Virulence and Metabolism

ANTHONY R. RICHARDSON

42

INTRODUCTION

Of the many species of staphylococci, *Staphylococcus aureus* has evolved to be far and away the most virulent. This stems largely from the horizontal acquisition of virulence determinants that are all coordinately regulated by several transcription factors covered elsewhere (e.g., AgrA, SaeR, Rot, and SarA) (117). In parallel, a separate set of transcription factors act in concert to control the expression of enzymes in various metabolic pathways (e.g., CcpA, CcpE, CodY, RpiRc, SrrA, and Rex). Of note, recent findings have demonstrated that many of these metabolic transcriptional regulators both directly and indirectly influence the functions of the virulence gene regulators. Moreover, many of the virulence gene regulators also affect the expression of key metabolic pathways. Thus, *S. aureus* has intertwined transcriptional control of virulence and metabolism. In addition, several groups have published findings that shed light on the direct contributions of *S. aureus* metabolism to disease outcomes. Different sets of metabolites are available at different infection/colonization sites, thereby necessitating unique metabolic pathways. For instance, the skin surface has abundant lactate, urea, and certain amino acids, but carbohydrates are relatively scarce. This is in contrast to deep tissue sites where *S. aureus* would have access to serum glucose. In addition to metabolite availability, other environmental variables differ among infection sites, such as pH, oxygen tension, and the presence of robust inflammation. For instance, the skin surface is oxygenated and acidic (pH ~5.5) with minimal inflammation, whereas deep tissue infection sites become hypoxic, are relatively well buffered (pH ~6.5), and are almost always accompanied by an immune cell infiltrate. These contrasting environmental factors constrain and alter the metabolic landscape in *S. aureus*, requiring significant adaptation to cause infection/colonization. This chapter highlights recent findings in this area and outlines current knowledge about the linking of virulence with metabolism in this important human pathogen.

CARBOHYDRATE CARBON/ENERGY SOURCES

S. aureus is capable of utilizing at least 15 carbohydrates as primary carbon/energy sources (glucose, glucose-6-phosphate, mannose, fructose, galactose, mannitol, GlcNAc, ManNAc, ribose, maltose, sucrose, trehalose, lactose, turanose, and maltotriose) (1–7). All but four (glucose, glucose-6-phosphate, ribose, and maltotriose) are solely dependent on the phosphoenolpyruvate transport system (PTS) for import (1). PTS transport is coupled directly to phosphorylation of the sugar without the need for cytosolic glucokinase (*glk*, SACOL1604). Briefly, a high-energy phosphate is transferred from phosphoenolpyruvate to the enzyme I (EI) component (*ptsI*, SACOL1092) of the PTS shared by all transporters. This phosphate is then shuttled to His15 on the shared HPr protein (*ptsH*, SACOL1091), which then passes the phosphate onto the sugar-specific enzyme II (EII) component. These EII transporters are made up of three domains in *S. aureus* (EIIA, EIIB, and EIIC) and can be encoded by individual genes or together as fused polypeptides. The phosphate is shuttled from the EIIA subunit to the EIIB subunit, which finally phosphorylates the sugar as it passes through the EIIC pore. *S. aureus* encodes ~29 putative sugar transporter genes, 10 of which are unique to this pathogenic species (1). The substrates for many have been identified and independently validated in multiple strain backgrounds. For instance, *lacE* and *lacF* (SACOL2181-82) encode an EIIBC fusion protein and an EIIA subunit, respectively, that confer growth on lactose and galactose (8). Similarly, *mtlA* and *mtlF* (SACOL2146 and SACOL2148) confer growth on mannitol (9, 10). In addition, *fruA* encodes an EIIABC fusion polypeptide that allows growth on fructose. However, this locus is frameshifted in *S. aureus* COL, which consequently has trouble growing on fructose. Additionally, inactivation of SACOL2316 reduced growth on maltose and maltotriose, insertions in SACOL2376 reduced growth on sucrose, inactivation of SACOL0517 eliminated growth on trehalose and reduced growth on maltotriose, and loss of SACOL2663 limited growth on mannose (1).

Given the redundancy of substrate specificity for many PTS transporters, full identification of the substrates for each putative locus has proven difficult. For instance, glucose transport is highly redundant in *S. aureus*, far more than in coagulase-negative staphylococci (CoNS). While there is an EIIABC fusion peptide encoded by *glcB* (SACOL2552) and a non-PTS proton symporter encoded by *glcU* (SACOL2246) that are specific for glucose and shared by many species of staphylococci, there are additional glucose transporters that are specific to *S. aureus*. Specifically, *glcA* (SACOL0175) encodes an EIIABC fused polypeptide that is specific for glucose and GlcNAc and, to a lesser extent, mannose (1). This gene is not typically found in CoNS. Similarly, *glcC* (SACOL0224) encodes an EIIBC fusion peptide that transports glucose as well as ManNAc and is also absent from the genomes of many CoNS (1). Finally, *S. aureus* can also

doi:10.1128/microbiolspec.GPP3-0011-2018

use glucose-6-phosphate, which is imported via a transporter encoded by *uhpT* (SACOL0200) that is rarely found in CoNS other than *Staphylococcus epidermidis* (11, 12). This expansion of glucose transport capability in *S. aureus* is noteworthy because glucose is in low abundance on the skin surface. Likely, *S. aureus* encounters higher glucose levels in deeper tissue replete with serum glucose, a habitat less frequented by CoNS. In fact, it has been shown that the two PTS-dependent glucose transporters unique to *S. aureus* (GlcA and GlcC) contribute more to glucose uptake in this species than do the common shared glucose transporters (GlcB and GlcU) (1). Additionally, deletion of all four glucose transporters in *S. aureus* resulted in a highly attenuated mutant strain. This is significant, because this mutant was still capable of using all other carbohydrates yet was still avirulent. Conversely, mutating His15 of HPr eliminates PTS transport and the use of virtually all carbohydrates except glucose (glucose can still be imported via the proton symporter), and yet this mutant retained virulence in a murine skin abscess model (1). Thus, during skin infection, *S. aureus* requires host glucose to thrive, and consequently, it has evolved to maximize glucose uptake by acquiring additional glucose-specific transporters that are uncommon among CoNS.

Each compatible carbohydrate enters the Embden-Meyerhof-Parnas glycolytic pathway and/or the pentose phosphate pathway and is eventually converted to pyruvate, generating ATP and reducing equivalents in the form of NADH/NADPH. The fate of pyruvate depends on the redox state of the cell (see below). However, when grown aerobically on carbohydrates, very little pyruvate enters the tricarboxylic acid (TCA) cycle, because the genes that encode TCA-cycle enzymes are transcriptionally repressed by CcpA when glucose is present (see below). Rather, to yield additional ATP, most of the pyruvate is converted to acetate and then excreted, which can significantly impact pH in unbuffered media. However, once glucose in the media is exhausted, CcpA repression of the TCA cycle is relieved, and the excreted acetate can be reassimilated, provided the strain has an intact TCA cycle (13).

NONCARBOHYDRATE CARBON/ ENERGY SOURCES

S. aureus can utilize a number of noncarbohydrate nutrients, including peptides, free amino acids, fatty acids, and small organic acids. Peptides ranging from 3 to 8 amino acids in length are imported by the ATP-dependent Opp3BCDFA transporter (SACOL0991-95), whereas di- and tripeptides are imported by DtpT (SACOL0788) (14). *S. aureus* can also presumably utilize the cysteine-containing tripeptide glutathione as a nutrient/sulfur source by the ABC transporter SACOL0184-86, which is upstream of *ggt* (SACOL0188) encoding the first step in glutathione breakdown. *S. aureus* also encodes several transporters predicted to import single free amino acids, some of which have been implicated in virulence (15). Some amino acids can be directly catabolized as carbon/energy sources and are therefore rapidly consumed in culture medium, including alanine, arginine, aspartate, cysteine, glutamate, glycine, proline, serine, and to a lesser extent, histidine. Others are consumed much more slowly because they are used primarily for protein synthesis rather than energy sources (e.g., isoleucine, leucine, lysine, methionine, phenylalanine, tyrosine, and valine) (16). Most *S. aureus* strains are conditionally auxotrophic for arginine and proline in that CcpA represses *de novo* synthesis of these pathways in the presence of a preferred carbohydrate (17, 18). However, *de novo* arginine synthesis is required for virulence in a murine model of sepsis, likely due to a limitation of host arginine in the context of inflammation (18). In addition, cysteine and methionine serve as the primary sulfur sources during infection because *S. aureus* cannot assimilate sulfur-oxides and is sensitive to excess sulfide (19).

