carboxyl-group of MurNAc (6, 7). Wall peptides of neighboring peptidoglycan strands are cross-linked by amide bonds formed from the amino group of pentaglycyl and the carboxyl-group of D-alanyl (8). During peptidoglycan synthesis, the bactoprenol-linked intermediate, lipid II $[C_{55}\text{-}(PO_4)_2\text{-}MurNac(\text{-}Ala\text{-}iGln\text{-}(NH_2\text{-}Gly_5)Lys\text{-}Ala\text{-}Ala\text{-}COOH)\text{-}GlcNAc]$, is translocated across the staphylococcal plasma membrane (9, 10). Penicillin binding protein 2 polymerizes lipid II substrate to generate glycan strands and cross-linked wall peptides via hydrolysis of its phosphodiester and Ala-Ala bonds (11–13).

WTAs and capsular polysaccharide are also synthesized as bactoprenol-linked intermediates (14, 15). Once translocated across the membrane, WTAs and capsular polysaccharides are anchored to the peptidoglycan scaffold (16, 17). Staphylococci replicate by forming cell division septa at midcell and by synthesizing peptidoglycan in the cross-wall compartment, which is bounded by the septal membranes of newly dividing staphylococci (3, 18). Once completed, cross-wall peptidoglycan is split to separate the dividing cells (3). Staphylococcal murein sacculi are not permeable for proteins and other large macromolecules. Cell division, assembly of secondary polymers, and the secretion of proteins across the bacterial cell wall requires specific murein hydrolases that modify murein sacculi, thereby enabling protein secretion across the cell wall envelope and the anchoring of secondary cell wall polymers to peptidoglycan (19, 20).

TEICHOIC ACID SYNTHESIS AND ENVELOPE ASSEMBLY

The envelope of *S. aureus* encompasses both polyribitol-phosphate and polyglycerol-phosphate polymers (21, 22). Polyribitol-phosphate $[(Rib\text{-}PO_4)_n]$, also designated WTA, is synthesized in the bacterial cytoplasm from CDP-ribitol and tethered to its bactoprenol-linked carrier, thereby generating lipid III $[C_{55}\text{-}(PO_4)_2\text{-}GlcNAc\text{-}ManNAc\text{-}(Gro\text{-}PO_4)_2\text{-}(Rib\text{-}PO_4)_{11\text{–}40}]$ (23, 24). Rib-PO_4 is polymerized via phosphodiester bonds engaging ribitol hydroxyls at *O*1 and *O*5; the remaining hydroxyl moieties (*O*2, *O*3, and *O*4) are variably substituted with α- or β-linked GlcNAc (25–27). Following translocation of lipid III across the membrane, LCP enzymes tether WTA to peptidoglycan, generating phosphodiester bonds between the *O*1 of GlcNAc and the *O*6 of MurNAc (28). The Rib-PO_4 polymer of anchored WTA is further modified via esterification with D-alanyl (29, 30). Peptidoglycan synthesized at the cross-wall is initially devoid of WTA (31) (Fig. 1). Upon cross-wall splitting and cell separation, cross-wall peptidoglycan is modified with WTA (31). LtaS polymerizes polyglycerol-phosphate $[(Gro\text{-}PO_4)_n]$, also designated lipoteichoic acid (LTA), from phosphatidylglycerol, transferring the assembled Gro-PO_4 polymer onto its glycolipid anchor gentiobiosyldiacylglycerol: Glc-β-(1→6)-Glc-β-(1→3)-diacylglycerol $[Glc_2\text{-}DAG]$ (32–34). The *O*2 hydroxyl of Gro-PO_4 is variably substituted with esterified D-alanyl (30, 35). LtaS and LTA synthesis are restricted to septal membranes and are required for staphylococcal cell division and growth (36) (Fig. 1). Thus, assembly sites of WTA and LTA synthesis are unevenly distributed in the envelope of dividing staphylococci.

doi:10.1128/microbiolspec.GPP3-0070-2019

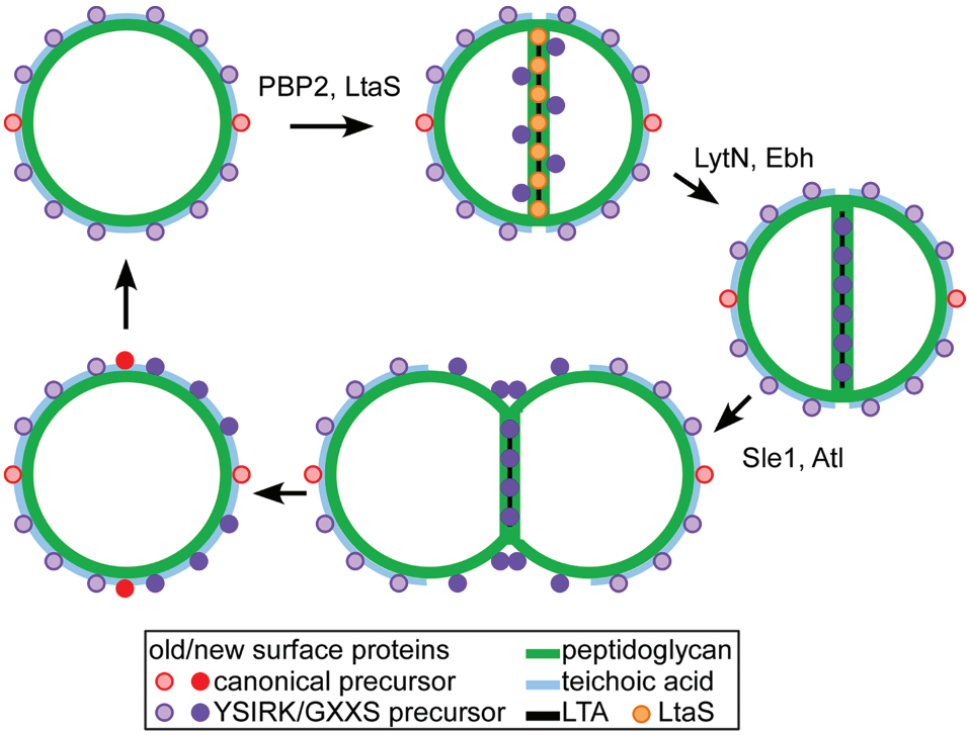

FIGURE 1 Schematic illustrating *S. aureus* cell division, PBP2-mediated synthesis of cross-wall peptidoglycan, LtaS-mediated synthesis of lipoteichoic acid (LTA) in septal membranes, and the trafficking of surface protein precursors with YSIRK-GXXS motif signal peptides (blue circles) to septal membranes. Following translocation, sortase A-mediated cell wall sorting, and incorporation into the cross-wall, the peptidoglycan layer is split and divided cells are separated, exposing cross-wall-incorporated proteins on the bacterial surface. Surface proteins with canonical signal peptides (red circles) are deposited into polar segments of the peptidoglycan layer.

PROTEIN SECRETION

The genome of *S. aureus* carries more than 1,300 genes with products encompassing predicted N-terminal signal peptides (37). When subjected to proteomic analysis, most of these gene products can be identified in the filtered supernatant of centrifuged *S. aureus* cultures (38). Genetic and biochemical experiments characterized the Sec secretion pathway in the model organism *Escherichia coli* (39–41). Elements of this pathway are conserved among all bacteria, including staphylococci (42). Some of the *sec* genes have also been characterized in *S. aureus*. Signal peptide-bearing precursors are translocated across the plasma membrane through the Sec translocon, a complex formed from three membrane proteins, SecY, SecE, and SecG (43). Protein translocation requires SecA, a cytoplasmic ATPase that pushes unfolded precursors through the translocon (44, 45). SecDF, a chaperone whose activity is sustained by the proton motive force, assists in the folding of translocated proteins (46, 47). Similar to *E. coli*, *S. aureus secA* is absolutely essential for bacterial growth and protein secretion, whereas *secDF* is not essential, providing auxiliary functions to protein secretion (48–50). Translocated precursors are cleaved by signal peptidase I, LepB in *E. coli* (51). *S. aureus* carries two signal peptidase I genes, *spsA* and *spsB* (52). SpsB, but not SpsA (it lacks a critical catalytic residue), can substitute for *E. coli* LepB, and expression of *spsB* is required for staphylococcal growth and the cleavage of secreted precursors in *S. aureus* (52). Suppressor mutations that induce expression of a putative ABC transporter (ABC1-3) can restore both growth and precursor secretion in *S. aureus spsB* mutants (53, 54). A physiological role has not yet been assigned to the putative ABC1-3 transporter. SagB glucosaminidase cleaves staphylococcal peptidoglycan to generate short glycan strands with variable lengths $(MurNAc\text{-}GlcNAc)_{3–10}$. *S. aureus sagB* mutants exhibit diminished growth, cross-wall separation defects during cell division, and reduced secretion of proteins into the extracellular medium (19). Thus, the generation of short glycan strands is a prerequisite for the transport of protein across the cell wall peptidoglycan. Three other murein hydrolases—autolysin (Atl amidase and glucosaminidase), Sle1, and LytN (CHAP domain amidases and endopeptidases)—contribute to cell division, cross-wall separation, and likely also to protein secretion across the staphylococcal cell wall envelope (55–59).

PROTEIN ANCHORING TO THE CELL WALL

Surface proteins of staphylococci are covalently linked to peptidoglycan (60). Following translocation of signal peptide-bearing precursors across the plasma membrane, the C-terminal end of surface proteins is cleaved between the threonyl (T) and the glycyl (G) of their LPXTG motif sorting signal by sortase A, which generates a thioester-linked acyl-enzyme intermediate (61–64) (Fig. 2). Nucleophilic attack of the peptidoglycan biosynthetic intermediate, i.e., of the amino-group of pentaglycyl within lipid II, resolves the sortase A acyl-enzyme, synthesizing an amide linkage between the carboxyl group of the C-terminal threonyl of surface proteins and the amino-group of pentaglycyl (65, 66). The surface protein-lipid II intermediate is subsequently incorporated into the peptidoglycan via penicillin binding protein

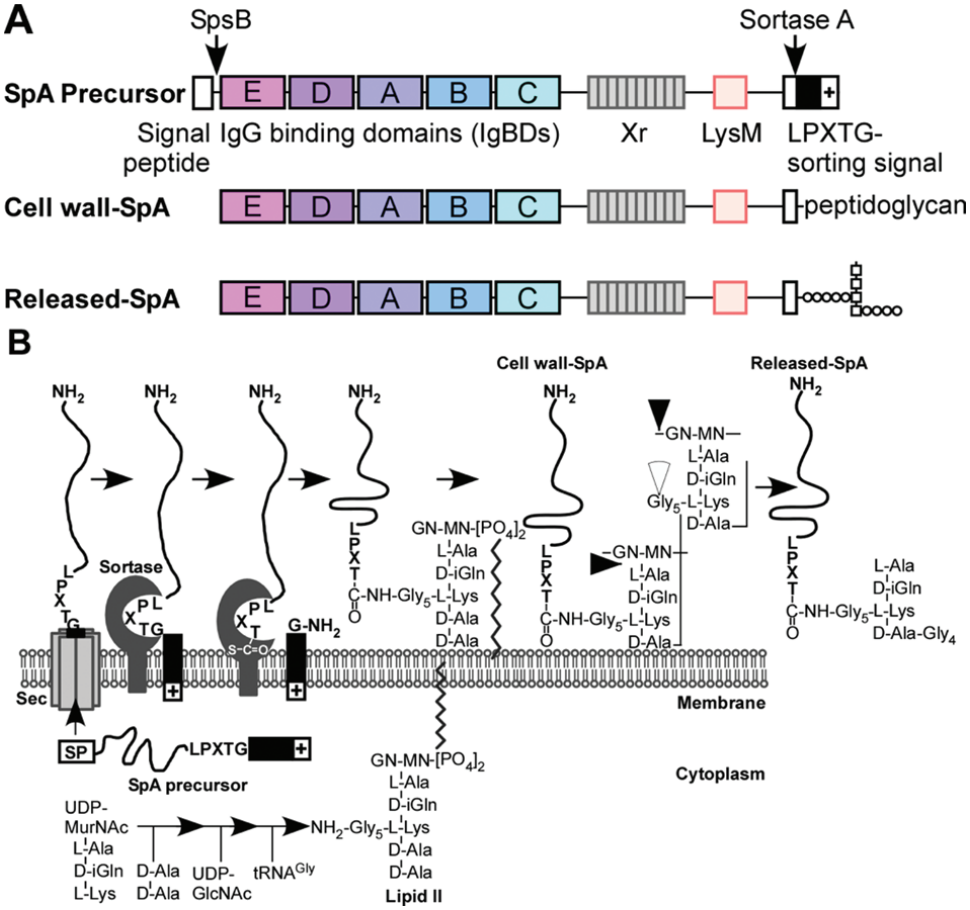

FIGURE 2 Surface protein anchoring to the cell wall of *S. aureus*. **(A)** Primary structure of the precursor for staphylococcal protein A (SpA) with an N-terminal signal peptide, signal peptidase (SpsB) cleavage site, five immunoglobulin binding domains (IgBDs), region X (Xr), LysM domain, and C-terminal LPXTG-motif sorting signal. Cell wall-anchored SpA is tethered to the envelope via an amide bond between the carboxyl-group of its C-terminal threonyl (T in the LPXTG motif) and the amino group of the pentaglycine cross-bridge within peptidoglycan. Released nSpA encompasses murein tetrapeptide-tetraglycyl [L-Ala-D-iGln-(SpA-Gly_5)L-Lys-D-Ala-Gly_4] linked to the C-terminal threonyl of the surface protein. **(B)** Cell wall sorting pathway of surface proteins in *S. aureus*. Following Sec-mediated translocation of surface protein precursors across the membrane, sortase A cleaves the LPXTG-motif of the C-terminal sorting signal between the threonyl (T) and the glycyl (G) residues and forms a thioester bond between its active site cysteinyl and the carboxyl-group of the C-terminal threonyl. The sortase acyl-enzyme intermediate is relieved by the nucleophilic attack of lipid II, thereby generating surface protein linked to peptidoglycan precursor, which is subsequently incorporated by penicillin binding protein 2 into the cell wall peptidoglycan. Through the action of murein hydrolases, surface protein is released from the cell wall into the extracellular milieu.

2-catalyzed transglycosylation and transpeptidation reactions (67) (Fig. 2). Sortase A and surface protein anchoring to the cell wall envelope occur both within the cross-wall compartment and within polar peptidoglycan (68, 69) (Fig. 1). Genome sequences of thousands of isolates reveal between 18 and 23 genes for sortase A-anchored surface proteins in *S. aureus* (70).

PROTEIN SECRETION INTO THE CROSS-WALL COMPARTMENT

Thirteen *S. aureus* surface protein genes encode precursors with YSIRK-GXXS signal peptides, and their products are secreted across septal membranes into the cross-wall compartment (69, 71). Septal secretion promotes abundant deposition and broad distribution of these proteins over the staphylococcal surface (68). In contrast, surface proteins secreted via canonical signal peptides are deposited with low abundance into polar peptidoglycan (69). In addition to sortase A-anchored surface proteins, four other staphylococcal precursors carry YSIRK-GXXS signal peptides: the LytN murein hydrolase (55), the giant protein Ebh (72), and two glycerol-ester hydrolases, GehA and GehB (73). Septal secretion of LytN into the cross-wall promotes cleavage of peptidoglycan and the separation of cells that have completed the division process (55). The 10,421-residue Ebh precursor comprises an N-terminal YSIRK-GXXS signal peptide, a hyperosmolarity resistance domain (residues 179 to 2530), 7 repeats of the 54-residue FIVAR domain (possibly associated with polysaccharide binding), 50 repeats of the

123-residue FIVAR-GA domain, 7 repeats of DUF1542 (a 72-residue domain of unknown function), a putative SMC domain (structural maintenance of chromosomes; residues 8976 to 9576), a transmembrane domain (residues 10227 to 10247), and a positively charged cytoplasmic domain (72). Mutations that abolish *ebh* expression increase staphylococcal cell size and perturb the integrity of the cell wall envelope, suggesting that Ebh is a size determinant for the staphylococcal murein sacculus (72). GehA and GehB are secreted as 72-kDa pro-proteins with 250-residue N-terminal domains that are thought to assist in the folding of C-terminal glycerol-ester hydrolase domains (74). GehA cleaves the ester bonds of short-chain fatty acids within acyl-glycerol, whereas GehB hydrolyzes preferentially long-chain fatty acid esters (75–77). Following cell division, GehB pro-protein is released into the extracellular medium and cleaved by aureolysin, a cysteine protease that is secreted via the canonical Sec pathway (75). A specific role for GehA and GehB during staphylococcal cell division has thus far not been revealed.

During secretion, the precursor of SpA (staphylococcal protein A) is cleaved at Gly^{13}, i.e., between the conserved (underlined) elements of its YSIRKLG^{13}VGIAS motif (50). After translocation across the plasma membrane, SpsB signal peptidase cleaves SpA at Ala^{37}, thereby removing the N-terminal hydrophobic signal peptide (78). Translocated SpA is retained within the secretory pathway by its C-terminal sorting signal and is subsequently anchored to the cell wall envelope (79). Amino acid substitutions in the YSIRK-GXXS motif perturb both the proteolysis and the secretion of SpA precursors, suggesting that cleavage of the YSIRK-GXXS motif is a prerequisite for septal secretion (50). SecA ATPase and SecDF foldase promote the secretion of precursor proteins at septal and polar membranes (50). In contrast, LtaS and LTA synthesis are required for septal, but not polar, secretion in *S. aureus* (50). Thus, synthesis of LTA within septal membranes represents a unique trait of staphylococcal biology that directs precursors with YSIRK-GXXS signal peptides into the cross-wall compartment (Fig. 1). It is not yet clear, however, whether the abundance of LTA, the depletion of phosphatidylglycerol, i.e., the lipid substrate of LtaS, or the accumulation of di-acylglycerol, i.e., the byproduct of LTA synthesis, make specific contributions toward septal secretion. It is also conceivable that septal secretion of GehA and GehB may contribute to the specific features of septal membranes that support trafficking of YSIRK-GXXS precursors into the cross-wall compartment.

RELEASE OF SURFACE PROTEINS FROM THE STAPHYLOCOCCAL ENVELOPE

During staphylococcal growth, cell wall-anchored surface proteins are released from the staphylococcal envelope into the extracellular milieu, where they fulfill specific functions (80). For example, release of SpA requires LytN CHAP amidase and LytM endopeptidase, releasing surface protein with murein tetrapeptide-tetraglycyl [L-Ala-D-iGln-(SpA-Gly_5)L-Lys-D-Ala-Gly_4] linked to the C-terminal threonyl (81) (Fig. 2). Surface proteins of staphylococci fulfill complex biological functions both on the bacterial surface and following their release from the peptidoglycan scaffold by murein hydrolases (82).

STAPHYLOCOCCAL PROTEIN A

All clinical isolates of *S. aureus* harbor the *spa* gene for staphylococcal protein A (SpA), which generates a precursor product composed of an N-terminal YSIRK/GXXS signal peptide followed by 4 or 5 immunoglobulin-binding domains (IgBDs), region X repeats (Xr), an LysM domain, and an LPXTG sorting signal (70, 83, 84). Following septal secretion and anchoring to cross-wall peptidoglycan, SpA is displayed on the bacterial surface (68). The IgBDs of SpA bind to the Fcγ domain of human and animal IgG, effectively blocking effector functions of antibodies, i.e., the binding of C1q complement or the engagement of Fc receptors, thereby inhibiting opsonophagocytic killing of staphylococci (85–87). SpA released from the bacterial envelope crosslinks V_H3 idiotype IgM B cell receptors and promotes the nonproductive proliferation of B cells and secretion of V_H3 idiotype antibodies that do not recognize staphylococcal antigens (88, 89). This B cell superantigen activity requires endocytosis of SpA crosslinked to B cell receptors, signaling via RIPK2 kinase, and $CD4^+$ T helper cell functions (90). The B cell superantigen activity of SpA effectively blocks host adaptive immune responses and the establishment of protective immunity against *S. aureus* (85).

SURFACE PROTEINS AND HEME-IRON TRANSPORT

S. aureus encodes a second sortase gene, designated sortase B (*srtB*) (91). Sortase B cleaves the NPQTN-motif sorting signal of IsdC (iron-regulated surface determinant C) (92). Unlike sortase A, the sortase B acyl-enzyme intermediate is resolved by nucleophilic attack of the amino group of pentaglycyl within polymerized peptidoglycan, thereby anchoring of IsdC to peptidoglycan in the vicinity of the staphylococcal membrane (92). The sortase B anchoring mechanism enables *S. aureus* surface proteins to promote heme-iron scavenging from host hemoglobin and haptoglobin (93, 94). Initially, sortase A-anchored IsdB and IsdH retrieve heme-iron from host hemoproteins (95, 96). IsdA, another sortase A-anchored surface protein, captures the heme-iron from IsdB and IsdH for passage of the nutrient across the staphylococcal cell wall envelope and transfer to IsdC (97). IsdE lipoprotein and IsdF transporter are thought to capture heme-iron from IsdC for import into the bacterial cytoplasm (97, 98). IsdG and IsdI cleave the tetrapyrrol ring of heme to generate staphylobilin and iron for the assembly of iron-sulfur cluster proteins (99, 100). NEAT domains (near-iron transporter domains about 120 residues in length) promote the heme-iron binding and transfer reactions and are found in variable numbers within IsdA, IsdB, IsdC, IsdE, and IsdH (93, 101, 102).

Surface Proteins of *Staphylococcus aureus*

TIMOTHY J. FOSTER

38

INTRODUCTION

Cell wall-anchored (CWA) proteins are characterized by the presence of a sorting signal at the C-terminus which is responsible for coupling the protein covalently to peptidoglycan. The surface of *Staphylococcus aureus* is decorated with up to 24 CWA proteins. The precise number depends on the strain and the growth conditions. The repertoire of CWA proteins expressed by *S. aureus* is limited and many have evolved to perform important interactions with the host. They can be categorized into distinct structural and functional groups (Fig. 1, Table 1). Several are multifunctional due to the proteins comprising distinct domains which recognize different ligands, while for others a single domain is capable of binding different ligands by different mechanisms.

The multifunctionality of CWA proteins has resulted in some confusion over nomenclature, with the original names often referring to the first-assigned function, while in other cases proteins were named *S. aureus* surface protein (Sas) prior to a function being ascribed and were then assigned a new name when a function or structural feature was discovered; e.g., SasH is now called AdsA (extracellular adenosine synthase), and SasA is now SraP (serine-rich surface protein).

This review will describe our current understanding of the structure and functions of CWA proteins of *S. aureus* in adhesion to the extracellular matrix (ECM), invasion of host cells, evasion of immune responses, biofilm formation, and acquisition of iron. The review will include a discussion of posttranslational modifications that contribute to function and will describe the contribution of CWA proteins to colonization of the host and to pathogenesis.

CWA PROTEINS: STRUCTURE AND FUNCTION

Several distinct structural and/or functional classes of CWA protein occur in *S. aureus* (Fig. 1, Table 1). N-terminal domains are projected away from the cell surface and are the part of the protein that is usually engaged in interactions with the host. An important exception is the fibronectin binding repeats of fibronectin binding proteins (FnBPs), which are located toward the C-terminus.

The MSCRAMM Family

"Microbial surface components recognizing adhesive matrix molecules" (MSCRAMMs) is a term that was originally applied to CWA proteins that bind to host proteins from the ECM, such as fibrinogen and fibronectin (1). It has become widely used to encompass all CWA proteins whether or not they bind ECM molecules. It was recently proposed that the term "MSCRAMM" should be reserved for proteins with a common structure motif, *viz.*, two adjacent IgG-like folds and similar mechanisms of ligand binding exemplified by dock lock latch (DLL) and the collagen hug (2).

Ligand binding by DLL: the basic mechanism

Proteins in the Clf-Sdr subfamily of MSCRAMMs have an N-terminal A domain comprising three subdomains called N1, N2, and N3, with N2 and N3 being the minimum required for ligand binding by DLL. The N2 and N3 subdomains each comprise two β-sheets that are arranged in a variation of the IgG fold called DEv-IgG (3). The DLL mechanism was originally defined by analyzing the structure of the *Staphylococcus epidermidis* protein SdrG in the apo form and in complex with the β-chain peptide of fibrinogen (4). The same mechanism was found to apply to clumping factor A (ClfA) and the A domains of FnBPA and FnBPB binding to the γ-chain peptide of fibrinogen and to ClfB binding to cytokeratin 10, loricrin, and the α-chain of fibrinogen (5–7).

In essence, an unfolded peptide ligand binds to the open form of the MSCRAMM in a hydrophobic trench located between the N2 and N3 subdomains (Fig. 2). This stimulates a conformational change which results in the unfolded extension of N3 covering the peptide to lock it in place and creating the latch by forming an extra β-strand in one of the β-sheets of N2 by β-strand complementation (2, 4). The peptide ligand binds β-strand G′ in N3 through backbone interactions while side chains of residues in the peptide and residues in the binding trench of the MSCRAMM determine binding specificity.

Recent studies using atomic force microscopy showed that the rupture force of SdrG in complex with fibrinogen is very high, being equivalent to that of a covalent bond (8). Similar forces were required to separate cells expressing Cna binding to collagen (9) and ClfB expressing cells binding to loricrin (10). In the latter the strength of the interaction between ClfB and loricrin increased when mechanical forces were applied, suggesting that shear forces might induce the conformational changes involved in DLL. When the MSCRAMM is attached to the surface of a staphylococcal cell, these changes must result in considerable reorientation of the protein (Fig. 3) with implications for binding to other ligands (see section FnBPs bind plasminogen).

doi:10.1128/microbiolspec.GPP3-0046-2018

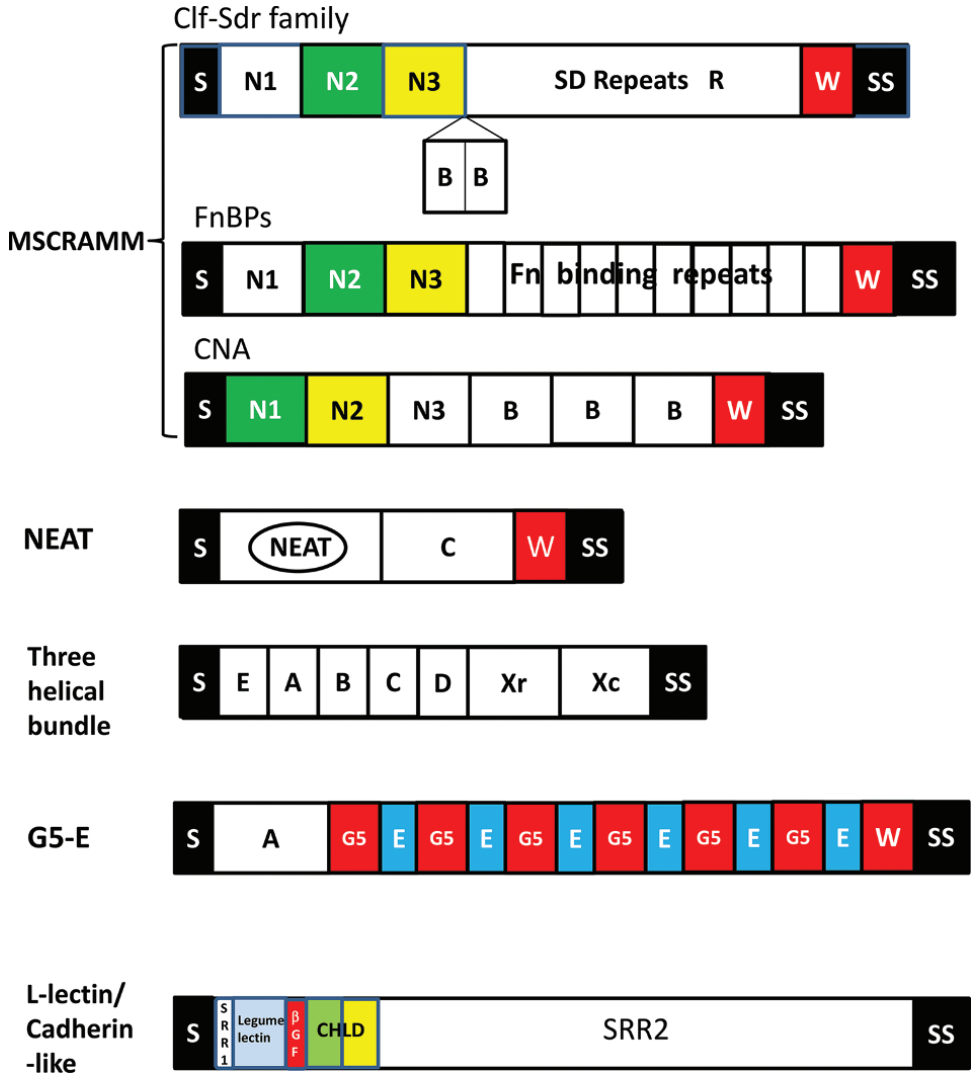

FIGURE 1 CWA surface proteins classified based on structural motifs. The primary translation products of all CWA proteins contain a signal sequence (S) at the amino terminus and a wall-spanning region (W, Xc) and sorting signal (SS) at the carboxyl terminus. The CWA proteins that are depicted are those for which structural analysis has facilitated classification into five distinct groups. (A) Microbial surface components recognizing adhesive matrix molecules (MSCRAMMs). The clumping factor (Clf)-serine aspartate repeat (Sdr) group comprises proteins that are closely related to ClfA. ClfA and ClfB have a similar domain organization, whereas SdrC, SdrD, and SdrE contain additional B_{SDR} repeats that are located between the A domain and the serine-aspartate SD repeat R region. The N-terminal A region contains three separately folded domains, called N1, N2, and N3. Structurally, N2 and N3 form IgG-like folds that bind ligands by the DLL mechanism. Fibronectin-binding protein A (FnBPA) and FnBPB have A domains that are structurally and functionally similar to the A domain of the Clf-Sdr group. Located in place of the serine-aspartate repeat region are tandemly repeated fibronectin-binding domains (11 in FnBPA, 10 in FnBPB). The A region of the collagen adhesin (Cna) protein is organized differently than other MSCRAMMs, with N1 and N2 comprising IgG-like folds that bind to ligands using the collagen hug mechanism. The A region is linked to the wall-spanning and anchorage domains by variable numbers of B_{CNA} repeats. (B) Near iron transporter (NEAT) motif protein family. The iron-regulated surface determinant (Isd) proteins have one (for IsdA), two (for IsdB), or three (for IsdH) NEAT motifs that bind to hemoglobin or heme. The figure depicts IsdA, which has a C-terminal hydrophilic stretch that reduces cell surface hydrophobicity and contributes to resistance to bactericidal lipids and antimicrobial peptides. (C) Three-helical bundle motif protein A. The five N-terminal tandemly linked triple-helical bundle domains (known as EABCD) that bind to IgG and other ligands are followed by the repeat-containing Xr region and the nonrepetitive Xc region. (D) G5-E repeat family. The alternating repeats of the G5 and E domains of *S. aureus* surface protein G (SasG) (and the accumulation-associated protein [Aap] from *S. epidermidis*) link the N-terminal A region to the wall-spanning and anchorage domains. If the A domain is removed, the G5-E region can promote cell aggregation. (E) Legume-lectin, cadherin-like domain protein. The BR region of the serine rich adhesin of platelets (SraP) protein is flanked by serine-rich repeat domains. The BR region comprises three distinct structural domains: the legume lectin-like, the β-grasp fold (β-GF), and the cadherin-like (CHLD) domains.

Ligand binding by DLL: variations on a theme

Several subtle variations on the DLL theme have been observed. Both parallel and antiparallel orientations of ligand peptide binding to the trench occur (SdrG parallel; ClfA and ClfB antiparallel), which results in the ligands binding in opposite orientations with respect to the MSCRAMM (3, 4, 7).

The ligand residues bound by SdrG and ClfB have extensive flanking residues located both C-terminally and N-terminally and thus can only bind to the open apo form of the MSCRAMM. In contrast, the ClfA ligand binding residues occur at the extreme C-terminus of the γ-chain of fibrinogen and are able to penetrate the MSCRAMM in the locked position (11).

ClfA has a second binding site on fibrinogen in addition to the γ-chain peptide (12). The epitope for the monoclonal antibody tefibazumab that blocks binding of ClfA to fibrinogen was mapped to a location on the "top" of subdomain N3 well away from the ligand binding trench involved in DLL. Molecular modeling predicted that tefibazumab partially blocks a second fibrinogen binding site involving the fibrinogen γ-globule and that this is required for high-affinity binding to the ligand (Fig. 3). Indeed, tefibazumab has a high affinity for ClfA but has only a half maximal inhibitory concentration for blocking ClfA binding to fibrinogen. Studies with ClfA variants showed that high-affinity binding requires the two sites to act cooperatively in a complex multicontact binding mechanism. It is possible that other MSCRAMMs bind ligands by similar multistep mechanisms, particularly where the affinity of a peptide is lower than the full-length protein. Ultimately, proof of two binding sites requires x-ray crystal structures of the proteins in complex.

SdrE binds to the host recognition C-terminal unit 20 of the complement control protein factor H by a variation of DLL called "closed dock lock latch" (13). In SdrE the ligand binding trench is occluded by loop A-B that protrudes from N2 forming four main chain H bonds with β-strand G′ in N3. For the factor H unit 20 to bind by DLL, it must first displace the AB loop, which is flipped out of the way (Fig. 4).

ClfB binds several ligands by DLL

ClfB binds to cytokeratin 10, loricrin, and the α-chain of fibrinogen by DLL (5, 7, 14). Thus, several different ligands can be accommodated by the same binding trench. This has allowed the definition of a consensus ligand binding sequence (7). Another example is the A region of FnBPA and FnBPB, which can bind to elastin as well as the γ-chain peptide of fibrinogen like ClfA (15, 16). However, this conclusion resulted from the study of FnBP variants with substitutions in residues predicted to be involved in DLL and not from x-ray crystal structures. It is possible that other MSCRAMMs bind several different ligands by DLL.

Collagen binding

The collagen binding protein Cna binds collagen by a variation of the DLL mechanism called the collagen hug (17). The N1 and N2 subdomains of the A region of Cna are composed of IgG-like folds and perform roles corresponding to the N2 and N3 subdomains of other MSCRAMMs, with the C-terminal extension of N2 forming the latch (Fig. 5).

The linker separating N1 and N2 is long and is able to accommodate the thick rod of the collagen triple helix. The ligand binds to a shallow trench in N2. This stimulates a conformational change, which enables the linker to wrap around collagen. Latching then takes place by β-strand complementation between the C-terminal extension of N2 and a β sheet in subdomain N1 (17).

Cna also binds to complement factor C1q

The complement pathway is initiated when complement protein C1q binds to antibodies attached to the surface of a pathogen. C1q forms a bouquet-like structure that is composed of six identical heterotrimers, each comprising a globular head that forms the antibody recognition domain and a long collagenous triple helix (Fig. 6) (18). These coalesce to form a stalk. The C1r and C1s proteins are associated with the C1q complex and are necessary for initiating the complement cascade. Cna can bind to the C1q triple helices and displace C1s-C1r, resulting in inhibition of complement fixation (19). The collagen hug mechanism is most likely to be involved because Cna variants with reduced collagen binding also bind C1q with lower affinity. Thus, Cna and other members of the Cna family can act both as adhesins to collagenous tissue and as immune evasion factors by inhibiting complement fixation.

SdrC and FnBPs engage in homophilic interactions and promote biofilm formation

The MSCRAMMs SdrC, FnBPA, and FnBPB can promote cell-cell attachment and biofilm formation (20–22). In both cases the A domains on adjacent cells undergo homophilic interactions (Fig. 7). SdrC subdomain N2 has two interaction sites that were identified by screening phage display libraries for inhibitory peptides (21). Molecular modeling showed that a β-neurexin peptide which binds SdrC occludes one of the interaction sites and can prevent biofilm formation (23, 24). Studies with bacterial cells expressing FnBPs and variants thereof confirmed that the A domains are required for biofilm formation and that in the case of FnBPA, the ability to engage in DLL is not involved (20).

Atomic force microscopy has been employed to study forces involved in interactions between MSCRAMMs either with the atomic force microscopy cantilever tip conditioned with the purified A domain protein or with a single bacterial cell. It was concluded that cell-cell binding results from multiple weak interactions between proteins occurring in parallel between molecules on two individual cells (23, 25). The rupture force required to separate a single CWA protein-protein interaction was very low compared to that required to separate an MSCRAMM from a ligand bound by DLL or the collagen hug. Weak interactions might facilitate detachment of bacterial cells from the mature biofilm and their dissemination.

In the case of SdrC, the A domain can also promote attachment to hydrophobic surfaces and could thus be involved both in attachment to an indwelling medical device and in biofilm accumulation (23).

FnBPs bind plasminogen

Several CWA proteins contribute to the ability of *S. aureus* cells to capture plasminogen from serum (26). Mutants lacking FnBPs are only partially defective in plasminogen binding, whereas a sortase A defective mutant lacking all CWA proteins binds very little. Thus, the full repertoire of CWA proteins that bind plasminogen is not known, with the two studies published so far focusing only on FnBPs (26, 27). The A domain of all seven isoforms of FnBPB bind plasminogen with similar affinity (26). Binding of FnBPB was inhibited by ε-amino caproic acid and lysine, which implies that binding occurs between lysine residues on the MSCRAMM and negatively charged residues on plasminogen. Indeed, alanine substitutions of the two conserved patches of lysines in FnBPB N2 resulted in reduced plasminogen binding. The ability of whole cells expressing FnBPs to bind to plasminogen is greatly enhanced by fibrinogen

TABLE 1 Properties of CSA surface proteins[a]

Protein structural and functional group	Ligand and binding mechanism	Function	References
MSCRAMM family			
Clumping factor A (ClfA)	Fibrinogen γ chain C-terminus (DLL)	Adhesion to immobilized fibrinogen, immune evasion by binding soluble fibrinogen	3, 11
	Complement factor I Mechanism unknown	Immune evasion, degradation of C3b	130, 131
Clumping factor B (ClfB)	Fibrinogen α-chain repeat 5, keratin 10 and loricrin (DLL)	Adhesion to desquamated cells from nares and from skin of AD patients; nasal colonization and colonization of AD skin	5, 7, 14, 118, 150
Serine aspartate repeat protein C (SdrC)	β-neurexin (DLL)	Unknown	23, 24
	Unknown	Adhesion to desquamated epithelial cells Nasal colonization?	93
	SdrC	Homophilic SdrC-SdrC interaction; biofilm formation	21, 23
Serine aspartate repeat protein D (SdrD)	Desmoglein-1 Mechanism unknown	Adhesion to desquamated epithelial cells Nasal colonization?	93, 120
Serine aspartate repeat protein E (SdrE)	Complement factor H	Immune evasion, degradation of C3b	132
	Close DLL		13
Bone sialoprotein binding protein (isoform of SdrE)	Fibrinogen α-chain (DLL)	Adhesion to immobilized fibrinogen	151
Fibronectin binding protein A and B	FnBPA A domain binds fibrinogen γ-chain C-terminus and elastin (FnBPA A domain, DLL)	Adhesion to ECM	6, 16, 152
A domains			
	FnBPB A domain also binds fibronectin but not by DLL		152
	FnBPA, FnBPB	FnBPA-FnBPA A domain homophilic interaction; biofilm formation	20, 25
Fibronectin binding repeats	Fibronectin, tandem β-zipper	Adhesion to ECM Invasion of mammalian cells	73–75, 86, 153
Collagen binding protein (Cna)	Collagen triple helix (CH)	Adhesion to collagen-rich tissue	17
	Complement protein C1q (CH)	Prevent classical pathway of complement activation	19
	Laminin	Adhesion to basement membrane	154
NEAT motif family			
Iron-regulated surface protein A (IsdA)	Heme, fibrinogen, fibronectin, cytokeratin 10, loricrin (N-terminal NEAT motif region)	Heme uptake and iron acquisition	64
		Adhesion to desquamated epithelial cells	65, 119, 155
	Unknown ligand(s); C-terminal domain NEAT motif region	Resistance to lactoferrin	156
		Resistance to bactericidal lipids and antimicrobial peptides Survival in neutrophils	66
IsdB	Hemoglobin, heme (N-terminal NEAT motif region)	Heme uptake and iron acquisition	64, 157
	β3 integrins (NEAT motif regions)	Invasion of nonphagocytic cells	68
IsdH	Heme, hemoglobin (N-terminal and/or C-terminal NEAT motif region)	Heme uptake and iron acquisition	69

[a]AD, atopic dermatitis; CH, collagen hug; CHDL, cadherin-like domain; C1q and C3a, complement components; DLL, dock lock latch; ECM, extracellular matrix; FIVAR, found in various architectures; NEAT, near iron transporter; MRSA, methicillin-resistant *S. aureus*; *S. aureus* surface protein, Sas; Pls, plasmin-sensitive; SraP, serine-rich repeat protein.

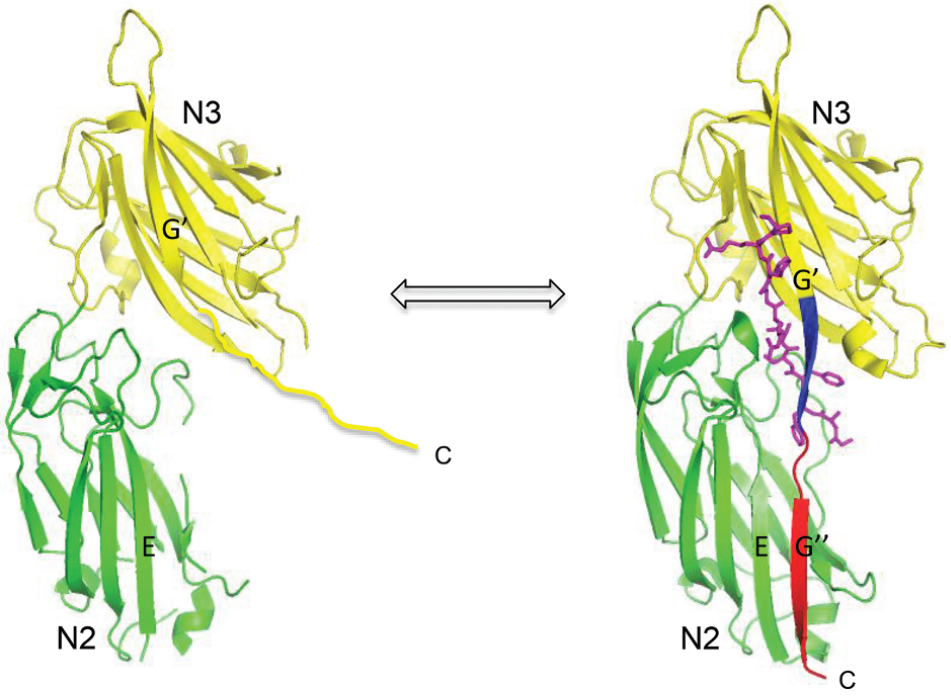

FIGURE 2 MSCRAMM binding to ligand by DLL. Ribbon diagram showing the structure of the N2 (green) and N3 (yellow) subdomains of SdrG in the apo form and in complex with a peptide from the β-chain (purple) of fibrinogen following ligand binding by the DLL mechanism. The C-terminal extension of N3 in the apo form undergoes a conformational change following ligand binding, resulting in an additional β-strand in a β-sheet in subdomain N2 forming the latch (red) and lock (blue). The letters refer to β-strands.