While *S. aureus* cannot grow using fatty acids as a sole carbon/energy source since it lacks a glyoxylate shunt, it has a full complement of genes encoding enzymes for fatty acid beta oxidation (SACOL0215-0211). However, cells cultivated *in vitro* appear to incorporate exogenous fatty acids into membrane phospholipid, and they are not oxidized for energy (20). The role for fatty acid oxidation in *S. aureus* metabolism and virulence has not been studied in detail, but it likely provides the pathogen with a source of energy. In contrast, the use of short 2- hydroxyacids such as lactate in *S. aureus* has been thoroughly studied. Reports describing NAD-dependent and -independent lactate dehydrogenase activities span the last 50 years (21, 22). Only recently, however, have the genes encoding some of these systems been characterized. *S. aureus* can utilize both D- and L-lactate with NAD-dependent Ddh (D-lactate, SACOL2535) or Ldh1/2 (L-lactate, SACOL0222/2618) (23). However, these enzymes generally operate in the lactate-producing reaction to maintain redox balance during respiratory stress (see below). In addition, *S. aureus* encodes an NAD-independent lactate dehydrogenase, lactate-quinone oxidoreductase (Lqo, SACOL2623), that is largely responsible for respiration-dependent lactate utilization (24). Lactate generation/utilization is critical to *S. aureus* virulence because strains with mutations affecting these enzymes exhibit attenuated phenotypes in a variety of murine infection models (25, 26).

Beyond short chain 2-hydroxyacids, *S. aureus* has also been demonstrated to use sialic acid as a carbon/energy source (27). Furthermore, the catabolic gene segment for sialic acid utilization has been identified and characterized. Interestingly, while present in many CoNS, it was absent from those more closely related to *S. aureus*, including *S. epidermidis*, potentially indicating a patchy phylogenetic history for this metabolic pathway (27). While sialic acid adducts are abundant modifications of host proteins and lipids, *S. aureus* apparently lacks a cognate glycosidase to liberate free sialic acid. Accordingly, it must rely on cohabiting commensal species known to possess sialic acid-specific glycosidases or neurominidases (e.g., *Streptococcus* spp.). Thus, sialic acid utilization likely contributes to *S. aureus* colonization, whereas a role in invasive infection has not been demonstrated directly and is less likely since deep infections are generally mono-associated.

MICRONUTRIENTS

In addition to carbon/energy sources, *S. aureus* must acquire a variety of micronutrients during infection to cause disease. For instance, detailed work has outlined the mechanisms by which this pathogen acquires transition metals. Iron acquisition is critical because this element serves in the active sites in enzymes that detoxify immune radicals such as superoxide dismutase (SodM, SACOL0118), catalase (SACOL1368), and flavohemoprotein (Hmp, SACOL0220) as well as enzymes involved in the TCA cycle and respiration. Similarly, manganese is critical for radical-detoxifying enzymes (SodA, SACOL1610) and key glycolytic and gluconeogenic reactions. Zinc is critical for bacterial DNA replication/repair as well as serving in the active sites of key glycolytic enzymes.

Thus, for pathogens to successfully cause disease, they must be able to acquire all of these metal micronutrients.

Given the above, the host exerts significant resources to preclude would-be bacterial invaders from accessing these key micronutrient metals. For instance, free iron is systemically limited by host scavenging proteins such as albumin, transferrin, and lactoferrin. Similarly, iron atoms coordinated in heme, either free or associated with hemoglobin, are another rich iron source and are actually preferred by *S. aureus* (28). Accordingly, free heme is scavenged by the host hemopexin, and free hemoglobin is protected by host haptoglobin. *S. aureus* has acquired the means to obtain iron from all of these sources save hemopexin. High-affinity nonprotein iron scavengers known as siderophores are secreted by numerous bacterial pathogens and act to tightly bind free iron or strip it from iron scavenging proteins such as transferrin and lactoferrin. The iron-bound siderophore is then taken up by bacterial siderophore receptor/transporters replenishing intracellular iron pools. *S. aureus* synthesizes two independent citrate-based siderophores, staphyloferrin A and B (29). Staphyloferrin A is synthesized by enzymes encoded by *sfaABCD* (SACOL2168-71), and iron-bound staphyloferrin A is transported back into *S. aureus* by the ABC transporter HtsABC (SACOL2165-67) under the control of the FhuC ATPase (SACOL0704) (30, 31). Likewise, staphyloferrin B is synthesized by enzymes encoded in the *sbnABCDEFGHI* operon (SACOL0100-08), and iron-loaded staphyloferrin B is brought into the cell by the SirABC transporter (SACOL0096-98) (32, 33). In addition to endogenously produced siderophores, *S. aureus* is capable of utilizing siderophores from other species (xenosiderophores) including hydroxamate- and catecholate-based siderophores via the FhuCBGD1/2 (SACOL0704-06, SACOL2010/2227) and SstABCD (SACOL0796-99) ABC transport systems, respectively (34–36). While siderophores and xenosiderophores are capable of stripping iron from many iron-binding host proteins, they cannot obtain iron coordinated in heme. However, *S. aureus* can still use free heme, hemoglobin, and haptoglobin-bound hemoglobin as heme/iron sources via the iron-regulated surface determinant (Isd) system encoded by *isdBACDEFGHI* (SACOL1139-44, SACOL1146, SACOL1781, and SACOL0152) (37). Hemoglobin and haptoglobin-hemoglobin are recognized by IsdB and IsdH, respectively, and upon heme removal, the iron source is passed to IsdA, then to IsdC, and finally through the ABC-transporter IsdDEF (38–42). Once cytosolic, the iron can be liberated by one of two independent heme oxygenases encoded by *isdG* and *isdI* (43). Thus, *S. aureus* can acquire heme-iron from most host sources except the heme-scavenging protein, hemopexin.

In addition to the systemic scavenging of iron, manganese and zinc are scavenged away from pathogens locally by neutrophils, which express high levels of calprotectin (44, 45). This highly abundant protein binds both manganese and zinc at two distinct sites with high affinity (46, 47). Moreover, *S. aureus* residing within acidic phagosomes is faced with divalent metal deficiencies (including iron, manganese, and zinc), owing to the presence of eukaryotic NRAMP1, a proton/divalent metal symporter (48, 49). NRAMP1 has been shown to effectively remove metals from the phagosomes and transport them into the cytoplasm out of reach of engulfed bacteria (48). To combat these host nutritional immunities, *S. aureus* expresses two independent manganese transporters: the ABC transporter MntABC (SACOL0690-688) and the bacterial NRAMP-family transporter MntH (SACOL1114). Inactivation of *mntABC* when *S. aureus* is cultivated under manganese-depleted conditions results in a significant growth defect, while inactivation of *mntH* does not (50). However, both transporters must be inactivated to cause significant reductions in organism burden in a murine sepsis model (51). The two transporters are regulated by MntR (SACOL0691), the gene for which is positioned upstream of *mntABC*. MntR represses *mntABC* in a manganese-dependent fashion, while it seems to activate *mntH* in response to manganese in the environment (50).

In addition to manganese acquisition, recent advances have revealed how *S. aureus* competes with the host for available zinc. This pathogen expresses two zinc transporters, the ABC transporter AdcABC (SACOL2403, SACOL1612-13) and an Opp/NikA-family transporter, CntABCDF (SACOL2476-72) (52, 53). The two transport systems are partially redundant in that both have to be inactivated to cause growth defects in Zn-depleted culture conditions. In contrast, the two serve two distinct roles during infection. While AdcABC imports free zinc, CntABCDF imports a broad-spectrum metallophore known as staphylopine (54). This "siderophore-like" metal chelator is synthesized by CntKLM (SACOL2479-77) and is presumably exported via the MFS-family transporter CntE (SACOL2471). While the Cnt system can bind and transport a variety of metals, the Adc/Cnt double mutant only failed to accumulate zinc, prompting staphylopine to be designated as a "zincophore" (52). Given the high affinity of calprotectin toward zinc, the Adc system contributes little to zinc acquisition in the presence of this host protein. However, the high affinity of staphylopine toward zinc allows this metallophore to "steal" zinc from calprotectin. Both of these transporters contribute to virulence in that the double mutant was highly attenuated in murine sepsis models, though the Cnt system alone measurably contributes to virulence, presumably due to its ability to scavenge zinc from host calprotectin (52). In total, *S. aureus* has amassed an impressive arsenal of metal transporters to compete with host nutritional immunity.

Apart from metal micronutrients, recent advances have highlighted the role of sulfur in *S. aureus* virulence. In addition to being required for cysteine and methionine synthesis, sulfur is a key component of proteins that employ iron-sulfur clusters or enzymes that utilize the lipoic acid cofactor. Sulfur is also a key component of several vitamins, including biotin, thiamin, pantothenate, and consequently coenzyme A (CoA). Finally, *S. aureus* synthesizes the small-molecular-weight sulfur-containing bacillithiol (Fig. 1), which is critical to the intracellular detoxification of a variety of molecules (55). Sulfur sources for *S. aureus* during infection include cysteine or its oxidized-dimer form, cystine, via the sodium symporter TcyP (SACOL0454) or the ABC transporter TcyABC (SACOL2412-10) (19). Additionally, sulfur can be obtained from methionine via the ABC transporters MetNPQ1 (SACOL0882-84) and MetNPQ2 (SACOL0504-06) or the Na^+/H^+-symporter MetT (SACOL2319) (19). *S. aureus* can also potentially utilize host glutathione as a sulfur source (see above). While *S. aureus* cannot assimilate sulfur from sulfate or sulfite, it can assimilate hydrogen sulfide, thiosulfate, or taurine, though the abundance of these molecules during infection may be well below that of the sulfur-containing amino acids (56, 57). Assimilated cysteine sulfur can be used to synthesize iron sulfur clusters in TCA cycle enzymes such as aconitase and succinate dehydrogenase. *S. aureus* utilizes a Suf system for Fe-S cluster assembly, encoded by the *sufCDSUB* operon (SACOL0914-18) (58). SufS is the cysteine desulfurase that removes S^0 from cysteine and transfers it as persulfide to SufU