(27). This implies that the conformational changes that occur when fibrinogen binds FnBPA by DLL reorients the cell-bound MSCRAMM and exposes the plasminogen binding domain (Fig. 3).

It is likely that MSCRAMMs and, indeed, other CWA proteins are also able to bind several ligands. Indeed, the A domain of FnBPB can also bind to fibronectin by a mechanism that does not involve DLL (15).

Functions of other regions of MSCRAMMs

The SdrC, SdrD, and SdrE proteins have two or more repeated domains of 110 to 113 residues (B_{SDR}) located between the A region and the SD region (Fig. 1) (28). The B_{SDR} repeats are folded separately and form rigid rod-like structures that depend on Ca^{2+} for their structural integrity. They have no known ligand binding activity (29), although the related B_{SDR} region of SdrF from *S. epidermidis* can bind weakly to collagen (30).

It has been suggested that the B1 domain of SdrD makes contact with the adjacent N3 subdomain of region A, resulting in the ligand binding groove between N2 and N3 opening further than seen in the structure of the A domain alone, which possibly influences binding activity (31).

Cna proteins have 2 to 4 repeats of the B_{Cna} domain (Fig. 1) that are not related to the B repeats of Sdr proteins. Atomic force microscopy studies of bacteria expressing Cna proteins on their surface indicated that the B repeats act as nanosprings that project the A domain from the cell surface to facilitate the conformational changes required for the A domain to engage in ligand binding by the collagen hug (9). The B_{SDR} repeats might have a similar function.

Flexible stalks

MSCRAMMs from the Clf-Sdr family are attached to the cell wall via long flexible unfolded peptides comprising either serine-aspartate dipeptide repeats (ClfA, ClfB, SdrC, SdrD, SdrE) or 10/11 tandem repeats of ~38 residues that bind fibronectin by the tandem β-zipper mechanism (see below). The SD repeats of ClfA act like a stalk that projects the N-terminal ligand binding A domain away from the cell surface (32). Bacteria expressing ClfA truncates lacking SD repeats bound fibrinogen less avidly, perhaps because the A region was impaired by the proximity of the cell surface and could not undergo the conformational changes required for DLL.

Posttranslational modifications

The Sdr proteins are glycosylated by the action of the glysosyltransferases SdgA and SdgB that are encoded by genes located near the *sdrCDE* locus (33). They attach two *N*-acetylglucosamine molecules to serines in the SD repeat domain in a stepwise fashion (Fig. 3). Glycosylation creates a dominant epitope for human antibodies, which can represent up to 1% of IgG. Glycosylation protects the MSCRAMMs from degradation by host proteases such as the neutrophil cathepsin G and could thus contribute to virulence (33). Indeed, Sdg mutants have reduced virulence in a mouse sepsis infection model (34).

The Pls protein encoded by the type I staphylococcal cassette chromosome *mec* (SCC*mec*) element has a short C-terminal SD repeat region that is glycosylated by a combination of glycosyltransferases encoded by the genes *gtfC* and *gtfD*, which that are closely linked to the *pls* gene in SCC*mecI* along with SdgA and SdgB (35). Proteases can

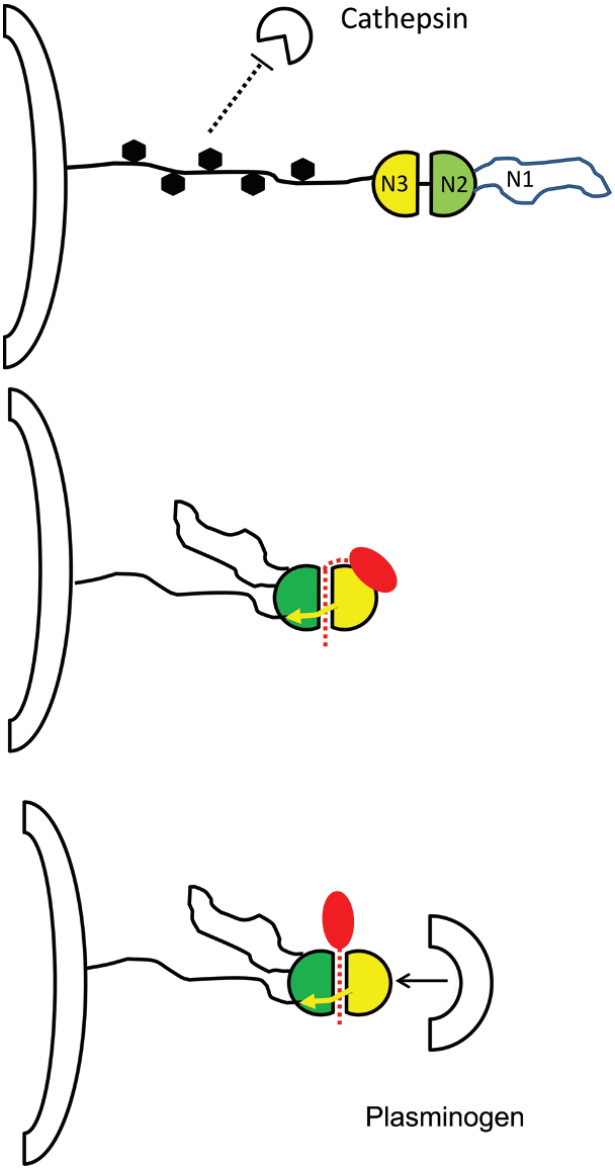

FIGURE 3 Schematic diagrams of MSCRAMMs before and after ligand binding. The top figure depicts an MSCRAMM in the apo form with the N2 (green) and N3 (yellow) subdomains shown as semicircles and the unstructured N1 subdomain. Serine residues in the flexible stalk are glycosylated, which prevents degradation by cathepsin. The middle diagram shows the conformational change in an MSCRAMM with respect to the bacterial cell that occurs following ligand binding by DLL. The C-terminal γ-chain peptide of fibrinogen is depicted by the red dashed line, and the gamma globule domain is in contact with the second ligand binding site in ClfA subdomain N3. It is not known if other MSCRAMMs have two binding sites on their ligands. The bottom diagram indicates that binding to fibrinogen by FnBPs exposes the N3 subdomain to plasminogen, which binds the MSCRAMM more efficiently in the presence of fibrinogen.

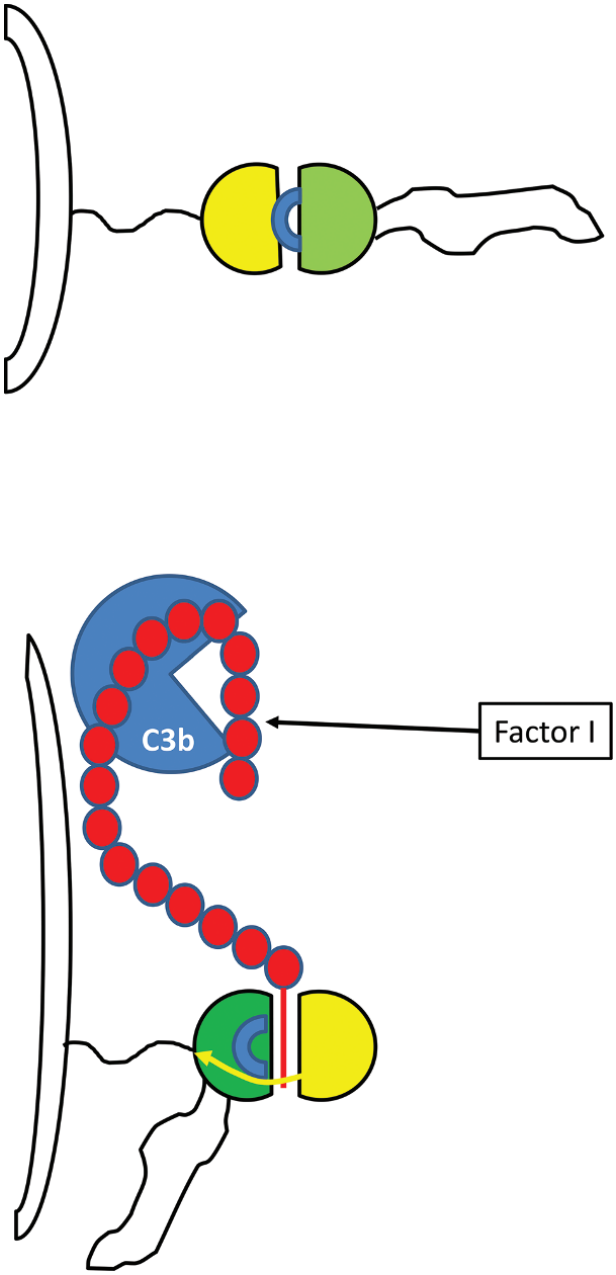

FIGURE 4 SdrE binding to complement factor H. The top figure shows SdrE in the apo form with the unstructured N1 subdomain and the N2 and N3 subdomains (yellow and green semicircles, respectively). The loop that occludes the ligand binding trench is shown in blue. The bottom figure shows the conformational changes that occur when complement factor H binds by closed DLL. Factor H (red) can then engage nearby C3b molecules (blue) and facilitate binding and activation of the protease factor I, which cleaves C3b.

remove subdomain N1 from MSCRAMMs. The staphylococcal protease aureolysin cleaves close to the boundary between subdomains N1 and N2 of ClfA and ClfB, while the host protease thrombin removes the N1 subdomain of FnBPA. Following removal of N1, ClfB can no longer bind to fibrinogen (36). It is possible that removal of subdomain N1 also reduces the capacity of *S. aureus* to adhere to loricrin and cytokeratin 10 since these ligands share a common binding site in ClfB. The molecular basis for the loss of ligand binding is not known (7). The biological significance of the removal of subdomain N1 from ClfA and FnBPA is unclear since it does not reduce the ability of FnBPA to promote biofilm accumulation or the ability of ClfA and FnBPA to mediate

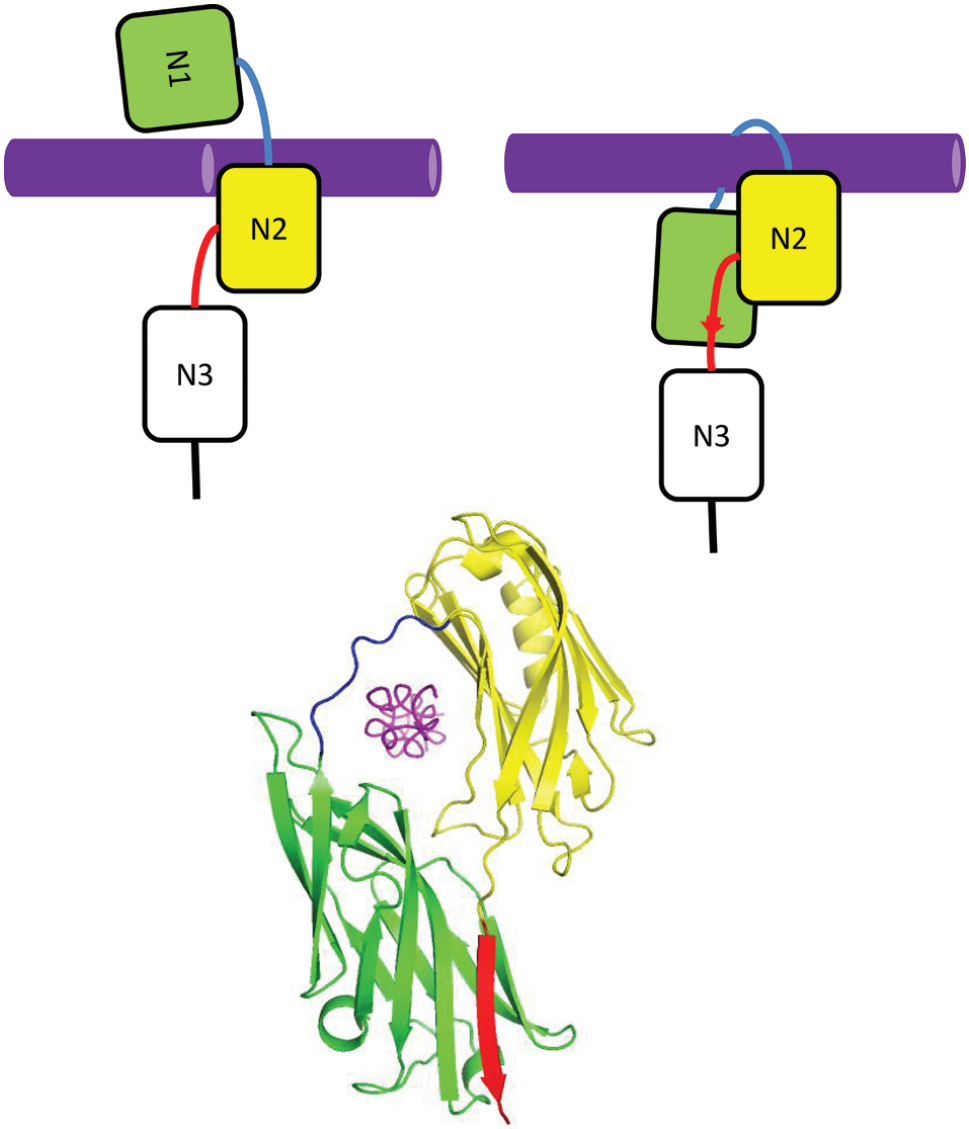

FIGURE 5 Collagen binding protein and the collagen hug. The upper part shows a schematic diagram of the Cna protein in the apo form on the left and following binding by the collagen hug to the collagen triple helix on the right. Below is a ribbon diagram of the Cna protein in complex with the collagen triple helix. The N1 subdomain (green) and N2 subdomain (yellow) are separated by a long unfolded region (blue) that forms the lock around collagen (purple). β-strand complementation by the red strand completes the hug.

adherence to fibrinogen (20, 37). Under certain conditions, FnBPs are degraded by the *S. aureus* protease V8 (38).

G5-E Repeat Proteins

Three staphylococcal proteins are characterized by the presence of G5-E repeats: SasG and Pls of *S. aureus* and Aap of *S. epidermidis*. Pls is encoded within the type I SCC*mec* cassette and is therefore only expressed by hospital-associated methicillin-resistant *S. aureus* strains carrying that element (39).

The proteins form highly extended fibrillar structures due to the unusual properties of the G5-E repeats and are able to mask the ability of shorter adhesins such as ClfA and FnBPs to promote adhesion to the ECM or invasion of mammalian cells (40–43). The G5-E repeats can also engage in homophilic interactions and promote biofilm formation (see below).

The N-terminal A domains of these proteins bind to cornified squamous epithelial cells by recognizing as yet unknown ligands and thus might contribute to nasal colonization (41, 43, 44). The A domain of Aap also promotes adhesion to hydrophobic surfaces in the initiation of biofilm formation by *S. epidermidis* (45, 46).

The ability to form very strong and stable (long and strong) extended structures is an unusual property of the intrinsically unstable repeated region (47–49). Both the G5 and E domains comprise two triple-stranded β-sheets with a central collagen-like triple helical region (Fig. 8). When an E domain is expressed alone or combined with a single G5 domain, the proteins are intrinsically disordered and

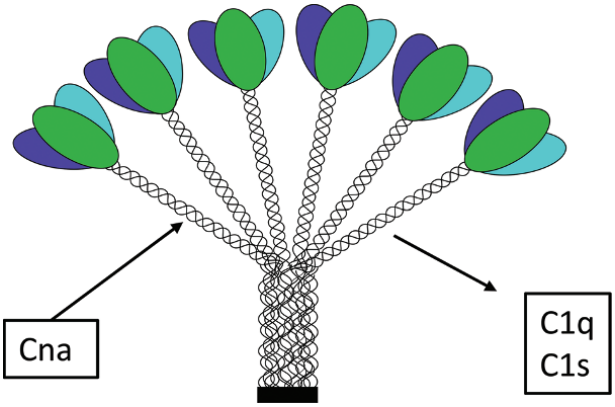

FIGURE 6 Complement protein C1q. C1q is a complex of six identical heterotrimers that form a bouquet-like structure. The globular domains (blue, green, and cyan ovals) make up the six IgG binding sites. Each heterotrimer forms an extended collagen-like triple-helix stalk which coalesces into a complex stem. C1r and C1s bind to the triple-helix region and are displaced when Cna binds. The figure was kindly provided by Nicole Thielens, CNRA-CFE-Université Joseph Fournier, Grenoble, France.

unfolded (47). However, a $G5_1$-E-$G5_2$ moiety folds to form an elongated structure. When $G5_2$ folds, it triggers folding of the central E domain, which in turn promotes folding of $G5_1$. Thus, the entire repeat region can be considered to comprise overlapping G5-E-G5 cooperative folding units.

Cell-cell adhesion and biofilm formation can be promoted by G5-E repeats. First, the N-terminal A domain must be removed by proteolysis (49–51). Only then can the folded G5-E repeats engage in the homophilic interactions involving multiple contacts along the lengths of the two molecules. Molecular modeling suggested that the G5-E domains twist around each other in a twisted rope-like structure (Fig. 7). Atomic force microscopy allowed measurement of the forces involved in cell-cell interactions, and in cases where full engagement was likely to have occurred, separation required

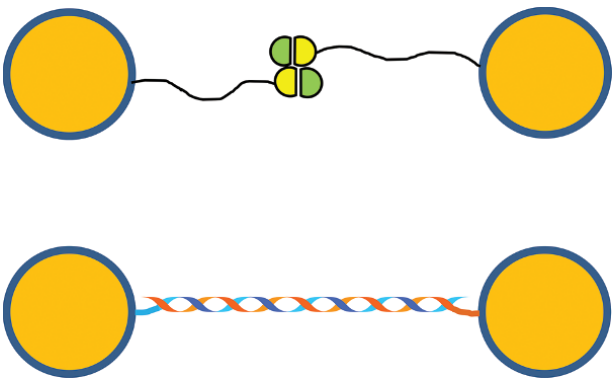

FIGURE 7 Homophilic interactions and biofilm formation. The upper part shows a schematic diagram of the model for homophilic interactions between the A domains of the MSCRAMMs FnBPA, FnBPB, and SdrC, which promote cell-cell accumulation of staphylococcal cells (yellow spheres) during biofilm formation. See Fig. 2 and 3 for the key. The lower part shows the extended fibrillar region of SdrG and Aap (orange and blue strands), which form extended zinc-dependent zipper interactions predicted to form a twisted rope-like structure.

the two proteins to become unwound by successively unfolding the E and G5 subdomains (52).

Protein A, a Protein Comprising Three-Helical Bundle Repeats

The N-terminal region of protein A (Spa) comprises a tandem array of five separately folded three-helical bundles, each of which can bind to several different ligands (Fig. 1, Table 1). The A1 domain of von Willebrand factor, tumor necrosis factor receptor 1, and the Fc region of IgG each bind to the interface between helices 1 and 2, while the Fab region of IgM binds to the interface of helices 2 and 3 (53–56). The three-helical bundles of Spa can exist in slightly different conformations, a conformational plasticity that facilitates binding to structurally diverse ligands (57). Upon binding to the Fc region of IgG, there is considerable loss of conformational heterogeneity combined with structural rearrangements at the interface.

Located between the helical bundle domains and the cell wall-spanning region Xc is a an octapeptide repeat region Xr, which is highly variable in number. Region Xr is proinflammatory by activating interferon-β expression (58).

The *S. aureus* binder of Ig Sbi (59) contains four tandemly arrayed three-helical bundles, two of which can bind to IgG in a way similar to Spa. Sbi associates with the cell envelope by binding noncovalently to lipoteichoic acid (60). This allows the most N-terminal repeats to be exposed on the cell surface and to contribute to immune evasion. The C-terminal repeats are buried but are biologically active in promoting fruitless consumption of complement protein C3 when released into the medium (61).

The NEAT Motif Family

The near iron transporter (NEAT) domain proteins capture heme from hemoglobin and contribute to the survival of bacteria in the human host, where iron is restricted. Heme is transported by several CWA iron-regulated surface (Isd) proteins to the membrane transporter. Once in the cytoplasm, heme oxygenases release free iron (62, 63). The defining feature of Isd proteins is the presence of one or more NEAT motifs, which bind either hemoglobin or heme. The structures of NEAT domains have been solved and the molecular mechanisms of ligand binding elucidated (64).

Isd proteins have additional functions other than transport of heme. IsdA promotes adhesion to squamous epithelial cells and promotes nasal colonization (65). The C-terminal domain of IsdA also confers resistance to bactericidal lipids (66). IsdB binds directly to β3-containing integrins and promotes platelet activation and invasion of mammalian cells (67, 68). IsdH helps *S. aureus* to avoid phagocytosis by promoting degradation of complement opsonin C3b by an as yet unknown mechanism (69).

The Legume Lectin Domain of SraP

The serine-rich adhesin of platelets (SraP) is a member of a family of glycoproteins in Gram-positive cocci (70). The structural gene *sraP* is included in a locus comprising genes that encode glycosyltransferases (GtfA and GtfB) and accessory secretion factors (SecY2 and SecA2). A short serine-rich repeat region (SSR1) is located at the N-terminus of the CWA protein followed by the ligand binding BR domain (Fig. 1). The BR domain is composed of four separately folded subdomains that form a rigid bent rod (71). Two cadherin-like domains and a β-grasp fold domain act to project the legume-lectin domain. This has structural similarity to

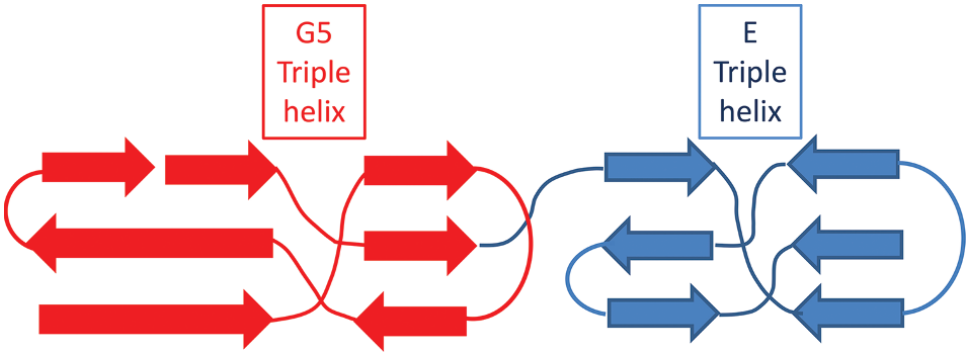

FIGURE 8 G5-E domains of SasG and Aap. The G5 (red) and E (blue) domains each form two triple-stranded β-helices separated by a short collagen-like triple helix.

legume lectins and binds *N*-acetyl neuraminic acid (Neu5Ac) containing glycoproteins that are attached to the surface of mammalian cells. It also binds to salivary glycoprotein gp340, which is rich in a 5NeuAc containing trisaccharide (72). SraP promotes bacterial adhesion to and invasion of mammalian cells (71). This was apparent using an experimental system where there was little or no fibronectin present and employing a strain that expressed low levels of FnBPs. Thus, there was minimal involvement of the highly efficient FnBP-mediated uptake (see below). SraP, like IsdB, might act as an accessory invasin. The cadherin-like domains dimerize in solution and promote cell-cell accumulation and biofilm formation (71).

The Tandem β-Zipper Binding to Fibronectin Promotes Invasion of Mammalian Cells

S. aureus can invade many types of mammalian cells that do not normally engage in phagocytosis, such as various epithelial cells, endothelial cells, fibroblasts, osteoblasts, and keratinocytes (73–80). This allows bacteria to evade host immune defenses and antibiotics. Bacteria can escape into the cytosol by lysing the phagosomal membrane and then multiply before eventually destroying the integrity of the cell and being released. In some cases staphylococci enter a semidormant state called the small colony variant (81). Small colony variants do not express cytolytic toxins, so the invaded cell stays intact. Small colony variants express FnBPs at high levels, which facilitates efficient uptake into nearby cells when they are released (82).

Fibronectin is a dimeric glycoprotein comprising three distinct domains: FI, FII, and FIII (83). In plasma fibronectin exists in a compact state which is held together by intramolecular interactions between F1 modules in the N-terminal domain and FIII modules in the C-terminal cell binding domain. The binding of FnBP to FI modules in the N-terminal domain of fibronectin by the tandem β-zipper mechanism (Fig. 9) forces a conformational change in fibronectin (84). This exposes a cryptic RGD integrin binding site in the 10th FIII module. This RGD motif is recognized by α5β1 integrins on the surface of mammalian cells. In this way, fibronectin acts as a bridge between *S. aureus* and host cells. Clustering of integrins triggers intracellular signaling by the focal adhesion kinase and Src kinase and subsequently endocytosis (77, 85, 86).

Nucleotidase Motif

A nucleotidase motif was discovered in a previously uncharacterized CWA protein called SasH. It was shown to be enzymatically active and, importantly, to contribute to the ability of *S. aureus* to evade innate immune responses in the infected host (87, 88). The ability of SasH (now called adenosine synthase [AdsA]) to convert intracellular ATP to the potent immunoregulatory molecule adenosine inhibited the oxidative burst and promoted survival within neutrophils.

Neutrophils also contribute to the host defenses by releasing DNA, which forms neutrophil extracellular traps (89). These can entrap bacteria and facilitate killing by their attached granule contents and histones. *S. aureus* expresses an extracellular deoxyribonuclease which degrades neutrophil extracellular trap DNA producing phosphomononucleotides, including 2′ deoxyadenosine 3′ monophosphate (dAMP) (90, 91). AdsA converts dAMP to 2′ deoxyadenosine, which triggers caspase 3-promoted apoptosis in macrophages and monocytes (90). By excluding macrophages from a developing abscess, AdsA helps to promote persistent infection.

CWA PROTEINS AS COLONIZATION AND VIRULENCE FACTORS

Investigating the Contribution of CWA Proteins to the Virulence of *S. aureus*

To investigate if a CWA protein can act as a virulence factor, a mutant defective in the protein can be isolated and its virulence compared to the wild type in an appropriate animal infection model. However, functional redundancy sometimes makes it difficult to show conclusively that a mutant lacking a single factor has reduced virulence. For example, *S. aureus* expresses several CWA proteins that bind fibrinogen, and most strains elaborate two fibronectin binding proteins. Another approach is to express the CWA protein in a surrogate host such as *Lactococcus lactis* (14, 92–94) or *Staphylococcus carnosus* (95). Until recently, it was difficult to isolate mutations in most clinically relevant strains, so earlier studies of the role of CWA proteins were performed with laboratory strains such as Newman and derivatives of NCTC8325. However, it is now possible to circumvent the restriction barriers that prevent transfer of plasmid DNA from *Escherichia coli* cloning hosts into *S. aureus*, rendering feasible genetic manipulation of diverse clinical isolates (96–98).

Another important consideration is differences in animals used for infection models compared to humans. Results of experimental infection studies must be interpreted with caution if the surface protein being analyzed has a lower affinity for ligands in the animal compared to humans. One way to circumvent such difficulties is to engineer a humanized mouse expressing the human version of the ligand (99). For

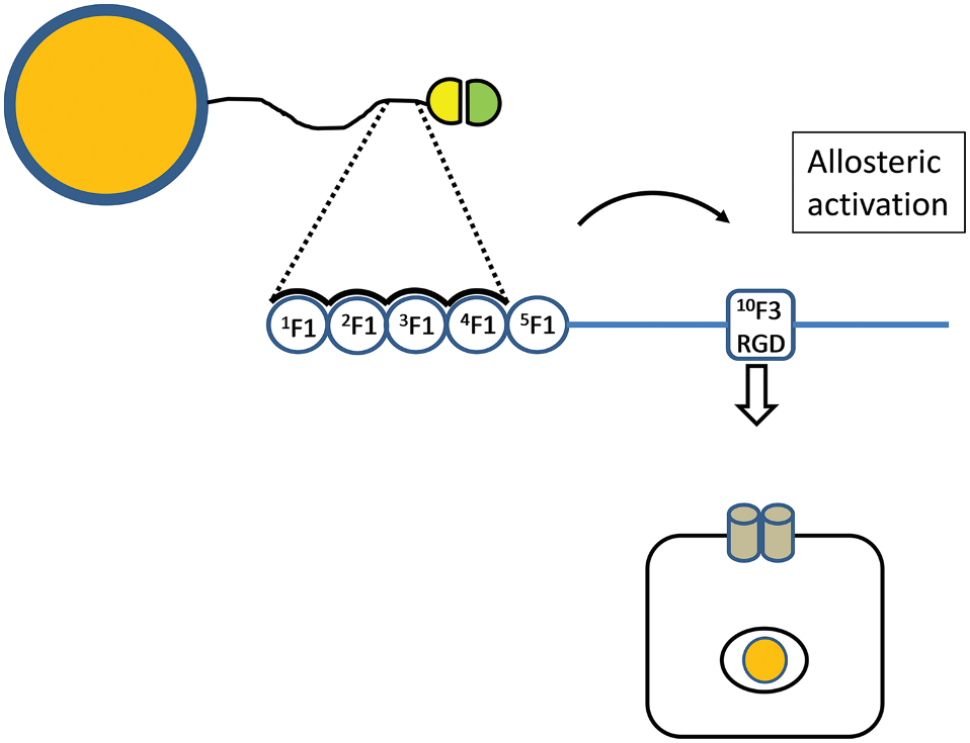

FIGURE 9 Fibronectin binding by FnBPs. The figure shows how one fibronectin binding repeat of the unstructured fibronectin binding region of FnBP binds to N-terminal type I modules of fibronectin by the tandem β zipper mechanism. Potentially up to 10 such interactions can occur per molecule of FnBP. Intramolecular interactions between the N-terminal type I modules and C-terminal type III modules result in allosteric activation of the 10th type III module, exposing an RGD motif which engages an $\alpha_5\beta_1$ integrin on the surface of a mammalian cell to promote invasion by endocytosis.

example, IsdB does not bind mouse hemoglobin, so a transgenic mouse expressing the human version of the protein has been employed in infection studies (100). Another option is to murinize the pathogen by engineering the virulence factor to bind to the murine version of the ligand as has been achieved with internalin A of *Listeria monocytogenes* (101).

A summary of studies demonstrating that bacterial mutants defective in CWA proteins have reduced virulence in different infection and colonization models is shown in Table 2. A systematic analysis of mutants defective in individual surface proteins was performed with mutants of strain Newman using a mouse model of bacteremia, dissemination, and abscess formation (102). Mice were injected intravenously with bacteria, and the bacterial load in the kidneys and the number of abscesses were measured. This model measured the ability of bacteria to survive in the bloodstream and to invade kidney tissue and establish an abscess. Several mutants had a statistically significant >1 log reduction in viable counts in kidney tissue, indicating the importance of CWA proteins, although the precise role of each protein is not known (103). The study was limited by the fact that strain Newman does not express Cna and lacks the ability to display FnBPs on its surface due to mutations in the *fnbA* and *fnbB* genes, which prevent anchorage of the proteins to the cell wall (104).

The collagen binding protein promotes virulence in infections where adhesion to collagen-rich tissue is important, such as ocular keratitis and septic arthritis. The strength of adhesion of the recombinant protein to immobilized collagen *in vitro* correlated with the severity of the disease (105). Cna also interferes with complement fixation and most likely contributes to innate immune evasion during infection (19).

Studies of *S. aureus* strains that colonized cardiac devices in human patients compared to those isolated from cases of uncomplicated bacteremia identified polymorphisms in the *fnbA* gene encoding FnBPA associated with complicated bacteremia that increased the affinity of the protein for fibronectin *in vitro* (106). This implies that selection occurred *in vivo* for strains that had a high affinity for fibronectin that coated the device implanted in the patient.

Rather than isolate null mutants that lack the ability to express a surface protein bacteria expressing variants, the protein on the cell surface with amino acid substitutions that cause loss of function can be studied. For example, mutants expressing mutants of ClfA (107) and Cna (105) with reduced ligand binding were shown to lack virulence in a model of septic arthritis. A mutant expressing AdsA that was defective in adenosine synthase survived less well than the wild type in blood stream infection (87). An advantage of this approach is that possible pleiotropic effects of the missing surface protein on the elaboration of other CWA proteins are avoided.

Infection studies with the surrogate host *L. lactis* expressing CWA proteins have been used to study aspects of the infection process. The ability of *L. lactis* to colonize a sterile thrombus on damaged heart valves in a rat model of endocarditis was dependent on bacteria being able to adhere to fibrinogen/fibrin on the damaged tissue. This could be mediated either by ClfA or the A domain of FnBPA (94). Subsequent bacterial proliferation and expansion of the lesion required FnBP-promoted invasion of cells of the surrounding endothelium.

TABLE 2 CWA proteins as colonization and virulence factors studied using animal models

Role in colonization or infection	CWA protein	Mechanism	References
Nasal or skin colonization	ClfB	Adhesion to loricrin on squames	14
	IsdA	Adhesion to squames	119
	SasX	Adhesion to squames	115
Endocarditis	ClfA	Adhesion to thrombus	163
	FnBPA	Adhesion to thrombus; invasion of adjacent endothelium	94
	ClfB	Adhesion to thrombus	164
	SraP	Adhesion to platelets; colonization of thrombus	165
Mastitis	FnBP	Invasion of epithelial cells in mammary gland	(166)
Pneumonia	Protein A	Enhanced inflammation of lung epithelium	167
Foreign body infection	FnBP	MRSA[a] biofilm-promoted infection	168
		Adhesion to intra-aortic patch	169
Ocular keratitis	Cna	Enhanced colonization and infection	170
Septic death	ClfA	Reduced opsonophagocytosis	102, 107, 141
Survival in blood	Protein A		171, 172

[a]MRSA, methicillin-resistant *S. aureus*

CWA Proteins Promote Colonization of the Host

Approximately 20 to 30% of the population are colonized persistently by *S. aureus* in the nares, with the remainder being intermittently colonized (108, 109). The factors that determine whether an individual is a persistent carrier are not completely understood (110). *S. aureus* colonizes the nares by adhering both to ciliated epithelial cells in the posterior region of the nares and to squamous epithelial cells in the anterior nares (111).

Adhesion to ciliated epithelial cells is mediated in part by the zwitterionic bacterial wall teichoic acid (WTA) binding to the scavenger receptor SREC-1 (112). This occurs through interactions involving positively charged D-alanine residues that decorate WTA binding to negatively charged residues on the host protein (112). Glycosylation of WTA contributes to the ability of *S. aureus* to colonize the nares of cotton rats, although the receptor for the *N*-acetyl glucosamine residues is not known (113).

Several CWA proteins promote adhesion of *S. aureus* to the cornified envelope of squamous cells (corneocytes). ClfB and IsdA have been shown to promote nasal colonization in rodent models and, in the case of ClfB, humans (14, 65, 114). SdrC, SdrD, SasG, Pls, and SasX contribute to bacterial adhesion to corneocytes *in vitro*, and SasX can also promote colonization of the nares of mice (43, 93, 115). Pls and SasX are encoded by genes located within mobile genetic elements and are thus only expressed by a subset of methicillin-resistant *S. aureus* strains carrying the relevant element. Pls is encoded by a gene carried within the type I SCC*mec* cassette (116), while the *sasX* gene is carried by a lysogenic phage found only in ST239 methicillin-resistant *S. aureus* strains that are prevalent in the Far East (115). The *sasG* gene is carried by 50% of the most prevalent lineages (clonal complex 1 [CC1], CC5, CC8, CC15, and CC22) but is absent from CC12, CC25, CC51, CC45, and CC30 strains (117).

It is well established that ClfB can bind to cytokeratin 10 and loricrin, proteins that only occur in corneocytes (5, 7, 118). Loricrin is probably the more important ligand *in vivo*; loricrin knockout mice are defective in colonization (14). ClfB binds to loricrin by the high-affinity DLL mechanism (14). IsdA can also bind to loricin, cytokeratin 10, and involucrin, but the mechanistic basis of these relatively weak interactions is not known (119). SdrD binds to desmoglein 1, a component of both the desmosomes that hold keratinocytes together and the corneodesmosones that regulate desquamation in the stratum corneum (120, 121).

S. aureus is regarded as a minor or transitory resident of healthy skin. However, in eczema (atopic dermatitis [AD]) patients suffering from a flare-up, the diversity of normal skin microbiota is reduced and *S. aureus* proliferates (122). The bacterium releases several proteins that can exacerbate inflammation in AD skin (123). Colonization of AD skin is at least in part promoted by the ability of bacteria to adhere to corneocytes in a ClfB-dependent fashion (124). Adhesion to loricrin and/or to ligands that become exposed on the surface of the deformed corneocytes where corneodesmosome proteins are present on villous-like protrusions is an important first step in colonization (125).

IMMUNE EVASION PROMOTED BY CWA PROTEINS

Evasion of Innate Immune Responses: Inhibition of Complement Activation

Protein A is a multifunctional CWA protein of *S. aureus* that promotes evasion of innate responses by its ability to capture IgG from serum. Bacterial cells become coated with IgG that is bound incorrectly so that the Fc region of the antibody cannot be recognized by the Fc receptor on neutrophils (126, 127). To initiate the classical pathway of complement fixation, the complement protein C1q must be able to bind to the Fc region of bound IgG (128, 129). Thus, opsonophagocytsosis is comprehensively inhibited by preventing recognition of the opsonins IgG and C3b by both the Fc receptor and the complement receptor on neutrophils.

The collagen binding protein also blocks initiation of the classical pathway of complement fixation by binding to the collagen triple-helix structures of C1q, displacing C1r-C1s and preventing complement activation (19).

Evasion of Innate Immune Responses: Enhanced Destruction of C3b

Complement activation results in the complement protein C3b being deposited on the bacterial cell surface, allowing it to be recognized by the complement receptor on phagocytic cells. Accumulation of C3b begins the amplification process of the alternative activation pathways and also triggers activation of C5 convertase (129). Three CWA proteins, SdrE, ClfA, and IsdH, contribute to enhanced complement degradation (69, 130–132). Only in the case of SdrE is the mechanistic basis understood. SdrE binds the host complement regulatory protein factor H, which in turn recruits and activates the specific C3b-degrading protease factor I (13). It is possible that ClfA can bind and activate factor I directly without the requirement of factor H, but evidence for this is incomplete and further work is required.

Interference with Adaptive Immune Responses

A hallmark of *S. aureus* infections is the elaboration of superantigens which interfere with adaptive immunity. Most strains have the ability to secrete one or more small proteins (enterotoxins and toxic shock syndrome toxin 1) that have the ability to bind the MHC-II receptor of antigen-presenting cells and promote binding to T cell receptors (133). This triggers activation and proliferation of a plethora of T cells without appropriate guidance and recognition by bound antigen fragments. The results is uncontrolled expression of cytokines, which in the worst case scenario can cause toxic shock syndrome. Depletion of T cells also results in failure to mount an appropriate adaptive immune response.

Recently, it has been recognized that protein A is a crucially important factor in the interaction of *S. aureus* with its host. Protein A is expressed by all clinical strains of *S. aureus* and is important in persistent nasal carriage and in disrupting adaptive immune responses during infection (134, 135). Protein A is released from the cell surface by the action of autolysins, resulting in soluble molecules with fragments of peptidoglycan bound to the C-terminus (136, 137). The Ig binding repeats of Spa bind to and cross-link the variant V_H3 chain of receptors on B cells in lymphoid tissue (55). This results in B cell proliferation. During infection there is a rise in the level of V_H3 clonal IgM and IgG in serum, but these antibodies lack the ability to bind to *S. aureus* antigens (137, 138). This inappropriate expression of Ig requires the cooperation of $CD4^+$ T cells (137), although it is not clear if antigen presentation is involved. The C-terminal peptidoglycan fragment is implicated in activation of (nucleotide-binding oligomerization domain) NOD1/NOD2 signaling, which in turn triggers maturation of the B cells into antibody-secreting plasma cells (55, 137, 139). Depletion of B cells from lymphoid tissues causes anergy, and the lack of immunological memory results in *S. aureus* being able to reinfect and is probably responsible for bacteria being able to proliferate in the nares of persistent carriers.

CONCLUDING REMARKS

CWA proteins provide opportunities for *S. aureus* to interact with the host, both in the commensal state and during infection. Given that the repertoire of CWA proteins is restricted, it is perhaps not surprising that several of these proteins have been found to be multifunctional.

Recently, it was proposed that CWA proteins should be categorized based on structural motifs and functional attributes (2, 140). There has been a tendency to use the acronym MSCRAMM inappropriately for all CWA proteins regardless of function and whether or not they bind to components of the ECM.

The functions of some CWA proteins have yet to be established, and it is likely that new ligands will be discovered for those with known functions. Structural analysis will provide clues about function as well as the application of high-throughput techniques for discovering binding partners. Far Western blotting, phage display, and two-hybrid analysis have identified potential ligands which must then be validated by detailed analysis to show biological relevance (21, 24, 26, 120).

Until recently, most studies were performed with laboratory strains. It is now possible to genetically manipulate strains from all genetic lineages so that clinically relevant bacteria can more easily be studied (96–98). This is important because since variations in the repertoire of surface proteins occur in different lineages, sequence variations in ligand binding domains might lead to different affinities for ligands, and the timing of and regulation of gene expression can result in different levels of protein abundance on the cell surface.