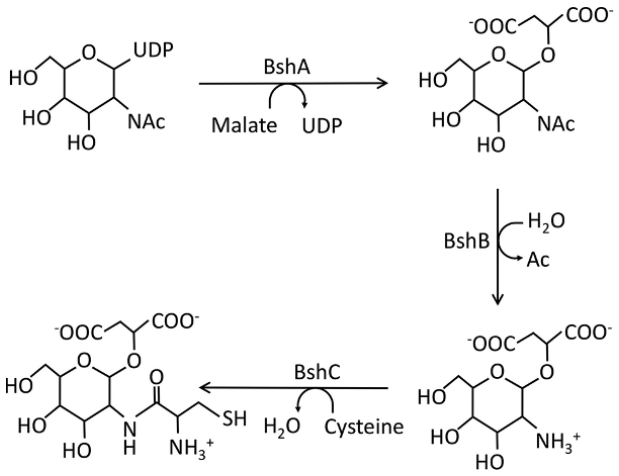

FIGURE 1 Biosynthetic pathway for bacillithiol in *S. aureus*. The major low-molecular-weight thiol in *Firmicutes* is bacillithiol, which is synthesized from UDP-GlcNAc, malate, and cysteine by BshABC. In *S. aureus*, the genes encoding these biosynthetic pathways are not linked in a discreet operon but are located individually throughout the genome.

for incorporation into the iron sulfur cluster on the SufB component of the SufBCD scaffold. The Fe-S cluster can then be transferred to target apoproteins by carriers such as SufA (SACOL0943) and Nfu (SACOL0939) (59). Fe-S assembly (but not repair) is also dependent on a newly characterized SufT protein (SACOL0977), which becomes essential in environments heavily dependent on Fe-S cluster enzymes or lipoic acid-containing enzymes (e.g., growth on peptides or amino acids) (60, 61). Loss of Suf function results in cells with significant fitness defects as well as hypersensitivity to immune radicals and killing by human neutrophils (58). Another important use of assimilated sulfur is in the synthesis of bacillithiol. This molecule is synthesized from UDP-GlcNAc, malate, and cysteine sulfur by the enzymes BshA, -B, and -C (SACOL1498, SACOL0614, and SACOL1190, respectively) (62, 63). Bacillithiol is used in critical detoxification schemes that limit damage caused by immune radicals, toxic electrophiles, certain antibiotics (e.g., fosfomycin), and excessive buildup of metals (55, 64). Furthermore, bacillithiol has a role in Fe-S cluster homeostasis, and mutants lacking the capability of synthesizing this molecule show decreased survival in whole human blood (65).

Respiration versus Fermentation

S. aureus is a facultative anaerobe, meaning it respires if oxygen is present but is capable of either fermentation or anaerobic respiration if oxygen is absent. However, aside from the mere presence or absence of oxygen, the facultative anaerobe designation has implications for virulence in that infection sites are often replete with immune radicals that are highly damaging to respiratory enzymes. Thus, *S. aureus* has evolved to ferment, even in the presence of oxygen, if it senses a drop in respiratory capacity due to the presence of host immune radicals. This likely contributed to the evolution of *S. aureus* pathogenesis. During aerobic respiration, cellular reducing equivalents (e.g., NADH) are recycled via one of the type 2 NADH-dehydrogenases encoded by *S. aureus* (NdhF and NdhC; SACOL0941 and SACOL0944, respectively) (66). Alternatively, electrons can enter the pathway via complex II (succinate dehydrogenase) as well as a host of quinone-dependent oxidoreductases (Fig. 2). Electrons are passed to the sole quinone species in *S. aureus*, menaquinone, and from there can be passed to oxygen-dependent terminal quinol-oxidases. *S. aureus* lacks cytochrome c because it lost the biosynthetic genes early on phylogenetically (Fig. 3). Instead, this species produces three cytochromes (aa_3, bd, and bo_3), which are the products of two independent gene clusters (67). Cyanide-sensitive cytochrome aa_3 is encoded by the *qoxBACD* (SACOL1070-67) gene cluster, as is cytochrome bo_3 when heme a becomes limiting (68). Cyanide-resistant cytochrome bd is encoded by the *cydAB* operon (SACOL1094-95), which is induced during periods of respiratory stress. While these quinol-oxidases are likely necessary for efficient skin colonization given the skin's inherent aeration, each is also required for the colonization of internal organs. Specifically, staphylococcal growth in the heart and liver requires CydAB and QoxABCD, respectively (67). In the absence of oxygen, *S. aureus* is capable of respiring on nitrate via the NarGHJI (SACOL2395-92) nitrate reductase. This molybdenum-dependent enzyme complex transfers electrons from quinol to reduce nitrate to nitrite. The nitrite is excreted but, upon nitrate exhaustion, can be further reduced to ammonia by the siroheme-dependent nitrite reductase, NirBD (SACOL2398-97) (69).

If no external electron acceptor is available, either due to the lack of oxygen/nitrate or if host immune radicals preclude efficient respiration, *S. aureus* enters into fermentative metabolism. The major fermentative end products produced are L-lactate, D-lactate, formate, ethanol, and 2,3-butanediol (70, 71). L-lactate is the dominant fermentative product and is generated by Ldh2 and Ldh1, the latter of which is unique to *S. aureus* (26). D-lactate is generated via Ddh, and all three of these enzymes serve to recycle NAD^+ by reducing pyruvate to lactic acid. Ethanol and 2,3-butanediol are produced from acetyl-CoA and pyruvate by AdhE (SACOL0135) and BudAB (SACOL2199-98), respectively. These are generally produced at much lower levels compared to the organic acids, but they do serve important functions in cells undergoing respiratory stress (72). Formate is generated from pyruvate by PflAB (SACOL204-05). This reaction circumvents the reduction of NAD^+ or quinone by pyruvate dehydrogenase or pyruvate oxidase, respectively, and the formate can be used for generation of formylated peptides (73). Given the inherent redundancy of fermentation pathways, individual loss of function mutations in fermentation genes have little or no phenotype during infection, with Ldh1 being the only exception (26). However, multiple mutations in fermentative pathways lead to severe virulence defects, suggesting that aerobic respiration is not always available to *S. aureus* during infection.

Fermentation inherently comes with metabolic limitations. For instance, fermenting carbohydrates is much less efficient with respect to energy production, and thus, *S. aureus* requires ~4-fold more carbohydrate per cell than during respiration (1). Furthermore, growing independently of respiration limits the compatibility of many carbon sources. With the exception of pyruvate, only glycolytic carbon/energy sources support fermentative growth (74). In fact, eliminating merely cytochrome aa_3 but not bd or bo_3 also necessitates glycolytic carbon/energy sources (68). This has important implications for *S. aureus* virulence. Most of the enzymes in the Embden-Meyerhof-Parnas pathway are reversible and therefore essential since they are required for both glycolysis and gluconeogenesis. However, certain

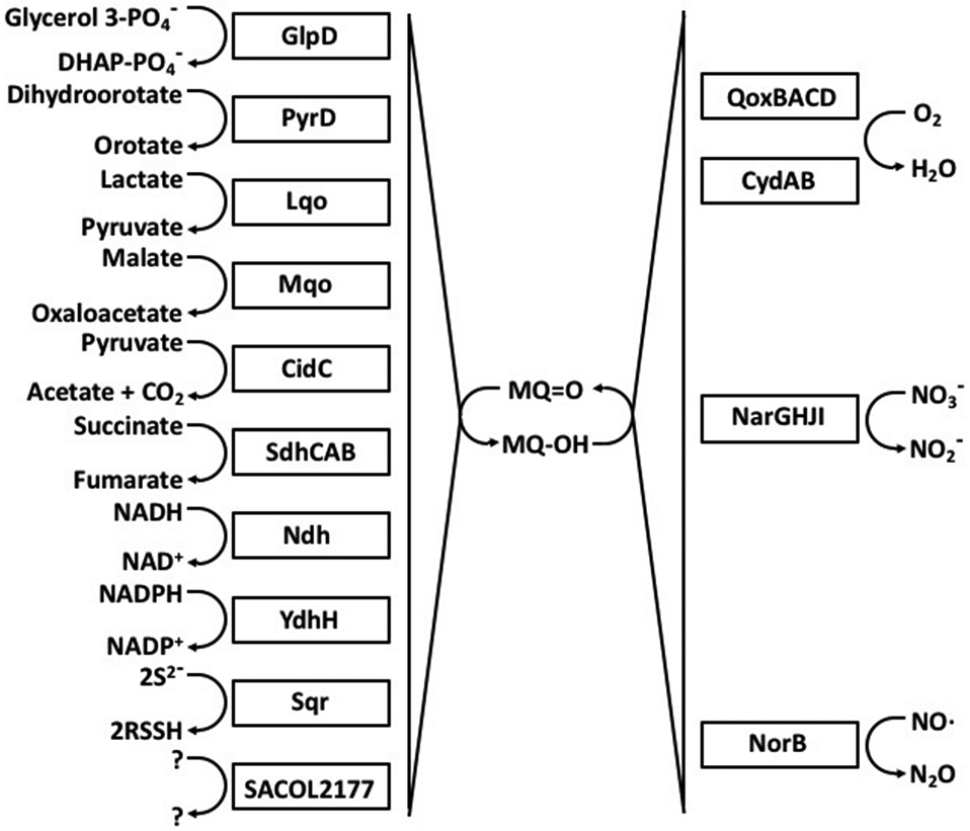

FIGURE 2 Branched respiratory scheme in *S. aureus*. The left side lists all of the known/putative quinone-oxidoreductases in *S. aureus* along with their substrates. Electrons are passed via these enzymes to the menaquinone pool and then to one of many terminal oxidases (right side with substrates). While most *S. aureus* organisms possess QoxBACD, CydAB, and NarGHJI, NorB seems to be limited to strains in clonal complex 30 (e.g., UAMS-1 and MRSA252).