Several CWA proteins have been investigated as potential antigens for vaccination to protect against *S. aureus* infections and have been shown to offer protection in murine models of infection (65, 141–143). Furthermore, recombinant truncates that have been engineered so as not to bind host ligands offer the potential for improved antigenicity (107, 144). Several combinations of antigens including fragments of CWA proteins and other surface components have been formulated (145–147). However, the only phase III clinical trial performed to date was with a single-antigen

IsdB and resulted in failure for reasons that are not clear (148, 149). Any future clinical trials will require the use of an adjuvant that triggers a cellular response involving T_H1 cells and/or T_H17 cells as well as interleukin-17 and interferon-γ-mediated recruitment of neutrophils and must avoid the immune dysregulation caused by expression of superantigens (146, 149).

In conclusion, CWA proteins carry out a range of important functions and are essential for successful colonization of the host and for infection. Structural and functional analysis has provided a rational framework for classification of CWA proteins and has helped to define the mechanistic basis of host-pathogen interactions.

Immune Evasion by *Staphylococcus aureus*

NIENKE W. M. DE JONG, KOK P. M. VAN KESSEL AND JOS A. G. VAN STRIJP

39

INTRODUCTION

The Gram-positive bacterium *Staphylococcus aureus* is considered a commensal bacterium because roughly one-third of the human population is colonized by it without developing disease (1). Colonization occurs in the human nose, whereby the host nasal microbiota plays a major role in promoting or inhibiting *S. aureus* colonization (2). Despite the fact that *S. aureus* is considered a commensal, nasal carriage of *S. aureus* is linked to bacteremia (3). The bacterium may cause a range of infections, from cellulitis and superficial skin disease to abscesses, bacteremia, sepsis, endocarditis, and pneumonia (4). Moreover, *S. aureus* has been shown to adapt in its interaction with humans by increasing resistance against methicillin and is currently a leading cause of human bacterial disease worldwide. Methicillin-resistant *S. aureus* (MRSA) was identified in the 1960s as a nosocomial pathogen, when hospitalized patients showed distinct risk factors for acquisition (5). The prevalence of methicillin resistance among nosocomial *S. aureus* isolates increased from 2.1% in 1975 to 35% in 1991 (6). MRSA epidemiology changed in the 1990s when infections of healthy individuals outside hospitals were reported. These strains, with increased virulence, were the first reports of community-acquired MRSA (7, 8). Now, community-acquired MRSA has been reported as the leading cause of bacterial infections in the bloodstream, skin, soft tissue, and lower respiratory tract in developed countries (9). As a consequence, research interest in the pathophysiology of *S. aureus* has increased.

This extensive research during the past decades resulted in the identification and characterization of around 40 proteins which are able to evade various processes of the innate and adaptive immune system (10), the so-called immune evasion proteins. A list of these evasion molecules with their abbreviation, what they evade and location on which MGE is listed in Table 1. Proteomics has shown that around 100 to 200 *S. aureus* proteins are secreted, many with a still unknown function (11). These unknown secreted proteins are potential evasion molecules, demonstrating that the identification and characterization of new evasion proteins is not yet complete and will most likely expand in the future.

Many evasion proteins are targeted against neutrophils. This is not a surprise, because neutrophils are the most prominent leukocytes in blood, covering 60% of the leukocyte population, and play a prominent role in fighting *S. aureus* infection. They are equipped with various granules with specific content to kill both Gram-negative and Gram-positive bacteria (12, 13). Neutrophils originate and mature in the bone marrow and are then released into the bloodstream. There, these end-stage cells are induced to circulate and migrate toward the site of infection by chemotactic signals produced both by the bacteria themselves and by host cells (13). Upon arrival at the infection site, neutrophils are able to "eat" microorganisms that are opsonized (labeled) by the complement system or immunoglobulins (antibodies). The complement system is especially important in clearing staphylococcal infections. Mice deficient in complement C5 showed decreased clearance of *S. aureus* after pulmonary and bloodstream infections (14, 15). In addition, antibodies play an important role in fighting staphylococcal infections. Opsonization of bacteria subsequently leads to phagocytosis and, ultimately, killing of microbes, because neutrophils release the content of their antimicrobial granules and produce reactive oxygen species (ROS) (13).

Impaired neutrophil function is linked to staphylococcal infections, as shown in multiple studies. For instance, patients suffering from congenital neutropenia often have severe infections, including staphylococcal infections, which can be fatal (16). Patients with chronic granulomatous disease have defects in their NADPH oxidase, which leads to impaired formation of ROS. Catalase-positive microorganisms in particular, such as *S. aureus*, cause recurrent infections in these patients because catalase breaks down the bacterial hydrogen peroxide and thereby prevents the generation of ROS (17). Another example where *S. aureus* infections play a major role is in burn patients. The burn wound is especially susceptible to bacterial colonization and infection, because neutrophils are known to be decreased in burn patients (18, 19). From these observations we can conclude that neutrophil-mediated killing in healthy individuals is crucial in the defense against *S. aureus*.

After the first response, the acquired immune system comes into the picture. However, this part of the immune system has an insignificant role in acute infection. Nonetheless, antibodies are important in the long term with recurrent staphylococcal infections, but antibodies against staphylococcal proteins do not show effective protection; even though most adult humans have high levels of circulating antibodies against different *S. aureus* proteins, these are not immunologically protective (20).

In this article we discuss the different facets of the antistaphylococcal innate immune system. First, we describe the mechanisms of neutrophil extravasation through the endo-

doi:10.1128/microbiolspec.GPP3-0061-2019

TABLE 1 Abbreviations of staphylococcal immune evasion proteins, what they evade, and on which MGE or paralogous gene cluster they are located[a]

Abbreviation	Full name	Evades process[b]	MGE[c]
Aur	Aureolysin	III, V	
CHIPS	Chemotaxis inhibitory protein of *Staphylococcus*	II	IEC-1/φSa3
Can	*S. aureus* collagen adhesion	III	
Eap and EapH	Extracellular adherence protein and extracellular adherence protein homologue	I, V	
Ecb	Extracellular complement-binding protein	III	IEC-2
Efb	Extracellular fibrinogen-binding protein	III	IEC-2
FLIPr	FPR2 inhibitory protein	II	IEC-2
Hla	Hemolysin-alpha	V	
Hlg	Hemolysin-gamma	V	
LukS-PV	Panton Valentine leukocidin	V	φSa2
Luk-AB	Leukocidin AB	V	
Luk-DE	Leukocidin DE	V	
Nuc	Nuclease	IV	
PSMs	Phenol-soluble modulins	V	
Sags	Superantigens	V	IEC1, SaPIn1, vSaβ[d]
SAK	Staphylokinase	III, V	IEC-1/φSa3
Sbi	Staphylococcal binding of IgG	III	
SCIN	Staphylococcal complement inhibitor	III	IEC-1/φSa3
ScpA	Staphopain A	II	
SdrE	Surface-associated serine-aspartate repeat protein E	III	
SelX	Staphylococcal enterotoxin-like X	I	
SpA	Staphylococcal protein A	III	
SPIN	Staphylococcal peroxidase inhibitor	V	vSaα[d]
SSL	Staphylococcal superantigen-like 1-11	I, II, III	vSaα[d]
SSL	Staphylococcal superantigen-like 12, 13, 14	I, II, III	vSaβ[d]

[a]MGE, mobile genetic element.
[b]The innate immune mechanisms that are inhibited: I, neutrophil extravasation; II, priming, chemotaxis, and activation of neutrophils; III, opsonization and phagocytosis; IV, NET formation; V, bacterial killing by neutrophils.
[c]IEC, immune evasion cluster; SaPI, staphylococcal pathogenicity island.
[d]vSaα and vSaβ are clusters of paralogous genes that have evolved in situ, are nearly universally conserved in *S. aureus*, and are not MGEs.

thelium. Second, we give an overview of the proteins and receptors involved in neutrophil priming, chemotaxis, and activation. Third, we describe the processes involved in bacterial opsonization and phagocytosis by neutrophils. Fourth, we provide an overview of the processes involved in bacterial killing by neutrophils. After each section we describe the various evasion molecules that interrupt that specific process. Finally, we discuss why *S. aureus* has evolved so many evasion proteins and the therapeutic implications of these proteins with respect to staphylococcal infections. Thus, we give an overview of what we know so far about *S. aureus* immune evasion and what lessons we can draw from this knowledge.

NEUTROPHIL EXTRAVASATION THROUGH THE ENDOTHELIUM

Once pathogens cause infections in tissues, neutrophils leave the bloodstream and migrate toward the site of infection. This multistep process is called extravasation and includes neutrophil rolling, crawling and firm adhesion to the endothelial cells, extravasation through the endothelium (diapedesis), and migration to the infection site over a chemokine gradient (21). An overview of this process is shown in Fig. 1.

First, the neutrophils in the bloodstream slow down near the site of infection. This is initiated by changes on the endothelial surface by inflammatory mediators (e.g., histamine, cytokines, and leukotrienes) (22). The endothelial cells are activated and start to express P-selectin and E-selectin, which interact with P-selectin glycoprotein ligand-1 (PSGL-1) on the surface of neutrophils (23). This leads to the tethering (capturing) of freely moving neutrophils to the endothelial surface as they start to roll along the vessel in the direction of the blood flow. In the second step the neutrophils adhere and "crawl" along the vessel wall by the interaction between intercellular adhesion molecule 1 (ICAM-1) on endothelial cells and β2 integrins (such as LFA-1 and Mac-1) on the surface of phagocytes (24–26). Neutrophils express constitutively high levels of β2 integrins, which undergo conformational change upon either intracellular activation ligand binding (outside-in signaling) or integrin adhesiveness

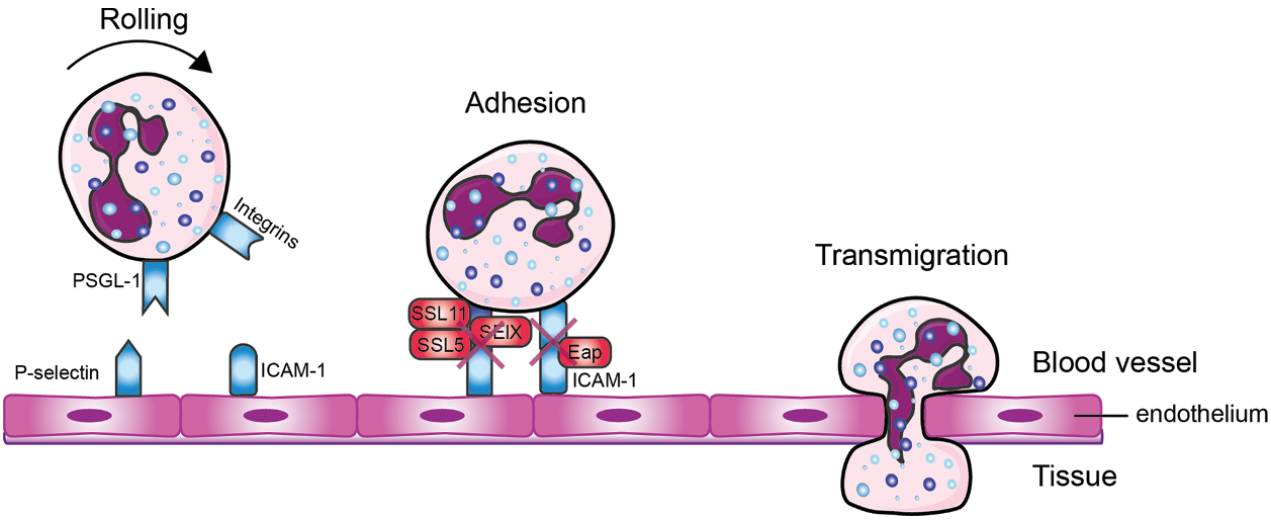

FIGURE 1 Evading neutrophil extravasation to the infection site. Mechanisms by which *S. aureus* evades the steps in neutrophil extravasation. Neutrophils start to roll on the activated endothelium, which leads to firm adhesion and subsequently to transmigration through the endothelium. Red boxes indicate staphylococcal proteins, and blue boxes indicate host proteins. Abbreviations: PSGL-1, P-selectin glycoprotein 1; SSL, staphylococcal superantigen-like protein; ICAM-1, intracellular adhesion molecule 1; Eap, extracellular adherence protein; SElX, staphylococcal enterotoxin-like X. The figure was adapted from Servier Medical Art.

(inside-out signaling). β2 integrins are relocalized to the cell surface upon activation by chemokines (27, 28). The neutrophils enter the arrested state after expressing high levels of ICAM-1. This leads to the initiation of transendothelial cell migration through a paracellular (passing through the endothelium between the cells) or a transcellular (movement through the endothelial cell) pathway. Leukocytes mainly migrate via the paracellular route but follow the transcellular route in the central nervous system and in various inflammatory settings (29). After extravasation, the neutrophils continue their journey toward the infection site via chemotaxis.

EVADING NEUTROPHIL EXTRAVASATION

An overview of the molecules interfering with the extravasation of neutrophils is shown in Fig. 1. *S. aureus* is able to modulate the first step in neutrophil extravasation, rolling of neutrophils on endothelial cells, by secreting staphylococcal superantigen-like 5 (SSL5). SSL5 directly binds PSGL-1 on leukocytes and human HL-60 leukemia cells. This prevents the interaction of PSGL-1 with its natural ligand, P-selectin, in a sulfation- and sialylation-dependent manner (30, 31). Cocrystallization data revealed SSL5 in complex with tetrasaccharide sialyl Lewis X, a key posttranslational modification of PSGL-1 binding to P-selectin (32). SSL5 is part of a larger group of 14 structurally related proteins (SSL1 to SSL14), which are involved in innate immune evasion. SSL11, of all the SSLs, shares the highest amino acid sequence identity to SSL5 and also shows binding to sialyl Lewis X, as seen in the cocrystal structure of the complex. SSL11 also binds other sialic acid-containing glycoproteins, such as FcαRI, the Fc receptor for IgA (33). *S. aureus* secretes another immune evasion molecule, named SElX, which also interacts with PSGL-1 in a glycosylation-dependent manner (34). Before the molecular mechanism was identified, SElX was thought to possess superantigenic activity and was associated with a virulence factor in MRSA necrotizing pneumonia (35). Recently, SElX was also found to have the sialylated-glycan-dependent active site, similar to a subfamily in SSLs (SSL2 to SSL4 and SSL6) (36). This leads to binding of neutrophils and monocytes via multiple glycosylated neutrophil surface receptors, thereby disrupting IgG-mediated phagocytosis and contributing to pathogenesis, as revealed in a necrotizing pneumonia rabbit infection model (37, 38).

The second step of extravasation, the adhesion of neutrophils to endothelial cells, is also targeted by *S. aureus*. The pathogen secretes extracellular adherence protein (Eap) that directly binds ICAM-1 and thereby inhibits neutrophil recruitment to the infection site (39).

PRIMING, CHEMOTAXIS, AND ACTIVATION OF NEUTROPHILS

When neutrophils have migrated through the endothelial barrier, they are primed, recruited toward the site of infection by various chemoattractants, and activated by multiple inflammatory stimulants. Here, we will discuss various sets of proteins and receptors involved in this process. An overview is shown in Fig. 2.

Priming occurs when a neutrophil is exposed to a primary priming stimulus which enhances the neutrophil's functional response (for example, adhesion, phagocytosis, degranulation, and superoxide production [40]), although the priming stimulus does not give the functional response itself (41). Examples of known priming molecules for neutrophils are complement components C3a and C5a (42), interleukin-8 (IL-8) (43), granulocyte colony-stimulating factor (43), tumor-necrosis factor-α (44), and interferon-γ (45).

Chemoattractants are chemokines and bacteria- and complement-derived products that activate phagocytes by interacting with receptors at the surface of neutrophils which belong to the superfamily of G protein-coupled receptors (GPCRs) (46). These GPCRs also belong to the rhodopsin subfamily of GPCRs. Rhodopsin is a seven-transmembrane receptor with seven helical membrane-spanning regions connected by six extramembrane loops, as shown by crystallization (47). The mechanism of stimulation of the GPCR depends on the type of ligand. For example, small peptides (e.g., *N*-formyl-methionyl-leucyl-phenylalanine [fMLP]) and

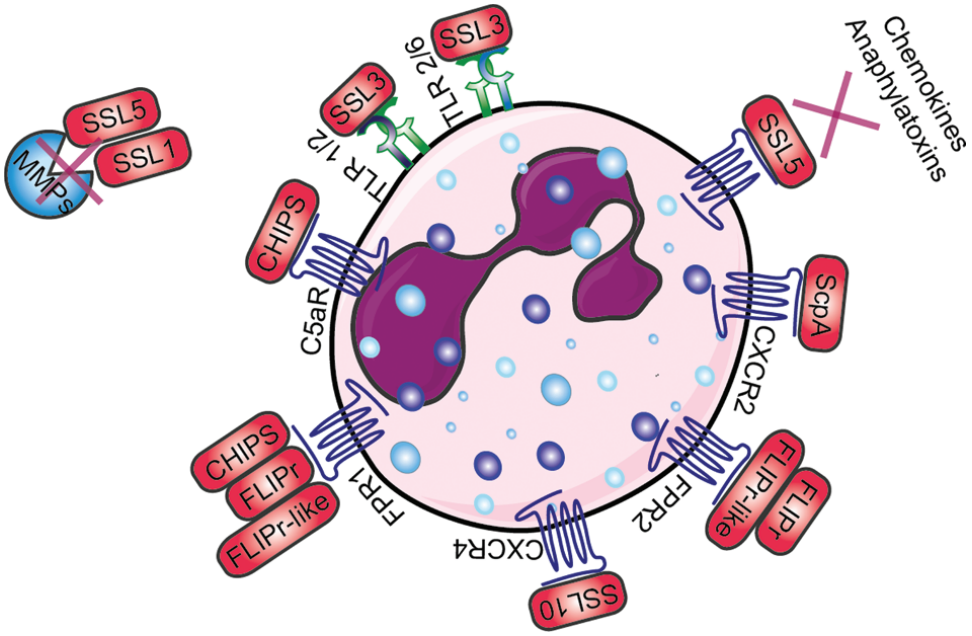

FIGURE 2 Schematic overview of how *S. aureus* evades priming, chemotaxis, and activation of neutrophils. Red boxes indicate staphylococcal proteins, and proteins shown in blue indicate host proteins. Abbreviations: TLR, Toll-like receptor; CXCR, chemokine receptor; ScpA, staphopain A; SSL, staphylococcal superantigen-like protein; FPR, formyl peptide receptor; FLIPr, FPR2 inhibitory protein; C5aR, C5a receptor; CHIPS, chemotaxis inhibitory protein of *Staphylococcus*; MMP, matrix metalloproteinase. The figure was adapted from Servier Medical Art.

lipid-derived stimuli (e.g., platelet-activating factor and leukotriene B4) primarily activate their GPCRs through the transmembrane regions. Larger stimulatory molecules (e.g., chemokines and anaphylatoxins) activate GPCRs via a two-step process whereby the stimulus binds the N-terminus of the specific GPCR, whereupon conformational change of the receptor leads to activation by the interaction with the pocket formed by the transmembrane domains (48). CXC chemokine receptors expressed on the surface of various immune cells also belong to the family of GPCRs, and to date, seven receptors have been described (named CXCR1 through CXCR7). They interact with chemokines, a large family of 8- to 12-kDa proteins. The CXC chemokines are one of the most prominent groups and are mostly chemotactic for neutrophils, such as CXCL8 (also known as IL-8) (49).

Newly synthesized bacterial proteins contain formylated methionine, so bacteria secrete a lot of N-formylated proteins and peptides, which were identified as chemoattractants in 1975 (50). These formylated peptides interact with formyl peptide receptors 1 (FPR1) and 2 (FPR2) (FPR2 is also known as FPRL1) on neutrophils (51), both belonging to the GPCR family. The prototype *N*-formyl-peptide, fMLP, binds with higher affinity to FPR1 than its homologue, FPR2 (52). Neutrophils and monocytes express FPR1 and FPR2, whereas the third homologue, FPR3 (also known as FPRL2), is only expressed in monocytes (52). Staphylococci produce phenol-soluble modulins (PSMs) in addition to formyl peptides. PSMs are not only important secreted staphylococcal toxins, but they are also sensed by FPR2, which leads to activation and attraction of leukocytes (53).

Two complement receptors (CRs) on neutrophils also belong to the family of GPCRs, namely, the C3a receptor (C3aR) and the C5a receptor (C5aR). Their ligands are the small complement components C3a and C5a, formed during complement activation. C5a and C3a are commonly also called anaphylatoxins and are both chemoattractants, acting by attracting phagocytes to the site of infection (54).

Neutrophils also express another class of innate immune receptors that are involved in pathogen recognition, the Toll-like receptors (TLRs). The discovery of these proteins in the mid-1990s revealed that pathogen recognition by the innate immune system is specific, because it recognizes different components of foreign pathogens, which are called pathogen-associated molecular patterns. Pathogen-associated molecular patterns that are important for staphylococcal infections are bacterial lipoproteins (recognized by TLR1, TLR2, and TLR6) and unmethylated CpG sequences in DNA molecules (recognized by TLR9) (55). Ligand binding to the extracellular domains of TLRs causes dimerization of the receptor complexes and triggers recruitment of MyD88 to the intracellular TLR domains, which ultimately leads to the activation of transcription factor NF-κB (56). Most TLRs appear to function as homodimers, although TLR2 forms heterodimers with TLR1 or TLR6. TLR1/2 recognizes triacylated lipoproteins, whereas TLR2/6 specifically responds to diacylated lipoproteins (57). TLRs are not directly involved in chemotaxis, but they contribute to phagocytosis.

Another class of proteins important for controlling inflammation are the matrix metalloproteinases (MMPs). Members of this family of 23 endopeptidases are secreted by numerous cells and are important in the recruitment and migration of neutrophils during bacterial infections. They break down extracellular matrix components so neutrophils can migrate toward the infection, but they also stimulate proinflammatory signals and cleave chemokines. This leads to enhanced inflammation and improved bacterial clearance. The two main neutrophil MMPs are MMP8 (also known as neutrophil collagenase) and MMP9 (also known as neutrophil gelatinase B) (58).

EVADING PRIMING, CHEMOTAXIS, AND ACTIVATION OF NEUTROPHILS

Studies thus far have not shown whether *S. aureus* can directly modulate neutrophil priming to influence the function of neutrophils. Additional studies are necessary to understand the influence of *S. aureus* on neutrophil priming (59). However, more knowledge has been gained about the impact of *S. aureus* on neutrophil chemotaxis and activation. Here, we describe the function of the evasion proteins SSL5, SSL10, SSL3, and SSL4; staphopain A; CHIPS; FPR2 inhibitory protein (FLIPr); and FLIPr-like in their role in evading neutrophil chemotaxis and activation, as shown in Fig. 2.

SSL5 not only binds to PSGL-1 to block neutrophil extravasation, but it also binds glycosylated N-termini GPCRs, thereby inhibiting the ligands that require the N-terminus of the receptor for activation. Therefore, it binds but does not interfere with the activation of FPR1 and FPR2, leukotriene B4 receptor, platelet-activating factor receptor, and nucleotide receptor P2Y2, since ligands of these receptors are small and signal via the transmembrane domains of the GPCRs (60). Pretreating neutrophils with SSL5 blocks the activation induced by C3a and C5a, because chemokines and anaphylatoxins bind the N-termini of their receptors. SSL5 also inhibits activation and neutrophil migration induced by IL-8, which interacts with CXCR1 and CXCR2, but it also targets the response induced by chemokine ligand 1 (CXCL1), which acts only on CXCR2 (60). SSL5 together with SSL1 inhibits neutrophil migration through breakdown of collagen and potentiation of IL-8 by inhibiting cleavage of the neutrophil-specific MMP8 (neutrophil collagenase) and MMP9 (neutrophil gelatinase B) as well as other members of the MMP family (MMP1, 2, 7, 12, 13, and 14) (61, 62). Additionally, SSL5 activates and aggregates platelets by interacting with platelet membrane receptor GPIbα and collagen receptor GPVI, leading to a beneficial environment for staphylococcal colonization (63, 64).

SSL10 targets another chemokine receptor, CXCR4, expressed on neutrophils and cancer cells. It binds to human T-cell acute lymphoblastic leukemia, lymphoma, and cervical carcinoma cell lines and inhibits calcium mobilization and cell migration induced by the ligand of CXCR4, CXCL12 (also known as stromal cell-derived factor-1α) (65).

SSL3 binds the extracellular domain of TLR2 and inhibits its activity on human and murine neutrophils and monocytes (66, 67). The cocrystal structure of SSL3 in complex with TLR2 reveals that SSL3 blocks ligand binding and prevents TLR heterodimerization of TLR1 and TLR6 and downstream signaling by interacting with an already formed TLR2-lipopeptide complex (68). SSL4 shares the highest homology with SSL3 and also blocks TLR2 activation, albeit less potently compared to SSL3. Therefore, it remains unknown whether this is the primary function of SSL4, because SSL4 was also shown to bind myeloid cells in a glycan-dependent manner (66, 69). Recently, antibodies against SSL3 and SSL4 were detected in human serum, showing that both evasion proteins are secreted *in vivo*. SSL3 is able to bind both murine and human TLR2, so SSL3 was investigated in an intravenous murine infection model, where it was shown that the presence of the gene correlates with high virulence. To circumvent low expression rates of SSL3 in mice, an SSL3-overproducing strain was used (70).

S. aureus also secretes a protease that interferes with chemokine signaling. Staphopain A cleaves the N-terminus of CXCR2 and thereby causes unresponsive neutrophils to undergo activation by CXCR2. The protease also hampers neutrophil migration toward CXCR2 chemokines (71). Mature staphopain A has a broader substrate specificity than CXCR2 alone because it is also able to degrade elastin fibers. However, it is also prone to autolytic degradation, which could explain the loss of activity of staphopain A over time (71, 72).

S. aureus supernatant showed chemotaxis-inhibiting properties by targeting the fMLP and C5a response of neutrophils (73). Later, the protein responsible in the supernatant was identified, and this 14.1-kDa evasion protein was named chemotaxis inhibitory protein of *Staphylococcus* (CHIPS). CHIPS binds and inhibits the GPCRs FPR1 and C5aR on neutrophils and monocytes. Thus, it blocks the binding of these receptors by their ligands, namely, C5a and fMLP, and thereby impairs the activation and chemotaxis of phagocytes (74, 75). N-terminal peptides of CHIPS inhibited FPR1, while the activity of C5aR was unaffected (76). This showed that the N-terminus of CHIPS is specific for its activity toward FPR1 and that CHIPS probably had another binding site for C5aR. Indeed, CHIPS specifically targets via its C-terminal domain the N-terminus of C5aR through binding to amino acids 10 to 18 and thereby prevents the binding of C5a to its receptor (77, 78). Arginine 44 and lysine 95 of CHIPS in particular appear to be highly important in the antagonism of C5aR (78).

The importance of CHIPS as a potential virulence factor led to the search for homologous excreted proteins in the genome of *S. aureus*. This resulted in the discovery of the gene encoding FLIPr, which showed 49% similarity to the gene for CHIPS (*chp*). Similar to CHIPS, FLIPr is able to inhibit FPR1 but can also inhibit FPR2, whereas binding with FPR3 was not observed (79). Later, the evasion protein FLIPr-like was discovered by a BLAST search through sequenced *S. aureus* genomes with FLIPr as the reference sequence. FLIPr and FLIPr-like are two allelic variants of the same gene, with 73% similarity on the amino acid level. The function of FLIPr-like is also similar to that of FLIPr, because it is an antagonist of both FPR1 and FPR2 (80). Moreover, FLIPr and FLIPr-like also target FcγR, the receptor for IgG, where FLIPr is almost exclusively restricted to class II receptors, with a preference for FcγRIIa, while FLIPr-like binds to most FcγR isoforms (81).

OPSONIZATION AND PHAGOCYTOSIS

Opsonization

The next step in clearing a bacterial infection, after neutrophils have been attracted to the site of infection, is uptake of the pathogens by phagocytes. For this phagocytosis to be effective, bacteria have to be opsonized: coated with components of the complement system, immunoglobulins, or other innate immune components. We will first describe opsonization by the complement system, followed by opsonization by immunoglobulins.

Opsonization by the complement system

Complement is a proteolytic cascade comprising more than 30 proteins in plasma that can (i) opsonize bacteria by depositing complement activation products on the bacterial surface, (ii) attract and activate other immune cells by formation of chemoattractants, and (iii) lyse and kill Gram-negative bacteria directly by the formation of the membrane attack complex (54). The complement system can be activated via three separate pathways that differ in their method of recognition but come together at one central step: formation of C3 convertase, which cleaves C3. One pathway, the lectin pathway, is activated upon recognition of conserved microbial sugars such as ficolins and mannan-binding lectin. The second pathway, the classical pathway, is primarily ini-

tiated by the interaction of C1q with antigen-antibody complexes (54). The third pathway, the alternative pathway, is initiated on the surfaces of neutral or positively charged pathogens that do not contain complement inhibitors. Its activation is due to the spontaneous "tick-over" reaction of C3 with water to form hydrolyzed C3, and it exists in an activated state at all times. Importantly, this pathway serves as an amplification loop after C3b is formed on bacterial cells via the lectin and classical pathways (54). C3 convertases are enzyme complexes with proteolytic activity that cleave C3. The classical and lectin C3 convertase is formed by cleavage of C4 by C1s to C4b, after which C4b covalently attaches to the bacterial surface and binds C2. C1s is then able to cleave C2 as well, thereby forming the C3 convertase C4b2a. The alternative pathway C3 convertase is different in that it contains a surface-bound C3b molecule attached to protease Bb, a subunit of factor B. Factor H controls complement activation by stimulating the decay of Bb from the alternative pathway convertase (C3bBb) and is a cofactor for factor I-mediated cleavage and inactivation of C3b (82).

Cleavage of C3 results in the formation of chemoattractant C3a and the deposition of C3b at the bacterial surface. C3b can be cleaved to the proteolytically inactive product iC3b by factor I on the surface of bacteria. iC3b is still able to opsonize bacteria, but it cannot associate with Bb (83). Both C3 convertases can bind an additional C3b molecule to form C5 convertases, and this convertase can cleave C5 into C5a and C5b. C5a is a chemoattractant and has been shown to have a protective role during staphylococcal bloodstream infections in mice (15). C5b together with C6, C7, C8, and multiple copies of C9 form the membrane attack complex (54). The membrane attack complex is able to directly lyse Gram-negative bacteria, whereas Gram-positive bacteria are unaffected due to their thick peptidoglycan layer (84). However, the complement system is important in the opsonization process because it deposits C3b on the surface of Gram-positive bacteria, such as *S. aureus*. Together, this sequence of events results in rapid and efficient detection and elimination of bacterial invaders.

Opsonization by immunoglobulins

Immunoglobulins (Igs) are a class of proteins that not only enable highly efficient opsonization, but are also involved in agglutination, neutralization of toxins and other virulence factors, and inhibition of adhesion. After binding to antigens on pathogens via their Fab segments, they are recognized by Fc receptors on the surface of phagocytes via their Fc region. The four isotypes of Igs vary in complement activation and are recognized by their own Fc receptor (FcγR, FcαR, FcεR, and FcμR). IgG, IgA, and IgM play roles in controlling infections, whereas IgE is more important in immunity to parasites. IgM is especially effective at opsonization through complement activation due to its polymeric structure (85). IgG consists of four subclasses (IgG1, IgG2, IgG3, and IgG4), and the differences in effector functions between the four IgGs are caused by differences in structure, especially the length and flexibility between the variable Fab segments and the stable Fc segment (86). Therefore the different subclasses of IgG bind differently to C1q, which is at the start of the classical pathway cascade. IgG3 binds the most strongly, whereas IgG1 and IgG2 bind more weakly (IgG1 > IgG2). IgG4 completely lacks the ability to activate the complement system (87).

Phagocytosis

Phagocytosis is a process by which other cells, cell fragments, and microorganisms are engulfed by white blood cells and end up in an internal compartment called the phagosome. As described above, opsonized microorganisms bind to specific receptors on the phagocyte surface. Subsequently, invagination of the cell membrane causes envelopment of the bacterium. This uptake is aided and highly enhanced by factors such as C5a, TLR ligands on the surface of the bacterium, and ligands for C-type lectins (such as DC-SIGN, dectin-1, and the mannose receptor on the surface of neutrophils) (88).

Cross-linking of FcγR by ligand binding on the surface of neutrophils activates several effector functions directed toward killing of pathogens and an inflammatory response (16). FcγRs are members of the immunoglobulin superfamily, and they are capable of binding the Fc region of IgG antibodies. There are several activating receptors (FcγRI/CD64, FcγRIIa/CD32a, FcγRIIc/CD32c, and FcγRIIIa/CD16a), one inhibitory receptor (FcγRIIb/CD32b), and one glycosylphosphatidylinositol-anchored receptor that contains no signal motif (FcγRIIIb/CD16b) (89). Human neutrophils express only two FcγRs, FcγRIIa and FcγRIIIb, and FcγRIIa induces mainly phagocytosis (89).

CR1 (CD35) is found on circulating monocytes, neutrophils, and B-lymphocytes. This receptor binds C4b, C3b, and iC3b and induces phagocytosis (90). CR3 (CD11b/CD18, Mac-1) and CR4 (CD11c/CD18, p150/95) are heterodimeric glycoproteins of the integrin family with a shared β-chain (CD18). They bind the iC3b fragment and to a lesser extent also C3b (91). Stimulation of neutrophils and monocytes via CR3 and CR4 results in induction and enhancement of phagocytosis, degranulation, and generation of ROS (91).

EVADING OPSONIZATION AND PHAGOCYTOSIS

S. aureus has evolved numerous molecules that enable it to evade the different parts of the complement cascade, immunoglobulins, and elements of the phagocytic process. These molecules are illustrated in Fig. 3. Evasion of these components results in a highly effective delay or reduction of the immune response and creates a beneficial situation for the bacterium to survive and multiply within its host.

Capsule Production

The best way for the bacterium to prevent phagocytosis is to hide the antigenic or immunogenic proteins at the surface of the bacterial cell wall with a polysaccharide capsule. Up to ~75% of all clinical *S. aureus* isolates have a capsule or microcapsule whereby most of them contain either capsular polysaccharide 5 (CP5) or capsular polysaccharide 8 (CP8). These bacteria grown under optimal capsule-production conditions showed resistance to opsonophagocytosis and thus killing (92). However, the capsule of *S. aureus* does not completely block deposition of complement components at the bacterial surface or binding of specific antibodies (93). Other bacteria, such as *Streptococcus pneumoniae*, produce a very thick capsule (94).

Proteins Targeting Immunoglobulins

The first evasion molecule described to have antiopsonic properties is staphylococcal protein A (SpA). SpA is linked to the staphylococcal cell wall via its LPXTG anchor but can be released upon hydrolysis during growth (95, 96). This protein contains four or five immunoglobulin-binding domains capable of binding the Fc part of IgG, which leads to blockage of FcR-mediated phagocytosis (97). SpA also binds to the Fab domain of variable heavy 3 type B cell receptors of

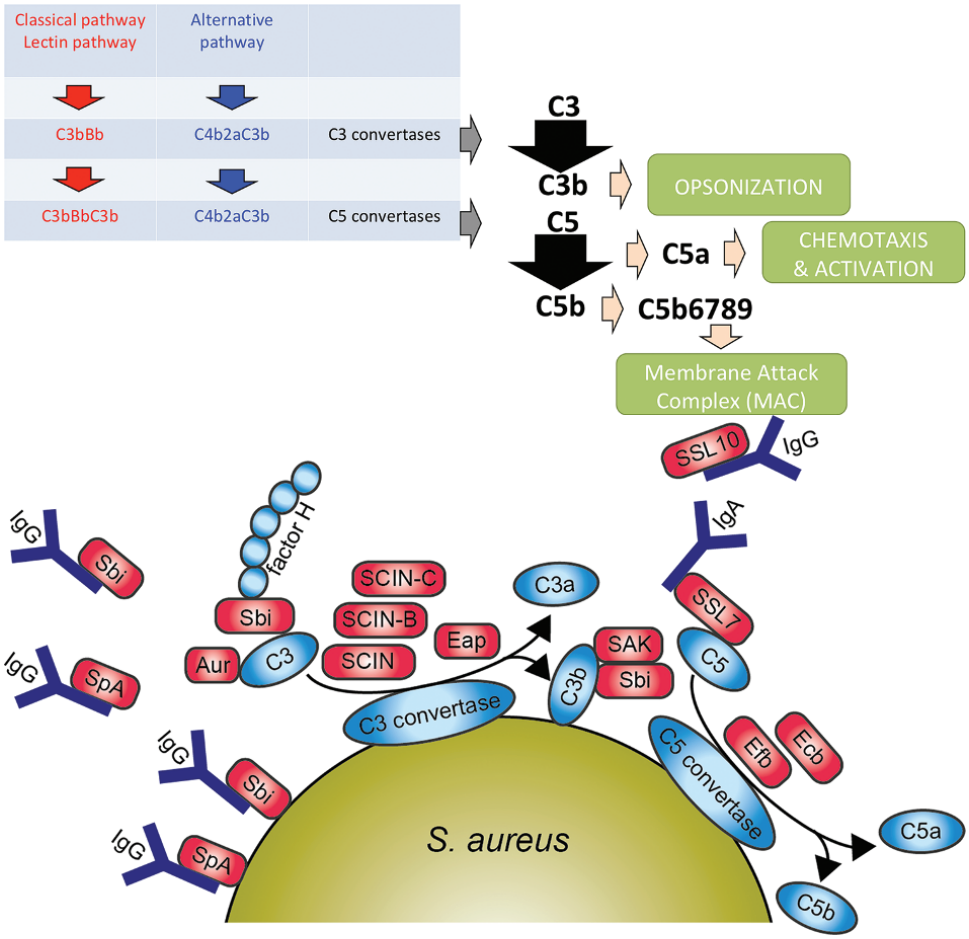

FIGURE 3 Diagram of the main pathways and components of the human complement system 3a and a schematic representation of *S. aureus* evading opsonization and phagocytic uptake by neutrophil 3b. Red boxes indicate staphylococcal proteins, and blue boxes indicate host proteins. Abbreviations: IgG, immunoglobulin G; SpA, staphylococcal protein A; Sbi, staphylococcal binding of IgG; SCIN, staphylococcal complement inhibitor; SAK, staphylokinase; Aur, aureolysin; SSL, staphylococcal superantigen-like protein; Efb, extracellular fibrinogen-binding protein; Ecb, extracellular complement-binding protein. The figure was adapted from Servier Medical Art.

IgM and thus serves as a B cell antigen by stimulating B cell activation (98–100). Consequently, this shows that SpA effectively interferes with the adaptive immune response. Recently, guinea pigs were shown to be a good model to test this therapeutic approach *in vivo*, which will be important for vaccination strategies in the future (101).

A second IgG-binding protein, *S. aureus* binder of IgG (Sbi), was identified through a phage display screen against immobilized human IgG (102). Like SpA, Sbi is also expressed at the staphylococcal cell surface and is secreted during bacterial growth (103, 104). Sbi also has two binding targets because it is able to bind to another serum component, β_2-glycoprotein I, also known as apolipoprotein H. This was similarly identified by phage display, and the binding site was clearly different from the IgG-binding domain (103). However, in contrast to SpA, Sbi can only interact with the Fc domain of IgG (105). Furthermore, the extracellular region of Sbi consists of four globular domains, where domains I and II are immunoglobulin-binding domains and domains III and IV are able to bind complement component C3 and factor H, forming a stable tripartite complex (Sbi:C3:factor H) (106, 107). Thus, Sbi is a versatile evasion protein, interfering with the innate immune system by binding IgG and apolipoprotein H, as well as the complement components factor H and C3.

SSL10, a multifunctional evasion protein, is yet another protein able to bind IgG1 (108). This leads to the inhibition of complement activation via the classical pathway, and this is the second function of SSL10, since it is also a CXCR4 antagonist. The N-terminus of SSL10 binds to the Fc domain of IgG1, preventing association with C1q and FcγRs and leading to inhibition of FcγR-mediated phagocytosis (109). Furthermore, SSL10 also targets prothrombin and factor Xa to inhibit blood coagulation (110), binds to phosphatidylserine, and recognizes apoptotic cells (111). Finally, *S. aureus* secretes a serine protease, V8, which is able to cleave immunoglobulins (112).

Proteins Targeting the Complement System

Not all known evasion proteins interfering with opsonization target immunoglobulins. Some of them are specialized in evading the complement system. For example, the secreted metalloprotease aureolysin cleaves the central complement

component C3 in a zinc-dependent manner. The cleavage site on C3 of aureolysin differs by two amino acids from the C3 convertase cleavage site generating active C3a′ and C3b′. This suggests that aureolysin mimics C3 convertases, but it also degrades the cleaved C3b′ as well as factors I and H. This cleavage is more effective *in vivo* than *in vitro* because it is more effective in serum than without serum. Aureolysin is a secreted protease, and thus it can cleave C3, removing it from the bacterial surface and creating a C3-free microenvironment and thus preventing C3b′ from covalently attaching via its thioester to bacteria (113).

Staphylococcal complement inhibitor (SCIN), initially identified as a prophage-coded protein, inhibits all three complement pathways: the alternative, classical, and lectin pathways. SCIN stabilizes and inhibits surface-bound C3 convertases, and this results in a decline of C3b deposition and release of chemoattractant C5a, which results in the inhibition of phagocytosis (114). Later, SCIN-B, SCIN-C, and open reading frame D were identified in the *S. aureus* genome. Characterization of these homologues shows that SCIN-B and SCIN-C also inhibit complement, whereas open reading frame D shows no inhibitory activity (115). Cocrystallization studies of SCIN with C3 convertase reveals that SCIN inhibits convertase activity in three ways: (i) SCIN prevents Bb mobility, which prevents Bb from accessing substrate C3 (116); (ii) SCIN may dimerize two C3 convertases and thereby prevent substrate binding (116); (iii) by binding to a single C3b molecule, SCIN slows the rate of factor B loading onto C3b and thus lowers the amount of C3 convertase formation (117). This all leads to inhibition of phagocytosis, C3b deposition, and C5a generation (114). Furthermore, a new SCIN variant was recently identified in equid *S. aureus* isolates. This equine SCIN has adapted to horses by inhibiting the equine complement system.