reactions are not readily reversed, such as those of phosphofructokinase (*pfkA*, SACOL1746) and pyruvate kinase (*pyk*, SACOL1745). These genes encode enzymes required only for glycolysis, and therefore, mutants grow like wild type on gluconeogenic substrates (e.g., peptides) but cannot grow in the presence of glucose. These mutants are particularly attenuated for survival within activated macrophages (74). In contrast, gluconeogenic mutants (e.g., Δ*pckA*) were not. Moreover, eliminating macrophage nitric oxide (NO·) production enhanced survival of glycolytic mutants to wild-type

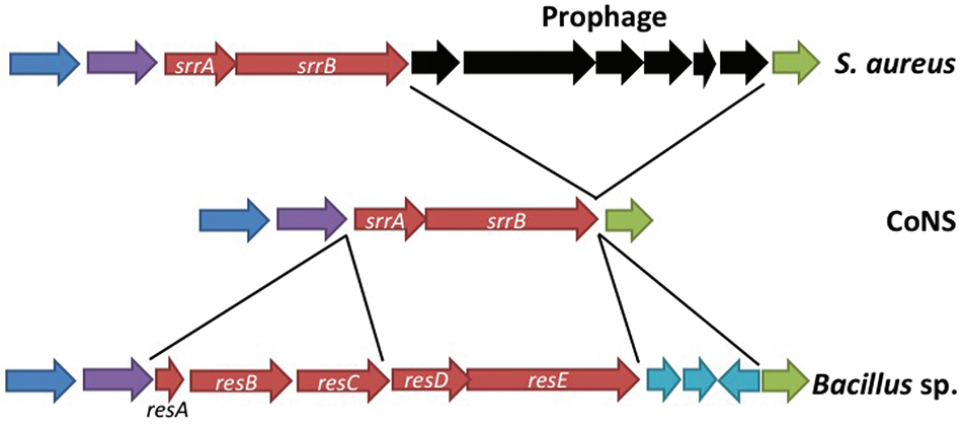

FIGURE 3 Loss of cytochrome C synthesis while retaining SrrAB. In other *Firmicutes*, SrrAB homologues (termed ResDE) are encoded in the same operon as ResABC, which are involved in cytochrome c biosynthesis. Across most staphylococci, the *resABC* genes are missing, while *resDE* (*srrAB*) the two-component system was retained.

levels, suggesting that *S. aureus* has access to a variety of carbon/energy sources within the phagosome, but host NO· blocks respiration, thereby necessitating the use of glycolytic carbohydrates. Also, given the importance of host glucose to infection (see above), it is not surprising that these glycolytic mutants were highly attenuated in murine infection models (74).

Wild-type *S. aureus* can switch between fermentative and respiratory modes of energy production via the coordination of metabolic gene expression by a set of transcriptional regulators that monitor the redox status of the cell (see below). However, many chronic or recurrent *S. aureus* infections are caused by persistent antibiotic-tolerant small colony variants (SCVs) (75). These arise commonly through mutations that eliminate the cell's ability to respire (e.g., heme or menadione biosynthetic mutations). These slow-growing, nonrespiring SCVs exhibit reduced membrane potential and consequently are more resistant to many antibiotics. However, it has been proposed that mixed populations of SCVs with different genetic etiologies (e.g., a mixed infection with heme- and menadione-deficient subpopulations) can "cross-feed" each other any deficient metabolites. This restores growth and virulence but does not return the population to full antibiotic susceptibility (76). Whether this phenomenon occurs clinically has yet to be described. Furthermore, over time, nonrespiring SCVs evolve faster growth rates, in some cases through mutations that enhance fermentative capacity (77). This also improves growth without restoring antibiotic susceptibility. Additional studies of SCVs have uncovered a number of causes beyond the direct loss of respiratory capacity, including mutations in *thy*A that result in loss of thymidine synthesis, thereby reducing trimethoprim/sulfonamide susceptibility (78). However, due to effects of *thy*A mutations on TCA cycle enzyme expression, these SCVs also exhibit reduced respiratory flux. Other means of achieving the SCV phenotype involve mutations in components of the RNA degradasome, changes in small noncoding RNA expression including toxin-antitoxin systems, and persistent stringent response mutations (75). In addition to decreased antibiotic sensitivity, SCVs also exhibit reduced virulence factor production and increased uptake and survival within host cells, accounting for their association with chronic and recurrent infections (79).

Metabolic Gene Regulation

While it would be highly cumbersome to outline all of the metabolic gene regulation in *S. aureus*, here, I focus on regulators that intersect between metabolism and virulence. Specifically, the sensing of carbon sources and redox homeostasis is discussed, because these pathways have been outlined above. Compatible carbohydrates are sensed and responded to by CcpA, while a close homologue, CcpE, responds to citrate levels in the cell. In parallel, the availability of amino acids and nucleotides is sensed by CodY. Finally, *S. aureus* senses respiratory capacity via a two-component system, SrrAB, and the cytosolic redox state via Rex. Nearly all of these regulators are conserved among *Firmicutes*, and most have direct and indirect intersections with virulence factor expression and pathogenesis. Of note, compared with *Bacillus subtilis* and *Escherichia coli*, *S. aureus* lacks an FNR homologue. This Fe-S cluster-containing regulator is conserved in many bacterial species and is required for the maximal expression of anaerobic respiration and fermentative pathways (80). The Fe-S cluster is oxygen labile; therefore, in the presence of oxygen, *B. subtilis* and *E. coli* do not efficiently express fermentative enzymes (81). In contrast, *S. aureus* can fully express fermentative pathways in the presence of oxygen since it does not utilize this oxygen-sensing scheme. Thus, in the presence of host immune radicals, *S. aureus* can ferment available carbohydrates regardless of the aeration of the local environment. The following subsections describe a few of the key metabolic regulators employed by *S. aureus* to coordinately regulate metabolic genes with virulence factor production.

CcpA

In general, CcpA (SACOL1786) mediates carbon catabolite regulation in Gram-positive *Firmicutes*. It binds along with its coregulator (HPr~P) to weakly conserved catabolite-responsive elements (CRE sites; TGTAAA/TTTACA) in the genome (82). While HPr can accept a phosphate from EI at His15 during PTS phosphotransfer (see above), it can also be phosphorylated at Ser46 by the serine kinase HprK (SACOL0825) (83). HprK becomes active once it senses the build-up of the glycolytic intermediate fructose bisphosphate, signifying the presence of a compatible carbohydrate (84). HprK-mediated Ser46 phosphorylation of HPr allows this coregulator to associate with CcpA, rendering it capable of high-affinity CRE binding. Activation of CcpA alters the expression of many genes in *S. aureus*. It leads to the activation of glycolytic genes as well as the repression of TCA cycle genes, genes encoding amino acid catabolism, and in some cases, biosynthetic pathways (16, 85). Another complicating feature is that the conserved serine/threonine kinase 1 (Stk1, SACOL1232) can phosphorylate CcpA at residues Thr18 and Thr33 within the DNA-binding domain, rendering CcpA inactive (86). This mode of regulation is not evident in *Bacillus* spp. and thus may be unique to staphylococci. CcpA is known to be responsible for the glucose stimulation of biofilm formation and expression of the regulatory RNA III as well as toxic-shock syndrome toxin 1 (82, 87, 88). However, caution should be used when interpreting gene expression associated with CcpA, specifically glucose-dependent gene regulation that is absent in a Δ*ccp*A mutant. This pattern of regulation was observed for the *S. aureus*-specific *ldh*1 gene, yet it was shown to be indirectly regulated by CcpA (89). Rather, Δ*ccp*A mutants do not efficiently catabolize glucose in the medium; instead, these mutants preferentially break down amino acids and other TCA cycle/gluconeogenic substrates. It appears that the utilization of glucose, not merely its presence, stimulated *ldh*1 transcription by an unknown mechanism despite the presence of a putative CRE site upstream of the *ldh*1 promoter (89). Whether a similar mechanism mediates glucose-dependent toxic-shock syndrome toxin 1, RNA III, or biofilm production has yet to be determined. Indeed, glucose can stimulate Agr activity, leading to increased virulence factor production so long as the medium is buffered (82). Otherwise, glucose in the medium leads to acetate production and concomitant acidification that seems to repress Agr activity (90). Given the buffering capacity of human blood, but the acidity of human sweat, it is hard to say whether glucose stimulates Agr activity in the host. However, recent work has demonstrated that hyperglycemia in nonobese diabetic mice can affect pathogenicity and virulence factor production in a CcpA-dependent fashion (91).

CcpE and RpiRc

Fructose bisphosphate is not the only metabolite signal that can alter virulence factor production in *S. aureus*. CcpE is a citrate-sensing LysR-type CcpA-homologue that directly binds to and activates the aconitase (*citB*, SACOL1385) promoter (92, 93). Two conserved arginine residues (Arg145

and Arg256) assist in coordinating the citrate molecule. In addition to *citB*, CcpE directly influences the expression of genes involved in iron acquisition, toxin production, pigmentation, and capsule biosynthesis (94). Additionally, several secreted and surface exposed virulence determinants were reduced in the Δ*ccpE* mutant (95). Still, mutants lacking CcpE appear to be more virulent in several murine infection models and survive better in whole human blood. Metabolomic profiling of the Δ*ccpE* mutant shows that carbon becomes rerouted away from the TCA cycle, resulting in a buildup of citrate, lactate, acetate, and alanine (93). Beyond CcpE-mediated citrate sensing, *S. aureus* encodes three homologues of ribose-responsive regulators: RpiRa, RpiRb, and RpiRc (96). Recently, RpiRc has been implicated in dampening expression of RNA III, which has impacts on virulence factor production (97). As such, Δ*rpiRc* mutants exhibit enhanced exotoxin production and are hypervirulent in murine sepsis and skin infection models (97, 98). Additionally, loss of RpiRc limits expression of TCA cycle genes and induces central glycolytic and amino acid metabolic pathways. Taken together, *S. aureus* has integrated virulence factor regulation with the sensing of key metabolic intermediates, specifically, fructose bisphosphate, citrate, and potentially, ribose.

CodY

This repressor senses both branched-chain amino acids (BCAAs) and cytosolic GTP to control many genes involved in amino acid biosynthesis and import as well as virulence factor production (99). Abundant BCAAs bind to CodY and afford it the ability to recognize its cognate DNA sequence (AATTTTCWGAAAATT) (100). GTP also binds CodY and, in combination with BCAAs, improves the DNA-binding capacity of this repressor. BCAAs (Iso, Leu, and Val) are often the most common codons in many genomes, including that of *S. aureus*. Thus, as amino acids become depleted, these BCAAs may become scarce relatively quickly. As BCAAs become depleted, CodY loses affinity for DNA. Furthermore, as general amino acid depletion ensues, the stringent response is activated and a bulk conversion of GTP to the alarmone ppGpp(p) occurs (99). This reduction in the cytosolic GTP pool further reduces the binding capacity of CodY, resulting in derepression of global amino acid synthesis/acquisition. Additionally, CodY negatively affects the expression of extracellular proteases and many secreted virulence factors. In fact, CodY seems to negatively impact Agr signaling, though likely in an indirect fashion (101), and this could be responsible for downregulation of virulence factor production by CodY. It was suggested that in Δ*codY* mutants that constitutively express amino acid synthesis/import functions, intracellular amino acid pools would be high, maximizing the amount of secreted Agr autoinducer. The effects are reduced biofilm formation and hypervirulence in murine skin models for Δ*codY* mutants (102). However, while the impact of CodY on biofilm production has been well described (103), in a murine sepsis model of infection, the Δ*codY* mutant was recently shown to be attenuated (104). Thus, loss of CodY hinders the pathogen's ability to balance virulence factor and extracellular protease production, leading to a variety of outcomes in different infection settings.

Rex

This redox-sensing regulator is also highly conserved among *Firmicutes* and generally represses genes encoding fermentation enzymes that harbor well-conserved Rex sites ($TGTGAN_6TCACA$) near their promoters. Specifically, three lactate dehydrogenases, a lactate permease, two alcohol dehydrogenases, an alanine dehydrogenase, and pyruvate-formate lyase are all directly repressed by Rex (Table 1) (105). However, as redox imbalance ensues, the ratio of

TABLE 1 Dehydrogenases of *S. aureus*

Gene name[b]	Locus name	Putative function	Rex-Reg[a]
*ald*1	SACOL1478	Alanine dehydrogenase	Yes

[a]Rex-Reg: Indicates Rex binding to confirmed Rex sites directly demonstrated from reference 103.
[b]–, Dashes indicate genes that have not had a gene name assigned.

NAD^+:NADH diminishes. While Rex binds both NAD^+ and NADH, it binds the latter with higher affinity (K_M < 100 nM) (105). Furthermore, while NAD^+-bound Rex can effectively bind DNA and repress gene expression, NADH-bound Rex cannot. So as NADH accumulates, Rex loses affinity for DNA, and expression of dehydrogenases specifically designed to restore NAD^+:NADH ratios become highly expressed. In addition, Rex also represses transcriptional regulators, including *srrAB* and *nirR*, thereby indirectly affecting the expression of genes involved in aerobic and anaerobic respiration (105). However, Rex does not appear to directly affect virulence factor expression, and consequently, the effect of Rex on virulence remains unclear.

SrrAB

This two-component system is thought to sense the redox status of the menaquinone pool analogous to the ArcAB system in *E. coli* (106). While this has not been directly demonstrated, many indirect observations support this hypothesis. For instance, genes known to be directly regulated by SrrA can be induced in a Δ*hemB* mutant but not in a Δ*menD* mutant (107). Loss of HemB results in cells that cannot synthesize heme and therefore are unable to respire, since no terminal oxidases function without heme. Consequently, the menaquinone pool becomes completely reduced, presumably activating SrrB. In contrast, a Δ*menD* mutant, while also being devoid of respiration, has no menaquinone, and therefore, SrrB is not stimulated. Similarly, SrrAB affects biofilm formation because it affects the expression of the murein hydrolase Atl as well as *cidABC* and the *ica*-dependent extracellular polysaccharide (108–110). As such, a Δ*hemB* mutant exhibits SrrAB-dependent hyperbiofilm formation, while a menaquinone mutant does not (110). By sensing a reduced menaquinone pool, SrrB can detect drops in respiratory flux. In response, the SrrAB regulon stimulates the production of respiratory cytochromes to increase respiratory capacity (111). It also stimulates pyruvate-formate lyase and alcohol dehydrogenase analogously to Rex. If the drop in respiratory flux is due to the lack of oxygen, SrrA induces the expression of the anaerobic ribonucleotide reductase (NrdDG, SACOL2635-34) (112). If respiration is being inhibited by host immune radicals, SrrA stimulates NO·-detoxifying *hmp* as well as *scdA*, which is involved in Fe-S repair (111, 113). In general, SrrAB senses respiratory flux and responds to a drop in respiration, whether the drop stems from hypoxia or respiration inhibition by host immunity. However, this two-component system also affects virulence factor production (113). Hypoxia was shown to induce the Agr system in an SrrAB-dependent fashion (110). SrrAB has also been implicated in driving toxic-shock syndrome toxin 1 and Spa expression. SrrAB mutants are sensitive to NO· and H_2O_2 as well as to neutrophil killing, and they are attenuated in murine sepsis and osteomyelitis models of infection (112, 114–116). Whether the attenuation stems from the inability to restore respiratory capacity during infection or from the inability to fully express key virulence factors remains unknown.

Staphylococcal Biofilms

MICHAEL OTTO

43

Over the last decades, biofilms have gained more and more recognition as the common mode of growth that microorganisms adapt in nature (1). Furthermore, many types of human infection have been found to progress with the involvement of biofilms or originate from biofilm-associated primary infections (2). Second only to the Gram-negative *Pseudomonas aeruginosa*, staphylococci have been the focus of biofilm researchers. As common colonizers of the human skin, staphylococci are the most frequent sources of biofilm infections on surgically implanted indwelling medical devices. These include serious infections, including endocarditis and prosthetic joint infections (PJIs), and may lead to life-threatening conditions, such as sepsis (3–5).

For the longest time, biofilm research even in pathogenic bacteria has been characterized predominantly by *in vitro* investigation, from which—despite the obvious limitations—researchers attempted to extrapolate to biofilm-associated infection. More recently, biofilm research has begun to integrate *in vivo* infection models to obtain a better understanding of the mechanisms governing biofilm-associated infection. Infection models for *P. aeruginosa*, the biofilm-forming pathogen most intensely studied with *in vitro* research, are extremely challenging to establish and perform (6). Thus, due to the possibility of performing biofilm-associated infection models that reflect human biofilm infection, staphylococcal biofilm research has gained considerably in relative importance. As an important further prerequisite to perform mechanistic biofilm research, methods to genetically manipulate staphylococci are continuously being improved.

This article will discuss the role of staphylococcal biofilms in the commensal state and during infection, our current knowledge of the molecular basis of staphylococcal biofilm formation and its regulation, and the role of biofilm formation *in vivo* as an important means of immune evasion. Finally, potential strategies to develop therapeutics to treat biofilm-associated infections by staphylococci will be presented. There will be a focus on *Staphylococcus aureus* and *Staphylococcus epidermidis*, because we know the most about biofilms in these two species.