Extracellular fibrinogen-binding protein (Efb) and extracellular complement-binding protein (Ecb) are homologous proteins (118). The first characteristic described for Efb was that it binds via its N-terminus to fibrinogen—hence its name (119). Efb can also bind to platelets, as identified by phage display, interfering with platelet aggregation, contributing to virulence in wound infections, and delaying the healing process in rats (120–122). Additionally, the C-terminus of Efb is able to bind C3 and its cleavage products containing the thioester domain (C3d) (123, 124). Efb blocks phagocytosis *in vitro* of *S. aureus* by neutrophils in plasma and human whole blood as well as *in vivo* in a mouse peritonitis model. This evasion protein forms a unique bridge between complement and coagulation systems, since it can bind both C3 and fibrinogen. Efb covers bacteria with a thick layer of fibrinogen, which leads to shielding of surface-bound C3b and antibodies from recognition by phagocytic receptors (125). This mechanism to shield the bacterial surface from phagocytosis together with the formation of a capsule enhances the evasion of *S. aureus* against phagocytosis (126). It also causes clumping of staphylococcal cells *in vivo*, thus enhancing *agr* quorum-sensing (127).

Ecb (also known as Ehp) compared to Efb lacks fibrinogen binding activity, but like Efb, it does inhibit the complement system by binding the C3d domain of C3 (118, 128). This results in blocking of C3 convertases of the alternative pathway and C5 convertases of all three complement pathways (129). The binding of Ecb to C3d is stronger than Efb to C3d, because Ecb contains a second, lower-affinity, C3 binding site. This results in enhanced complement inhibitory effect of Ecb compared to Efb (128). The function of many evasion molecules is restricted to the human host; however, Ecb and Efb efficiently inhibit the complement system in both humans and mice. Therefore, the importance of Ecb and Efb could be examined *in vivo* in a murine infection model. Mice experienced higher mortality rates in an intravenous model with wild-type bacteria (79%) compared to an isogenic ΔEcbΔEfb mutant (21%). In addition, Ecb and Efb promoted bacterial survival and blocked neutrophil influx in the lungs. These results indicate that Ecb and Efb are essential to *S. aureus* virulence *in vivo* and could be attractive targets for vaccine development (130).

S. aureus recruits factor H to its surface with the surface-associated serine-aspartate repeat protein E (SdrE), and this leads to inhibition of the alternative pathway of the complement system (131). Recombinant SdrE recognizes its ligand via a unique "close, dock, lock, and latch" mechanism as determined by crystallographic studies (132). Moreover, factor H bound to SdrE retains its activity for factor I-mediated cleavage of C3b to iC3b (131). Factor I is directly targeted by the full-length cell wall component clumping factor A as well as a secreted moiety of around 50 kDa. Binding of cell wall component clumping factor A to factor I promotes cleavage of C3b to iC3b, which results in disruption of opsonophagocytosis (133, 134).

Extracellular adherence protein (Eap) has a variety of functions in evading the immune system. We already discussed the binding of Eap to ICAM-1 causing impaired function in neutrophil extravasation (39), but Eap is also able to inhibit the complement system. C4b is targeted by Eap, and this leads to inhibition of C2 binding to C4b and thus blocks formation of the active C3 convertase of the lectin and classical pathway (135).

Staphylokinase (SAK) also acts as an antiopsonic immune evasion protein by converting human plasminogen into the active bacterium-bound serine protease plasmin. Plasmin, from its location on the bacterial surface, degrades IgG and C3bf, resulting in decreased phagocytosis by human neutrophils (136).

SSL7 inhibits opsonization in two ways: it selectively binds both IgA and complement C5 (137). The binding of SSL7 to the Fc region of IgA, mediated via its N-terminus, causes interference with antibody recognition (138), whereas its C-terminus binds to C5 and thereby inhibits terminal complement activation and cleavage of C5 by interfering with the binding of C5 to C5 convertases (139). SSL7 was also found to be important *in vivo* by inhibiting complement-induced neutrophil influx in a murine inflammatory model (139).

S. aureus has also evolved a protein attached to the cell wall that specifically inhibits the classical pathway of the complement system. This protein, *S. aureus* collagen adhesin (Cna), belongs to the microbial surface component recognizing the adhesive matrix molecule (MSCRAMM) family of adhesins. Cna binds C1q and thus inhibits classical pathway activation. Cna belongs to the structurally related Cna-like family, members of which are found in many other Gram-positive bacterial species. Thus, the function of Cna-like MSCRAMMs as inhibitors of the classical pathway could serve as an immune evasion strategy for numerous Gram-positive pathogens (140).

NEUTROPHIL EXTRACELLULAR TRAP FORMATION

Neutrophils have recently been shown to have an antibacterial defense mechanism whereby they release their DNA, in association with antimicrobial peptides, histones, and proteases, to form a network of extracellular fibers which entrap

and kill various microbes. These networks are known as neutrophil extracellular traps (NETs) (141). There are current studies to address the molecular mechanism behind NET formation, but more research is needed to fully understand this phenomenon (142). The formation of NETs *in vitro* is activated via different proinflammatory stimuli, including hydrogen peroxide, phorbol myristate acetate, lipopolysaccharide, IL-8, and various bacteria, including *S. aureus* (143). The formation of NETs has also been shown *in vivo*, where intravascular NETs were observed in the mouse liver during sepsis induced by *S. aureus* (144).

EVADING NET FORMATION

A secreted nuclease of *S. aureus*, Nuc, is important in the breakdown of NETs. This has been shown both *in vitro* and *in vivo*, whereby an isogenic nuclease knock-out of *S. aureus* shows impaired degradation of NETs compared to the wild-type strain. This leads to the linkage of nuclease production to delayed bacterial clearance in the lung and increased mortality after intranasal infection *in vivo* (145). Thus, Nuc helps staphylococci to escape from the extracellular fibers and to avoid getting killed by antimicrobial peptides and proteases. Nuc was also shown to play a role in immune cell death together with secreted adenosine synthase. These two enzymes are able to convert NETs to deoxyadenosine, which triggers the caspase-3-mediated death of immune cells (146).

BACTERIAL KILLING BY NEUTROPHILS

Neutrophils are end-stage cells with a high concentration of antimicrobial proteins safely stored within different granules. They kill pathogens by releasing their granules containing antimicrobial proteins into the phagosome (also called degranulation) and generating ROS (also known as the oxidative burst) upon phagocytosis of bacteria. Phagocytes, especially macrophages, also form reactive nitrogen species via the oxidation of nitric oxide (NO•), which is produced by an inducible nitric oxide synthase (147). The granules of neutrophils can be divided into three groups: the primary or peroxidase-positive granules, the secondary or specific granules, and the tertiary or gelatinase granules. The peroxidase-positive granules are also called azurophilic granules due to their affinity for the basic dye azure A (12). Secretory vesicles contain plasma proteins and are probably formed by endocytosis (12). Azurophilic granules contain a variety of antimicrobial proteins, such as pore-forming peptides (α-defensins), neutrophil serine proteases (NSPs; proteinase 3 and 4, cathepsin G, and elastase), myeloperoxidase (MPO), the bactericidal/permeability-increasing protein, and lysozyme. Secondary granules contain hCAP-18, lactoferrin, neutrophil gelatinase-associated lipocalin, and lysozyme. Tertiary granules contain a number of metalloproteases, such as MMP8 (collagenase) and MMP9 (gelatinase). Secretory vesicles contain plasma proteins and membrane-associated receptors essential at the earliest phase of neutrophil-mediated inflammatory response, such as the extremely rapid upregulation of β_2-integrin CD11b/CD18, CR1, and FPR1 and FPR2 (148). However, it should be mentioned that heterogeneity exists between the different granules and that their granule contents overlap, because they are sequentially formed during myeloid cell differentiation (149).

Oxygen-Independent Killing by Neutrophils

Oxygen-independent killing mechanisms by neutrophils greatly contribute to microbial killing (150). Agents that contribute to oxygen-independent microbicidal activity include antimicrobial peptides and proteins such as lactoferrin, lysozyme, α-defensins, cathelicidins such as hCAP-18, azurocidin, proteinase 3, cathepsin G, and neutrophil elastase (12). The C-terminal part of hCAP-18, named LL-37, forms an amphipathic α-helix and has antimicrobial properties against Gram-negative bacteria and Gram-positive bacteria, such as *S. aureus* (151). LL-37 is effective against both intra- and extracellular *S. aureus* (152). Other antimicrobial peptides include α-defensins (also known as human neutrophil peptide-1). These peptides are antimicrobial, acting by the formation of multimeric pores and applying this on various microorganisms (153). The structurally related serine proteases (cathepsin G, elastase, and proteinase 3 and 4) have various functions, including the cleavage of bacterial virulence factors and regulation of immune responses by cleaving receptors and chemokines, and they are able to kill bacteria in the extracellular milieu after being secreted (154). The serine proteases also proved to be important *in vivo*, since mice lacking cathepsin G showed impaired clearance of *S. aureus* during infection (155). Lactoferrin and calprotectin are chelating proteins; lactoferrin sequesters iron needed for microbial growth, and calprotectin chelates zinc and manganese and thereby inhibits staphylococcal growth (156). Calprotectin is located in the cytoplasm of neutrophils and makes up more than 60% of the proteins in the cytosol (157). Lysozyme is a cationic antimicrobial peptide and is present in all granule subsets, with a peak concentration in secondary granules. Lysozyme cleaves bacterial cell wall peptidoglycan polymers by breaking the β-1,4 glycosidic bonds between *N*-acetylmuramic acid and *N*-acetylglucosamine (158). This results in lysis of various bacteria, such as *Bacillus subtilis*, in human plasma, but has only limited action against staphylococci because of their modified peptidoglycan (159).

Oxygen-Dependent Killing by Neutrophils

Upon phagocytosis of bacteria, the azurophilic granules are the first to fuse with the phagosome, and this leads to assembly of the five essential parts of the NADPH oxidase complex and activation of the complex (160). Active NADPH oxidase transfers electrons across the phagosomal membrane from cytosolic NADPH to intraphagosomal molecular oxygen to produce superoxide, which is compensated for by an influx of cations or protons. Although superoxide has limited direct microbicidal capacity, the molecule is involved in generating secondary derived ROS such as hypochlorous acid, chloramines, hydroxyl radicals, and singlet oxygen, which directly contribute to polymorphonuclear microbicidal activity. The superoxide anion is converted to hydrogen peroxide spontaneously or with the help of superoxide dismutase. MPO catalyzes the reaction of hydrogen peroxide with chloride to form the highly bactericidal agent hypochlorous acid (161, 162). Chlorine, chloramines (e.g., monochloramines, dichloramines, and taurine chloramine), singlet oxygen, hydroxyl radicals, and ozone are subsequently formed in secondary reactions and are also potent antimicrobial compounds (163).

The role of MPO in intracellular bacterial killing is controversial. In the early 1970s it was thought that MPO was the main factor in killing of *S. aureus* by hypochlorous acid production, because MPO-deficient patients showed a 10-fold decrease in killing bacteria after phagocytosis (164). However, this process is incompletely understood, and reproducible results are lacking. Later, MPO was shown to contribute poorly to the pulmonary defense when comparing wild-type mice with MPO-deficient mice infected with

S. aureus. In contrast, MPO-deficient mice showed a significant decrease in clearing other microorganisms (e.g., *Candida albicans*, *Candida tropicalis*, *Pseudomonas aeruginosa*) compared to wild-type mice (165). Back then it was believed that the pH inside the phagosome dropped to 4.0 (166). Later, the pH inside the phagosome was believed to be 7.8 and to drop to 6.9 after 15 minutes of phagocytosis (167) or even to 5.7 after 60 minutes (168). Recently, data revealed that the pH becomes more alkaline due to K^+ influx, which is optimal for granule proteases (155). This brings into question the role of MPO in bacterial killing because an alkaline pH results in a virtual absence of the peroxidase and chlorinating activities of MPO (169). It is possible that MPO has two functions *in vivo*: (i) peroxidase activity at pH ~6 when the neutrophil is unable to fully engulf an organism and (ii) superoxide dismutase (161) or catalase (170) activity in an alkaline milieu in a fully enclosed vacuole with a pH of ~9 to favor conditions for the granule proteases (e.g., proteinase 3, cathepsin G, and elastase) (171). MPO could also protect the microbicidal enzymes against oxidative damage, so both oxygen-dependent and oxygen-independent machineries inside the phagosome synergize for most effective killing of microbes. In our own experiments we have demonstrated that the MPO-dependent part of killing of *S. aureus* in neutrophils is 26% in the first 60 minutes (172).

EVADING KILLING

In this section we give an overview of the evasion proteins and pigments that are involved in staphylococcal survival of oxygen-dependent and -independent killing. These proteins are summarized in Fig. 4. Then the various staphylococcal toxins will be discussed. An overview of these toxins is shown in Fig. 5.

Evading Oxygen-Dependent Killing by Neutrophils

S. aureus's species name is derived from the fact that this bacterium has "a jacket" of the golden pigment staphyloxanthin. This staphyloxanthin serves as an antioxidant and is protective in killing by hydrogen peroxide and singlet oxygen. Bacteria lacking staphyloxanthin showed impaired survival *in vitro* and *in vivo* (173). The genes *crtM* (dehydrosqualene synthase) and *crtN* (dehydrosqualene desaturase) are essential in the biosynthetic pathway to produce staphyloxanthin. Therefore, synthetic inhibitors of CrtM are interesting new virulence factor-based therapies that act by targeting the biosynthesis of staphyloxanthin (174, 175).

S. aureus has developed other proteins that contribute to the resistance against ROS. The bacterium produces two superoxide dismutases, *sodA* and *sodM*, that convert the harmful superoxide radicals into hydrogen peroxide and oxygen (176). Isogenic *sodA* and/or *sodM* knockout bacteria had reduced virulence in a mouse abscess model, showing that both *sodA* and *sodM* contribute to the virulence of *S. aureus* (176). Probably, *sodA* has the major SOD activity in *S. aureus* throughout all growth stages, whereas *sodM* becomes active under oxidative stress during the late exponential and stationary growth phases (177). The hydrogen peroxide generated by the neutrophil is degraded into water and oxygen by KatA, a staphylococcal catalase, which is described to be a major virulence factor (178). However, studies conducted with a catalase mutant strain showed no difference in virulence in a murine abscess infection model (179). Another

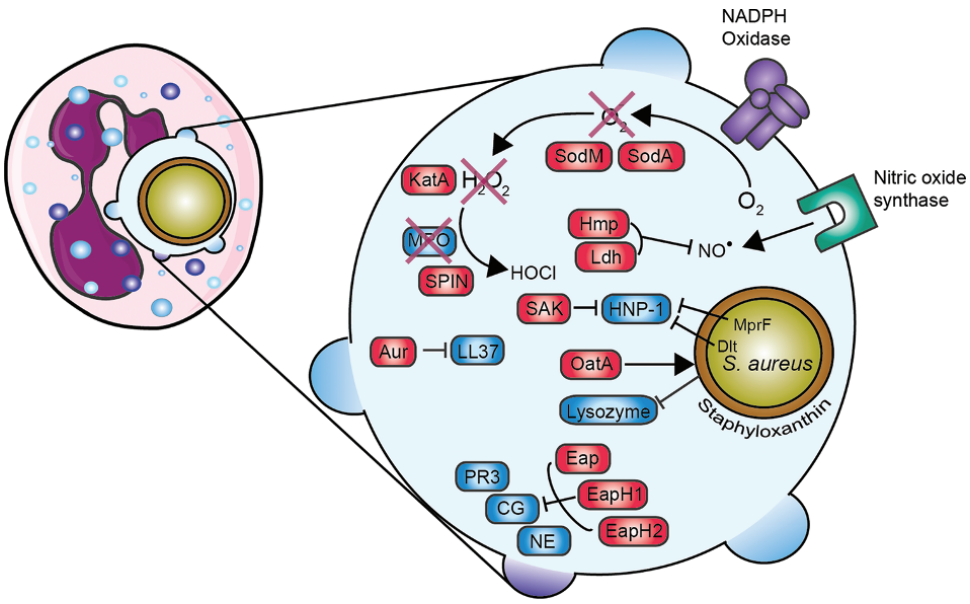

FIGURE 4 Overview of evasion proteins that are involved in evading neutrophil killing. Enlargement of the phagosome is shown on the right. Red boxes indicate staphylococcal proteins, and blue boxes indicate host proteins. Staphyloxanthin provides a protective shield, KatA neutralizes hydrogen peroxide (H_2O_2) into water (H_2O) and oxygen (O_2), and SPIN inhibits MPO activity. MprF and the Dlt operon lead to an increase in positive charge of the bacterial surface. Abbreviations: SOD, superoxide dismutase; SAK, staphylokinase; KatA, catalase; MPO, myeloperoxidase; SPIN, staphylococcal peroxidase inhibitor; Aur, aureolysin; Hmp, flavohemoglobin; Ldh, L-lactate dehydrogenase; Eap, extracellular adherence protein; EapH, extracellular adherence protein homologue; PR3, proteinase 3; CG, cathepsin G; NE, neutrophil elastase. The figure was adapted from Servier Medical Art.

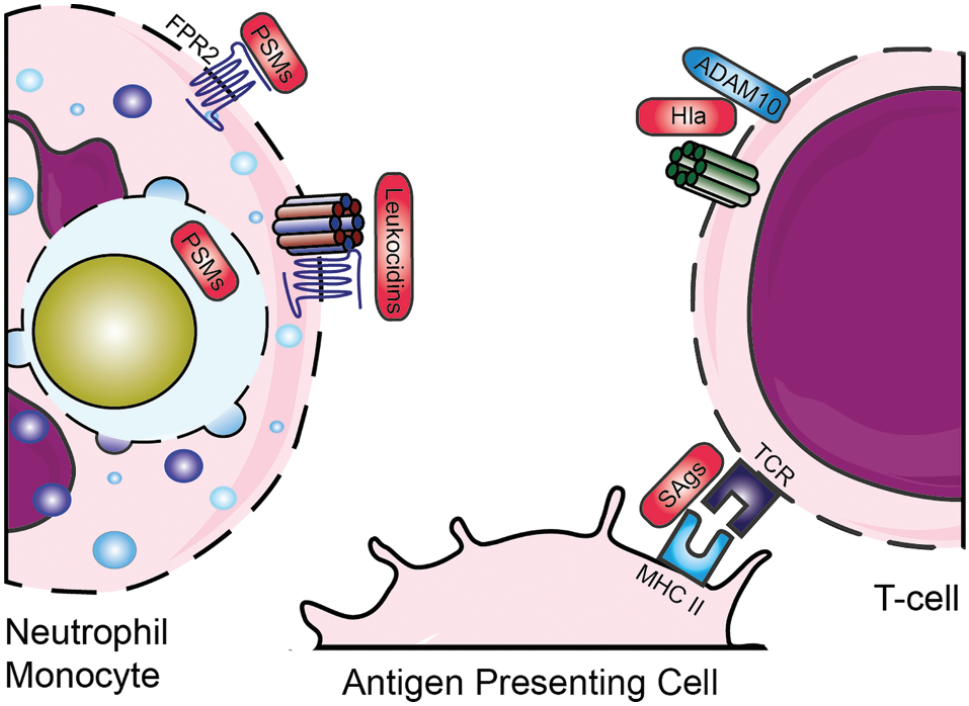

FIGURE 5 Evasion by staphylococcal toxins. Various leukocidins bind specific GPCRs, after which they form a pore and lyse host cells. PSMs are released inside the phagosome and can bind via FPR2. SAgs cross-link major histocompatibility complex class II and T-cell receptors. Abbreviations: GPCR, G-protein-coupled receptor; FPR, formyl protein receptor; PSMs, phenol-soluble modulins; Hla, hemolysin-alpha; SAgs, superantigens; MHC II, major histocompatibility complex II; TCR, T-cell receptor. The figure was adapted from Servier Medical Art.

catalase-like protein produced by *S. aureus* is alkyl hydroperoxide reductase (AhpC). KatA catalase appears to be important for protection against external oxidative stress, whereas AhpC clears endogenously produced hydrogen peroxide. In that study, AhpC and KatA were not required for virulence of *S. aureus*, but AhpC and/or KatA are important for nasal colonization (180). Another virulence factor, at first unidentified, regulated via the SaeR/S two-component system was suspected to play a role in the decrease of hydrogen peroxide and hypochlorous acid production. This factor was independent of SOD and catalase, since their expression is not regulated by SaeR/S (181). Later, this factor was identified as staphylococcal peroxidase inhibitor (SPIN), a secreted protein of 8.4 kDa which is able to bind and inhibit MPO. From crystallographic studies, we know that SPIN acts as a molecular plug that prevents access of substrate hydrogen peroxide to the MPO active site. Despite the controversy concerning the importance of MPO in bacterial clearance, SPIN protects *S. aureus* from MPO-mediated killing (172).

S. aureus has also evolved two proteins to resist the stress of nitric oxide produced in activated phagocytes. Flavohemoglobin scavenges host-derived NO•, and the NO•–inducible L-lactate dehydrogenase catalyzes the production of L-lactate, which maintains redox homeostasis during nitrosative stress (182, 183).

Evading Oxygen-Independent Killing by Neutrophils

S. aureus contains two independent loci (*dltABCD* and *mprF*) that affect susceptibility to defensins and other cationic pore-forming peptides by modifying the net charge of the cell wall envelope. The *dlt* operon is responsible for the incorporation of D-alanine into teichoic acids, and this leads to a decrease in negative charge on the bacterial surface and tolerance of high concentrations of positively charged antimicrobial peptides (184). A *dlt* knockout mutant was more susceptible to killing by defensin peptides and human neutrophils, even in the absence of a functional respiratory burst. As a control, there was no difference in killing between wild-type and *dlt* knockout bacteria by monocytes, which do not produce defensins (185). The *mprF* (multiple peptide resistance factor) gene encodes a lysylphosphatidylglycerol synthetase which is involved in modification of membrane phosphatidylglycerol with L-lysine, which also results in a reduction of the negatively charged membrane surface (186, 187). In contrast to most defensins, cathelicidin-derived bactericidal peptides, such as LL-37, have substantial activity against staphylococci. However, *S. aureus* has also evolved a protein to evade the antimicrobial effects of LL-37 by degrading and thereby inactivating LL-37 by the staphylococcal metalloproteinase aureolysin (which is also involved in the opsonization process by cleaving C3) (188). As described above, lysozyme degrades the cell wall peptidoglycan layer. Nonetheless, *S. aureus* resists lysozyme by expressing the enzyme *O*-acetyltransferase A (OatA). OatA causes *O*-acetylation of the peptidoglycan, and this leads to resistance to the muramidase activity of lysozyme. OatA is regarded as a virulence factor since it is expressed only in pathogenic, lysozyme-resistant staphylococci (for example *S. aureus*, *S. epidermidis*, and *S. lugdunensis*) (189, 190).

Eap inhibits the activity of NSPs (neutrophil elastase, cathepsin G, and proteinase 3). Its homologues, EapH1 and EapH2, each contain one EAP domain, whereas the earlier described Eap usually contains four or five EAP repeats.

A single EAP domain impairs the function of NSPs; therefore, EapH1 and EapH2 also inhibit NSP activity (191). Recently, the interaction between EAP and NSPs was investigated, and despite the homology between EapH1 and EapH2, they form different complexes with NSPs (192). *S. aureus* protects its own immune evasion arsenal from degradation and cleavage by inhibiting these NSPs (193). For example, the N-terminus of SPIN is susceptible to proteolysis by NSPs, which results in a loss of function to inhibit MPO, but it is protected again by Eap. SAK is not only involved in evading opsonization by cleaving plasminogen to active plasmin (136), but it also binds and inhibits α-defensin (human neutrophil peptide 1). Human neutrophil peptide 1 is an important antibacterial peptide in neutrophil granules. This inhibition affects intracellular killing (194).

Escape by Toxins

S. aureus also protects itself by the secretion of toxins (Fig. 5). Toxins can directly lyse and thereby kill (immune) cells by disrupting the cell membrane and protecting the pathogen both before and after engulfment by neutrophils. These lytic toxins can be divided into two groups based on their structure: the β-barrel pore-forming toxins such as α-hemolysin and leukocidins and the small α-helical peptides such as the PSMs. A different group of toxins, the superantigens, activate T-cells by cross-linking major histocompatibility complex class II and T-cell receptors, resulting in massive nonspecific activation of T-cells. This temporary overactivation of a large population of T-cells causes secondary inhibition of the adaptive immune system and thereby contributes to immune escape.

β-Barrel pore-forming toxins target eukaryotic cells expressing specific factors. Hemolysin-alpha (Hla, also known as α-toxin) is secreted as a monomer, which forms a homo-heptameric pore upon binding to its receptor, the zinc-dependent metalloprotease ADAM-10 (195). Hla also upregulates ADAM10 on endothelial and epithelial cells, causing disruption of the endothelial and epithelial barrier (196, 197). Hla does not lyse granulocytes (e.g., neutrophils), but it does lyse other blood cells, such as erythrocytes, macrophages, and subpopulations of lymphocytes (198). Other β-barrel pore-forming toxins are leukocidins. These toxins consist of two independent secreted monomers known as F (fast) and S (slow) and form octamer pores of four F and four S subunits in membranes of host cells (199). Currently, seven *S. aureus* leukocidins have been described, including five in human-associated strains: LukAB (also known as LukGH), LukSF (also known as PVL), LukED, and two γ-hemolysins (HlgAB and HlgCB). Two animal-associated leukocidins (LukPQ [200] and LukMF′ [201]) were recently added to the arsenal (202). The receptors for these leukocidins have recently been identified, and this explains the cellular tropism and biological consequences of these pore-forming toxins during infection (203). Their receptors, all GPCRs and almost exclusively chemoattractant receptors, are located on various immune cells, but mainly on phagocytes. This indicates that the major role of these toxins is in immune evasion. They are designed to kill those cells that are crucial in eliminating staphylococci. HlgAB and LukED, however, also target the Duffy antigen receptor for chemokines expressed on erythrocytes, which leads to release of hemoglobin and promotes bacterial growth (204). Furthermore, LukAB has been shown to play a role in intracellular lysis of neutrophils, thereby promoting bacterial replication and outgrowth (205). Interestingly, the presence of these leukocidins in the genome of *S. aureus* is highly diverse. For example, the *HlgACB* and *lukAB* genes are located in the core genome and are present in more than 95.5% of human *S. aureus* isolates, whereas PVL is located on a phage and is found in fewer than 2% of all clinical isolates, but it is found in the majority of community-acquired MRSA strains in the United States. The presence of the PVL genes (lukS-PV and LukF-PV) in staphylococci correlates with the occurrence of necrotizing pneumonitis, a severe and devastating form of bacterial pneumonia (206).

The other class of toxins is PSMs, which are small α-helical peptides. These peptides are associated with enhanced virulence in community-acquired MRSA and are produced at high concentrations. PSMs contain a common amphipathic α-helical region which is responsible for disrupting the cell membrane; nonetheless, they are categorized in two groups: the β-type PSMs (around 44 amino acids long) and the shorter α-type PSMs (20 to 25 amino acids long), which have more enhanced toxic characteristics (207). The function of PSMs is inhibited by serum lipoproteins, which are present in large quantities in human serum (208). Therefore, their function is mainly intracellular, where they are able to lyse phagocytes from the inside out. The critical concentration of PSM is easily reached inside the condensed phagosome (209). Through the interaction between PSMs and FPR2 (see "Opsonization," above), PSMs can not only lyse neutrophils, but can also attract and activate leukocytes via FPR2 (53).

S. aureus also encodes a variety of toxins (the superantigens) that modulate the adaptive immune system. Around 20 serologically distinct staphylococcal superantigens are known, which are divided into enterotoxins, enterotoxin-like, and toxic shock syndrome toxin-1. Their nomenclature is differentiated on the basis of proven emetic activity when orally ingested (enterotoxins SEA-E, G-J, and S-T) or unconfirmed activity (enterotoxin-like SEIK-R, U and U2, V, and X-Y) (210). Superantigens cross-link major histocompatibility complex class II and T-cell receptors. This causes massive nonspecific activation of T-cells and an increase of many cytokines to toxic levels, which leads to damage of tissue and organs. This is called the toxic shock syndrome, and it is often lethal (211). The SSLs were first annotated as SET proteins for "staphylococcal enterotoxin-like" but were later renamed staphylococcal superantigen-like (SSL) since these proteins lack enterotoxic activity (210). Even though their enterotoxic activity is lacking, the SSLs have distinct functions in evading the innate immune system.

DISCUSSION AND CONCLUSION

Staphylococcal Innate Immune Evasion

Bacteria adapt to their environment. Pathogenic bacteria adapt to survival in their host. In the human host this means that they have evolved various virulence strategies to overcome innate and adaptive immunity. These virulence strategies are (i) camouflage of the microbial surface to avoid immune recognition by the production of an inert capsule, often composed of sugars, (ii) hiding from the immune system by adapting to an intracellular lifestyle in immune cells or other cells, and (iii) secretion of small proteins that inhibit specific elements of the immune system (212). These approaches all have advantages and disadvantages. Production of a capsule requires a considerable amount of energy. In addition, at some stages during infection, the bacteria need to remove their capsule, for example, for adherence to host cells, thereby exposing themselves to the immune system. For example, pneumococcal capsules are 60 nm thick, covering

all surface structures on the bacterium. Hiding from the immune system through survival inside cells is also a challenge owing to the presence of multiple microbicidal enzymes and proteins inside these cells. Moreover, discovery of intracellular TLRs, NOD-like receptors, and inflammasomes revealed that bacteria can also be recognized inside cells (55). Therefore, the production of small secreted inhibitory proteins is, by itself or in combination with the other strategies, a strong evasion strategy to survive within the host and works extracellularly as well as intracellularly. *S. aureus* has extensively evolved proteins to evade all facets of the initial attack by the host immune system.

S. aureus remains a leading cause of bacterial infections and has an increasing risk for human health with the rise of antibiotic resistance in community-acquired strains. Also, the financial burden is growing due to increasing pressure on the health care system. Research into immune evasion molecules is very important, since these proteins determine staphylococcal virulence and pathogenesis. Understanding the mode of action of these evasion molecules will help us to find new therapeutics for prophylaxis or will improve treatment against *S. aureus*, since a functional vaccine is still lacking.

So Many Evasion Molecules: Luxury or Necessity?

To date, the functions of around 40 immune evasion proteins have been identified, and this number is still growing. These evasion molecules are present in clinical isolates and are expressed in the human host, since healthy carriers and noncarriers in adults and even young children have antibodies against these proteins (20, 213). Some of these evasion molecules were detected by high-resolution mass spectrometry from nasal polyp tissue from patients with chronic rhinosinusitis (214). One question arising from this observation is Why is *S. aureus* expressing so many evasion molecules? It seems a waste of time and energy for the bacterium to produce and secrete all of these proteins. Most of them target different specific parts of the immune system. We think that this demonstrates the strength, the significance, and the redundancy of our innate immune system. A very efficient and redundant immune system can only be overcome by a redundant counterattack. Moreover, other microbes have different methods to avoid recognition and killing by the immune system. As said before, a thick capsule is an efficient method to hide and sterically hinder access to the highly immunogenic surface, for example, masking the binding of C3 fragments to the complement receptor. This leads to decreased opsonization, phagocytosis, and subsequently, killing of the microorganisms by neutrophils (94). Gram-negative bacteria such as *Neisseria meningitides* and Gram-positive bacteria such as group A *Streptococcus* and *S. pneumoniae* are known to produce this thick capsule (94, 215, 216). A typical capsule is encoded by at least 15 large glycosyltranferases that are encoded by 3 to 4% of all base pairs in the genome, because the average size of a glycosyltransferase is between 200 and 300 kDa. Evasion proteins are much smaller, typically between 10 and 30 kDa, and encoding 40 of these therefore amounts to less than 1% of the whole *S. aureus* genome. Also, the production and maintenance of a thick polysaccharide capsule consumes a large amount of energy. Therefore, the production of 40 small proteins that directly attack the immune system is cheaper for the bacterium than the strategy of making a thick capsule.

Another explanation for the enormous number of different immune evasion proteins is variability in the human's defense. The arsenal of immune evasion molecules makes it easier to fight the immune system of different individuals with variable antigens and genomic variation in their immune response. In addition, the expression of the various evasion molecules is tightly regulated via multiple regulation systems, and this results in differential expression during different growth stages. Interestingly, some of these relatively small molecules have multiple functions. The total number of secreted proteins in *S. aureus* is 100 to 200, and many of these proteins still have no known function (11). Thus, it is likely not only that new evasion molecules will be identified in the future, but also that new functions will be associated with already known proteins (11).

Despite the fact that *S. aureus* produces so many evasion molecules, the majority of colonized individuals will not suffer a staphylococcal infection. This tells us how complex and efficient our own immune system is. Invading microorganisms can be cleared within minutes by our innate immune system, possibly before some immune evasion proteins are produced. The pathogens are recognized by pattern recognition receptors and opsonized by components of the complement system and immunoglobulins. These immunoglobulins from the adaptive immune system are also able to neutralize bacterial components, such as superantigens, toxins, and other immune evasion proteins. The opsonized bacteria are efficiently ingested by neutrophils and killed by oxidative and nonoxidative proteins, which are safely stored inside their granules.

In conclusion, it seems that there is a delicate balance between the immune system and *S. aureus* in their ongoing battle to fight each other. However, *S. aureus* is gaining ground due to the rise of antibiotic resistance and community-acquired and highly virulent strains.

Evasion Proteins and Therapeutic Strategies

Over the past 2 decades we have gained in-depth knowledge about the existence, the importance, and the molecular mode of action of many immune evasion proteins. Now, what can we do with this knowledge? As illustrated below, one crucial goal is to find a treatment specifically against staphylococcal infections, but these immune evasion proteins can also be used to dampen the immune response in inflammatory diseases.

Combating *S. aureus* with (new) antibiotics is a challenge, since the bacterium has the extraordinary ability to develop resistance against antibiotics and the discovery of new antibiotics is declining (7). Vaccination is a strategy that could solve many of the problems that we encounter with antibiotic resistance. A few vaccine candidates have been tested in clinical trials, but none of them successfully passed phase III studies (217). For example, the vaccine candidates against the relatively small capsule of *S. aureus*, capsular polysaccharides types 5 and 8, have not passed clinical trials yet (218). This is possibly due to the presence of natural nonopsonic antibodies to another *S. aureus* cell surface polysaccharide, poly-*N*-acetylglucosamine, in human serum, and this interferes with the vaccine (219). Other vaccines targeting a single cell surface-associated antigen have failed clinical trials, for example, the iron surface determinant B (IsdB). Antibody against IsdB showed good tolerance in healthy volunteers, but in phase III studies patients administered with this vaccine were more susceptible to developing *S. aureus* infections and were five times more likely to die than unvaccinated patients with *S. aureus* infections (220). A recent overview of vaccine candidates and the status of their clinical trials was described, and this shows that

although there is still ongoing research in this field, no functional vaccine will be available in the near future (217).

Another way to neutralize evasion molecules is by the generation of small inhibitory peptides or neutralizing antibodies via passive immunization, which is short-term immunity provided by antibodies obtained outside the body. For example, a CCR5 antagonist often used in HIV treatment, maraviroc, also protects T-cells and myeloid cells from LukED-mediated toxicity (221). Thus, these types of drugs could also be used as therapeutic alternatives against staphylococcal infections. Also, it might be a good approach to target one of the toxins produced by *S. aureus*. Currently, there are three antistaphylococcal monoclonal antibodies in clinical trials. Two of them target the secreted virulence factor alpha-toxin, which has recently been shown to protect against *S. aureus*-induced pneumonia (222). Unfortunately, so far, antibody-based therapy has not passed clinical trial phase II. Earlier research focused on single antigens displayed at the bacterial surface, but recently, this has moved toward agents targeting multiple *S. aureus* proteins, for example, immune evasion molecules and intracellular reservoirs of the bacterium (223). For example, the monoclonal antibody 6D4 interferes with the activity of SCIN, but it is likely that this will not be the only target in antistaphylococcal therapy since SCIN-deficient *S. aureus* strains still cause infections (224). Nevertheless, despite the lack of a functional monoclonal antibody/antibodies at this moment, antibody-based therapy is a promising therapeutic agent to use against staphylococcal infections in the future (225).

The fact that, so far, the development of an antistaphylococcal vaccine has failed can be attributed to several factors. Vaccines targeting single antigens without adjuvants were insufficient to give protection. This is likely due to the secretion of the manifold evasion molecules. Therefore, research focus has switched to developing a vaccine against a combination of proteins. Also, the lack of a highly reliable animal model is another factor and is partially caused by immune evasion molecules since many of the evasion proteins have high-affinity binding capacity to only human targets. These high-affinity protein-protein interactions between virulence factor and target cause a lack of affinity in targets in other, less related hosts. Because multiple immune evasion proteins are restricted to the human host, it leads to difficulties in studying *S. aureus* infections *in vivo*, such as in mice. Therefore, *in vivo* studies of SCIN, CHIPS, SAK, and PVL are difficult. Some isolated virulence factors are, however, not human specific and do allow studies in other species, for example, Ecb and Efb in a murine infection model (130). The genes located in the core variable genome are immobile and generally have a broad species specificity, whereas mobile genetic element-encoded immune evasion proteins (e.g., pathogenicity islands and prophages) are highly species specific (226). The third reason for the failure of previous vaccination attempts is the existence of immune evasion by itself, which leads to lower local immunity. Even if the vaccine raises sufficient opsonizing antibodies during this lowered local immunity, the induced antibodies cannot confer protection by the lack of an effector system (such as complement and neutrophils). A way to overcome this is to incorporate evasion molecules into the vaccine and raise neutralizing antibodies against these evasion molecules. Inhibiting the inhibitor and restoring local immunity could be a solution to solve vaccination issues in the future. Nevertheless, redundancy of immune evasion molecules and a good animal model remain obstacles to be overcome.

The evasion molecules can also be used as anti-inflammatory therapy in diseases where there is a deflecting immune activation. This is a growing area of research due to the increased prevalence of staphylococcal infections in Western countries. There are numerous inflammatory diseases, for example, allergy, asthma, autoimmune diseases, vasculitis, and inflammatory bowel disease. Many evasion molecules inhibit the central players in human inflammatory diseases, such as some GPCRs, complement components, and TLRSs, and are therefore interesting therapeutic targets (227–229). This approach has already been used in several studies; for example, SCIN-derived peptides were screened for complement inhibition through phage display to develop new complement-directed therapies (230). However, the evasion molecules are immunogenic by themselves. Thus, we need something else that is based on these evasion proteins, such as small peptides or derivatives which are no longer immunogenic. The (co)crystal structure is known from many evasion molecules, and this shows us where the exact binding interface at the amino acid level is between the staphylococcal protein and its binding partner of the immune system (226). This is very helpful in designing (structured) peptides.

Another way to use peptides derived from evasion molecules is in anticancer strategies. Some of these immune receptors promote cancer growth, such as FPR1 in brain tumors. Thus, the staphylococcal inhibitor of FPR1, CHIPS, is a potential anticancer drug. Recent research with mice expressing human FPR1 on astrocytoma cells treated with CHIPS showed increased survival of the mice and reduced tumor growth (231).

Immune Evasion Cluster 1/φSa3: a Mobile Element on a Quintuple Converting Bacteriophage

CHIPS, SCIN, and SAK (136) are small, secreted proteins that play a crucial role in the staphylococcal defense against the human innate immune system (complement and neutrophils) (46). The genes for SAK (*sak*), CHIPS (*chp*), and SCIN (*scn*), and also for the superantigen SEA (*sea*), are clustered on an innate immune evasion cluster (ϕSa3) in *S. aureus*, an 8-kb region at the 3′ end of β-hemolysin-converting bacteriophages. When this phage inserts into the β-hemolysin gene, it inactivates the gene itself, and the bacterium can no longer produce β-hemolysin. In addition, the bacterium now can produce four virulence/evasion factors, which have roles in different aspects of the pathogenetic strategy of the organism, as described above. Therefore, these phages are known as quintuple converting phages (226). When studying the occurrence of this mobile element in different *S. aureus* strains, it becomes immediately clear that it is strictly limited to human strains and is absent in, for example, bovine strains (226). Further, when studying the functional interaction between the four evasion molecules present on this element, it becomes clear that all four proteins act only on human targets, never on animal receptors or molecules. This is true for CHIPS in its interaction with C5aR and FPR, is true for SCIN in its interaction with the complement components C3b and Bb, and is true for SAK and even for the superantigen SEA. CHIPS does not work on animal neutrophils, and SEA does not work on animal T-cells. SCIN does not work in animal sera (116). From the molecular data from crystallography and nuclear magnetic resonance studies between evasion molecules and targets, we can now deduce the action on the precise amino acids in the host (78, 115). Taken together, the conclusions from epidemiological studies of various animals and humans, the functional studies conducted with sera and isolated cells versus recombinant bacterial proteins, and the structural data

generated over the years are very clear: this mobile element and all of the components located on it are strictly human specific. It can transform a staphylococcus into a human pathogen. This also illustrates the importance of these virulence factors in the pathophysiology of infections in humans.

Concluding Remarks on Biological Warfare between Staphylococci and their Hosts

Our immune system can rapidly clear bacteria from our body after infection. However, infecting bacteria do not idly stand by when confronted by the host immune response. The following bacterial immune evasion strategies are often employed by pathogenic bacteria to resist our immune system.

1. Form a capsule.
2. Invade host cells and survive within them (intracellular lifestyle).
3. Change surface/change recognition molecules.
4. Secrete modulators/inhibitors/immune evasion molecules.

Hiding within an inert capsule is the hallmark of pneumococci. Mycobacteria are renowned for their capacity to hide within host cells. Staphylococci are the masters of surface modulation and immune evasion by secreted proteins. On the one hand, in the past 15 years, these phenomena have been studied extensively in *S. aureus*; on the other hand, in the next decades, it is likely to become clear how far this understanding can be extended to other bacteria. For any pathogenic bacterium, we know that there are still hundreds of nonannotated secreted proteins.

Staphylococcal immune evasion is very important for the bacterium, especially to fight the immune system during acute infection. Therefore, most evasion proteins are directed against this initial attack by neutrophils. This review gave an overview of the various evasion proteins and their function(s) during infection. Interestingly, the repertoire is still expanding with the recent discovery of novel proteins and new functions of existing evasion molecules. It is an important field of research, since functional therapeutics against staphylococcal infections are still lacking, while the economic burden increases. However, with the current speed of experiments, our knowledge is growing every year, and most likely it will only be a matter of time before we find the appropriate therapeutics for prophylaxis or treatment of this extremely clever bacterium.

We thank Kobus Bosman and Seline Zwarthoff for useful discussions and critical review of the manuscript.