STAPHYLOCOCCAL BIOFILMS IN THEIR NATURAL HABITAT AND DURING INFECTION

Many definitions have been used for biofilms. Most define a biofilm as a microbial community of cells that is embedded in a matrix of extracellular polymeric substances that they have produced. Some researchers restrict the term "biofilm" to aggregates attached to a surface, which can be biotic or abiotic. For others, free-floating bacterial aggregates also represent biofilms. Cells in a biofilm characteristically show a phenotype, with respect to metabolism, gene transcription, and protein production, that is different from that during planktonic growth. This has been shown for both *S. aureus* and *S. epidermidis* (7, 8).

Microbial aggregates on infected catheters or other indwelling medical devices obtained from patients resemble biofilms grown in *in vitro* microtiter plates or biofilm reactors, and there is no doubt that these fit the definition of a biofilm (9). Macro- or microscopic evaluation from wound infections also indicates that those infections, which often contain staphylococci among other pathogenic microbes, can be described as biofilm associated (10). The situation becomes less clear when looking at the commensal colonization of the skin, nares, or intestines or at disease-associated colonization, such as during atopic dermatitis. Some researchers would argue that the physiological situation of bacterial aggregates in those habitats may resemble that commonly found in biofilms, while others have raised doubt (11–13). Currently preventing a more detailed analysis of those potential "colonizing" biofilms is the lack of animal models that closely resemble human colonization. Therefore, in the following, only biofilms on devices and wound infections will be discussed.

Medical devices particularly prone to infection include contact lenses, peritoneal dialysis catheters, urinary and central venous catheters (CVCs), endotracheal tubes, mechanical heart valves, pacemakers, and prosthetic joints (9). Staphylococci generally are the most frequent causes of infections on indwelling medical devices, with *S. aureus* and *S. epidermidis* representing the leading species (14). This is mostly due to their predominance in causing intravascular and prosthetic device-associated infections. However, on some devices, such as urinary catheters, other bacteria may dominate (15). Most commonly, indwelling medical devices are contaminated with the biofilm-forming bacteria during surgery. The source can be the skin or other colonized body sites of the patient or the health care personnel (9). In that regard, it is important that only ~20% of individuals are colonized by *S. aureus*—in contrast to many coagulase-negative staphylococci, including *S. epidermidis*, which are ubiquitous skin colonizers in humans (16, 17). Thus, the *S. aureus* carrier state of the patient is a risk factor for device

doi:10.1128/microbiolspec.GPP3-0023-2018

infection, as it is for other types of *S. aureus* infection (18). Alternatively, already implanted devices can be infected via hematogenous seeding, although this is considered to be less frequent (19). Not surprisingly, immune- or otherwise compromised patients, such as AIDS patients, patients receiving immunosuppressive therapy, or premature newborns, are at increased risk of developing biofilm-associated infections on indwelling devices (9). These populations are also at increased risk regarding serious complications that may arise from infected devices. The most notable among those is blood infection (bacteremia), which may result in life-threatening sepsis. Central line (CVC)-associated bloodstream infections are among the most frequent and serious complications of medical device infection and cause thousands of deaths annually. In a 2004 study including 24,179 cases of health care-associated bloodstream infections (most of which stem from contaminated devices) in 49 U.S. hospitals over a 7-year period from March 1995 through September 2002, coagulase-negative staphylococci were responsible for 31% and *S. aureus* for 20% of cases, far ahead any other microorganism (20).

Chronic wounds, such as chronic skin ulcers in diabetes patients and acute burn wounds, are highly susceptible for infection by many pathogenic microorganisms. According to clinical observation, the infecting organisms, which usually include more than one type, present as a biofilm (21). The species most often found in wound infections is *S. aureus* (22, 23). From a microbiological point of view, the multispecies biofilms in wounds are much more difficult to understand than infections of indwelling medical devices, which usually present as a monospecies infections. Several studies claim that bacterial interactions exist in wounds between *S. aureus* and, for example, *P. aeruginosa*, but there is no commonly accepted view of their exact nature and role (24).

THE MOLECULAR BASIS OF BIOFILM FORMATION IN STAPHYLOCOCCI

Attachment Phase

Biofilm development has been extensively studied *in vitro* using many different setups and microorganisms. Commonly, it is described as a process of three main stages: attachment, proliferation/maturation, and detachment (dispersal) (25) (Fig. 1).

Attachment to a surface is considered the first stage of biofilm development, although in "free-floating" biofilms, this stage is not relevant. In contrast to motile organisms, which may reach a surface in an active fashion, staphylococci gain contact with a surface passively. Staphylococci may directly attach to the abiotic surface of indwelling medical devices or other abiotic surfaces in the environment (26). The hydrophobic character is the main factor enabling attachment to the usually hydrophobic material surface. However, specific staphylococcal molecules also have been implicated in surface attachment. These include the *S. epidermidis* major autolysin AtlE and its *S. aureus* homologue Atl (27, 28) and wall teichoic acids (WTAs) in *S. aureus* (29). These two may be linked mechanistically, because WTAs impact binding of Atl to the cell surface, controlling cell separation (30). Of note, primary attachment is often measured merely as a short-term variation of the frequently used simple microtiter-based biofilm assay. Whether results represent true primary attachment or initial phases of proliferation cannot be determined clearly using that assay.

In vivo, direct interaction of staphylococcal cells with the abiotic surface is not considered relevant, because indwelling devices rapidly become covered by host matrix material, including fibronectin, fibrinogen, vitronectin, and other matrix molecules (26). Under those conditions, attachment to the device is facilitated by a series of specific staphylococcal surface proteins that interact with those human matrix proteins. The most important family of such surface-expressed staphylococcal binding proteins is the MSCRAMMs (microbial surface components recognizing adhesive matrix molecules). MSCRAMMs consist, from the N- to C-terminus, of a signal peptide, a ligand binding domain with characteristic repeat sequences, a cell wall-anchoring region, a membrane-spanning region, and a positively charged tail (31). At the C-terminus, the MSCRAMM contains a conserved LPXTG motif, which is covalently linked by the enzyme sortase to peptidoglycan (32). According to genome analysis, *S. aureus* has about 20 and *S. epidermidis* about 12 MSCRAMMs (33). Prominent members are the fibrinogen- and fibronectin proteins, which include clumping factors A and B (ClfA, ClfB), the serine/aspartate-rich (Sdr) protein family, and fibronectin-binding proteins A and B (FnBPA, FnBPB) (31). Non-covalently bound surface proteins may also mediate attachment. Among them are predominantly enzymes that have a primary catalytic role, such as the Atl-type autolysins. Furthermore, there is a loosely defined group of non-covalently surface-attached proteins collectively called SERAMs (secretable expanded repertoire adhesive molecules), which bind to the surface by not yet characterized mechanisms and usually show broad specificity in human matrix protein binding (34). The extracellular adherence protein Eap (also called MHC class II analogous protein [Map]) and the extracellular matrix and plasma binding protein Emp of *S. aureus* belong to this group. Finally, the giant 1.1-MDa Embp protein of *S. epidermidis* and its *S. aureus* homologue Ebh (extracellular matrix binding protein homologues) are non-covalently surface-bound fibronectin-binding proteins (35, 36).

Proliferation and Matrix Formation

During the second stage of biofilm development, the microcolonies that have formed after attachment grow by proliferation. Additionally, cells secrete polymeric molecules to form the biofilm matrix. Among all aspects of biofilm development, the polymeric molecules that form the biofilm matrix have received the most attention. Biofilm matrix polymers have a divergent chemical nature and include polysaccharides, proteins, and teichoic acids. In addition to those actively secreted molecules, polymeric substances from dead cells are also believed to contribute to the biofilm matrix. The most notable among those is DNA, which after release from dying cells is known as extracellular DNA (eDNA).

In many biofilm-forming bacteria, exopolysaccharides represent the matrix components that are most specifically implicated with biofilm formation. Staphylococci produce one main biofilm exopolysaccharide, which is called polysaccharide intercellular adhesin (PIA), or according to its chemical composition, poly-*N*-acetylglucosamine (37) (Fig. 2). In contrast to chitin, another important *N*-acetylglucosamine homopolymer found in nature, the *N*-acetylglucosaminyl moieties in PIA are β-1-6 linked. One characteristic feature that distinguishes PIA from most other staphylococcal surface molecules, and also from many other bacterial biofilm exopolysaccharides, is its cationic character, which is due to the enzyme-catalyzed removal of ~15 to 20% of *N*-acetyl groups after secretion. This feature may be important for electrostatic interaction with other surface polymers, and thus the

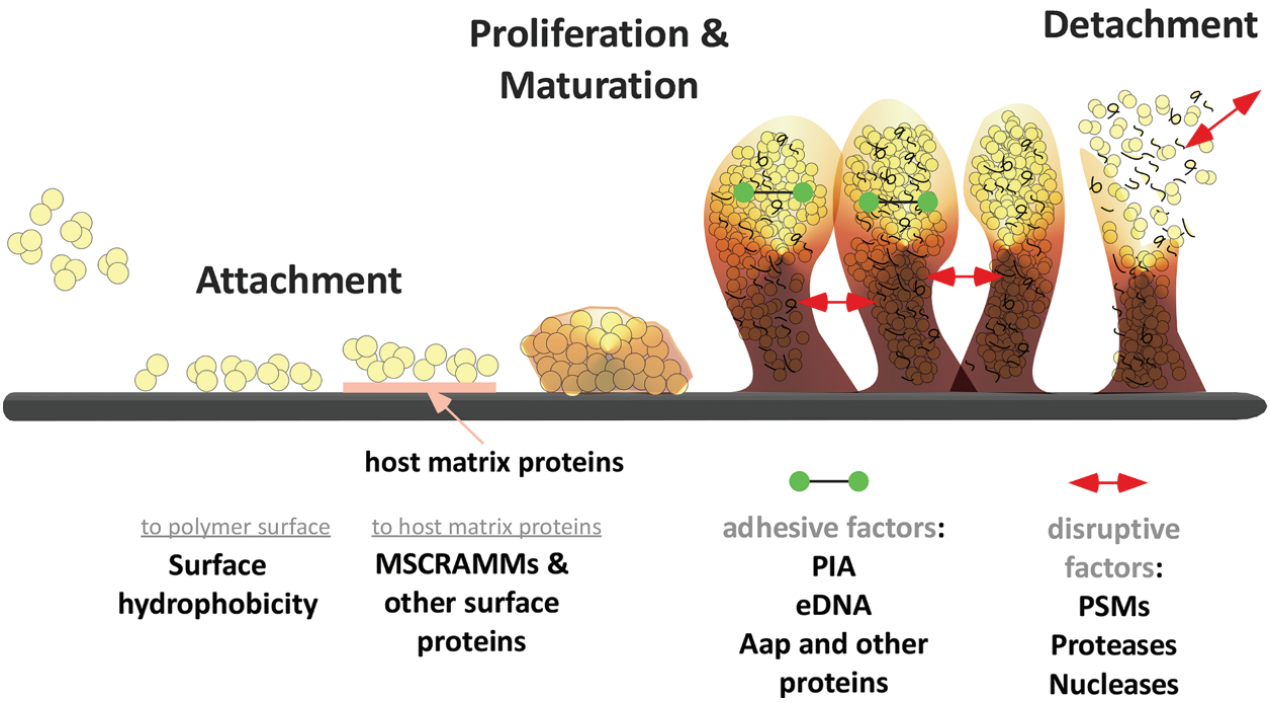

FIGURE 1 Staphylococcal biofilm development. Attachment of cells to a surface (in the case of surface-attached biofilms) occurs via hydrophobic interactions to an abiotic surface or via surface proteins that bind in a specific fashion to host matrix proteins covering an indwelling medical device. Growth of the biofilm in the proliferation/maturation stage is accompanied by the production of cell-cell adhesive matrix components (such as PIA, eDNA, and proteins), as well as disruptive factors (such as PSMs and degradative secreted enzymes). Those disruptive factors can also cause detachment, a process of great importance for the initiation of complications of biofilm-associated infection, such as bacteremia.

formation of the sticky extracellular biofilm matrix (37, 38). There appears to be no specific "anchor" for PIA on the cell surface, and it has been shown directly that this function is not accomplished by wall teichoic acids (39).

PIA biosynthesis is accomplished by the products of the *ica* (intercellular adhesion) gene locus, which comprises the *icaA*, *icaD*, *icaB*, and *icaC* genes (40). IcaA is the *N*-acteylglucosamine transferase, which together with IcaD has been shown to produce an *N*-acetylglucosamine oligomer (41). Chain growth is dependent on the presence of IcaC, a membrane protein assumed to be the PIA exporter. IcaB, which is located on the bacterial surface, is the PIA deacetylase (38). Deacetylation is crucial for the retention of PIA on the surface and the various functions PIA fulfills in staphylococcal physiology, which in addition to biofilm formation comprise increased resistance to antimicrobial peptides (AMPs) and neutrophil phagocytosis (38). Upstream of the *ica* operon is the *icaR* gene, which is transcribed in the opposite direction of the *icaADBC* operon. IcaR works as a repressor of the *ica* operon (42).

Several studies have shown that biofilm formation *in vitro* or *in vivo* can be accomplished by *S. epidermidis* or *S. aureus* isolates that do not harbor the *ica* locus (43–45), although the extension, structuring, and robustness of PIA-negative biofilms appears to be lower than those formed by PIA, at least in *S. epidermidis* (46, 47). In *S. aureus* isolates, biofilm formation appears to be predominantly protein-dependent (48). Earlier studies reported differences between methicillin-resistant and -sensitive isolates in that regard, while a more recent study indicates that both methicillin-resistant and -sensitive *S. aureus* isolates form almost exclusively protein-dependent biofilms (48, 49). In contrast, *S. epidermidis* more frequently relies on PIA to form biofilms, with an additional protein-mediated contribution (45). Replacing PIA in *ica*-negative isolates, or adding to its function in *ica*-positive isolates, are a series of macromolecules that include polymeric proteins and nonprotein polymers. Among the many surface-located proteins implicated in staphylococcal biofilm formation, the *S. epidermidis* accumulation-associated protein (Aap) and its *S. aureus* homologue, SasG (50), stand out due to their capacity to self-polymerize and form fibrils that interconnect cells (51–53) (Fig. 2). Aap is a 220-kD protein that is cleaved by the SepA protease to an active, mature form (54–56). At the N-terminus, the A domain of Aap contains repeats that may initiate biofilm formation in some strains and also bind to human corneocytes (57). It is followed by a lectin domain. These two domains are not present in mature Aap, which contains a large stretch of B repeats in front of a C-terminal proline/glycine-rich region and the cell wall-anchoring domain. The B repeats are responsible for self- and intercellular adhesion in a Zn^{2+}-dependent manner, assisted by cooperative folding (52, 58–60). Recently, the proline/glycine-rich region was shown to form an extended stalk that pushes the B repeat binding domain away from the cell surface, likely to enable better interaction with Aap from other cells, promoting biofilm formation (61). Notably, it has been shown that the homologous proteins SasG and Aap can interact, enabling interspecies biofilm connections (62). Several other surface proteins have also been implicated in intercellular adhesion, but in many of those cases it is difficult to distinguish between a surface/tissue attachment and genuine intercellular adhesion function. These proteins contain many surface binding proteins of the MSCRAMM family in addition to the biofilm-associated protein (Bap),