Staphylococcus aureus Secreted Toxins and Extracellular Enzymes

KAYAN TAM AND VICTOR J. TORRES

40

EXOTOXINS

Introduction

Staphylococcus aureus is a highly successful pathogen that colonizes ~30% of the population asymptomatically, but it is also capable of causing infections ranging from mild skin and soft tissue infections to invasive infections, such as sepsis and pneumonia (1). When *S. aureus* infects the host, it produces many virulence factors that promote the manipulation of the host's immune responses while ensuring bacterial survival. These virulence factors include secreted toxins (exotoxins), which represent approximately 10% of the total secretome (2). While there are over 40 known exotoxins produced by these bacteria, many of them have similar functions and have high structural similarities. Closer examination of these seemingly redundant exotoxins revealed that each has unique properties. Exotoxins fall into three broad groups based on their known functions: cytotoxins, superantigens (SAgs), and cytotoxic enzymes (Table 1). Cytotoxins act on the host cell membranes, resulting in lysis of target cells and inflammation. Superantigens mediate massive cytokine production and trigger T and B cell proliferation. Secreted cytotoxic enzymes damage mammalian cells. Collectively, these exotoxins modulate the host immune system and are critical for *S. aureus* infections.

Cytotoxins

β-barrel pore-forming toxins

α-Toxin: the prototypic pore forming toxin (PFT)

α-Toxin (also known as α-hemolysin or Hla) is encoded by the gene *hla* as part of a monocistronic operon in the core genome of *S. aureus*. Like all conventionally secreted proteins, α-toxin is synthesized with an N-terminal signal peptide. Water-soluble, α-toxin monomers form heptameric β-barrel pores in target cell membranes, resulting in cell lysis (Fig. 1A) (3). The α-toxin heptamer resembles a mushroom and has three major domains: an extracellular cap domain, a stem domain that forms the β-barrel pore, and a rim domain that confers receptor specificity (Fig. 2A to C) (4). The β-barrel pore is formed from a prepore by a conformational change in a toxin substructure known as the amino latch (5). The critical role of the amino latch in the β-barrel pore formation is exemplified by a single amino acid mutation at His-35, which disrupts interprotomer stabilization, thus preventing pore formation and inactivating the toxin (6–8).

The role of α-toxin in disease has been studied extensively. α-Toxin causes lysis of many cell types: erythrocytes, platelets, endothelial cells, epithelial cells, and certain leukocytes (9–12). For many years, α-toxin was thought to mediate cytolysis through nonspecific binding to the lipid bilayer of cells. However, this model did not explain the species specificity exhibited by the toxin (i.e., lysis of rabbit but not human erythrocytes). In 2010, Wilke et al. identified the protein ADAM-10 (a disintegrin and metalloprotease 10), as the cellular receptor for α-toxin, thus providing an explanation for the observed species and cell type specificities (Fig. 3) (13). Recently, the mammalian junction protein, PLEKHA7 (plekstrin-homology domain-containing protein A7), was also demonstrated to be involved in α-toxin cytotoxicity and is thought to contribute to α-toxin-mediated tissue injuries in murine skin infection and pneumonia models (14).

α-Toxin is not only lethal, but can also modulate cellular responses at sublytic concentrations, including the release of nitric oxide from endothelial and epithelial cells, extracellular Ca^{2+} influx, production of proinflammatory cytokines, and pyroptosis of monocytes through the activation of caspase-1 and the nucleotide binding oligomerization domain-like receptor protein 3 (NLRP3) inflammasome (10, 15–19). Additionally, sublytic levels of α-toxin upregulate the expression of ADAM10 and activate the ADAM10 protease to cleave the junction protein E-cadherin, resulting in disruption of the epithelial barrier (11). Nanogram to microgram amounts of α-toxin can cause severe dermonecrosis when administered subcutaneously in rabbits and mice (20, 21). Moreover, intravenous administration of this toxin also results in rapid lethality of the animals (20, 21). *S. aureus* Δ*hla* strains are severely attenuated in several infection models, resulting in enhanced host survival, decreased bacterial burden, inflammation, and tissue injuries (22–27).

The bicomponent PFTs

The bicomponent PFTs are relatives of α-toxin (Fig. 4), share structural homology with α-toxin, and have a similar pore formation mechanism (Fig. 1 and 2). However, in contrast to α-toxin, the bicomponent PFTs require two subunits: the fast-eluting subunit, F-subunit, and the

doi:10.1128/microbiolspec.GPP3-0039-2018

TABLE 1 Major exotoxins produced by *S. aureus*

Exotoxin(s)	Gene(s)	Function(s)
α-Toxin	*hla*	Pore-forming toxin
PVL (LukSF-PV)	*lukS*, *lukF*	Pore-forming toxin
HlgAB	*hlgA*, *hlgB*	Pore-forming toxin
HlgCB	*hlgC*, *hlgB*	Pore-forming toxin
LukED	*lukE*, *lukD*	Pore-forming toxin
LukAB/HG	*lukA/H*, *lukB/G*	Pore-forming toxin
LukMF′	*lukM*, *lukF′*	Pore-forming toxin
LukPQ	*lukP*, *lukQ*	Pore-forming toxin
PSMα1 to PSMα4	*psmα1* to *psmα4*	Phenol soluble modulins
PSMβ1, PSMβ2	*psmβ1*, *psmβ2*	Phenol soluble modulins
δ-Toxin	*hld*	Phenol soluble modulins
PSM-mec	*psm-mec*	Phenol soluble modulins
ε-Toxin	*cytE*	Cytotoxin
SEA to SEE, SEG	*sea* to *see*, *seg*	Enterotoxins, T cell superantigens
SE-l H to SE-l Y	*selh* to *sely*	T cell superantigens
TSST-1	*tst*	T cell superantigen
SpA	*spa*	B cell superantigen
β-Toxin	*hlb*	Sphingomyelinase, biofilm ligase
Exfoliative toxin A	*eta*	Serine protease
Exfoliative toxin B	*etb*	Serine protease

slow-eluting subunit, S-subunit, named on the basis of their liquid chromatography behavior (28, 29). The current model for leukocidin pore formation suggests that the S-subunit recognizes and binds to a surface receptor on the target cell and then recruits the F-subunit for dimerization (30–32). This is followed by oligomerization with three additional dimers to form an octameric prepore on the target cell membrane (33). Next, the stem domains of the prepore extend in the center of the structure, forming a β-barrel pore that inserts into the target cell membrane, resulting in cell lysis (Fig. 1B) (33, 34). Similar to the α-toxin heptamer, the bicomponent PFT octamer also resembles a mushroom, consisting of the cap, the rim, and the stem domains (Fig. 2).

The bicomponent PFTs primarily target leukocytes, and thus they are known as leukocidins (Luk). Currently, five of the leukocidins are known to be associated with human infections: LukSF-PV (originally known as the Panton-Valentine leukocidin [PVL]), γ-hemolysins AB and CB (HlgAB, HlgCB), LukED, and LukAB (also known as LukHG) (30–32). Two other bicomponent PFTs, LukMF′ and LukPQ, are associated with animal infections (35–37).

All the leukocidins share structural homology and sequence identity, ranging from 40 to 90% within each S-subunit and F-subunit family (Fig. 4) (38). The only exception is LukAB, which shares only ~30% sequence similarity with the others (38). LukA has an ~33-amino acid sequence at the N-terminus and a 10-amino acid C-terminal tail that are absent from other S-subunits, contributing to its divergence. Nevertheless, the structure of LukAB remains homologous to the other bicomponent PFTs (39).

In additional to mediating cell lysis, many of the leukocidins have sublytic effects, causing extracellular Ca^{2+} influx on host cells (40–42) and production of proinflammatory cytokines (40, 43–47). Several of the leukocidins, PVL, HlgAB, and LukAB, stimulate K^+ efflux, which is involved in the activation of the NLRP3 inflammasomes and caspase-1, resulting in a form of inflammatory cell death known as pyroptosis (43, 45–47).

Although the bicomponent PFTs exhibit many similarities, there are subtle differences that confer unique properties on each of them, which are briefly summarized below (see references 30–32 for in-depth summaries).

LukSF-PV (PVL). The *pvl* locus is encoded within the genomes of at least six prophages (48–51). Although less than 40% of clinical isolates from the United States carry a *pvl*-encoding prophage, over 90% of strains associated with severe necrotizing pneumonia and community-acquired infections carry *pvl* (1, 52). The relationship between *pvl*-encoding *S. aureus* and severe infections in humans is supported by strong epidemiological data and recent data using animal models of infection (53–57).

PVL exhibits species specificity, killing only rabbit and human leukocytes. The species specificity is due to the targeting of the human and rabbit G-protein-coupled receptors, C5aR1 and C5aR2, but not the murine counterparts (Fig. 3) (58, 59). Consequently, regular mice are inappropriate for the study of this toxin; the availability of rabbit models and human *ex vivo* models has provided insight into the complexity of PVL-mediated pathology. PVL is a critical factor in invasive diseases such as osteomyelitis and pneumonia in rabbits. Deletion of *pvl* results in less inflammation, reduces tissue injuries and bacterial burden, and promotes host survival (57, 60). Remarkably, sublytic levels of PVL can enhance phagocytosis and killing of the bacteria by primary human neutrophils (61). In contrast, the role of PVL during skin and soft tissue infections is unclear. While one study demonstrated that PVL did not contribute to lesion sizes and bacterial burden (62), another study showed that infections caused by Δ*pvl* strains have smaller lesions compared to the wild type and complemented controls (63). These studies seem to suggest that the pathogenic effect of PVL could be dependent on the site of infection, but more work must be done to test this hypothesis.

γ-Hemolysin (HlgAB, HlgCB). The γ-hemolysin locus is part of the core *S. aureus* genome, present in ~99% of sequenced *S. aureus* genomes (64, 65). This locus comprises three genes: the *hlgA* gene, transcribed by its own promoter, followed by an operon containing *hlgC* and *hlgB*, transcribed by a different promoter (66). HlgA and HlgC are S-subunits that share the same F-subunit, HlgB, to form two leukocidins, HlgAB and HlgCB, each possessing its own unique properties.

HlgAB binds to the human receptors CXCR1, CXCR2, CCR2, and DARC (the Duffy antigen receptor for chemokines), lysing human erythrocytes, neutrophils, monocytes, and macrophages (Fig. 3) (44, 67). HlgAB can also target murine monocytes and macrophages but cannot target murine neutrophils, because it cannot bind to murine CXCR2 (44). In contrast, HlgCB is a human-specific toxin that targets cells expressing the receptors C5aR1 and C5aR2 (the same receptors targeted by PVL) (Fig. 3) (44).

γ-Hemolysins cause acute tissue injury and inflammation and contribute to *S. aureus* disease in various animal models. Retroorbital administration of microgram amounts of HlgAB is lethal to mice (68). Intravitreal injection of γ-hemolysins in rabbits is highly toxic, resulting in destruction of the eye and tissue injury in surrounding areas (69). The tissue damage could be the result of a combination of toxin-mediated cell lysis and pyroptosis caused by sublytic concentration of the

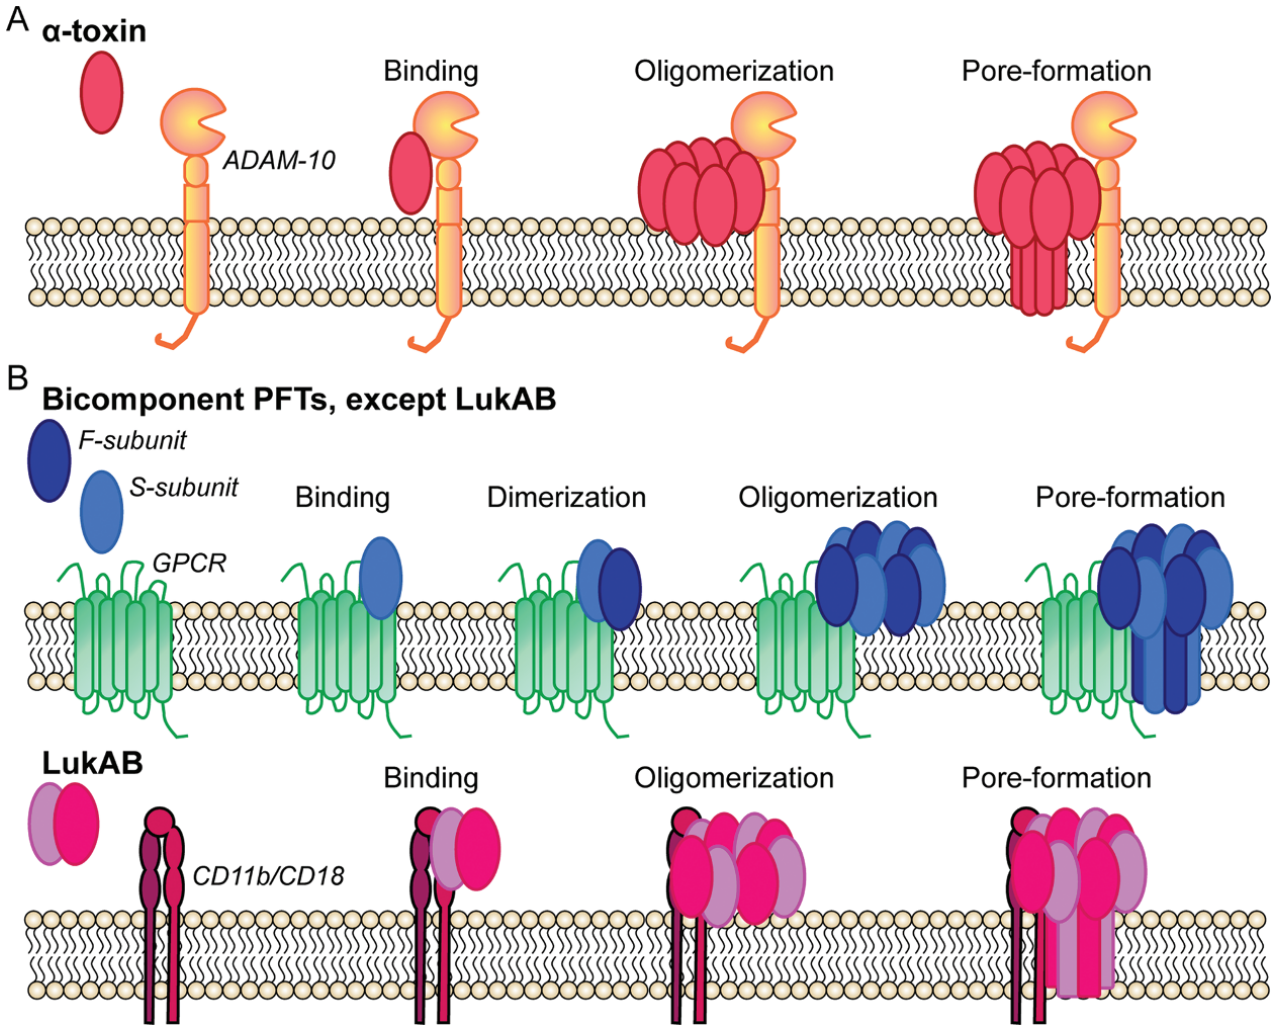

FIGURE 1 Current models for PFT pore formation for (A) α-toxin and (B) the bicomponent PFTs. (A) α-toxin is secreted as a monomer. Upon binding to the host receptor, ADAM-10, the toxin monomers oligomerize to form a heptameric prepore on the target cell surface. The prestem domains of the prepore then extend to form a β-barrel pore that punctures the target cell membrane. (B) The bicomponent PFTs are also secreted as monomers (except LukAB, which is secreted as dimers). The S-subunit recognizes the target cell by binding to cell surface receptors (LukPQ is an exception; the F-subunit LukQ is the receptor recognition subunit). These receptors are typically G-protein-coupled receptors (except for LukAB, which binds to the integrin CD11b). Upon receptor binding, the S-subunit dimerizes with the F-subunit, followed by oligomerization of three additional leukocidin dimers, resulting in an octameric prepore. Similar to the α-toxin pore formation model, the prestem domains of the prepore extend to form a β-barrel pore, thus disrupting the target cell membrane.

toxins (47). The contribution of HlgAB to disease has been further demonstrated in several infection models with strains that do not produce HlgAB. With such strains, there is reduced neutrophil lysis, less inflammation, reduced bacterial burden, and enhanced host survival (44, 70–72).

LukED. The *lukED* locus is in the νSaβ gene cluster. The *lukED* locus is present in ~70% of *S. aureus* isolates and is conserved in a lineage-specific manner (64, 65). The two genes in the locus, *lukE* and *lukD*, are cotranscribed during the late exponential phase (73).

Early studies of LukED demonstrated the lytic activity of the toxin in rabbit and human erythrocytes and neutrophils (74). Subsequently, LukED was demonstrated to also mediate lysis of many different human and murine bone-marrow-derived cells (75, 76). LukED targets the G-protein-coupled receptors (CXCR1, CXCR2, CCR5, and DARC) on neutrophils, monocytes, macrophages, dendritic cells, NK cells, T-cells, and red blood cells, conferring on the toxin broad leukocidal activity (Fig. 3) (67, 76, 77). Moreover, the pathogenic effects of LukED are receptor-dependent (75–77).

LukED is an important contributor to the virulence of *S. aureus*. Initial studies of LukED demonstrated toxin-induced dermonecrosis of rabbit skin (73). Retroorbital administration of microgram amounts of the toxin leads to acute lethality in mice (68). Corroborating the intoxication studies, Δ*lukED* strains are severely attenuated, resulting in lowered inflammatory responses, reduced bacterial burden, and enhanced host survival in murine systemic infections (75–77).

LukAB (also known as LukHG). The *lukAB* locus is part of the core *S. aureus* genome found in 99% of *S. aureus*.

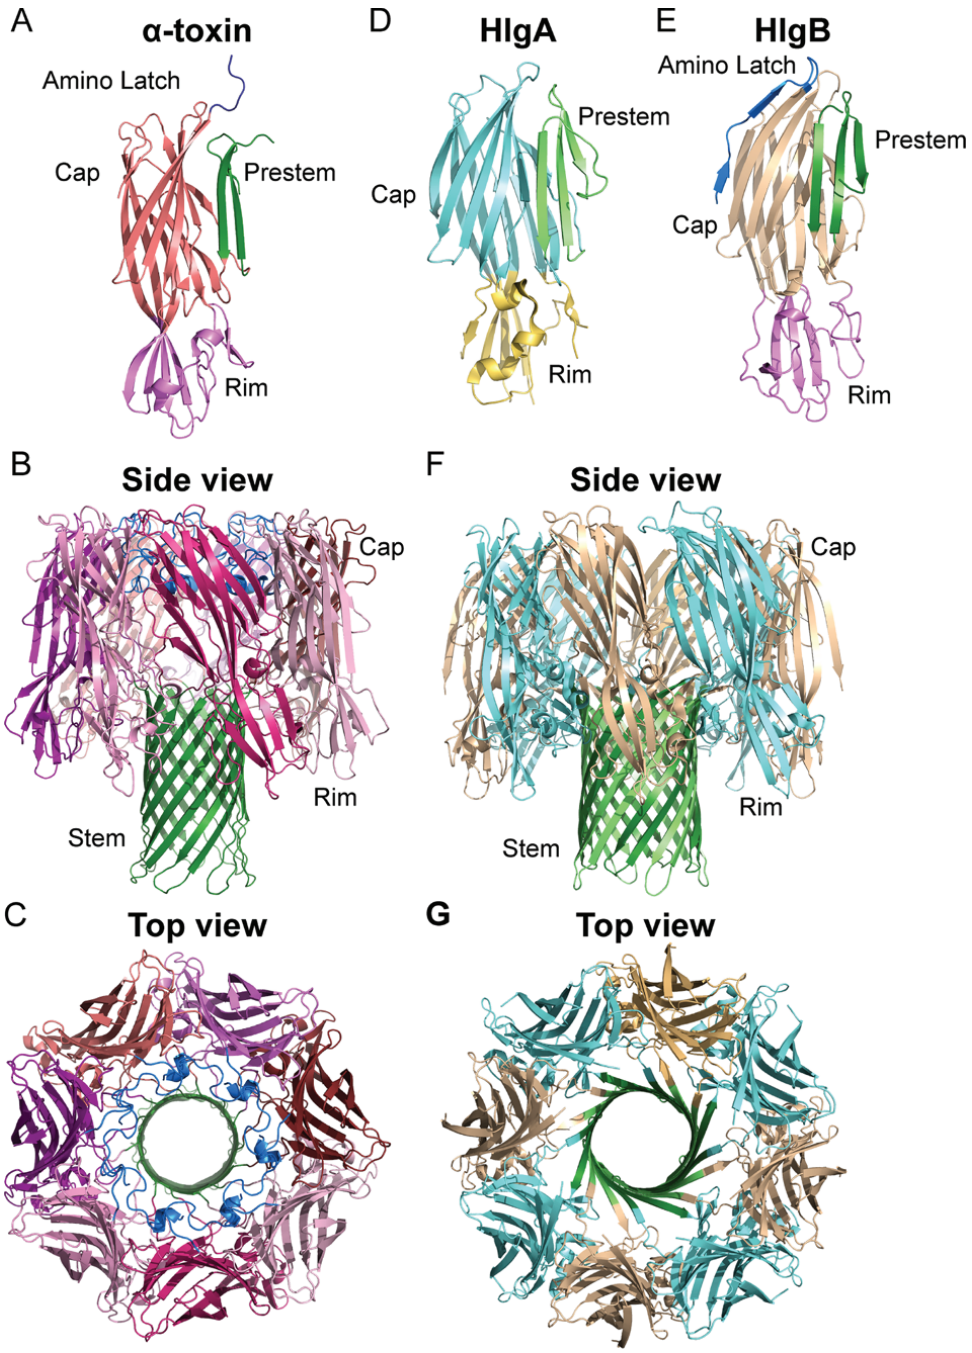

FIGURE 2 Structures of (A to C) α-toxin and (D to G) the bicomponent PFT, HlgAB. (A) The α-toxin monomer (PDB:4U6V) (351). The amino latch is colored blue, the cap domain red, the rim domain pink, and the prestem domain green. (B, C) The α-toxin heptamer (7AHL) (4). Each α-toxin is colored a different shade of pink to denote individual protomers. The amino latches are highlighted in blue, and the β-barrel pore is green. The monomers of (D) HlgA (2QK7) (352) and (E) HlgB (1LKF) (353). The amino latch of HlgB is blue; the cap domain for HlgA is cyan and HlgB is beige; the rim domains are yellow for HlgA and pink for HlgB; and the prestem domains are green. (F, G) The HlgAB octamer (3B07) (33). The HlgA protomers are cyan, the HlgB protomers are beige, and the β-barrel pore is green.

The toxin is found in abundance in the secreted proteome during the late exponential growth phase, which led to its discovery (78, 79). The C-terminal region of LukA is critical for toxin activity, because its deletion or mutation within this region (i.e., the E323A mutation) renders the toxin inactive (80). Unlike the other leukocidins, which are secreted as monomers, LukAB is secreted as heterodimers (80).

LukAB exhibits sharp species specificity, with its greatest potency being for human and primate cells, followed by

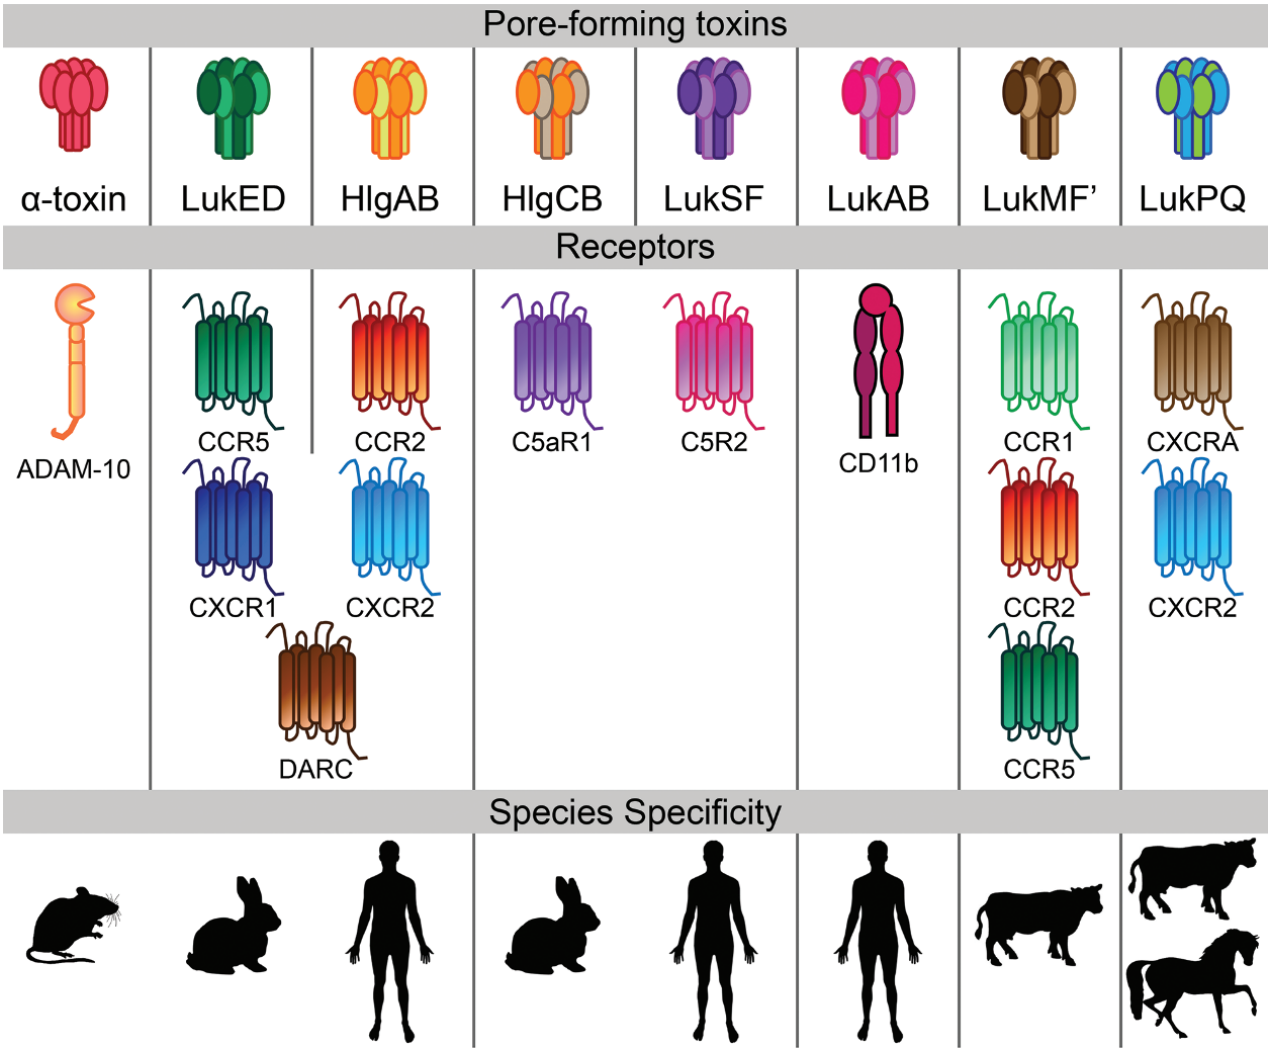

FIGURE 3 *S. aureus* PFTs and their receptor, species, and cell type specificities. Currently, *S. aureus* is known to produce eight β-barrel PFTs. Each of these PFTs targets different cell surface receptors. While some PFTs share the same receptors, they can differ in their species specificity. Collectively, the PFTs exert their sublytic and lytic effects on a variety of cells, including erythrocytes, endothelial cells, epithelial cells, neutrophils, monocytes, macrophages, dendritic cells, and T cells.

rabbit, and it is ~1,000-fold less active in mice (81). The selectivity of LukAB was explained when it was discovered that it mediates cytotoxicity through targeting the I-domain of the CD11b receptor present on leukocytes, including neutrophils, monocytes, macrophages, dendritic cells, and NK cells (Fig. 3) (80, 82).

Since LukAB is only weakly active toward murine leukocytes and mildly active with rabbit cells, the role of LukAB during infection remains to be fully elucidated. Although the field currently lacks robust *in vivo* models to directly assess the pathogenicity of the toxin, *in vitro* and *ex vivo* studies have provided insights into the role of LukAB in disease, revealing that *lukAB*-defective mutants are greatly attenuated for virulence. For example, primary human neutrophils infected with Δ*lukAB* strains exhibit enhanced survival compared to wild type (78). Additionally, LukAB promotes the escape of phagocytosed *S. aureus* from neutrophils and monocytes (46, 83). Anti-LukAB antibodies were observed in the serum of patients with invasive *S. aureus* disease, thus demonstrating production of the toxin during infection (84, 85).

LukMF′. The *lukMF′* locus is encoded by the temperate phage ΦSa1 (37). While *lukMF′* is infrequently found among human isolates, it is commonly found among animal isolates (86). LukMF′ exhibits high cytolytic activity toward bovine neutrophils and macrophages through targeting the surface receptor bovine CCR1, CCR2, and CCR5 (Fig. 3) (87). LukMF′ can be isolated from bovine mastitis tissue samples, indicating a role of this toxin in disease progression (36). However, unlike the other leukocidins, purified LukMF′ does not elicit a strong proinflammatory response when incubated with primary bovine macrophages (88).

LukPQ. LukPQ is encoded by the temperate phage ΦSaeq1 (35). Like other bicomponent PFTs, LukPQ demonstrates species and cell type specificities. Equine neutrophils are most sensitive to the lytic effect of LukPQ, followed by bovine neutrophils; human neutrophils are relatively insensitive to the toxin (Fig. 3) (35). LukPQ targets the equine G-protein-coupled receptors, CXCRA and CXCR2, to initiate cytolysis (35). At a high concentration, the toxin also targets equine CCR5. However, toxin binding can be

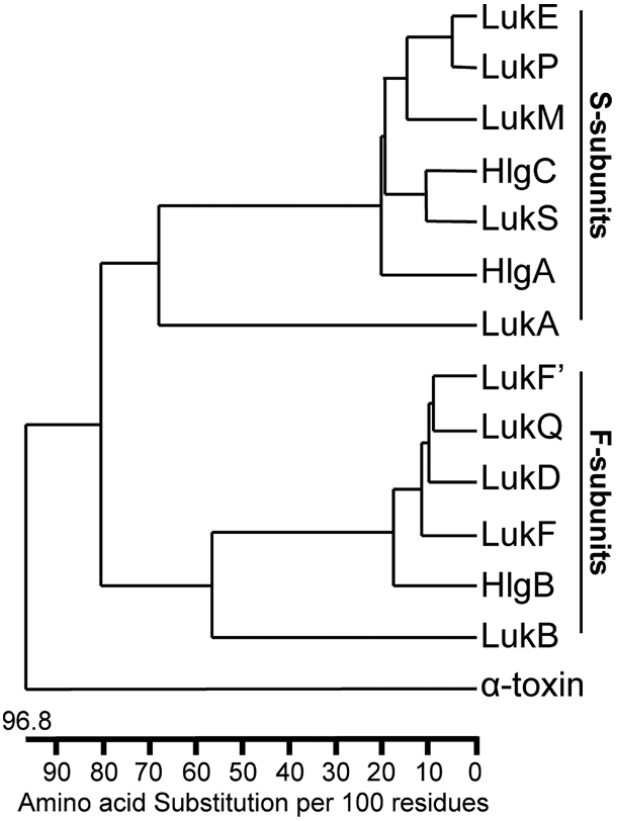

FIGURE 4 Phylogenic tree of *S. aureus* PFTs. The tree is constructed based on the mature protein sequences using the DNASTAR MegAlign ClustalW method for multiple sequence alignment.

inhibited by cytokines binding to these receptors, suggesting that LukP and the receptor ligands may share a common binding site (35). Uniquely, the F-subunit, LukQ, is responsible for conferring species specificity of LukPQ, whereas species specificity is conferred by the S-subunit in the other leukocidins (35).

Other cytotoxins

Phenol soluble modulins

Phenol soluble modulins (PSMs) belong to a family of amphipathic peptides uniquely found in staphylococci. In *S. aureus*, PSMs are encoded in three loci in the core genome: (i) the *psmα* operon, encoding PSMα1-4, (ii) the *psmβ* operon, encoding PSMβ1-2, and (iii) *hld*, encoding δ-toxin (89, 90). *hld* is also part of the coding sequence of RNA III, the master regulatory RNA in staphylococci. Additionally, certain methicillin-resistant staphylococci carry PSM-mec, encoded by *psm-mec* in the staphylococcal cassette chromosome *mec* (SCC*mec*) (91). Like *hld*, *psm-mec* is encoded within a regulatory RNA (92).

Unlike the other cytotoxins described thus far, PSM peptides are often secreted without a signal peptide (90). Therefore, most PSM peptides isolated from staphylococci contain an N-terminal formylmethionine. However, some PSM peptides lack this N-formylmethionine due to the cytoplasmic enzyme N-deformylase (93). PSMs are secreted by the ABC transporter phenol-soluble modulin transporter (Pmt). The absence of Pmt causes accumulation of PSM in the cytosol, resulting in cell death (94).

PSMs are classified based on length (95). The α-type PSMs are typically 20 to 25 amino acids long, most having a neutral or positive net charge. PSMα and δ-toxin are α-type PSMs, the entire protein forming one α-helix (96, 97). In contrast, the β-type PSMs are longer, typically 43 to 45 amino acids in length, most having a negative net charge. The structure of the β-type PSM, PSMβ2, consists of three α-helices that fold to a "v"-like shape (97).

PSMs have multiple roles in *S. aureus* pathogenesis, including cell lysis, biofilm formation, and immune modulation. α-type PSM peptides have high potency in lysing eukaryotic cells in a receptor-independent manner through targeting the cell membranes (90, 98–100). However, lipoproteins present in the serum can inhibit the cytolytic activity of PSMs (101). Therefore, the role of PSMs in extracellular cytolysis *in vivo* is unclear. In contrast, phagocytosed *S. aureus* produces PSMs to lyse neutrophils and osteoblasts intracellularly (99, 100). As such, the role of PSMs could be to mediate intracellular escape of *S. aureus*.

Sublytic concentrations of PSMs have immune modulatory effects on host cells. In humans, PSMs are detected by the pattern recognition receptor formyl peptide receptor 2 (FPR2) (102). FPR2 is a member of the G-protein-coupled receptor family that specializes in recognizing pathogen-associated molecular patterns produced by bacteria. FPR2 is predominately expressed on innate immune cell types, including neutrophils, monocytes, macrophages, and immature dendritic cells. Upon activation by PSMs, FPR2 induces a series of proinflammatory responses, including cytokine production, neutrophil chemotaxis, and leukocyte activation (102).

PSMs can shape biofilms by forming channels needed for nutrient delivery and dissemination (103). Additionally, the α-type can cause a leaky *S. aureus* membrane, resulting in the release of cytoplasmic proteins (104).

ε-toxin

Merriman et al. identified ε-toxin in 2015. The gene encoding ε-toxin, *cytE*, is conserved in the core genome of *S. aureus* (105). Since this is a recently identified toxin, the regulation of ε-toxin expression and the mode of action of the toxin are unknown. However, ε-toxin lyses rabbit erythrocytes and human keratinocytes. Lytic concentration of ε-toxin in keratinocytes promotes the secretion proinflammatory cytokine, interleukin 8 (105). In contrast, sublytic concentration of ε-toxin slows the rate of keratinocyte proliferation, suggesting a role for the toxin in impairing normal wound healing (105). A microgram amount of ε-toxin can result in neutrophil recruitment to the injection site when administered subcutaneously in rabbits (105). Moreover, the same dosage of ε-toxin can cause rabbits to develop fever after intravenous administration of the toxin (105). The role of this toxin in *S. aureus* infections remains to be fully elucidated.

Staphylococcal Superantigens

T cell Superantigens

T cell superantigens (SAgs) represent the largest family of exotoxins produced by *S. aureus*. Their molecular weights range from 19 to 30 kDa. SAgs are unique because they are resistant to heat, proteolysis, and desiccation (106). Due to their extreme stability and high toxicity in humans, some of them are classified as select agents for bioterrorism (i.e., staphylococcal enterotoxin B).

The genes encoding SAgs are found in various components of the *S. aureus* genome. The recently discovered *selX*

and *selW* are part of the core genome (107, 354). The other SAgs are encoded in different mobile genetic elements, such as bacteriophages, plasmids, and pathogenicity islands (108–111). However, the distribution of SAgs is highly variable in the same mobile genetic element found in different strains (112).

SAgs share structural homology with another family of closely related proteins, the SSLs (staphylococcal superantigen-like proteins). The *ssl* genes are encoded in the gene cluster νSaα (113). This family of proteins was originally called SETs for staphylococcal enterotoxin-like proteins (113). However, the International Nomenclature Committee for Staphylococcal Superantigens renamed them in 2004 to reflect their lack of emetic and mitogenic properties (114). The primary role of these proteins seems to be immune evasion (see reference 111 for a review on the SAg-like proteins).

SAgs exhibit tremendous sequence diversity (Fig. 5), but their overall structures are similar. SAgs have two primary domains: an N-terminal oligosaccharide/oligonucleotide binding fold that is shaped like a β-barrel and a C-terminal β-grasp domain composed of antiparallel β-sheets. The two domains are connected by an α-helix (115). Additionally, all SAgs have a dodecapeptide binding site, a Vβ T cell receptor (TCR) binding site, and up to two major histocompatibility complex (MHC) binding sites (106).

An SAg exerts its mitogenic property by cross-linking the Vβ TCR on a T cell with the MHC class II molecule (MHCII) on an antigen presenting cell, resulting in polyclonal T cell proliferation (Fig. 6) (116). SAgs are highly effective T cell mitogens that can stimulate up to 50% of T cells (106). SAg-induced T cell proliferation is followed by a state of T cell anergy, when activated T cells failed to proliferate and/or undergo apoptosis. SAgs are one of the many ways *S. aureus* manipulates the host immune system to prevent the generation of functional adaptive immunity.

SAgs can be broadly divided into three groups: staphylococcal enterotoxins (SEs), staphylococcal enterotoxin-like (SE-*l*) SAgs, and toxic shock syndrome toxin-1 (TSST-1). Each group of SAgs is briefly summarized below (see references 106, 355).

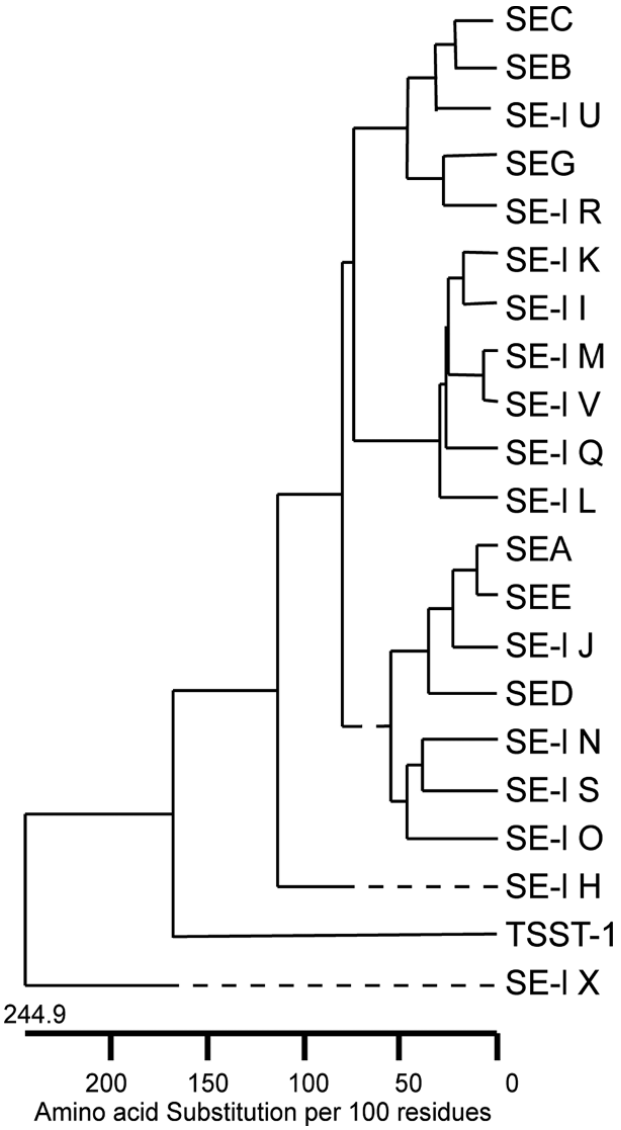

FIGURE 5 Phylogenic tree of *S. aureus* SAgs. The tree is constructed based on the mature protein sequences using the DNASTAR MegAlign ClustalW method for multiple sequence alignment.

Staphylococcal enterotoxins

There are six distinct SEs: SEA to SEE and SEG. Additionally, several variants of SEB and SEC have been identified. They were originally named for their ability to induce emesis, a key characteristic of staphylococcal food poisoning (114). Ingestion of SEs causes vomiting and diarrhea. However, the disease is usually self-limiting. The emetic activity of SEs is correlated with the presence of a 9- to 19-amino acid-long disulfide loop in the protein.

SEs can have up to two MHC binding sites. SEBs and SECs contain only one MHC binding site, while the other SEs have two MHC binding sites (106, 117, 118). The low-affinity binding site targeting the MHCII α-chain is common to all SAgs. The second site is a Zn^{2+}-dependent high-affinity binding site that targets the β-chain of MHCII (119). SAgs that have two MHC binding sites are 10- to 1,000-fold more potent than SAgs that have only one. However, they are produced at a much lower abundance compared to some other SAgs that contain one MHC binding site, such as TSST-1 and SEB (106).

Staphylococcal enterotoxin-like SAgs. The other SAgs are SE-*l* H to SE-*l* Y (106, 114, 355). SE-*ls* include all newly identified SAgs that are T cell mitogens but have unproven emetic activity (114). However, this group also contains SE-*ls* that lack the emesis-associated disulfide loop and are proven to not induce emesis (106). SE-*ls* can have up to two MHC binding sites and a 15-amino acid extension for specific TCR interactions (106, 120).

Toxic shock syndrome toxin-1. The gene *tst* is encoded in several pathogenicity islands, including SaPI1, SaPI2, and SaPIbov1 (121). TSST-1 has only one low-affinity MHC binding site that targets the MHCII α-chain, a Vβ TCR binding site, and a dodecapeptide binding site (122). This dodecapeptide binding site is proposed to be important for the interaction of TSST-1 with epithelial cells and the immune stimulatory molecules, CD40 and CD28 (123–125).

TSST-1 originally was known as SEF. In 1984, it was renamed to reflect the lack of emetic activity and to emphasize its association to toxic shock syndrome (TSS). TSS is an acute systemic illness characterized by hypotension, fever, rash, and desquamation 1 to 2 weeks after onset. As

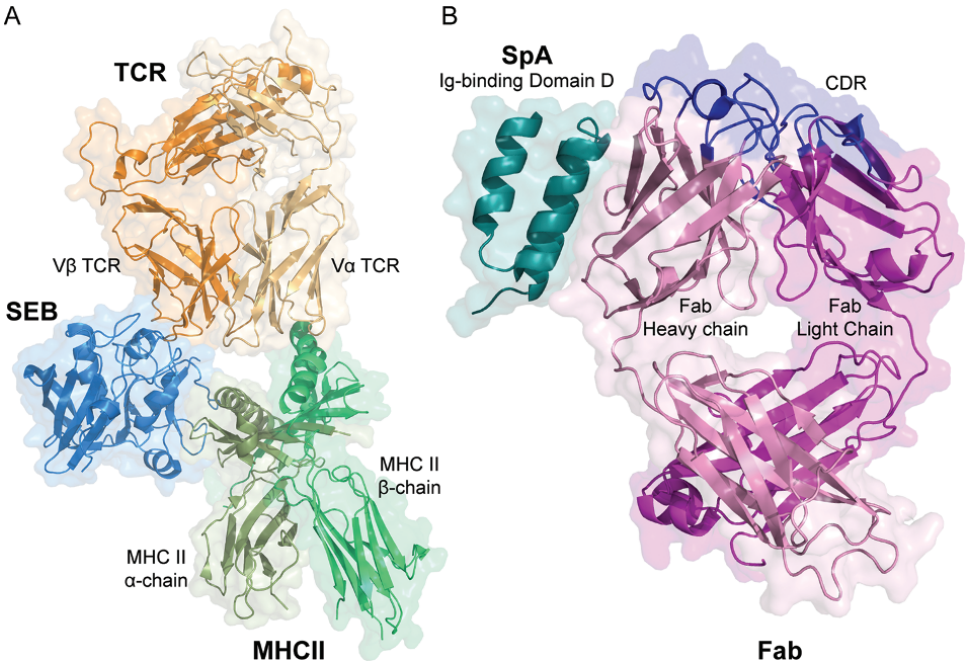

FIGURE 6 Crystal structures of *S. aureus* superantigens in complex with their cellular targets. (A) The T cell superantigen, SEB, in complex with the TCR and MHC II molecule (4C56) (116). SEB (blue) cross-links the α-chain of MHC (dark green) to the Vβ TCR (orange) to induce T cell proliferation that results in T cell anergy and/or apoptosis. (B) The B cell superantigen, SpA (teal), in complex with the Fab fragment (pink/magenta) (1DEE) (138). Conventional antigens bind to B cell receptors at the complementarity-determining region (blue), a hypervariable region that confers antigen specificities. SpA binds at a constant region of the receptor to activate B cells for supraclonal expansion, which leads to clonal deletion of SpA-activated B cells.

defined by the Centers for Disease Control, TSS involves at least three of the following organ systems—gastrointestinal, muscular, mucous membrane, renal, hepatic, hematologic, or central nervous system (126). TSS can be further classified as menstrual and nonmenstrual TSS. Menstrual TSS is usually associated with vaginal/cervical mucosae colonization of TSST-1-producing *S. aureus* and tampon use (127, 128). Approximately 50% of nonmenstrual TSS cases are caused by TSST-1-producing strains, and the remaining are caused by strains that produce SEB or SEC (129).

B cell Superantigen

Staphylococcal protein A (SpA) is the only known B cell superantigen produced by *S. aureus*. A majority of clinical isolates contain *spa* in the core genome (130). The SpA precursor has an N-terminal signal peptide that is cleaved prior to the secretion of the mature protein. Mature SpA has four to five highly conserved immunoglobulin (Ig) binding domains connected by short linkers at the N-terminus (131). These are followed by a hypervariable region called region X, which comprises subregions Xr and Xc (132). The highly variable and repetitive octapeptide in Xr is the basis of SpA-typing, a high-throughput method of grouping *S. aureus* isolates (130). Region X is followed by the C-terminal LPXTG motif for covalent anchoring of the protein to the cell wall (131). However, SpA proteins can be released from the cell wall by the cell wall hydrolase, LytM (133).

The Ig binding domains confer upon SpA the ability to bind the Fcγ portion of Igs to prevent opsonization (134). These Ig binding domains also mediate SpA binding to B cells by cross-linking V_H3-expresssing B cell receptor, which results in B cell activation; however, activation without costimulatory signals results in death and subsequent clonal deletion of B cells (135–137).

Conventional antigen recognition by a B cell receptor requires antigen recognition at the complementarity-determining region. In contrast, SpA exerts its mitogenic activity by binding to the variable region of the heavy chain, away from the complementarity-determining region, thus bypassing the antigen specificity requirement for B cell activation (Fig. 6) (138, 139). SpA-mediated clonal deletion of V_H3-expressing B cells can lead to the impairment of the B cell repertoire that is important for mounting effective antimicrobial defenses against the pathogen (140, 141).

During intravenous infection, SpA prevents opsonophagocytosis of the bacteria by sequestering Igs and impedes the development of specific anti-*S. aureus* antibodies (142). In contrast, isogenic strains that lack *spa* or express variants that cannot bind to Ig exhibited reduced kidney abscess formation and elicited specific anti-*S. aureus* antibodies (142). Mice immunized with the Ig binding-deficient SpA variant, SpA_{KKAA}, acquired protective immunity and could mount a more effective humoral response against *S. aureus* antigens (143).

Cytotoxic Enzymes

β-toxin (also known as β-hemolysin)

The β-toxin encoding gene, *hlb*, is part of the core *S. aureus* genome. However, due to the presence of the *hlb*-converting prophage (i.e., ΦSa3, Φ13), which disrupts the gene, only a

limited number of human clinical isolates produce β-toxin (144, 145). The prophage carries the immune evasion gene cluster encoding for immune evasion factors, such as the staphylococcal complement inhibitor proteins, chemotaxis-inhibitory proteins, and staphylokinase (145). These virulence factors are thought to be involved in *S. aureus* immune evasion and survival in the human host. The *hlb*-converting prophage is prevalent in strains associated with human infections (~90%), but it is less frequently found in animal isolates (~30%) (146). However, chronic infections or environmental pressures (i.e., oxidative stress, antibiotics, temperature) can promote the excision of the prophage and the production of β-toxin (147–150). Thus, the contribution of β-toxin during human infection is unclear.

β-toxin is a Mg^{2+}-dependent neutral sphingomyelinase (SMase), a phospholipase that specifically cleaves sphingomyelin to produce ceramide and phosphocholine (151). This toxin was first identified in 1935 by Glenny and Stevens based on several unique observations: hemolysis of erythrocytes in the presence of α-toxin neutralizing serum, lysis of sheep but not rabbit erythrocytes, and enhanced hemolysis caused by the temperature shifting from 37°C to a lower temperature (152). As such, β-toxin is also known as a hot-cold hemolysin. This unique phenomenon is the result of ceramide hydrolysis products at 37°C being held together by cohesive forces in the membrane. When the temperature decreases (i.e., to 4°C), this causes a phase separation that condenses ceramide into pools and collapses the lipid bilayer, resulting in the invaginations observed on erythrocyte membranes by electron microscopy (153).

The crystal structure of β-toxin reveals structural homology to members of the DNase I superfamily (154). β-toxin is a single domain protein consisting of four layers: two layers of β-sheets at the center and two outer layers that comprise α-helices and β-strands (154). Based on the structural homology to the DNase I superfamily, a secondary function for β-toxin was hypothesized. Later, β-toxin was shown to enhance biofilm formation through catalyzing the formation of nucleoprotein matrix in biofilms; therefore, β-toxin is also a biofilm ligase (155).

β-toxin exhibits species-dependent hemolytic activity that correlates with the amount of sphingomyelin content in erythrocytes: sheep, cow, and goat erythrocytes are highly sensitive to the toxin, rabbit and human erythrocytes exhibit intermediate sensitivity, and murine and canine erythrocytes are resistant (156). The SMase activity of β-toxin also causes the lysis of human keratinocytes, monocytes, T cells, and bovine epithelial cells (154, 157–159). β-toxin stimulates the production of proinflammatory cytokines in human monocytes (158) but suppresses IL8 production and cell adhesion molecule expression in human endothelial cells, and therefore the toxin can prevent leukocyte migration across the endothelium (160).

Infection with β-toxin-producing *S. aureus* results in larger lesions in the organs without affecting the overall bacterial burden in the rabbit endocarditis and pneumonia models (147). The presence of β-toxin enhances *S. aureus* colonization of the skin (159) and induces injuries to the scleral epithelial cells during ocular keratitis in mice (27). In an infective endocarditis model, rabbits infected with *S. aureus* that produce β-toxin mutants that lack SMase activity have enhanced survival and smaller lesions in the heart, but there were no differences in bacterial burden compared to the isogenic strain that produces active β-toxin (161). Intranasal administration of β-toxin induces the shedding of syndecan-1, a major heparan sulfate proteoglycan molecule on lung epithelial cells, and causes neutrophil infiltration into the lungs in mice (162). The shedding of sydecan-1 is caused by the SMase activity of β-toxin, because intranasal intoxication with SMase mutants reduced shedding of this protein *in vivo*, resulting in reduced lung pathology (162).

Exfoliative toxins

Exfoliative toxins (ETs) are also known as epidermolytic toxins. There are four antigenically distinct forms found in *S. aureus*: ETA, ETB, ETC, and ETD. Each ET is encoded on a different mobile genetic element: *eta* is encoded in the genome of a temperate phage that has been shown to convert *eta*-negative strains to toxin producers (163, 164). *etb* is found on the plasmid pETB (165), and *etd* is encoded as part of a pathogenicity island (166). ETC was purified from an *S. aureus* isolate from equine infection; however, the genetic locus of ETC has not been described (167).

Most of what is currently known about the ETs is based on ETA and ETB. ETs are the causative agents for staphylococcal scalded skin syndrome (SSSS), including Ritter's disease, toxic epidermal necrosis, bullous impetigo, and certain erythema cases. SSSS predominantly affects neonates, infants, and immunocompromised adult patients (168). Symptoms of SSSS are characterized by formation of blisters and superficial desquamation, involving only the skin layer (168). Although SSSS was initially described in 1878, its association with *S. aureus* infections was first suggested in 1967, and the contribution of ETs to the blistering symptoms was not identified until in the 1970s (163, 169–171). This delay was in part contributed by the ETs' unique mode of action. The lesions characteristic of SSSS are often sterile, because the ETs can be distributed through the bloodstream from a distant site to cause symptoms (171).

ETs are glutamate-specific serine proteases of the chymotrypsin family. The catalytic triad (histidine, aspartate, serine) is conserved in all ETs (168). ETA and ETB are similar in structure and share homology with other staphylococcal serine proteases: SspA and the serine protease-like proteins (Fig. 7) (172–174). The N-terminal α-helical extension is required for enzyme activity (172, 174). The crystal structures of both ETA and ETB show that the key residues in loop D occupy the oxyanion hole required for enzymatic activity of all serine proteases, and thus the crystal structures represent the inactive forms of the enzymes (172, 174). These findings suggest that the protease activity of ET may require a specific cellular target and occur under specific conditions.

In the early 2000s, ETs were shown to interact with human and mouse desmoglein 1 (Dsg1), causing blistering of the superficial skin (175, 176). ET recognition of Dsg1 is conformational, requiring the presence of Ca^{2+}. Lack of Ca^{2+} results in the unfolding of Dsg1 and thus the inability of ETs to cleave the protein (177). Through domain swapping and site mutagenesis studies, it was determined that five amino acids (Q271, Y274, T275, I276, E277) belonging to the extracellular domain 3 of Dsg1 are critical for ETA to exert its protease activity (178).

With the identification of Dsg1 as the substrate for ETs, the pathophysiology of the superficial skin blistering in SSSS was explained. In humans, there are four isoforms of desmogleins, Dsg1 to Dsg4 (179). Desmogleins are cadherins that are required for desmosome cell-to-cell adhesion to maintain the integrity of the epidermis. ETs target only Dsg1, which is expressed throughout the human epidermis. Cleavage of Dsg1 disrupts the cell-to-cell adhesion of the epidermis, resulting in blistering and desquamation of the superficial skin. The other strata of the epidermis are unaffected because of the presence

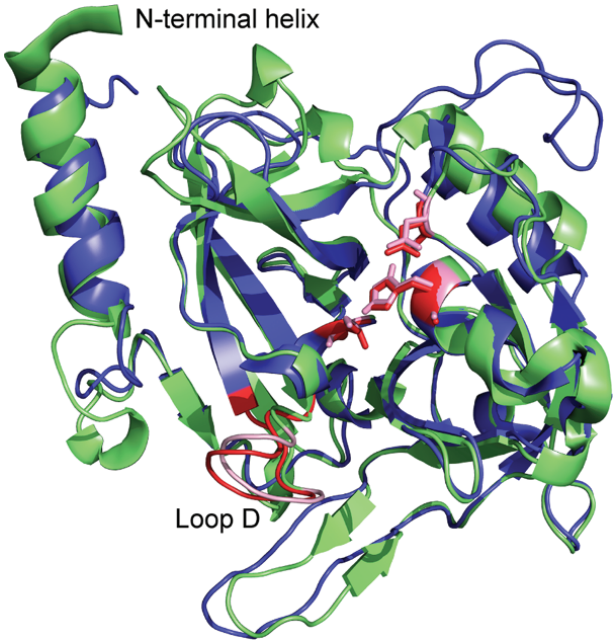

FIGURE 7 Overlay of the crystal structures of ETA and ETB. ETA (1EXF, green) (174) and ETB (1QTF, blue) (173) share high structural identity. ETs cause SSSS by cleaving Dsg1 at the epithelial cell junctions. Both ETs are serine proteases. Loop D and the catalytic triad are highlighted in pink for ETA and red for ETB.

of Dsg2 to Dsg4, which are not targeted by ETs and thus compensate for the destruction of Dsg1 (175, 180).

EXOENZYMES

Introduction

S. aureus devotes a significant amount of its resources to produce virulence factors to evade the host immune system and to acquire nutrients for its survival. The previous section discussed the mechanisms of toxin-mediated host immune evasion and their roles in *S. aureus* virulence. In addition to the toxins, *S. aureus* also produces a large number of virulence factors that have enzymatic properties. They can be broadly categorized into two groups: cofactors that activate host zymogens and enzymes for degradation of tissue components (Table 2). While these cofactors and secreted enzymes (exoenzymes) have different substrates and mechanisms of action, they function to break down bacterial and host molecules for nutrient acquisition, bacterial survival, and dissemination.

Cofactors for Host Enzyme Activation

Coagulase (Coa), von Willebrand factor binding protein (vWbp), and staphylokinase (Sak) are cofactors produced by *S. aureus* that have no enzymatic activities by themselves, but they can activate host zymogens. These three proteins hijack different aspects of the host coagulation system, thereby manipulating the host innate defenses to promote bacterial survival and dissemination.

Staphylococcal coagulases: Coa and vWbp

The ability to induce coagulation is one of the key criteria used in modern medical microbiology for species classification in the genus *Staphylococcus*—separating coagulase-positive and coagulase-negative species. A majority of staphylococci are coagulase negative, but a few are coagulase positive species, including *S. aureus* and *S. intermedius*; however, *S. schleiferi* has both coagulase-positive and coagulase-negative subspecies (181).

S. aureus-induced coagulation of human plasma was initially documented in 1903 (182). The causative agents, Coa and vWbp, are highly active in coagulating human and rabbit plasma (183).

Both *coa* and *vwb* are chromosomally encoded. There are 12 isoforms of *coa* that have been identified thus far; the majority of the variability is attributed to the high sequence variability (>50%) of the N-terminus coding region among different strains (184, 185). In contrast, *vwb*, which encodes vWbp, is relatively conserved, with only two known alleles (184). However, a recent report identified several *vwb* paralogues carried by SaPIs that produce vWbps that coagulate ruminant and equine plasma (186).

Coa and vWbp share ~30% protein sequence homology at the N-terminus (187). They both have a D1D2 domain for prothrombin binding (188, 189). However, they differ significantly at the C-terminus. The C-terminus of Coa has a 188-residue linker region followed by a repeat region composed of tandem repeats of 27 residues responsible for fibrinogen binding (188, 189). In contrast, the C-terminus of vWbp has a von Willebrand factor binding domain and a fibrinogen binding domain (188, 190).

TABLE 2 Major secreted cofactors and enzymes produced by *S. aureus*

Cofactor/enzyme	Gene	Function(s)
Coagulase	*coa*	Cofactor, activates prothrombin
vWbp	*vwb*	Cofactor, activates prothrombin
Staphylokinase	*sak*	Cofactor, activates plasminogen
Nuc (thermonuclease)	*nuc*	Nuclease
Aureolysin	*aur*	Metalloprotease
ScpA (V8 protease)	*sspA*	Serine protease
SplA	*splA*	Serine protease
SplB	*splB*	Serine protease
SplC	*splC*	Serine protease
SplD	*splD*	Serine protease
SplE	*splE*	Serine protease
SplF	*splF*	Serine protease
Exfoliative toxin A	*eta*	Serine protease
Exfoliative toxin B	*etb*	Serine protease
Staphopain A	*scpA*	Cysteine protease
Staphopain B	*sspB*	Cysteine protease
Hyaluronidase	*hysA*	Lyase
β-Toxin	*hlb*	Sphingomyelinase, biofilm ligase
PI-PLC	*plc*	Phospholipase
SAL1	*lip1*	Lipase
SAL2	*geh*	Lipase
FAME	Unknown	Detoxify free fatty acids

Coa or vWbp bind to prothrombin at a ratio of 1:1 to form staphylothrombin. Insertion of the N-terminus of Coa into the Ile16 pocket of prothrombin causes a conformational shift resulting in the activation of the zymogen (189, 191). Staphylothrombin is highly efficient in converting fibrinogen to fibrin (Fig. 8).

The activity of staphylothrombin cannot be inhibited by common anticoagulants (i.e., EDTA, heparin) or thrombin inhibitors, such as hirudin and bivalirudin (189, 191–193). However, two recently discovered small molecules, argatroband and dabigatran, can inhibit the activity of staphylothrombin (194, 195).

The Δ*coa*Δ*vwb* strain is less virulent than its wild-type parent, demonstrating a role of the coagulases during infection (187, 196, 197). However, coagulases must be present concurrently with the infecting strain to promote virulence. Ekstedt and Yotis demonstrated that while intracerebral coinjection of purified coagulase with coagulase-negative *S. aureus* enhances the virulence of coagulase-negative *S. aureus*; preinjection of purified coagulase before infection has no effect (198). Additionally, Coa is suggested to have a role in the formation of device-associated biofilm formation (199).

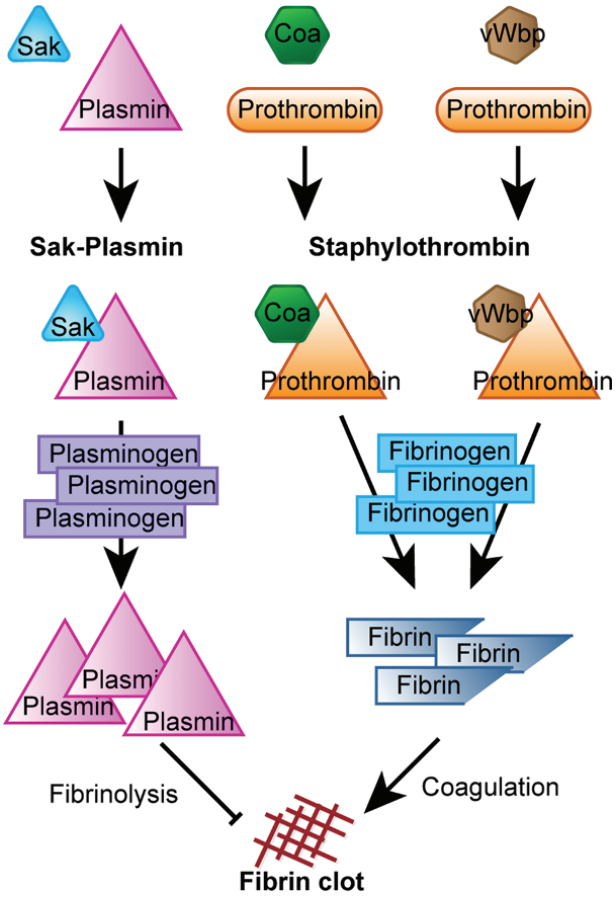

FIGURE 8 *S. aureus* produces cofactors that hijack the host's coagulation system. Coa and vWbp bind to prothrombin and alter the conformation of the protein to form the complex, staphylothrombin. This complex is highly active and cleaves fibrinogens to fibrins, promoting the formation of fibrinous clots. Sak binds to plasmin to form the Sak-plasmin complex. Sak stabilizes plasmin to enhance enzymatic activity. Sak-plasmin cleaves plasminogen to form plasmin, which breaks down fibrin clots.

In an abscess, the coagulases generate a fibrin shield to protect *S. aureus* from immune cell infiltration. Coa is required for the formation of pseudocapsule immediately surrounding the abscess, and both vWbp and Coa are required for fibrin formation around the pseudocapsule (187, 200).

Staphylokinase

Staphylokinase (Sak) is a cofactor that hijacks host plasmin to activate plasminogen for the breakdown of fibrin clots and promotes bacterial dissemination (Fig. 8). Sak is produced by lysogenic strains of staphylococci; the prophage encoding Sak typically carries other genes that encode virulence factors such as enterotoxin A and chemotaxis inhibitory proteins (201, 202). There are three groups of phages that carry the *sak* gene (203). Serotype B phages (i.e., ΦC) cause positive conversion of Sak without disrupting other genes (204, 205). Positive conversion of *sak* can also be mediated by some serotype F phages (i.e., ΦSa3, Φ42D), but the phage integration disrupts the *hlb* gene (144, 202, 206). The phage carrying *sak* has also been reported to disrupt the coding sequences of *N*-acetylmuramyl-L-alanine amidase and peptidoglycan hydrolase (207, 208).

Sak is a single-domain protein that consists of a central α-helix, a five-strand β-sheet, and two shorter β-strands (Fig. 9) (209). Sak forms a 1:1 complex with plasmin in the serum to form Sak-plasmin (210, 211). This complex is highly efficient in converting plasminogen to plasmin. Sak can also bind to plasminogen, but this complex is inactive and must be converted to Sak-plasmin to have enzymatic activity (212). In an active Sak-plasmin complex, the first 10 residues at the N-terminus of mature Sak are removed to expose the charged residue, Lys11 (213). Deletion of Lys11

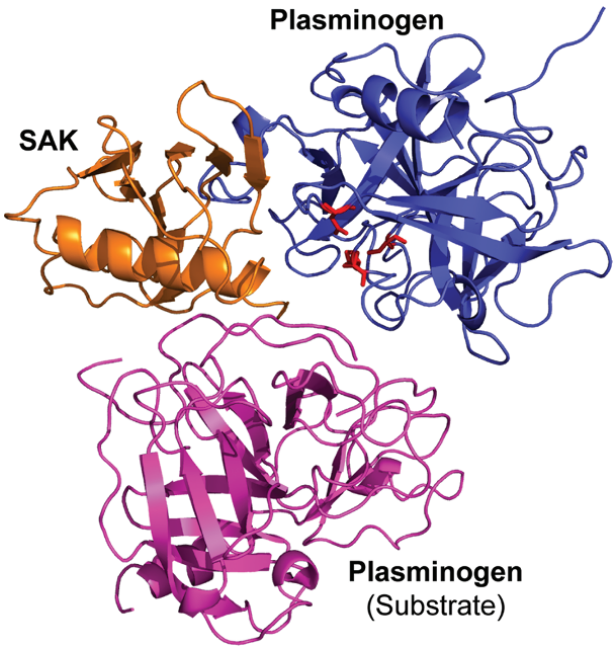

FIGURE 9 The crystal structure of Sak in complex with two plasminogen molecules (1BUI) (215). While Sak binding to plasminogen does not have enzymatic activity, the trimeric complex captures how Sak may bind to plasmin to cleave plasminogen. Sak (orange) is in complex with plasminogen (blue), exposing the catalytic site (red). Sak facilitates the docking of the substrate plasminogen (pink) to promote cleavage by plasmin.

inactivates Sak (214). The binding of Sak to plasmin directs the active site of plasmin to favor cleavage of the activation loop in plasminogen and promotes the conversion of plasminogen to plasmin by enhancing substrate presentation to plasmin. (Fig. 9) (215).

Circulating Sak-plasmin complexes are sensitive to dissociation by α_2-antiplasmin, but fibrin-bound complexes are protected from inactivation (216). The fibrin-bound complexes cleave IgG and human C3b, thus preventing opsonization of the bacteria by the complement system (217). Additionally, Sak-plasmin complexes can activate the matrix metalloprotease 1, which is important for leukocyte migration and activation (218). Importantly, Sak neutralizes the bactericidal activities of α-defensins and LL-37, two major human antimicrobial peptides (219, 220).

Sak is highly species specific. It is active for human, dog, goat, rabbit, and sheep plasminogen but is inactive for mouse, pig, cow, and buffalo plasminogen (221). Using transgenic mice that produce human plasminogen, studies demonstrated that Sak facilitates *S. aureus* invasion of the skin barrier to generate large and open lesions (222, 223). However, plasmin activation is known to promote wound healing and to reduce inflammation. Thus, during skin infection, Sak may function as a vanguard to establish the primary infection, but after the infection is established, Sak limits the severity of infections to promote dissemination (223).

Furthermore, Sak reduces biofilm formation and facilitates the detachment of mature biofilm by activating plasminogen (221). Corroborating these observations, high Sak-producing strains are often associated with less biofilm formation *in vitro* and noninvasive infections in humans (221, 223).

Enzymes that Degrade Host Tissue Components

Nucleases

Staphylococcal nuclease, originally known as micrococcal DNase, was identified in the culture supernatants of *S. aureus* by Cunningham et al. in 1956 (224). Nuclease requires Ca^{2+} ions for activity, but not other divalent cations (224, 225). Staphylococcal nuclease is also known as thermonuclease, named after its resistance to heat inactivation (224, 225). Staphylococcal nuclease functions as both an endo- and exo-nuclease that breaks down DNA and RNA substrates through the cleavage of the 5′-phosphoryl ester bond (224, 225).

With the availability of whole-genome sequencing in the late 1990s, the sequence of the *S. aureus* genome became available, which led to the identification of two staphylococcal nuclease genes, *nuc* (SA0746) and *nuc2* (SA1160) (226, 227). The two genes are located at disparate regions in the genome, under the control of separate promoters. The two nucleases share 34% amino acid similarity overall and 42% similarity within the catalytic domain (228). Both nucleases are Ca^{2+} dependent and heat resistant and are able to use DNA and RNA as substrates (226, 228). A major difference between Nuc and Nuc2 is their cellular localization. Nuc is a secreted enzyme with two isoforms, NucB and NucA (229, 230). In contrast, Nuc2 is surface bound (228).

Much of what is currently known about nucleases is gathered from studies performed on Nuc. During infections, Nuc regulates biofilm formation and mediates bacterial escape from neutrophil extracellular traps (NETs).

Nuc disperses biofilm by breaking down extracellular DNA. Biofilm formation is enhanced in strains that do not produce Nuc (230, 231). Expression of *nuc* is repressed during biofilm formation, providing evidence that *S. aureus* controls nuclease expression to regulate biofilm formation (230, 232). Furthermore, the *nuc* mutant has decreased fitness during intraperitoneal infection *in vivo* (232).

The second role of Nuc is to mediate bacterial escape from NETs. NET is an innate immune defense mechanism by which DNA released from dying neutrophils immobilizes and facilitates killing of invading pathogens (233). Nuc degrades NETs to allow *S. aureus* to escape (234).

Moreover, when Nuc degrades DNA in the abscess or NETs, the degradation products, monophosphate nucleotides, become a substrate for another enzyme, adenosine synthase A (235). Adenosine synthase A converts the degraded DNA to deoxyadenosine, which induces caspase-3 activation, leading to apoptosis of macrophages surrounding the abscess or the NET, thus promoting *S. aureus* survival (235).

The contribution of Nuc2 to *S. aureus* virulence is less clear due to its low expression level compared to Nuc (228). Purified Nuc2 has been demonstrated to disperse biofilms *in vitro* (228). A mutant expressing only Nuc2 but not Nuc showed that the nuclease is produced during intramuscular infections in mice, albeit at a much lower level (228). The identification of Nuc2 *in vivo* suggests that it may have a role in *S. aureus* virulence, possibly performing functions similar to those of the secreted Nuc but on the bacterial surface.

Proteases

Staphylococci encode three families of secreted proteases: metalloproteases, cysteine proteases, and serine proteases. Collectively, these proteases have roles in nutrient acquisition, bacterial dissemination, and immune evasion. Currently, *S. aureus* is known to produce 12 proteases: one metalloprotease (aureolysin [Aur]), two cysteine proteases (staphopain A [ScpA] and staphopain B [SspB]), and nine serine proteases. These serine proteases include V8 protease (SspA), serine protease-like proteins A to F (SplA to SplF), and ETA and ETB. Although Spls, ETA, and ETB are secreted as active enzymes, all the other proteases are secreted as zymogens, requiring proteolytic cleavage of the propeptide for activation (Fig. 10). The roles of ETA and ETB in *S. aureus* virulence are described in the exotoxin section, above.

In the following sections, we will discuss the mode of action of each protease family and its proposed role in *S. aureus* virulence.

Metalloprotease: Aureolysin

The *S. aureus* metalloprotease, aureolysin (Aur), also known as protease III, was identified in the culture supernatant of strain V8 by Arvidson et al. in 1972 (236, 237). The structure of Aur comprises two conserved domains common to bacterial metalloproteases of the thermolysin family: the N-terminal β-pleated domain and the C-terminal α-helical domain (238). The mechanisms of substrate binding and protein catalysis are also common among the proteases in this family. However, unlike other bacterial metalloproteases in the thermolysin family, Aur does not have elastase activity (238, 239).

Aur self-activates by autoproteolysis through the cleavage of the N-terminal propeptide (Fig. 10) (240). The active enzyme prefers to cleave peptide bonds at the N-terminal side of bulky hydrophobic residues, such as alanine, isoleucine, and tyrosine (241). The presence of Zn^{2+} is required for enzyme activity, but Co^{2+} can act as a substitute and increases enzyme activity (242). Additionally, binding to Ca^{2+} ions stabilizes Aur, whereas chelating agents, such as EDTA, irreversibly denature the protein (236, 238).

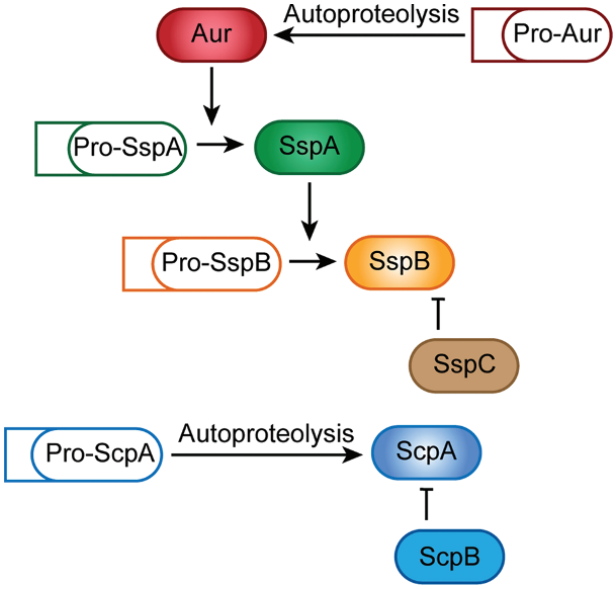

FIGURE 10 Staphylococcal protease cascade. The metalloprotease, Aur, is activated by autoproteolysis after protein secretion. Aur is required to activate the serine protease, SspA. SspA processes one of the staphopains, SspB, from zymogen to active enzyme. The other staphopain, ScpA, is activated by autoproteolysis. Both staphopains are inhibited by staphostatins prior to secretion. SspB is inhibited by SspC, and ScpA is inhibited by ScpB.

The broad substrate specificity of Aur allows the metalloprotease to target a variety of substrates, including other *S. aureus* proteins that are important for virulence and host proteins that are important for immune defense. Aur activates SspA, the second protease in the staphylococcal protease activation cascade (Fig. 10) (243). Additionally, Aur can degrade clumping factor B (ClfB) and the PSMα peptides (244, 245). Collectively, Aur can shape the secreted and surface proteome of *S. aureus* (246).

Aur contributes directly to *S. aureus* immune evasion and dissemination through the cleavage and inactivation of the antimicrobial peptide LL-37, thus promoting *S. aureus* survival (247). Aur can also degrade the human plasma protease inhibitors—α_1-proteinase inhibitor and α_1-antichymotrypsin present in the serum—albeit not as efficiently as SspA (248, 249). As such, Aur and SspA are proposed to work synergistically to achieve immune evasion.

Aur can affect complement activation by cleaving the complement proteins C3 to C3a and C3b in serum (250). The anaphylatoxin, C3a, is further degraded by Aur, preventing leukocyte activation (250). The soluble C3b fragment is inhibited and degraded by factor H and factor I in the serum (250, 251). Degradation of C3 by Aur results in the depletion of C3 proteins, thus preventing the formation of the membrane attack complex on the bacteria, and promotes bacterial survival. Furthermore, Aur activates prothrombin and prourokinases and inactivates plasminogen inhibitors, thereby manipulating the host coagulation system (252, 253). The various roles of Aur in modulating *S. aureus* proteome and host innate defense molecules suggest that Aur has an important role in promoting survival and dissemination of the bacteria *in vivo*. This is corroborated by the detection of Aur in phagocytosed *S. aureus*, suggesting that the protease may have a role during intracellular infection (254).

Serine proteases: SspA

The serine protease, SspA is also known as the V8 protease or GluV8. The gene encoding SspA (*sspA*) is part of the staphylococcal serine protease operon (*ssp*), which consists of three genes: *sspA*, *sspB*, and *sspC* (255). The functions of SspB and SspC are discussed later in this section.

SspA was identified in the culture supernatants of strain V8 by Drapeau et al. in 1972 (256). Around the same time, Arvidson et al. identified protease I, which exhibited properties similar to those of the SspA identified by Drapeau et al.; however, whether these two reports describe the same enzyme was difficult to decipher because there were differences in molecular weight and protease inhibitor sensitivity between the two reports (241, 257). Based on the report by Drapeau et al., the enzymatic activity of SspA can be inhibited by the serine protease inhibitor disopropyl flurophosphate (256).

SspA is a glutamyl endopeptidase, part of a small group of serine proteases that preferentially cleave substrates at the C-terminal side of glutamate and aspartate (256). The preference for negatively charged residues as substrates at neutral pH is due to the protein's positively charged N-terminus (258). The crystal structure of SspA showed that the protein lacks the disulfide bonds commonly found in other proteins of this family (258). However, SspA shares high structural homology to the serine proteases—staphylococcal ETs and bovine trypsin—despite having limited protein sequence similarity (258). The conserved trypsin-like serine protease catalytic triad, consisting of histidine, asparagine, and serine, is found in SspA. The C-terminal repeat domain consists of tandem repeats of Pro-Asp or Asn-Asn that range from 9 to 19 repeats (259–261); however, because this C-terminal repeat domain is not required for activity (262), its role in the function of the protein is unclear.

SspA is secreted by *S. aureus* as a zymogen. However, pro-SspA can undergo autoproteolysis to generate a shorter version of pro-SspA (243). Aur processing is required for both forms of pro-SspA to become active enzymes (Fig. 10) (243).

SspA contributes to *S. aureus* immune evasion and dissemination by breaking down self and host proteins. SspA cleaves fibrinogen binding factors on the *S. aureus* cell surface and thus reduces bacterial adhesion and enhances bacterial dissemination and ultimately results in the breakdown of biofilms (263, 264). SspA can also degrade host proteins such as α_1-proteinase inhibitor (248), the interleukin 6 cytokine (265), and immunoglobulins (266, 267); thus, SspA directly modulates immune activation and opsonization. SspA can cleave LL-37, but the cleavage does not inactivate the antimicrobial peptide (247).

SspA is produced upon *S. aureus* phagocytosis by neutrophils, suggesting its role in facilitating *S. aureus* intracellular escape, potentially through activating the cysteine protease, staphopain B (254). SspA can disrupt epithelial barriers, compromising cell junction integrity (265, 268). Skin infection models of *sspA* mutants suggest a slight decrease in bacterial fitness *in vivo* (269). However, since the activity of SspA can be inhibited by an α_2-macrogobulin present in the serum, its role as a soluble virulence factor in serum during *S. aureus* pathogenesis remains unclear (263).

Cysteine proteases: Staphopains

Staphopain A (ScpA) was the first cysteine protease identified in *S. aureus* by Arvidson et al. (described as protease II) in 1973 (257). Subsequently, staphopain B (SspB) was identified as ORFX in 1998 by Chan et al. (270). A third staphopain, staphopain, C was described in avian-associated

S. aureus isolates (271, 272). Most of what is known about staphopains is derived from studies of staphopains A and B.

ScpA and its intracellular inhibitor staphostatin A are encoded in the staphylococcal cysteine protease operon (*scp*) by the genes *scpA* and *scpB*, respectively (273). Staphopain B (SspB) and it intracellular inhibitor staphostatin B (SspC) are encoded in the staphylcoccal serine protease (*ssp*) operon by the genes *sspB* and *sspC*, respectively (255).

ScpA and SspB are secreted as zymogens. Pro-SspB is processed by SspA as the last step of the proteolytic cascade that begins with Aur (Fig. 10) (255, 274). In contrast, processing of pro-ScpA is not mediated by Aur, SspA, or SspB (269). Instead, pro-ScpA undergoes rapid autoproteolysis, but this process also leads to rapid degradation of the protease (275).

Despite limited primary sequence identity, crystal structures of both staphopains demonstrated structural similarity to papain. Classical papain-like proteases contain two domains: the helical L-domain is composed of the N-terminal part of the protein, containing the catalytic cysteine, and the R-domain is composed of the C-terminal part of the protein, which folds into antiparallel β-sheets, forming a β-barrel-like structure that contains the catalytic histidine and aspartate (Fig. 11) (276–278). The location of the catalytic triad is conserved in both staphopains (276, 277).

Although ScpA and SspB share high structural similarity, subtle differences between the proteases confer different substrate specificities. ScpA cleaves elastins found in connective tissues, pulmonary surfactant protein A in the lungs, and the chemokine receptor CXCR2 on leukocytes (239, 279–281). Additionally, ScpA promotes vascular leakage by activating the plasma kallikerin/kinin system, resulting in hypotension (281). The activity of ScpA in mediating vascular leakage is enhanced by SspB; however, SspB alone does not induce vascular leakage, demonstrating substrate specificity of the two proteases (281).

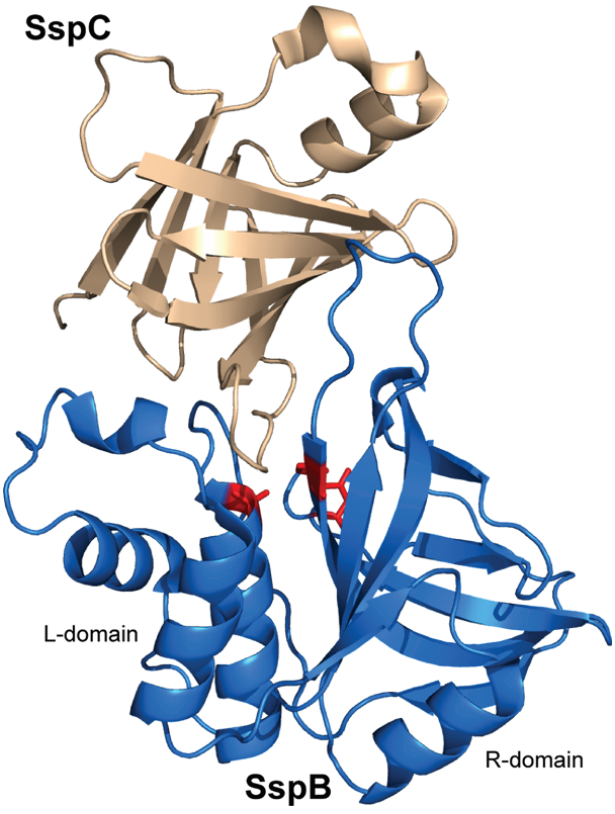

FIGURE 11 Staphopain-staphostatin complex (1PXV) (293). Staphopain SspB (blue) has two domains: the L-domain is helical, and the R-domain consists of β-strands that fold into a β-barrel-like structure. The catalytic site of SspB is highlighted in red. Staphopain SspC (beige) is a single domain protein composed of eight β-strands forming a single mixed β-barrel domain. SspC is a competitive inhibitor of SspB, directly blocking substrate access to the active site.

In contrast, SspB degrades the antimicrobial peptide LL-37, thereby promoting bacterial survival (282). SspB also cleaves CD11b and CD31, surface proteins that are important for the activation and survival, respectively, of phagocytes (283, 284). Thus, SspB prevents *S. aureus* from phagocytosis while diminishing the leukocytes' abilities to detect pathogens. Paradoxically, SspB is also a potent activator of chimerin, a chemoattractant for dendritic cells and macrophages (285). *S. aureus* thrives intracellularly in macrophages and dendritic cells (286, 287). Therefore, SspB may function to promote the intracellular lifestyle of *S. aureus* for persistent infections. In fact, *S. aureus* has been demonstrated to produce SspB, SspA, and Aur after neutrophil phagocytosis (254).

Both ScpA and SspB are implicated in modulating biofilm formation (288, 289). The expression of both staphopains is repressed during biofilm formation, and the production of staphopain results in the dispersal of biofilms (289).

In addition to promoting biofilm dispersal, staphopains have a direct effect on the host's connective tissues and coagulation system. Staphopains inactivate a number of host proteins, including α_1-proteinase inhibitor, collagen, and fibrinogens; however, SspB has higher activity in cleaving fibrinogen and collagen compared to ScpA (248, 290).

The activities of staphopains are inhibited by the cysteine protease inhibitor E-64; by heavy metals, such as Co^{2+}, Ag^{2+}, Hg^{+}, and Zn^{2+}; and by host-derived proteins, including α_2-macroglobulin in human plasma and the epithelial serpin, SCCA1 (239, 257, 291). Additionally, *S. aureus* produces inhibitors against the enzymes, known as staphostatins. Staphostatins are specific reversible inhibitors of staphopains. Staphostatin A can inhibit only staphopain A but not staphopain B (273). Similarly, staphostatin B inhibits only staphopain B (273). Both staphostatins are similar in size and structure. These small proteins (~13 kDa) each comprise eight β-strands that form a single mixed β-barrel domain (292). Staphostatin occupies the same binding site as substrate, and thus they are competitive inhibitors (Fig. 11) (276, 293). Staphostatins lack signal peptides, and thus they are proposed to inhibit intracellular staphopain activities prior to secretion of the proenzyme (273, 294).

Serine proteases: the serine protease-like proteins

Serine protease-like proteins A to F (SplA to SplF) are the newest group of secreted staphylococcal serine proteases identified. SplC (named ORF-2 in the study) was the first Spl identified from a screen of *S. aureus* antigens reactive to serum antibodies from endocarditis patients (295). Soon after, *splC* was discovered as part of the *spl* operon, encoding *splA to SplF* (296). This operon is located in the gene cluster νSaβ, which is present in over 60% of *S. aureus* genomes (296, 297).

Spls share 40 to 60% protein sequence identity, except for SplD and SplF, which have 95% sequence similarity with each other (Fig. 12) (296). The Spls are similar in size, ranging from 21 to 22 kDa. SplA to SplD have been characterized, and their structures were determined by X-ray crystallography (298–301). The crystal structures of the four Spls showed structural homology to the other staphylococcal

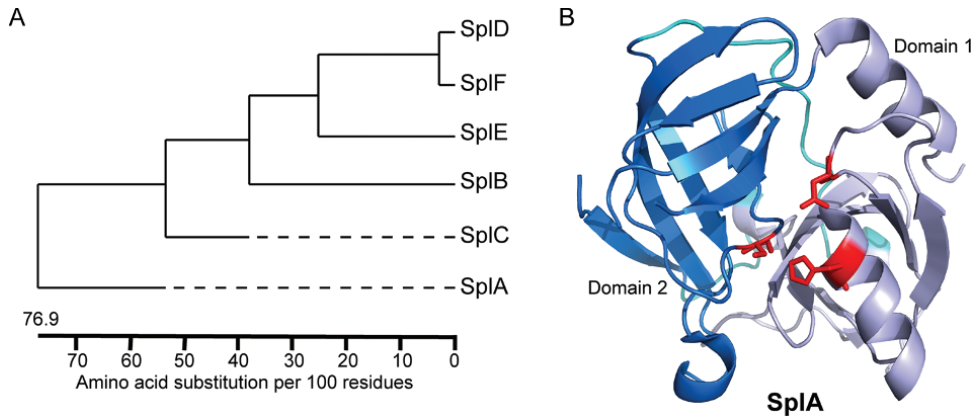

FIGURE 12 (A) Phylogenic tree of *S. aureus* Spls. The tree is constructed based on the mature protein sequences using the DNASTAR MegAlign ClustalW method for multiple sequence alignment. (B) Crystal structure of SplA (2W7S) (299). SplA has two domains connected by a linker (cyan). Domain 1 (light purple) consists of α-helices and β-strands, and domain 2 (blue) consists of of β-strands. Both domains fold into a β-barrel structure. The catalytic triad (red) is located at the center between the two domains.

serine proteases. Spls have a chymotrypsin-like fold, consisting of two β-barrel domains (Fig. 12) (298–301). The catalytic triad typical of serine proteases (His, Asp, Ser) is conserved and is present in the center between the two domains (296, 298–301).

Based on functional studies of the Spls, the precise cleavage of the signal peptide is critical for protease activity. An additional two amino acids (such as those resulting from a thrombin cleavage) in the N-terminus of SplA, SplB, and SplC are enough to render the enzymes inactive (296, 298, 299). Therefore, the signal peptides of Spls serve dual functions: (i) to direct the protein secretion and (ii) to serve as propeptides to prevent enzyme activation prior to secretion.

SplA, SplB, and SplD have extremely narrow substrate specificities, requiring the recognition of substrate consensus sequences that are 4 to 5 amino acids in length (Table 3) (298–300). Mucin-16, an *O*-glycosylated transmembrane protein present in the ocular epithelia, is a substrate for SplA (302). Additionally, searches based on the substrate consensus sequences identified many olfactory receptors as potential Spl substrates, but they remain to be verified experimentally (298–300). Nevertheless, these searches suggest that Spls may be important for nasal colonization. SplD contributes to airway inflammation and asthma by promoting IgE production and Th2 responses (303, 304). The role of SplD and SplF in asthma is supported by the identification of these proteins in nasal polyp samples from asthma patients who were also *S. aureus* nasal carriers (303).

However, the role of Spls in *S. aureus* pathogenesis remains unclear. While murine pneumonia and intraperitoneal infection models using Δ*spl* mutants had no effect on host survival or bacterial burden, the absence of *spl* limited the dissemination of bacteria *in vivo* in a pneumonia model (296, 303). Proteomic analysis of wild-type *S. aureus* and Δ*spl* mutant demonstrated significant changes in many virulence factors important for adhesion and immune evasion; thus, Spls have a role in shaping the *S. aureus* proteome (302).

TABLE 3 Consensus cleavage sequence of Spls

SplA	Trp/Tyr – Leu – Tyr – Tyr – Ser
SplB	Trp – Glu – Leu – Gln
SplC	To be determined
SplD	Arg – Trp/Tyr – Pro/Leu – The/Leu/Ile/Val
SplE	To be determined
SplF	To be determined

Hyaluronidase

Hyaluronic acid (HA) is a linear polysaccharide composed of repeating units of *N*-acetylglucosamine and glucuronic acid linked by alternating β-1,3 and β-1,4 glycosidic bonds (305). HA is a critical component of extracellular matrices in vertebrates, providing homeostasis and structural integrity to cells and tissues; it is also important for immune regulation (306, 307). The enzymes that break down HA are collectively known as hyaluronate lyase or hyaluronidase.

In nature, hyaluronidases can be found in vertebrates, invertebrates, and bacteria. Hyaluronidases found in vertebrates and invertebrates break down HA to tetrasaccharides (308). In contrast, bacterial hyaluronidases act as endo-*N*-acetylhexoaminidases and cleave the β-1,4 linkage in a process known as β-elimination, breaking down HA to unsaturated disaccharides (308).

S. aureus and *S. hyicus* are the only staphylococci known to produce hyaluronidase (309, 310). The activity of staphylococcal hyaluronidase was initially reported by Duran-Reynals in 1933 as a "spreading factor" that increased lesion sizes in a rabbit skin infection model (311). Subsequently, this spreading factor was identified by Chain and Duthie in 1940 as hyaluronidase (312). In 1995, the gene encoding for staphylococcal hyaluronidase, *hysA*, was eventually cloned and the corresponding protein purified (313).

As a spreading factor, hyaluronidase is implicated in the dissemination of bacteria through breaking down HA in extracellular matrices and biofilms. The skin and the lungs are two locations where extracellular matrices are abundant. Deletion of *hysA* resulted in reduced skin and lung pathology and lowered bacterial burden in skin and lung infection models, respectively (314, 315). Deletion of *hysA* was also demonstrated to cause increased biofilm formation and reduced bacterial dissemination (316).

Lipases

Phospholipases

S. aureus can produce two phospholipases: β-toxin and phosphatidylinositol-specific phospholipase C (PI-PLC). β-toxin is a neutral sphingomyelinase with hemolytic and cytolytic activities, discussed in the exotoxin section, above. The other staphylococcal phospholipase, PI-PLC was discovered in the 1960s in *S. aureus* culture supernatants where PI-PLC hydrolyzed phosphatidylinositol (PI) to diglyceride and inositol phosphate (317, 318). Today, *S. aureus* remains the only staphylococcus known to produce PI-PLC (319). *S. aureus* membrane does not contain PI, and thus *S. aureus* is thought to have acquired PI-PLC to adapt to the host environment (320).

Like other bacterial PI-PLCs, the staphylococcal PI-PLC has an imperfect $(\beta\alpha)_8$-barrel structure (also known as the TIM barrel) (321). The active site of PI-PLC is conserved and is located at the C-terminal end of the β-strands that form the β-barrel (321). The elucidation of the staphylococcal PI-PLC crystal structure provided explanations for many of PI-PLC's biochemical properties (321). PI-PLC is reported to have an optimum pH between 5.5 and 6.0 (319). This property can be explained by the unrestricted substrate access to the active site under acidic conditions. In contrast, accessibility of the substrate is restricted under basic conditions (321). PI-PLC is inactivated by NaCl, $HgCl_2$, and Cu_2SO_4 (319). The salt sensitivity of PI-PLC can be explained by the high electropositivity of the barrel rim region and the active site (321). The presence of phosphocholine enhances the activity of PI-PLC (321). Structural analysis of PI-PLC suggests that the presence of phosphocholine enables transient dimerization of two PI-PLC monomers, resulting in the enhancement of enzyme activity (322).

Bacterial PI-PLC hydrolyses PI in two steps: first, PI is hydrolyzed to diacylglycerol and the intermediate product myo-inositol 1,2-cyclic phosphate (cIP). This is followed by a second slower hydrolysis of cIP to myo-inositol 1-phosphate (323, 324). Diacylglycerol is an important secondary messenger for activating intracellular pathways in mammalian cells for growth and survival (325). PI-PLC can also release glycosyl-phosphatidylinositol-anchored proteins on the cell membrane (319). Two such proteins are C8 binding protein and the decay-accelerating factor (326, 327). Both proteins are complement regulators that are normally present on host cells to restrict complement activation on self (328, 329). Recently, PI-PLC was demonstrated to promote survival of *S. aureus* in human blood and neutrophils (330).

Glycerol ester hydrolases (lipases)

S. aureus has two lipases: *S. aureus* lipases 1 and 2 (SAL1 and SAL2). SAL1- and SAL2-encoding genes are sometimes annotated as *gehA and gehB*, respectively, for glycerol ester hydrolase (331–333). SAL1 has also been annotated as *lip1* in the literature (331). The two genes are encoded in disparate regions in the *S. aureus* genome, but they share protein sequence similarity with each other and with other lipases found in other staphylococcal species (332, 333).

The lipases are produced as pre-pro-enzymes (334). The pre-pro-enzyme is processed by signal peptidase I, which cleaves the signal peptide for secretion. The secreted pro-enzyme is cleaved by aureolysin to yield the mature lipase (331). However, cleavage of the propeptide is not required and has no effect on the enzymatic activity (331, 335). Utilizing chimeric lipases of *S. hyicus* expressed in *S. carnosus*, the lipase propeptides were found to be important for the translocation of the lipases to the extracellular milieu and for stabilizing the proteins to prevent degradation (336, 337).

Enzymatic activities of the lipases are conferred by the conserved catalytic triad, formed by serine, aspartate, and histidine (331, 332). Although sharing a similar catalytic mechanism, SAL1 and SAL2 differ biochemically and have different substrate preferences. SAL1 functions optimally at pH 6.0 and is stable under acidic conditions, but it is inactivated when the pH is above 10 (338). Biochemical and molecular analyses showed that Ca^{2+} stabilizes the structure of SAL1 and increases its activity (334, 338). Accordingly, chelators, such as EDTA and EGTA, inhibit SAL1 activity (338). SAL1 has a strong preference for short-chain triglycerides but cannot hydrolyze long-chain triglycerides (338).

In contrast, SAL2 functions optimally around pH 8.0 and is inactive under acidic conditions (339). The presence of Ca^{2+} does not enhance the activity of SAL2 (339). As such, chelators have minimal effects on activity. SAL2 prefers long-chain triglycerides as substrates (331). However, SAL2 has also been shown to hydrolyze short-chain triglycerides, monoglycerides, and diglycerides with lower efficiency and with no apparent positional specificity (331).

The conservation of lipases in staphylococcal species implies their evolutionary importance. However, the contribution of lipases during disease is unclear. *S. aureus* clinical isolates from deep tissue infections produce more lipases than isolates from superficial infections (340). Purified lipases cause aggregation of granulocytes and decrease phagocytosis at high concentrations (341, 342). During infection, SAL2 was shown to be important for biofilm formation and contributed to the virulence of *S. aureus* strain RN4220 in a murine intraperitoneal infection model (343). These observations suggest that lipases are involved in the overall virulence of *S. aureus* and promote bacterial survival in biofilms and abscesses. Paradoxically, lipase-mediated triglyceride hydrolysis liberates bactericidal free fatty acids, which can interfere with pathogenicity (344). For most lipase-producing strains, these bactericidal fatty acids can be detoxified by fatty acid-modifying enzymes (FAMEs).

Fatty acid-modifying enzyme

The FAME was first described in 1992 by Mortensen et al., who observed that *S. aureus* culture filtrates inhibited the bactericidal activities of host lipids in abscesses (345). Since the initial discovery, FAME activity has been well documented in many staphylococcal species (346, 347). Approximately 80% of *S. aureus* and *S. epidermidis* organisms produce this enzyme (347, 348). Despite its prevalence, the corresponding gene for FAME is not known and the protein has not yet been identified.

FAME promotes staphylococcal survival by esterifying the bactericidal free lipids with an alcohol substrate to form alcohol esters. Although FAME can esterify free lipids with methanol, ethanol, 1-propanol, 2-propanol, and 1-butanol, it prefers cholesterol, which is highly abundant in abscesses (345). Saturated and unsaturated fatty acids with 15 to 19 carbons are efficiently esterified by FAME; however, esterification is also observed for fatty acid chains of between 11 and 24 carbons (349). The optimal pH of the enzyme ranges between 5.0 and 5.5 and has an optimal temperature of about 40°C (345). Enzyme activity is inhibited by di- and triglycerides with unsaturated fatty acid side chains (349).

In abscesses, lipases and FAME are thought to complement each other to enhance staphylococcal survival (350). While lipases break down triglycerides that inhibit FAME activities, FAME processes the free fatty acids liberated

by lipases to protect the staphylococci. This hypothesis is corroborated by the observation that most *S. aureus* strains that carry genes encoding lipases have FAME activities and that they are correlated with the invasiveness of the bacteria *in vivo* (345, 348).

CONCLUSION

S. aureus devotes a significant amount of energy to the production of virulence factors to protect the bacteria from host immune surveillance and to promote bacterial survival in hostile environments (Fig. 13). The importance of these virulence factors during infection has been demonstrated extensively in various *ex vivo* and *in vivo* infection models. Pathogenic *S. aureus* is usually present in hostile host environments with limited resources; thus, it follows that the production of many virulence factors that serve the same purpose can be a waste of limited resources and be disadvantageous for survival. In contrast, this redundancy can ensure protection of the bacterium if one of the virulence factors is rendered ineffective. Alternatively, the bacterium may have acquired these seemingly redundant virulence factors during its evolution to better adapt to different types of infections or colonization sites.

Many of the exotoxins and secreted enzymes discussed in this article share structural and functional similarities. However, closer examination of these proteins reveals subtle differences that have functional significance. Minor differences in the PFTs lead to the cytolysis of various cell types that are critical for immune defense. Each of the SAgs target different Vβ TCRs, resulting in broad suppression of the T cell repertoire. Proteases, such as the serine proteases, which have structural homology have disparate substrate specificities. Other exotoxins and enzymes have similar functions but differ in when and where they are produced during growth and pathogenesis, suggesting that the complex and seemingly redundant virulence factor repertoire is critical for the success of *S. aureus* as a versatile pathogen. With the rise in antibiotic resistance in microbes, including *S. aureus*, there is an urgent need to develop novel therapeutics and vaccines to combat this deadly pathogen. Understanding the roles these important virulence factors have during diseases can provide the knowledge necessary for designing better therapeutics and identifying vaccine targets.

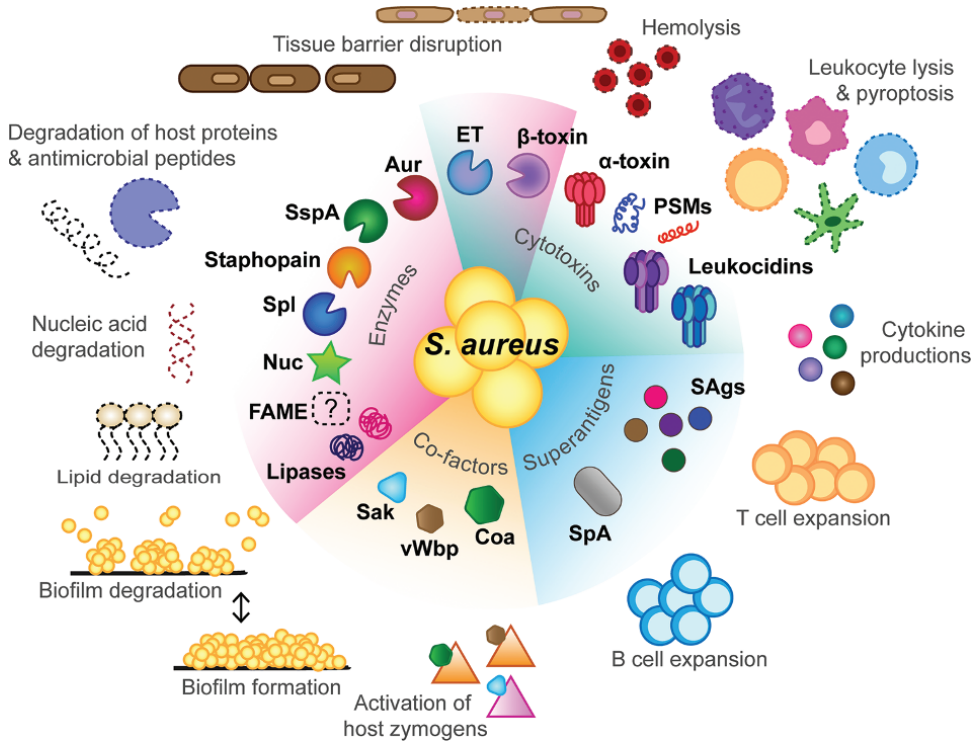

FIGURE 13 *S. aureus* secretes many different toxins and enzymes. Superantigens are proteins that have high mitogenic properties, causing T and B cell expansions that result in clonal deletion and massive cytokine production. Cytotoxins, such as α-toxin and the leukocidins, cause cytokine production, hemolysis, and leukocyte cell death through targeting specific cell surface receptors. The amphiphilic PSM peptides mediate cytolysis by inserting into the lipid bilayer of cell membranes. Enzymes, such as β-toxin and the ETs, cause cytotoxicity on mammalian cells, resulting in cell death, inflammation, and tissue barrier disruptions. Other enzymes, including various proteases and nucleases, mediate host protein degradations, thwarting many important host immune surveillance and defense molecules. These enzymes can also act on self-proteins to degrade biofilms for bacterial dissemination. Lipases and FAME work synergistically to degrade lipids in the environment for nutrients. Cofactors, including Coa, vWbp, and Sak, bind and activate host zymogens in the coagulation system to mediate clot formation and dissolution. Altogether, these toxins and enzymes provide critical nutrients (i.e., iron and carbon) that are important for the growth and survival of the bacteria. Importantly, they target various aspects of host immune defenses, thus contributing to the overall virulence of *S. aureus* during infections.

Regulation of *Staphylococcus aureus* Virulence

CHRISTIAN JENUL AND ALEXANDER R. HORSWILL

41

INTRODUCTION

Staphylococcus aureus is a Gram-positive commensal bacterium and opportunistic pathogen. The main sites of colonization are the skin and mucous membranes, and approximately 30% of the healthy adult population are colonized by *S. aureus* (1). Although *S. aureus* is primarily a commensal microbe, it has the potential to cause a wide range of diseases that can vary considerably in severity. The most common problems are skin infections, and some of the most severe are bloodstream infections, endocarditis, osteomyelitis, and necrotizing fasciitis (2). To survive and adapt to different environmental niches, *S. aureus* has evolved an intricate regulatory network to control virulence factor production in both a temporal and host location manner (3). The regulatory machinery and virulence factors are known as accessory genes, since they are not essential for normal growth. These accessory factors are used to establish dominance in the host and contribute to the pathogenicity of *S. aureus*, and they include cell surface components and proteins directly released into the extracellular environment. The functions of these molecules include adherence to host cells, evasion of host defenses, nutrient degradation, and acquisition. These accessory genetic elements are encoded directly on the chromosome and on mobile elements that include phages, plasmids, and pathogenicity islands.

S. aureus is a bacterial species with a conserved core genome (4), and its evolution is mainly driven through mutation and horizontal gene transfer. Mobile genetic elements, such as integrated bacteriophages (prophages), are one of the most common contributors to *S. aureus* strain-to-strain variation. Due to its low level of natural competence, bacteriophage transduction is a frequent mode of DNA transfer between *S. aureus* strains (5). Panton-Valentine leucocidin and the immune evasion cluster are two examples of virulence factors found on prophages (6, 7), with the latter being on a bacteriophage integrated into the *hlb* gene (8). Other important bacteriophage-encoded virulence factors include exfoliative toxin A (9, 10), cell wall-anchored virulence factor SasX (11), staphylococcal inhibitor of complement (*scn*) (12), staphylokinase (*sak*), chemotaxis inhibitory protein (*chp*) (13), and the enterotoxins encoded by *sea* (14), *selk2*, and *selp* (15). Staphylococcal pathogenicity islands are another mobile genetic element that can encode pyrogenic toxins called superantigens. The superantigen genes encoded on staphylococcal pathogenicity islands include toxic shock toxin (*tsst*) (16), enterotoxin B (*seb*), and enterotoxin-like protein Q (*selq*) (15). Plasmids play an important role in the acquisition of antibiotic resistance of *S. aureus*, but there are also a few examples documenting their importance for the acquisition of virulence factors. To date, it has been shown that several toxins can be plasmid encoded, including exfoliative toxin B (17–19), enterotoxin D (20), the enterotoxin-like protein SER (21), and enterotoxin-like protein J (22). The focus of this article is the regulation of these virulence factors in *S. aureus*.

REGULATION OF *S. AUREUS* VIRULENCE FACTORS

Within *S. aureus*, the regulation of the virulence factors is subject to a complex network that integrates host- and environment-derived cues into a coordinated response. Two-component systems (TCSs) are one mechanism to perceive environmental changes and transform them into a regulatory program. For a typical TCS, an external signal activates the membrane-associated histidine kinase, leading to its autophosphorylation and subsequent phosphorylation of the response regulator. Once phosphorylated, the response regulator can bind to a specific DNA sequence motif, resulting in the alteration of target gene expression. Most strains of *S. aureus* encode 16 different TCSs (23, 24); one of these is essential (WalKR), and the other 15 have been inactivated in multiple strains (25, 26). Some TCSs, such as *agrAC*, *saeRS*, and *arlRS*, are linked to *S. aureus* virulence and regulate a large number of host-impacting secreted proteins. The best studied of these regulatory systems is the accessory gene regulator (*agr*), which was first described in 1986 and encodes a quorum-sensing system that acts as a master virulence regulator (27). Coupled with these TCSs, *S. aureus* survives in the host environment using a suite of important cytoplasmic regulators (23). Most important among them are the SarA protein family of transcriptional regulators (SarA, Rot, MgrA, etc.) and the alternative sigma factors (SigB and SigH). The goal of this article is to provide an overview of these regulatory systems (summarized in Table 1), and the interplay and critical features of each system will be covered.

THE AGR QUORUM-SENSING SYSTEM

Architecture of the *agr* Quorum-Sensing System

The gene cluster that encodes the peptide quorum-sensing system in *S. aureus* is called the accessory gene regulator (*agr*)

doi:10.1128/microbiolspec.GPP3-0031-2018

TABLE 1 Major virulence regulatory systems of *S. aureus*

Regulator system	Role	*In vivo*	References
agr	Cell-to-cell communication (quorum sensing) with AIPs as signal; *agr* activation leads to expression of exo-toxins and exo-enzymes	Required for virulence in animal models of skin infection, pneumonia, and endocarditis	27, 30, 50–54, 56, 59, 62, 87, 89–92, 94
SaeRS	Induction of exo-protein production, including many virulence factors	Required for virulence in animal models of skin infection and pneumonia	97, 98, 105–108
SrrAB	Oxygen-responsive TCS; induction of *plc* and *ica* expression; repression of *agr*, TSST-1, and *spa*	Required for defense against neutrophils	71, 80, 113, 118
ArlRS	Autolysis and cell surface TCS; induction of MgrA expression and repression of *agr* and autolysis	Required for virulence in animal models of skin infection and endocarditis	121–123, 125, 202
SarA	Cytoplasmic regulator; induction of exo-proteins and repression of *spa*	Required for virulence in animal models of biofilm infection	135, 137, 139, 161
Rot	Cytoplasmic regulator of toxins and extracellular proteases; *agr* activation prevents Rot translation	Mutation of *rot* restores virulence in *agr*-null background in rabbit endocarditis model	61, 155–160
MgrA	Cytoplasmic regulator; induction of efflux pumps and capsule expression; repression of surface proteins	Required for virulence in animal models of skin infection and endocarditis	84, 163, 164
SigB	Stationary phase sigma factor; inhibits *agr* activity	Important for the establishment of chronic infection in rat lung model	134, 183–188, 190, 203

(Fig. 1). The signal sensed by the *agr* system is an autoinducing peptide (AIP), which can be 7 to 9 amino acids in length and contains a five-membered thiolactone ring between the C-terminal end and a conserved cysteine residue (3, 28, 29). The AIP signal accumulates in the extracellular environment, and once it reaches a critical concentration, usually at a "quorum" of cells in the population, the system is activated. *S. aureus* employs the *agr* system to adapt to changing environmental conditions during growth and to regulate virulence (27, 29, 30). The *agr* system consists of two adjacent transcripts, called RNAII and RNAIII, whose expressions are driven by the P2 and P3 promoters, respectively (31). The RNAII transcript is an operon of four genes, *agrBDCA*, that encode the machinery of the quorum-sensing system, and the RNAIII transcript is the major effector and regulates the expression of most *agr*-dependent target genes. As shown in Fig. 1, AgrD is the ribosomal peptide precursor of AIP (32) and is proteolytically processed by AgrB, an integral membrane-bound peptidase (33, 34). AgrB-mediated cleavage of AgrD results in the formation of an enzyme-bound thiolactone intermediate (33–35), and through an unclear mechanism this structure is transported across the membrane. The type I signal peptidase SpsB performs the final processing step to release the mature AIP into the extracellular environment (36). Once outside the cell, AIP is then sensed by AgrC, the membrane-bound histidine sensor kinase of the AgrCA TCS. The binding of AIP to the AgrC receptor leads to histidine autophosphorylation (37), and this signal is relayed to the aspartate receiver on the response regulator AgrA (38). The phosphorylated AgrA can then bind to the P2 and P3 promoters to drive expression of RNAII and RNAIII, respectively (39). Expression of RNAII, which encodes for all components of the *agr* system, effectively leads to a positive feedback loop. This autocatalytic regulation is a hallmark of quorum-sensing systems and enables *S. aureus* to readily produce exoproteins, even though growth is slowed down (38).

AIP Types

To date, four classes of AIP structures are known to exist in *S. aureus*. Their length ranges from 7 amino acids (type III) to 8 amino acids (type I and IV) to 9 amino acids (type II) (Fig. 2). AIP types I and IV are the most conserved, differing in only one amino acid, and as a result, they function interchangeably (40). Early studies of *agr* revealed that the AIPs can cross-inhibit the function of an AgrC receptor from another *S. aureus* strain in a mechanism termed "*agr* interference" (41). This cross-talk gave rise to three functional AIP groups, each of which can effectively cross-inhibit other *agr* systems within *S. aureus* (41), resulting in an intriguing mechanism of intraspecies signaling (Fig. 2). The divergence among the four AIP types stems from a highly variable region that spans the C-terminus of *agrB*, the whole *agrD* gene, and the N-terminal region of *agrC* (42). These differences also explain the variability of the AgrC protein and its specificity for its cognate AIP (41, 42). As mentioned above, the hypervariable region responsible for the four AIP types also reaches into the coding sequence of *agrB*, which suggests that AgrD processing might also be type specific. Indeed, it was demonstrated that AgrB of the AIP type II system can only process its cognate AgrD, while AgrB of the AIP type I and type III systems is not able to process the type II AgrD (41, 43).

Agr Regulon

AgrA directly regulates the expression of RNAII and RNAIII from the P2 and P3 promoters, respectively (Fig. 1). This was long thought to be the only relevant regulatory role of AgrA, until a study compared gene regulation between the wild-type, an *agrA* mutant, and an RNAIII mutant (44). It was discovered that AgrA also regulated the phenol-soluble modulin (PSM) genes, which have received considerable attention in recent years for their involvement in *S. aureus* virulence (45–47). Electromobility shift assays demonstrated that AgrA is capable of directly binding the promoters of the alpha- and beta-PSM-encoding operons (44). The main effector of the *agr* quorum-sensing system is RNAIII, a regulatory RNA that also encodes the delta-hemolysin gene (*hld*) (48), also known as delta-toxin. Interestingly, the translation of *hld* is delayed by 1 hour after RNAIII transcription by an unknown mechanism (49). Among the genes upregulated by RNAIII are many well-characterized

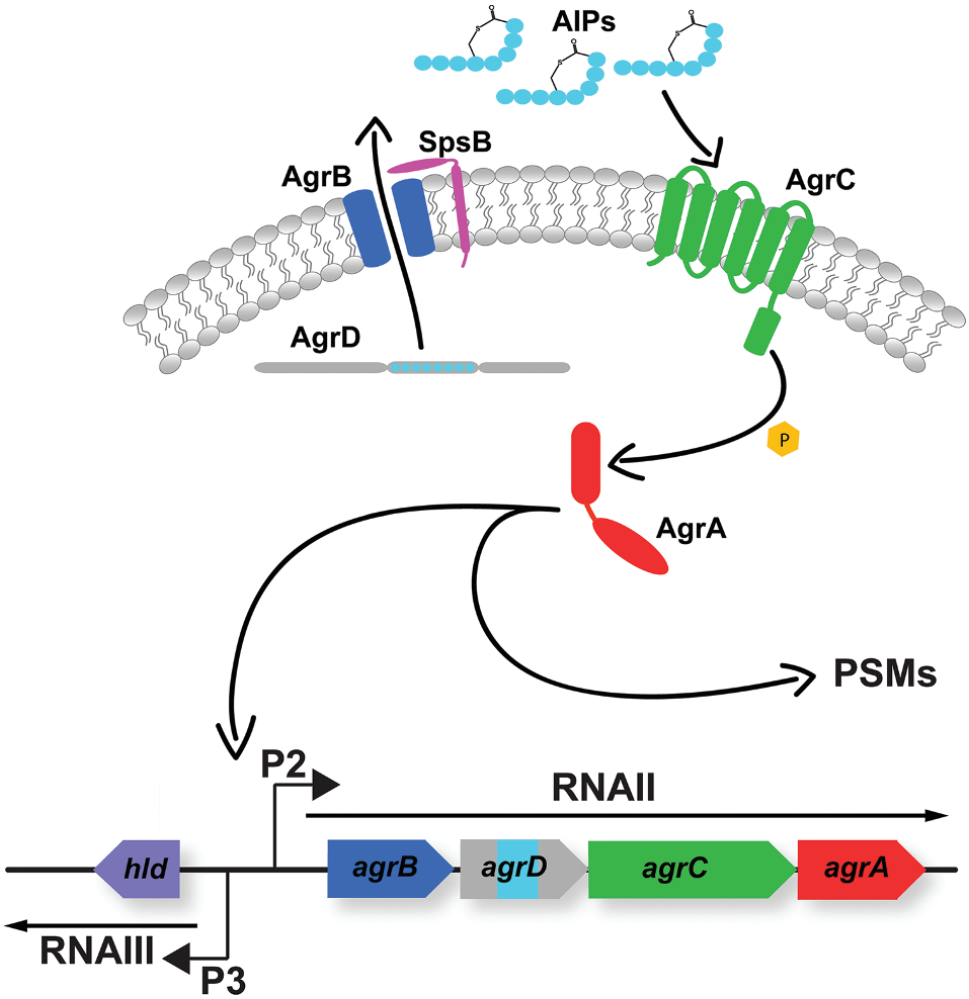

FIGURE 1 Schematic of the molecular organization, signal biosynthesis, and transduction cascade of the *agr* quorum-sensing system. The autoinducing peptide (AIP) signal is encoded within the AgrD peptide. AgrD is processed and transported into the environment by AgrB with the aid of signal peptidase SpsB. When the extracellular AIP concentration reaches a critical level, the signal is sensed by the histidine kinase AgrC, which undergoes autophosphorylation. Then the phosphate is relayed to AgrA, which in turn can bind the P2 and P3 promoters, driving expression of the RNAII and RNAIII transcripts, respectively. The RNAII transcript harbors the *agrBDCA* operon, encoding the primary machinery for AIP biosynthesis and detection. RNAIII is the main effector molecule of the *agr* system and drives expression of downstream target genes. Phosphorylated AgrA also binds the promoters for the phenol-soluble modulin (PSM) genes, leading to their expression.

virulence factors, including alpha-toxin (Hla), serine proteases (SplA-F, SspA), cysteine proteases (ScpA, SspB), gamma-hemolysin (Hlg), and lipase (Geh) (30, 50, 51). Alpha-toxin is one of the most prominent regulated toxins and is an important virulence determinant in skin and soft tissue infections (52, 53), pneumonia (54), and endovascular infections (55). In contrast, some surface proteins, including protein A (Spa), cell wall secretory protein (IsaA), and surface receptors (MnhA, MnhF, and MnhG), are downregulated by RNAIII (30, 50, 51). Among these surface proteins, protein A stands out due to its dominant role in pathogenicity in several types of *S. aureus* infections, including pneumonia (54, 56), bloodstream infections (57), and septic arthritis (58).

RNAIII enacts its regulatory role either directly on the transcriptional level by modulating transcription initiation or at the posttranscriptional level by interacting with the target gene transcript (48). RNAIII is a large regulatory RNA that has a complex secondary structure with several C-rich hairpins, which are important for the interaction of RNAIII and its target mRNAs (59). One well-studied example is the positive regulation of alpha-toxin (*hla*) by RNAIII. The *hla* mRNA normally forms a hairpin loop that prevents the ribosome from accessing the ribosome-binding site. RNAIII can bind to the *hla* mRNA, relieving the hairpin loop structure and allowing the ribosome to recognize the binding site for translation initiation (51). On some occasions, posttranscriptional control by RNAIII results in translational inhibition, rather than promotion. For example, RNAIII exerts its regulatory activity on *spa* (protein A) gene expression at the posttranscriptional level by two distinct mechanisms. The first mechanism is direct RNA-RNA interaction with the *spa* mRNA, which inhibits access to the ribosome-binding site, as well as the *spa* start codon, pre-

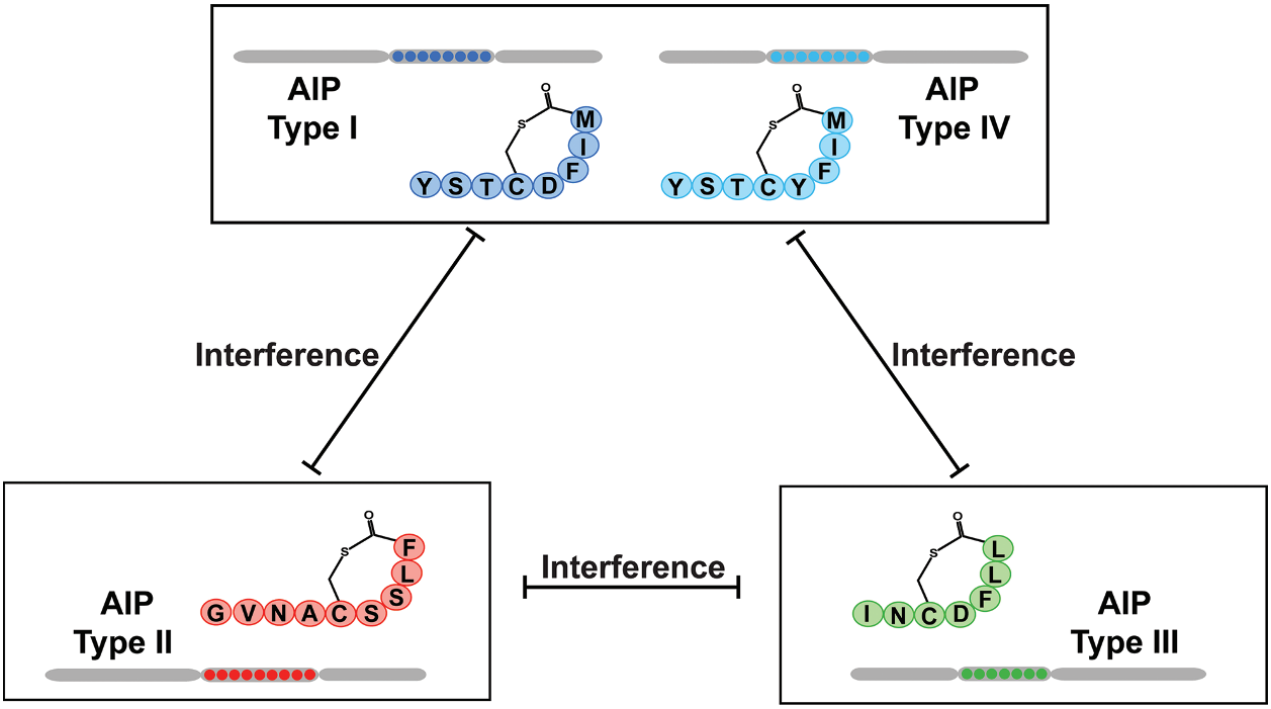

FIGURE 2 The autoinducing peptides (AIPs) and *agr* interference within *S. aureus* strains. Every *S. aureus* strain has a single *agr* system that can produce one of four different AIP signal structures. Each of the AIPs has a five-residue cyclic thiolactone ring, but the amino acids within the ring and the N-terminal extension are variable. The type I and IV AIPs differ by only one amino acid and can function interchangeably, while the type II and III AIPs are more divergent. Interference is observed between the three groups of AIPs as shown. In each case, the cognate AIP signal from a producing strain cross-inhibits the AgrC receptor, and in turn inhibits *agr* function, on an *S. aureus* strain representing a different *agr* group.

venting the initiation of translation (60). The complex formed between RNAIII and *spa* mRNA is also a substrate for RNAseIII. Thus, RNAIII can also inhibit protein A production by enhancing the degradation of *spa* mRNA (60). Although RNAIII is considered the major effector of the *agr* system, regulation of many genes is achieved indirectly through the global regulator Rot (61). Rot is part of the SarA family of cytoplasmic regulators, and Rot's regulatory mechanism is detailed later in this article. Similar to the protein A mechanism, RNAIII controls Rot expression by blocking the ribosome-binding site (59, 62, 63), facilitating *rot* mRNA cleavage by RNAseIII directly at this site (59, 63). When the *agr* system activates, RNAIII levels are high, which prevents the translation of Rot and alters the expression of downstream target genes (64).

Impact of Environmental and Host Stimuli on *agr* Function

Because the *agr* system plays a central role in pathogenesis, *S. aureus* has evolved many strategies to fine-tune the expression of *agr*, allowing it to adapt quickly to changing conditions. These *agr*-modulating factors include environmental cues, other *S. aureus* regulatory proteins, and host-derived stimuli. The following sections outline some of these factors and the mechanisms through which they influence the *agr* quorum-sensing system.

Environmental cues

One of the first abiotic factors described to influence the *agr* system is pH. It was shown that acidic pH inhibits *agr*, which can be achieved either through the catabolism of glucose (65) or by directly lowering the pH of the growth medium in the absence of glucose (66). Interestingly, alkaline pH also represses RNAIII transcription, and it is evident that maximum *agr* activity is observed near neutral pH (67). Reactive oxygen species can also influence the *agr* activity. Neutrophils are some of the first responders to *S. aureus* infection, and they bombard the bacteria with oxidative killing mechanisms. Myeloperoxidase transforms H_2O_2 and chloride to HOCl (bleach), which modulates the *agr* system by oxidizing the methionine side chain of AIP-I and -IV (Fig. 2), rendering the AIPs ineffective (68). Oxidative stress caused by reactive oxygen species can also induce disulfide bond formation in AgrA, leaving it incapable of binding its target promoters (69). In addition, indirect regulation of *agr* activity by reactive oxygen species is achieved by altering the activity of the AirSR (70) and the SrrAB TCS (71), which is discussed further elsewhere in this article.

Host-derived factors

Host serum was one of the first identified inhibitors of the *S. aureus agr* system (72). In follow-up studies, it was found that apolipoprotein B within serum is primarily responsible for this phenotype (73, 74). Apolipoprotein B sequesters AIP signal and prevents *agr* activation. In the host, *S. aureus* obtains iron from hemoglobin (75), but hemoglobin in turn can impact *agr* function. Initially, this was observed using the hemoglobin α and β chains, which inhibited exotoxin production and increased protein A levels, suggesting that the *agr* system was repressed (76). Later studies demonstrated that, indeed, hemoglobin downregulates the *agr* P3 promoter activity and that this can happen during colonization or infection (77).

Regulatory proteins

Many studies have defined how *S. aureus* regulators modulate *agr* activity, and a comprehensive list of these regulators impacting *agr* can be found in Table 2. Of these regulators, CodY, MgrA, and SarA are covered in more detail here. CodY is a transcription factor present in several low-G+C Gram-positive bacteria, and it senses the intracellular concentration of branched-chain amino acids and GTP. It regulates the cell's response to nutrient limitation and metabolic stress (78). In a *codY* mutant, expression of the *agr* locus is upregulated (79). The *agr* locus is overexpressed in the exponential growth phase in a *codY* mutant, which correlates with accumulation of AIP and the dependency on phosphorylated AgrC and AgrA. CodY only weakly binds to the P2 and P3 promoter regions, and instead binds to a region within *agr*C that contains the P1 promoter (79, 80). Although the P1 promoter is weak and only drives *agr*A expression, the binding of CodY to this region could explain the negative regulation of *agr* function. In contrast to CodY, MgrA is a positive regulator of *agr* expression and belongs to the SarA-family of regulators. Two independent studies have shown that an *mgr*A mutation results in a decrease of RNAII and RNAIII transcripts (81) or even complete loss of RNAIII production and P3 promoter activity (82). However, a subsequent microarray study did not observe an impact of MgrA on RNAIII production (83), and a more recent RNA sequencing study had the same observation (84). These studies used different strains, and therefore the regulation of *agr* by MgrA seems to be highly strain specific. Finally, SarA is a positive regulator of *agr* activity and one of the best-studied virulence regulators in *S. aureus*. SarA exerts its positive regulation over *agr* by binding to the P2 and P3 promoter regions and subsequently activating transcription of RNAII and RNAIII (85, 86). A comprehensive description of SarA's role in *S. aureus* virulence regulation is given in a later section of this article.

Importance of *agr* During Infection

Numerous studies have shown that the *agr* system is required for different animal models of infection. Strains with *agr* mutations show smaller lesion sizes and reduced bacterial load in murine skin infection models compared to wild-type strains (28, 87–90). These *agr* mutants are also attenuated in acute murine pneumonia models (54, 56, 89, 91), and they were shown to have decreased rates of infective endocarditis in rabbit models (92). Additionally, *agr* mutants display a decreased ability to establish osteomyelitis in a rabbit model (93). Using a P3-*lux* bioluminescence reporter strain, the dynamics of *agr* activation have been monitored in real time during infection (90, 94, 95), and there is evidence that *agr* activation occurs in repeating waves *in vivo* (94).

TWO-COMPONENT SYSTEMS

The SaeRS TCS

First described in 1994, the *sae* (*S. aureus* exoprotein expression) locus was initially characterized as a regulator of exoprotein production (96, 97). The SaeRS TCS consists of the histidine kinase SaeS and the SaeR response regulator (96–98). The operon encoding the SaeRS system contains four genes: *saeP*, *saeQ*, *saeR*, and *saeS* (Fig. 3). Expression of *saeR* and *saeS* is driven by the constitutive P3 promoter, which is located within the coding region of *saeQ* (99, 100). The P1 promoter is autoinduced by SaeRS and drives the expression of all four genes (101). Although expression of the SaeRS system from the P1 promoter is much stronger than expression driven by the P3 promoter, the overall SaeRS activity is not elevated. This is explained by the fact that SaePQ forms a complex with SaeS, leading to enhanced phosphatase activity (102) and resulting in reduced signal transduction between SaeS and SaeR. Topological studies of the SaeS sensor kinase revealed a 9-amino acid extracellular loop that plays an important role in signal transduction. Three amino acids in the extracellular loop (M31, W32, and F33) were found to be important for SaeS activity. Interestingly, site-directed mutation in M31 and F33 abolished the ability of SaeS to respond to α-defensins (HNP-1) (103), which activates the SaeRS system at subinhibitory concentrations (104). Interestingly, a mutation of SaeS W32 still allowed a response to HNP-1. Exposure to human neutrophils showed that changing the aromatic amino acids (W32 and F33) in the anchor region of SaeRS did not inhibit its activity, while mutating M31 rendered SaeS nonresponsive to neutrophils (103). In general, *S. aureus* wild-type strains survive better after neutrophil uptake compared with an *saeRS* mutant strain (105), indicating a crucial role for SaeRS in the sensing of and defense against neutrophils.

TABLE 2 Regulators impacting *agr* system function

Regulator	Impact on *agr*	Function	Reference(s)
ArlRS	Negative	Represses *agr* P2 and P3	121
CcpA	Positive	Activates *agr* P3	204
CodY	Negative	Repress *agr* P1 promoter in *agr*C	79, 80
MgrA	Positive	Activation of *agr* P3	82
Rsr	Negative	Represses *agr* P3	205
SarA	Positive	Activates *agr* P2 expression	136, 206
SarR	Negative	Represses *agr* P2 expression	136
SarT	Negative	Represses *agr* P3	147
SarU	Positive	Activation of *agr* P2 and P3	148
SarX	Negative	Represses *agr* P2 and P3	207
SarZ	Positive	Activates *agr* promoter	208

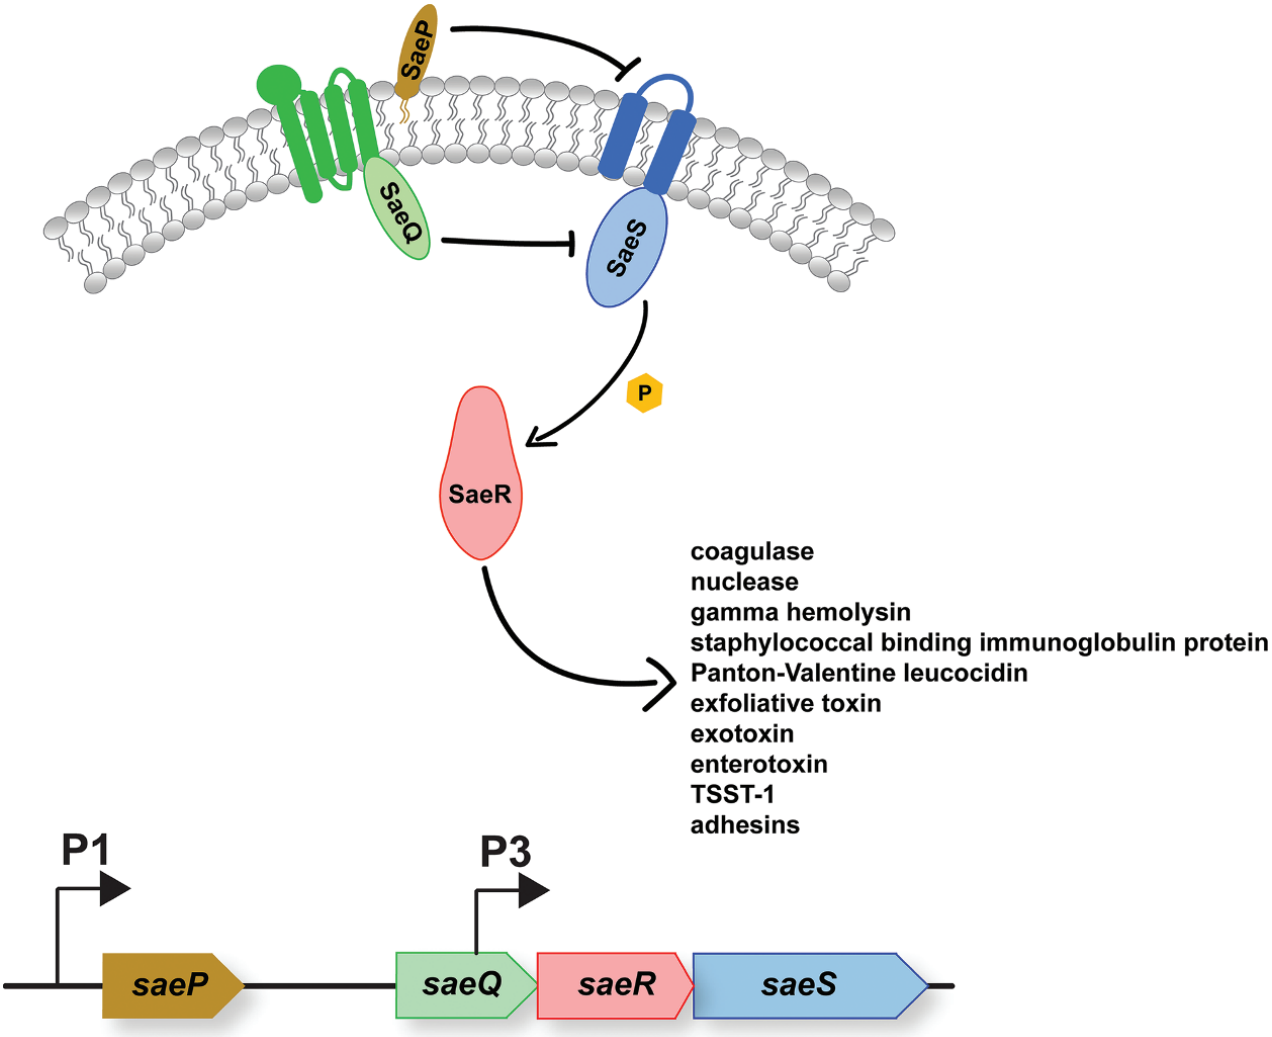

FIGURE 3 Schematic of the molecular organization and signal transduction of the SaeRS TCS. (Top) The histidine-kinase SaeS phosphorylates its cognate response regulator SaeR. Phosphorylated SaeR can then bind to the promoter region of target genes and induce expression of numerous virulence factors (listed). The phosphorelay from SaeS to SaeR is inhibited by the combined action of SaeP and SaeQ. (Bottom) The *sae* gene cluster consists of four genes: *saeP*, *saeQ*, *saeR*, and *saeS*. All four genes are transcribed from the P1 promoter. In addition, transcription of *saeS* and *saeR* is enhanced via the P3 promoter, which is located within the coding region of *saeQ*.

The SaeRS TCS drives the expression of several important exoproteins (Fig. 3), including coagulase, alpha-toxin, beta- and gamma-hemolysins, staphylococcal immunoglobulin-binding protein, Panton-Valentine leucocidin (LukGH), toxic shock syndrome toxin 1 (TSST-1), exfoliative toxin, and nuclease (97, 98, 105–107). The latter two were also shown to be SaeRS regulated *in vivo* during infection (107, 108). Across *S. aureus* strains, the sensor kinase SaeS has polymorphisms, and the three known variants are designated $SaeS^{P}$, $SaeS^{SK}$, and $SaeS^{SKT}$. The $SaeS^{P}$ variant, which is present in the *S. aureus* strain Newman, leads to SaeRS hyperactivity and higher transcription rates of numerous output genes, including *fnbA*, *coa*, *sib*, *efb*, *fib*, *eap*, and *sae*, while other target genes, such as *hla*, *hlb*, and *cap*, are not sensitive to the $SaeS^{P}$ variant (109). Besides its autoinducing regulation, the SaeRS system is regulated by environmental cues and host-specific signals. Low pH (5.5) and high salt concentration (1M NaCl) inhibit *sae* P1 promoter activity (66, 104). The inhibitory effect is relieved in an *saeP* mutant (110), suggesting that the SaeP lipoprotein contributes to this regulatory mechanism. Metals, specifically copper and zinc, interfere with the signal transduction from SaeS to SaeR by inhibiting the SaeS kinase activity. Interestingly, zinc-bound calprotectin, a neutrophil intracellular protein, protects the Sae system from metal-mediated inhibition through an indirect mechanism (111). In addition, the human skin-derived fatty acid *cis*-6-hexadecanoic acid was reported to inhibit the SaeRS system by an unknown mechanism (112).

The SrrAB TCS

The SrrAB (staphylococcal respiratory response) TCS, also known as SrhSR, was first described as a global regulator of virulence factor production under low-oxygen conditions (71, 113). The *srrAB*/*srhSR* locus encodes a histidine kinase SrrB (SrhS) and the paired response regulator SrrA (SrhR). The SrrAB TCS was shown to be important for resistance to

nitrosative stress (114). More recent studies have shown that SrrAB also confers H_2O_2 resistance during high dioxygen-dependent respiration, which is achieved by the positive regulation of the H_2O_2 resistance genes *kat*, *ahpC*, and *dps* (115). *S. aureus* Δ*srrAB* mutants are also attenuated in their fermentative biofilm-forming capacity. This phenotype is in part due to the decreased abundance of autolysin (*atlA*) transcript in a Δ*srrAB* mutant strain, resulting in impaired autolysis and extracellular DNA accumulation under fermentative conditions (116).

In regard to other global regulatory effects, the *agr* system, protein A (*spa*), and TSST-1 are repressed by SrrAB, especially under low-oxygen conditions (71). The observed repression is a result of a direct interaction of SrrA with the respective promoters (117). Besides the aforementioned virulence factors, the SrrAB TCS is also a major driver of *ica* operon expression under low-oxygen conditions, and this operon encodes the polysaccharide intercellular adhesin. An *srrAB* mutant is impaired in a neutrophil killing assay, suggesting that SrrAB-dependent polysaccharide intercellular adhesin production may protect *S. aureus* against nonoxidative killing by neutrophils (118). Transposon sequencing (TnSeq) analysis revealed SrrAB to be essential for *S. aureus* survival in an osteomyelitis model, which could be rescued by neutrophil depletion (119). SrrAB was also found to be a positive regulator of the phosphatidylinositol-specific phospholipase C (PI-PLC) enzyme. PI-PLC is important for *S. aureus* survival in human blood and in human neutrophils (25), which could in part explain the importance of SrrAB for defense in these environments.

The ArlRS TCS

Bacteria can undergo autolysis to remodel their cell walls by the action of murein hydrolases, which hydrolyze various components of peptidoglycan (120). The autolysis regulated locus (ArlRS) TCS was first described as a negative regulator of the autolytic process (121, 122), and it acts as a repressor of *agr* by downregulating RNAII and RNAIII expression (121). More recently, it was observed that ArlRS is a repressor of autolysis in methicillin-sensitive *S. aureus* strains (122, 123) but not in methicillin-resistant strains, including hospital- and community-acquired methicillin-resistant strains (123). In terms of virulence factors, ArlRS was reported to be a positive regulator of extracellular proteolytic activity, specifically serine protease activity (122). Serine proteases are involved in *S. aureus* virulence due to their ability to cleave antibodies and block their activity. This was, for example, demonstrated for the V8 serine protease of *S. aureus*, which cleaves immunoglobulin G *in vitro* (124). Although early reports demonstrated differential toxin regulation between wild-type and *arlRS* mutant strains, this was not observed in other studies using clinical isolates (125), supporting the notion that some of this reported regulation is highly strain specific.

In addition to *S. aureus* virulence, a microarray study showed that ArlRS represses sugar uptake systems and activates genes involved in amino acid utilization as a carbon source (126). These early results were corroborated by a recent study that showed positive regulation of genes involved in amino acid catabolism by ArlRS in the presence of calprotectin, an antimicrobial protein that starves bacteria for manganese and zinc (127, 128). A functional ArlRS system was necessary to facilitate resistance against calprotectin-mediated manganese starvation. Interestingly, manganese sequestration by calprotectin inhibited growth of *S. aureus* when glucose was utilized as the main energy source but not when amino acids served as the primary energy source. This implies that glucose utilization results in a higher demand for manganese compared to amino acid utilization. Therefore, *S. aureus* protects itself from calprotectin-mediated manganese starvation by switching its carbon source, and this process seems to be regulated by the ArlRS TCS (127).

Recently, it was demonstrated that the ArlRS TCS is required for *S. aureus* clumping in the presence of fibrinogen (125). *S. aureus* uses surface proteins, such as ClfA and ClfB, to interact with the abundant dimeric fibrinogen molecule, bringing cells together as a "clump" to survive in the host (129). The inactivation of *arlRS* results in the dramatic upregulation of the large surface protein Ebh, which is thought to inhibit clump formation. Indeed, the *arlRS* mutant strain also showed lower virulence in a rabbit model of sepsis and endocarditis, and this phenotype was partially restored by mutation of *ebh* (125). A subsequent study revealed that ArlRS directly regulates MgrA (84), which is the primary controller of the clumping mechanism. Through RNA transcriptome sequencing analysis, a total of eight large surface proteins (Ebh, SraP, Spa, FnbB, SasG, SasC, FmtB, and SdrD) were found to be repressed by MgrA (more on this regulator below). Depending on the strain, a deletion of SraP, SasG, or Ebh (in combination) within an *mgrA* mutant background restores the clumping phenotype to wild-type levels (84). The fibrinogen-mediated clumping phenotype of *S. aureus* was shown to have a major influence on *agr* signaling. Clumping creates a microenvironment in which the AIP concentration is increased and thus quorum sensing is uncoupled from the actual bacterial density. This results in a boost in *agr* activation and subsequent production of virulence factors, leading to increased bacterial burden as well as host morbidity and mortality (130).

THE SARA PROTEIN FAMILY

SarA

SarA is the prototypical member of the SarA protein family in *S. aureus*. As outlined in Fig. 4, SarA is expressed from three different promoters, leading to expression of three overlapping transcripts (131). SarA binds to its own promoter and auto-upregulates its own expression (132). It is negatively regulated by the SarA-like protein SarR (133) and positively regulated by the alternative sigma factor σ^B (133, 134). One of the ways SarA exerts its global regulatory function is via the upregulation of *agr* (Fig. 4), resulting in enhanced expression of toxins and the repression of protein A (*spa*) (135). More specifically, SarA significantly boosts the expression of the *agr* system from the P2 promoter (136). Besides indirect regulation through the *agr* system, SarA also exerts posttranscriptional regulation of targets (e.g., *spa*) by binding and altering the mRNA turnover (137).

Several studies have shown that SarA is a strong repressor of protease production, which effects several phenotypes, such as biofilm development (138), and the accumulation of proteins important for *S. aureus* virulence (139, 143). An *in vivo* study showed that a *sarA* mutant of the USA300 strain LAC was attenuated in a murine infection model. The *sarA* mutant displayed increased extracellular protease production, which facilitated the degradation of extracellular virulence factors. Subsequently, this phenotype could be reversed by eliminating extracellular protease activity (139). Another interesting aspect of SarA-mediated regulation is the decreased accumulation of alpha-toxin and PSMs in a USA300 strain. The altered virulence factor levels could be correlated with the increased extracellular degradative protease activity of the strain, rather than a direct regulatory effect of SarA on either

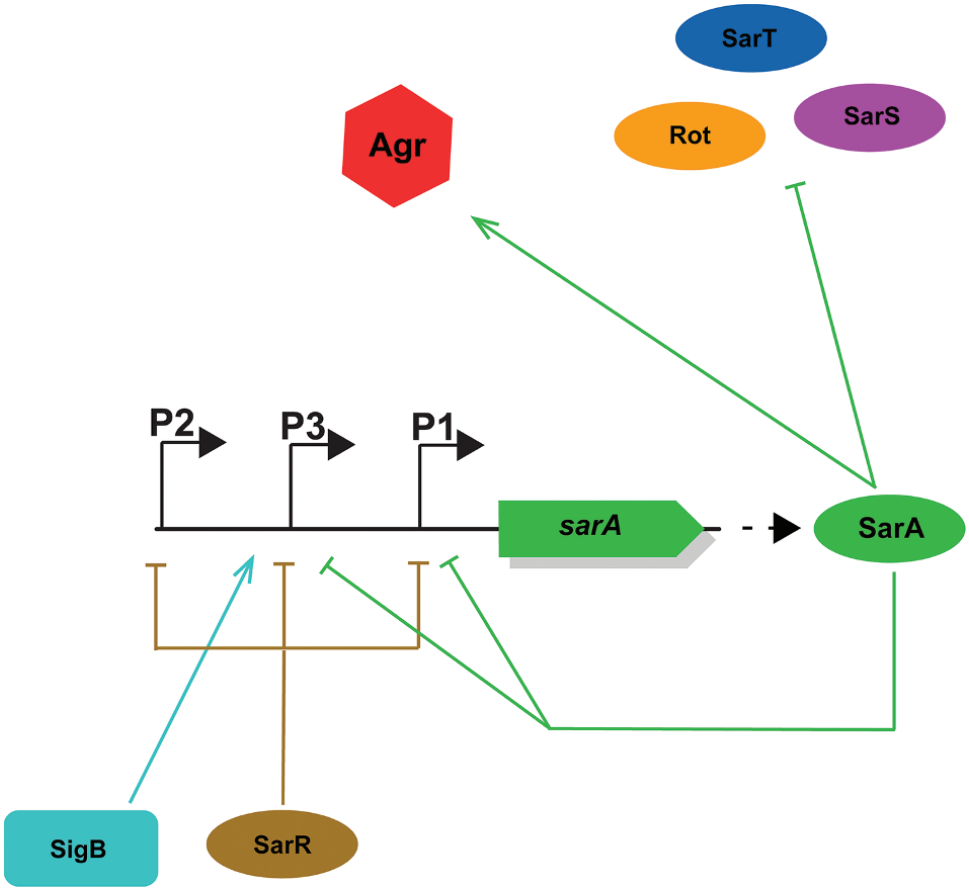

FIGURE 4 The *sarA* promoter region and SarA regulatory network. *sarA* gene expression is driven by three promoters (P1, P2, and P3) as shown. The alternative sigma factor σ^B (SigB) drives expression of *sarA* by binding to the P3 promoter. The binding of SarR to all three promoters inhibits expression and impedes autoregulation by SarA. Finally, SarA is an activator of the *agr* system, and it can also function as a negative regulator of the three SarA-like proteins SarH1, SarT, and Rot.

agr or *hla*. In contrast, mutation of *sarA* in strain Newman did not impact PSM or alpha-toxin accumulation (140), which might be explained by the fact that strain Newman has the $SaeS^P$ variant, leading to constitutive activity of the SaeRS system. A knockout mutation of *sarA* also leads to significant reduction of cytotoxicity against osteoblasts and osteoclasts and to reduced osteomyelitis in a murine model. This phenotype is thought to be mediated by the SarA-regulated production of alpha-PSMs (141).

Besides these regulatory functions, SarA also directly upregulates other virulence factors, including TSST-1, through direct promoter binding (142). Interestingly, the same research group identified SarA as a negative regulator of TSST-1 expression in another *S. aureus* strain background (134), suggesting that TSST-1 regulation by SarA is strain specific. Exfoliative toxin A and B, the causative agents of staphylococcal scalded-skin syndrome, are both downregulated by SarA *in vitro*. Negative regulation of exfoliative toxin B (ETB), but not exfoliative toxin A (ETA), by SarA was also observed in a neonatal mouse model (107). Another facet of SarA-mediated regulation is the recently discovered repression of the regulatory small RNAs *srn_3610* (*Spr*C), known to attenuate *S. aureus* virulence in an animal infection model (144), and *srn_9340* (145). Repression is achieved by direct binding of SarA to the respective promoters of the two small RNAs, which consequently blocks RNA polymerase loading (145).

SarR

SarR is a 13.6-kDa homolog of the SarA regulator protein and is a negative regulator of *sarA* expression (133) (Fig. 4). SarR accomplishes this regulation by binding to all three promoters of the *sarA* locus (146). SarR also acts as a negative regulator of *agr* expression from the P2 promoter, and SarR binds better to the *agr* promoter than SarA does. The result is that SarR can displace SarA and maintain negative regulation over *agr* function (136).

SarT and SarU

Two other members of the SarA protein family are encoded by the adjacent and divergently transcribed genes *sarT* and *sarU* (147, 148). Transcription of the *sarT* gene is regulated by *agr* and *sarA*, both of which repress *sarT* expression. While SarT has only a minimal effect on SarA and SarR expression, the mRNA levels of the *agr* effector RNAIII are increased in a *sarT* mutant (147). Therefore, SarT and the *agr* system seem to interact in a negative feedback loop. Besides this regulation, SarT also represses *hla* (147). In addition, SarT is also a

negative regulator of the *sarU* gene through binding to the promoter region. In contrast to a *sarT* mutation, the activities of the RNAII and RNAIII promoters are decreased in a *sarU* mutant when measured with a green fluorescent protein (GFP) reporter plasmid (148). In terms of the *agr* system, SarT and SarU play opposite roles in the regulatory mechanism. SarT production is also regulated by a small noncoding RNA called ArtR. The ArtR transcript binds to the 5′ untranslated region of the *sarT* mRNA, promoting its degradation (149).

SarH1

SarH1, also known as SarS (150), is a 29-kDa protein from the SarA family. Like other SarA family proteins, its regulation circuit is interwoven with other SarA family proteins and the *agr* system. Expression of SarH1 is strongly repressed by SarA as well as *agr* (150, 151), while it is upregulated by SarT (152). On the posttranscriptional level, SarH1 is regulated by GdpS. The mRNA product of the *gdpS* gene directly interacts with the 5′ untranslated region of *sarH1*, resulting in a more stable *sarH1* mRNA (153). SarH1 itself acts as a repressor of *hla*, and it also acts as a positive regulator of *spa*, which is located directly downstream the *sarH1* locus (151). The regulation of *spa* seems to be organized in a cascade. The *agr* system regulates SarT, which upregulates SarH1 and in turn positively regulates *spa* production (152). Another virulence factor regulated by SarH1 is exfoliative toxin. Two exfoliative toxins, ETA (*eta*) and ETB (*etb*), are expressed by *S. aureus* strains. Of these, SarH1 downregulates production of ETA, but it does not affect ETB production. ETB and ETA production is also negatively regulated by SigB and SarA, while *saeRS*, *arlRS*, and the *agr* system act as positive regulators (107). A recent study showed that SarH1 might also be involved in the spread of antibiotic resistance via the staphylococcal cassette chromosome *mec* element (SCC*mec*). SarH1 can upregulate the chromosome cassette recombinases A and B, which are responsible for the excision of SCC*mec* (154), which could possibly lead to its horizontal transfer.

Rot

The repressor of toxins (Rot) regulatory protein is a 15.6-kDa member of the SarA-like family. The name is derived from the fact that mutation of the *rot* locus in an *agr*-null background restores toxin production and protease activity and consequently restored virulence in a rabbit model of endocarditis (61, 155). In terms of toxin regulation, Rot acts as a repressor of enterotoxin B (*seb*), alpha-toxin (*hla*), proteases encoded by the *spl* and *ssp* operons, and lipase (*geh*). Enterotoxin B is directly repressed by Rot through binding to the *seb* promoter (156). The repression of *hla*, on the other hand, is exerted indirectly via the SaeRS TCS. Rot represses *sae* transcription from the P3 promoter, which then leads to reduced *hla* expression (157).

Rot also acts as a positive regulator of multiple virulence factors. Protein A (*spa*) and the SarA-family protein SarH1 (158) are upregulated by Rot, and by directly binding to its promoter, Rot can positively regulate superantigen-like proteins (Ssl) (159). A subsequent study demonstrated that Ssl production is also dependent on the SaeRS TCS, which synergizes with Rot to activate the Ssl promoter (160). The Rot regulon overlaps with the *agr* system, and Rot acts as an intermediate regulator of *agr* function. As described above, RNAIII, the main effector of the *agr* system, blocks the translation of the *rot* gene (59, 62). Besides RNAIII, Rot is also repressed by SarA, through direct binding to the Rot promoter (161), and by the sigma factor B (σ^B) during stationary growth (63). On the posttranscriptional level, Rot production is also dependent on the presence of the ClpX chaperone (162).

MgrA

MgrA is an important member of the MarR (multiple antibiotic resistance regulator)/SarA protein family. MgrA is a positive regulator of 175 genes and a negative regulator of 180 genes in *S. aureus* strain Newman, as shown in a microarray study (83). Among these regulated genes are several encoding for virulence factors, including alpha-toxin, coagulase, protein A, nuclease, extracellular serine proteases, and capsule production (163, 164). The regulation of genes responsible for capsule production (*cap5*) has also been implicated in infective endocarditis, while alpha-toxin production was not MgrA-dependent in the same model (163). MgrA also regulates the expression of SarZ, which itself controls exoprotein production (165). Looking at the regulatory pattern of MgrA, it is evident that exoproteins are positively regulated and surface proteins are negatively regulated by MgrA (83), with some parallels to the *agr* system. Related to this point, the *mgrA* gene is transcribed from two promoters (P1 and P2), and the mRNA transcript derived from the P2 promoter is stabilized by RNAIII (166).

In addition to RNAIII, MgrA production is regulated by another small RNA-mediated mechanism. The noncoding RNA RsaA represses MgrA production by interacting with its ribosome-binding site, making a loop-loop interaction with the *mgrA* mRNA (167, 168). The activity of MgrA is also regulated on the posttranslational level via the phosphorylation of a conserved cysteine residue. This phosphorylation is mediated by the Stk1-Stp1 proteins, a eukaryote-like kinase-phosphatase pair. Deletion of Stp1 results in elevated protein phosphorylation on cysteine residues and significantly reduces virulence in mouse infection models (169). The phosphorylation status of MgrA also plays a key role in the regulation of the NorA and NorB efflux pumps, which confer resistance to several antibiotics. Phosphorylated MgrA is able to bind to the NorB promoter, acting as a repressor, and unphosphorylated MgrA binds to the NorA promoter, acting as an activator (170–173). Further studies on MgrA suggest that it has the ability to regulate the *lytRS*, *lrgAB*, and *arlRS* TCSs, which are all involved in *S. aureus* autolysis (81). MgrA was called Rat (regulator of autolysis, in answer to "Rot") in early studies due to its role in autolysis regulation.

Several studies have shown that MgrA plays an important but conflicting role in *S. aureus* biofilm formation (Fig. 5). A mutation of *mgrA* has been reported to both promote (84, 174, 175) and repress biofilm formation (176). The disparity is most likely explained by the use of different *S. aureus* strains in these studies. The downregulation of surface proteins by MgrA has been corroborated in a recent study, which established a link between MgrA and the clumping activity of *S. aureus* in the presence of fibrinogen (84). As described above (in the ArlRS section), MgrA represses eight large surface proteins, and of these Ebh, SraP, and SasG are important in preventing clumping with fibrinogen. Fibrinogen-mediated clumping facilitates increased *agr*-mediated virulence factor production and decouples quorum sensing from the actual cell density (130). This can potentially be detrimental for *S. aureus*, because virulence factor production is often a trigger for host defense. Thus, MgrA might act as a fail-safe switch for premature virulence factor production. Relating to biofilm development, the derepression of SasG in an *mgrA* mutant strain promotes biofilm formation (84).

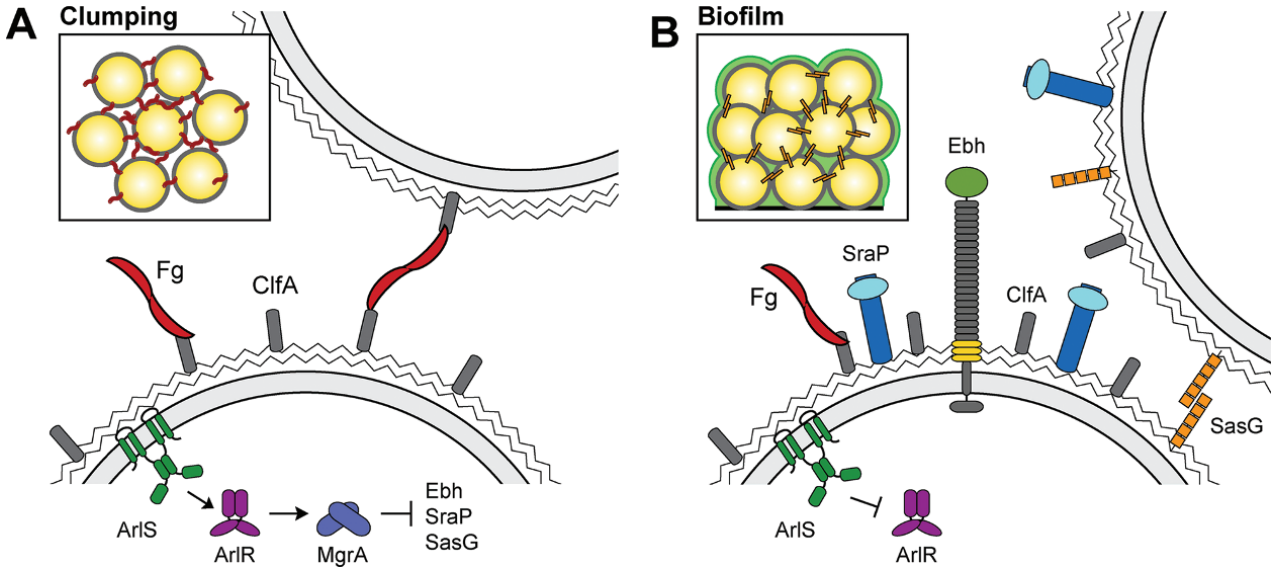

FIGURE 5 Regulatory pathway of ArlRS TCS and MgrA in biofilm formation and clumping. (A) The ArlRS TCS is activated by an unknown signal and subsequently activates MgrA, which in turn represses the production of large surface proteins (Ebh, SraP, and SasG), allowing ClfA/ClfB to interact with fibrinogen (Fg). Neighboring cells binding to the dimeric Fg molecule leads to clumping. (B) When ArlRS is inhibited, MgrA is not expressed and the repression of the large surface proteins (Ebh, SraP, and SasG) is relieved, preventing proper interactions of ClfA/ClfB with Fg. At the same time, SasG overproduction leads to homodimeric interactions with other cells expressing SasG, resulting in enhanced biofilm formation. This figure is a reproduction from one published in reference 84.

ALTERNATIVE SIGMA FACTORS

SigB

Sigma factors confer promoter specificity to the RNA polymerase holoenzyme and are required for transcription initiation. While the primary sigma factor controls housekeeping functions (177), alternative sigma factors regulate the response to changing conditions and allow *S. aureus* to adapt to different environments. Sigma factor B (σ^B) is known to respond to different stresses and accordingly regulates stress-response proteins. In addition, it counterbalances the activity of the *agr* system on virulence factor expression and thus overlaps with the *agr* regulon (178). In *S. aureus*, the *sigB* gene is part of an operon, formed with *rsbU*, *rsbV*, and *rsbW*. Expression *of sigB* is driven by SigA, which leads to the transcription of the whole operon, as well as through autoregulation by SigB itself, leading to transcription of *rsbV* and *rsbW* (179). SigB activity is regulated on the posttranslational level by the Rsb (regulation of sigma B) proteins. SigB is bound and kept inactive by the anti-sigma factor RsbW during exponential growth. Binding of the anti-anti-sigma factor RsbV leads to the release of SigB from RsbW and subsequently allows its binding to the RNA-polymerase holoenzyme (180). The first gene in the SigB operon, *rsbU*, was shown to be necessary for the activation of SigB (181) and is the major activator of SigB during acidic stress (182).

In *S. aureus*, SigB directly and indirectly controls approximately 200 genes, including genes with functions in virulence, biofilm formation, persistence, cell internalization, membrane transport, and antibiotic resistance (180). Several of these regulatory functions are executed by the regulation of known virulence regulators, such as *agr* and SarA (29). An early study of the phenotypic variation of wild-type *S. aureus* strains, and their corresponding *sigB* mutants, suggested a role of SigB in staphyloxanthin pigment production and sensitivity to hydrogen peroxide (183), demonstrating its role in stress response. Strain 8325-4 is a natural *rsbU* mutant and produces high levels of protease and alpha-toxin activity, and this phenotype is dramatically reduced when *rsbU* is repaired (184, 185). Similar results were obtained using the clinical isolate KS26, a prototype V8 protease producer, and strain Wood46, a hyper-alpha-toxin producer, and both of these strains were shown to have mutations in the *sigB* operon (186). Another natural *rsbU* mutant strain is BB255, rendering it effectively a SigB-deficient strain. Complementation of *rsbU*, as well as SigB overproduction in this strain background, increased the strain attachment to fibrinogen- and fibronectin-coated surfaces, as well as adherence to platelet-fibrin clots (187). These phenotypes are thought to derive from the positive regulation of the cell wall-attached adhesins ClfA and FnbA by SigB (187, 188). SigB also regulates TSST-1 through an indirect mechanism involving the two virulence regulators *agr* and SarA (134, 189). In addition, the enterotoxin Seh and the enterotoxin gene cluster *egc* are activated by SigB, while transcription of enterotoxin Seb is negatively regulated by SigB (189). SigB also plays an important role during conditions present in the pulmonary environment. When colonizing the lung, bacteria come into contact with pulmonary surfactant that damages the bacterial cell membrane. In response to the surfactant, *S. aureus* induces the expression of the gamma-hemolysin subunit B, a component of the type-VII secretion system, and the PsiA damage repair protein. The upregulation of these genes is dependent on SigB, indicating that SigB plays an important role in *S. aureus* adaption to the lung environment (190).

SigH

Besides SigB, *S. aureus* harbors a second alternative sigma factor, known as SigH. It was recently shown that overexpression of SigH leads to natural competence of *S. aureus*, although with very low efficiency (191). Indeed, some genes

known to be involved in natural competence of other bacterial species are regulated by SigH (192, 193), but several other competence genes are expressed poorly in *S. aureus* and are not effected by SigH (193). SigH also stabilizes the lysogenic state of *S. aureus* prophages (194). Because prophages often carry genes for virulence factor production, SigH might play an underappreciated role in *S. aureus* virulence.

CONCLUSION

As outlined in this article, the regulation of *S. aureus* virulence factors is subject to a complex and intricate network of factors that integrate physiological processes in response to environmental cues and host signals. This complex network allows *S. aureus* to readily adapt to changing conditions and establish itself in the available niches through its commensal and pathogenic life cycle. Some of the regulatory schemes outlined in this article are highly specialized and fine-tune gene expression in a unique environment, such as in a specific host site. On the other hand, *S. aureus* has evolved several master regulators of virulence that have more global effects, with the most prominent being the *agr* quorum-sensing system, SaeRS, SarA, Rot, ArlRS, and MgrA as summarized herein. An overview of the interconnections between these global regulators is depicted in Fig. 6.

Going forward, there is growing interest in targeting regulatory pathways as a means of preventing infection. As antibiotic resistance in *S. aureus* continues to spread (195), new and unconventional approaches to fight bacterial infections are needed to maintain antibiotic stewardship (196). Due to the importance of the *agr* system in virulence, researchers have extensively targeted this system as a potential means of therapy (197–199). Efforts have been made to target the other global regulators, but in some cases these inhibitors have had broader effects on numerous systems (200). In regard to the *agr* inhibitors, some of the best and most effective candidates are the AIPs themselves, and numerous synthetic studies have been performed to identify improved and more global AIP-based inhibitors (28, 198). More recently, it has been realized that commensal microbes sharing the same niche as *S. aureus* may compete through *agr* interference (90, 201), which ultimately may dictate the ability of *S. aureus* to colonize, or not colonize, the host. An improved understanding of these natural competition

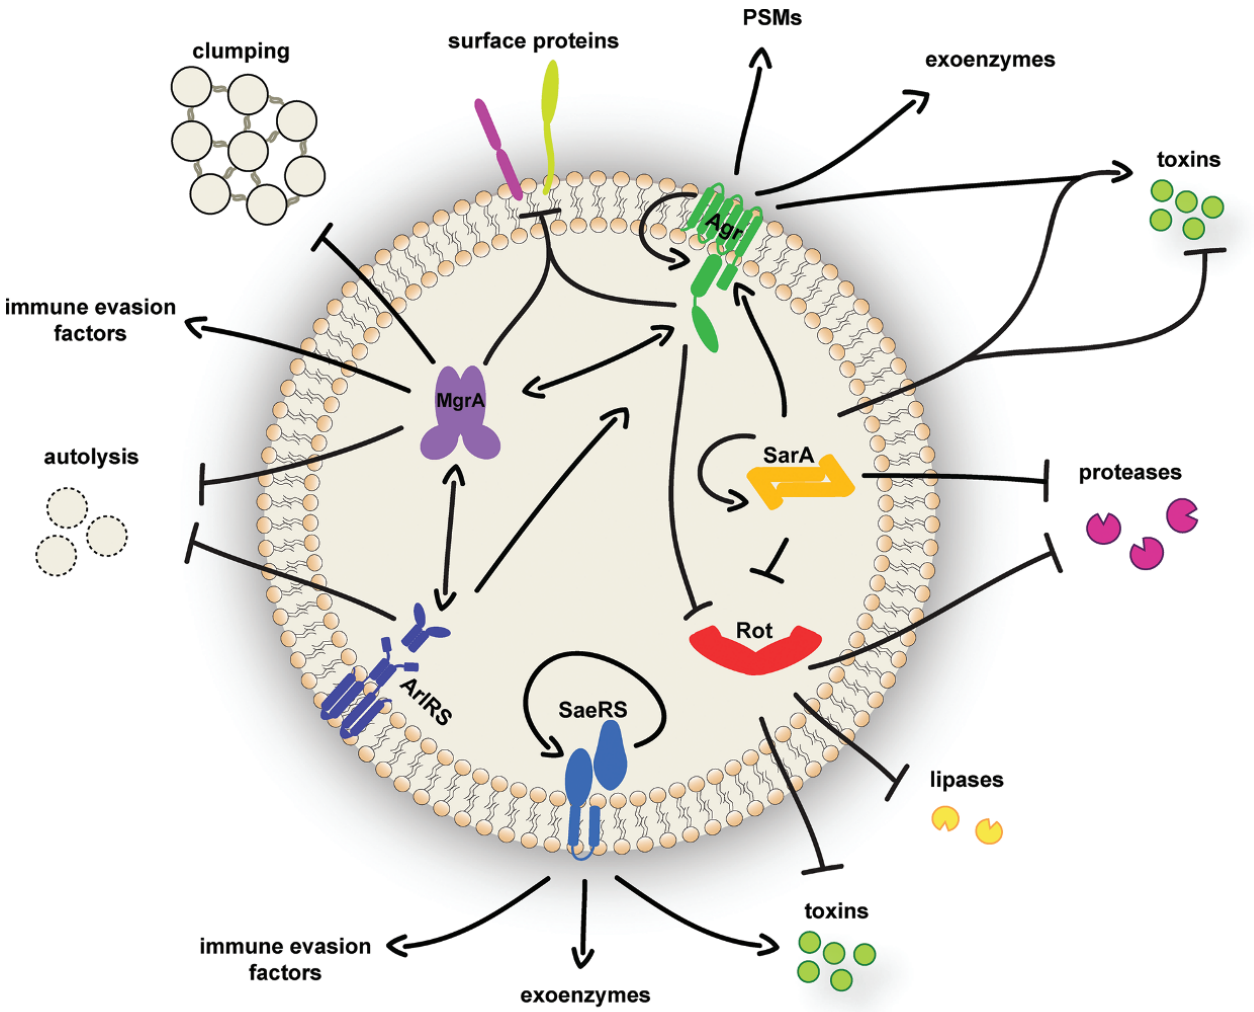

FIGURE 6 Interaction network of the major *S. aureus* global regulators. The schematic depicts a comprehensive overview of five regulatory systems, including the *agr* quorum-sensing system, the ArlRS and SaeRS TCS, and three members of the SarA-protein family (SarA, Rot, and MgrA). The virulence-associated traits controlled by each regulator are also shown.

mechanisms may shape future treatment approaches for certain types of infections.