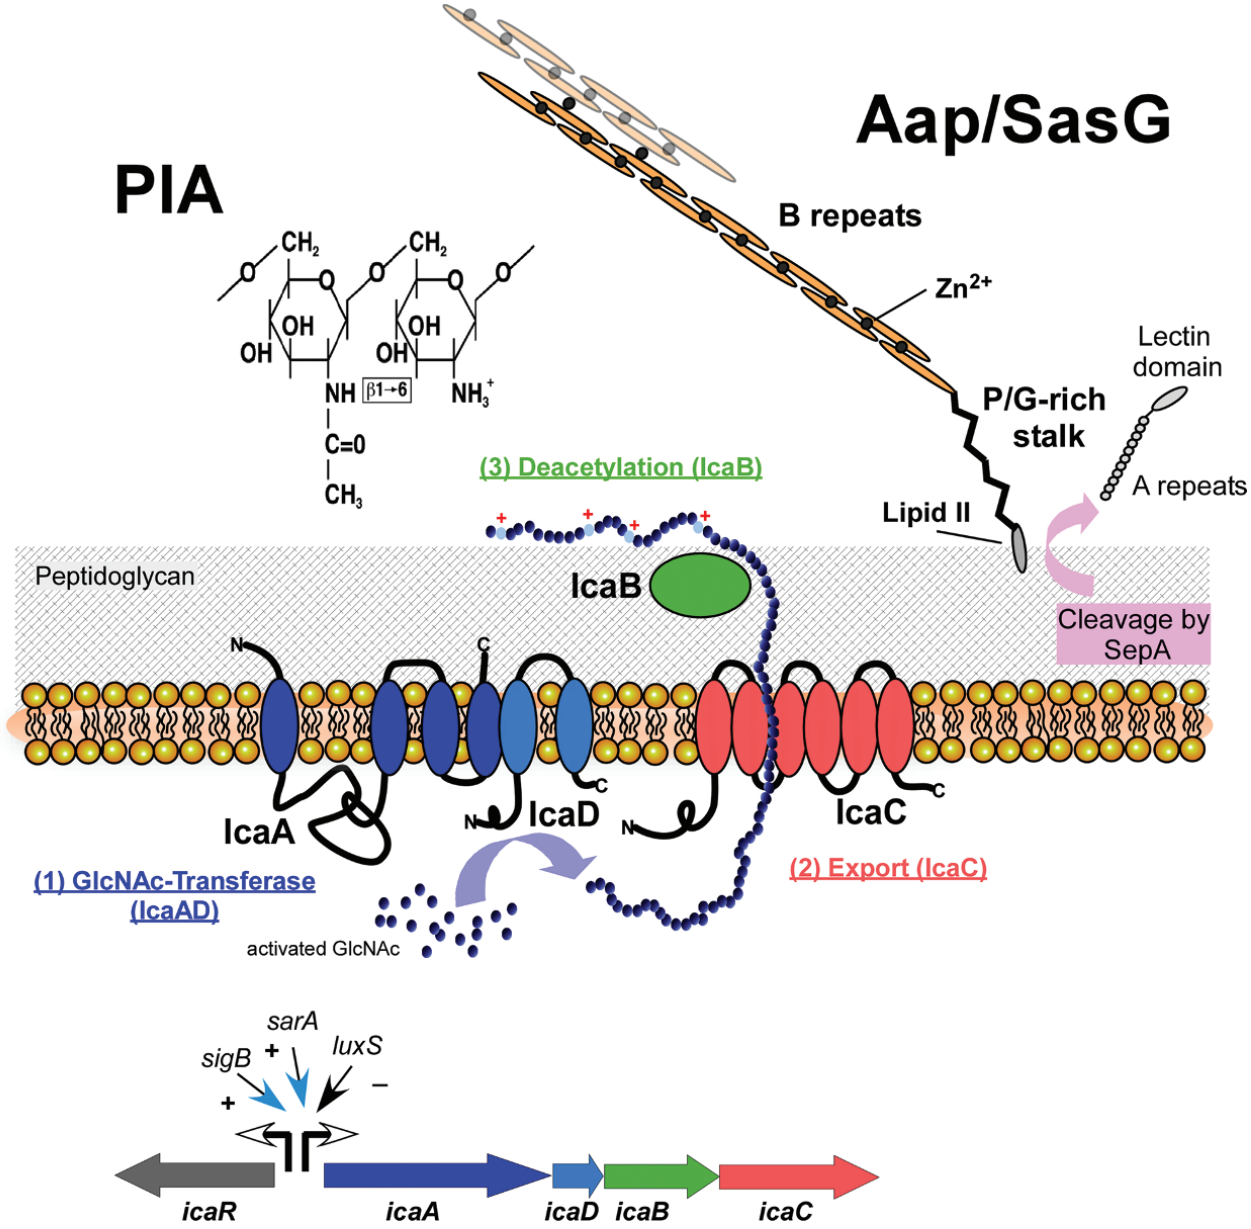

FIGURE 2 Predominant staphylococcal biofilm matrix components. The exopolysaccharide PIA (left), produced by many *S. aureus* and *S. epidermidis* isolates, is a β1-6-linked homopolymer of *N*-acetylglucosamine. It is synthesized in the cell by the combined activity of the membrane enzymes IcaA and IcaD and likely exported by IcaC. The extracellular surface-bound enzyme IcaB removes a certain percentage (~15 to 20%) of *N*-acetyl moieties, which gives the otherwise neutral PIA molecule a positive net charge, anchoring PIA to the negatively charged cell surface. In addition to the *ica* biosynthetic genes *icaADBC*, the PIA biosynthesis locus also contains a regulatory gene, *icaR*. Several global regulators impact transcription from the *icaR* and *icaADBC* promoters. The accumulation-associated protein (Aap), which is present in *S. epidermidis* and has a homologue in *S. aureus* called SasG, is produced as a 220-kD precursor protein, from which the secreted protease SepA cleaves off the N-terminal A-repeat and lectin domains. It is anchored to the cell wall via sortase-catalyzed covalent linkage to lipid II. Mature Aap forms extended fibrils out of B repeat domains, whose polymerization is dependent on Zn^{2+} ions. Zn^{2+} is also required for the interconnection of Aap/SasG proteins from different cells, which can happen in an interspecies manner.

found in *S. aureus* mastitis isolates, of which a homologue (Bhp) is present in *S. epidermidis* (63, 64). In support of a specific involvement in matrix formation, Bap has recently been reported to assemble into amyloid-like matrices to promote biofilm assembly (65), reminiscent of the function of Aap.

Nonprotein extracellular polymers implicated in biofilm formation include teichoic acids and eDNA. Teichoic acids occur in two forms: WTA, which is covalently linked to the cell wall, and lipoteichoic acid, which is surface-anchored via a lipid moiety that intercalates in the cytoplasmic membrane lipid bilayer (66). A specific contribution of the teichoic acid surface polymers to the biofilm matrix is likely but has only been shown for WTA of *S. epidermidis* (67). Teichoic acids devoid of D-alanylation, which alters their net charge, show diminished biofilm formation in *S. aureus* (29). Teichoic

acids are also implicated in receptor-mediated adhesion to the nasal epithelium (68). Finally, eDNA contributes to biofilm formation *in vitro* (69). Likely due to the highly polymeric and anionic character of DNA, it is extremely "sticky" and thus, eDNA is prone to interact with many other surface molecules, contributing to the formation of the extracellular biofilm matrix network.

Structuring and Detachment

Biofilms do not grow as undifferentiated "bricks" but have a characteristic three-dimensional structure, which contains towers, often described as "mushroom"-like, as well as fluid-filled channels between those towers (25). The second (maturation) stage of biofilm development comprises disruptive forces to create those structures in addition to the adhesive mechanisms described above. These are mediated by enzymes that degrade biofilm polymers, such as nucleases and proteases, and surfactant-like molecules, such as the staphylococcal phenol-soluble modulins (PSMs), which disrupt noncovalent interactions (70, 71). The same forces can also ultimately cause biofilm detachment, which facilitates systemic dissemination and subsequent complications during device-associated infection. Both biofilm structuring and detachment/dispersal effects have been described for the PSMs, while research on degradative enzymes has been mostly limited to detachment/dispersal.

PSMs are a family of alpha-helical peptides with pronounced amphipathy, thus exhibiting characteristics that give them surfactant-like properties (72). Members of the PSM family are produced in *S. aureus*, *S. epidermidis*, and most likely virtually all staphylococci (72, 73). PSMs can be grouped in α-type peptides (~20 to 25 amino acids in length), which in *S. aureus* comprise the PSMα and δ-toxin peptides, and the longer β-type PSMs (~44 to 45 amino acids) (72). Confocal laser scanning microscopy, a method often used to visualize biofilm structure, revealed that the characteristic channel-containing biofilm structure is not present in *psm* deletion mutants, which grow in an undifferentiated and extended fashion (47, 74). In contrast to biofilm polymer-degrading enzymes, PSMs structure PIA-dependent and -independent biofilms (47). PSMs work on growing biofilms; when biofilms are formed, external addition of PSMs has only limited biofilm-dispersing activity. Somewhat contrastingly, PSMs have also been described to form amyloid structures that prevent the enzymatic degradation of preformed biofilms (75). A double mutant in the *psm*α and *psm*β loci was impaired in preventing degradation, while the δ-toxin was not specifically addressed in that study. While there appears to be agreement about the *in vitro* capacity of PSMs to form amyloid-like structures, the role of PSM amyloids in biofilms remains controversial (76).

Among biofilm-degrading enzymes, proteases are the most important (71), while enzymes degrading PIA are not produced by staphylococci. *S. aureus* and *S. epidermidis* produce a series of exoproteases. *S. aureus* secretes ten proteases, including seven serine proteases (SspA and SplA-F), two cysteine proteases (SspB and ScpA), and one metalloprotease (Aur) (77). *S. epidermidis* produces at least three major proteases: a homologue of the staphopain cysteine protease SspB, a metalloprotease called SepA, and a homologue of the *S. aureus* SspA (V8) serine protease (16). Mutations in specific *S. aureus* protease genes, or addition of protease inhibitors, impair biofilm formation or lead to biofilm degradation, respectively, in biofilms that are protein dependent (48, 78). While specific matrix protein targets of several of the *S. aureus* proteases have been identified (79, 80), they overall show relatively low target sequence specificity (81). The *S. epidermidis* protease SspA (Esp) has been shown to be able to degrade protein-dependent *S. aureus* biofilms (82). Because biofilm formation in *S. epidermidis* is often strongly PIA-dependent, research on the role of *S. epidermidis* proteases in biofilm development has been limited.

The biofilm matrix component eDNA is subject to degradation by nucleases, which originally has been shown using human DNase I (69), which is abundant in human serum. Both *S. aureus* and *S. epidermidis* secrete nuclease activity. *S. aureus* is known to produce two secreted nucleases, Nuc1 and Nuc2 (83). Expression of Nuc1 reduces biofilms, and a *nuc1* mutation in strain USA300 shows increased *in vitro* biofilm formation (84), as would be expected from abolished eDNA degradation. However, isogenic *nuc1* or *nuc2*, or combined *nuc12* mutants in a different strain (UAMS-1), did not exhibit enhanced *in vitro* or, notably, *in vivo* biofilm formation (85).

REGULATION OF STAPHYLOCOCCAL BIOFILM FORMATION

Biofilms have been recognized as a common form of microbial growth. It is thus not surprising that many regulators that adapt staphylococcal gene expression to changing environmental conditions have an impact on biofilm formation. This section will focus on regulatory effects on the main biofilm-forming factors and on the biofilm effects of the major global regulators, the quorum-sensing system Agr, the Sar family of regulators, and the alternative sigma factor, SigB.

In 1998, Davies et al. reported that a quorum-sensing regulator in *P. aeruginosa* positively impacted biofilm formation (86), a result soon generalized regarding the relationship of quorum-sensing control and biofilm formation in bacteria. Soon after, Vuong et al. reported increased biofilm formation in isogenic mutants of the Agr quorum-sensing system in *S. aureus* (87), in clear contrast to the generalized *P. aeruginosa* finding. Since then, mechanistic investigation has shed more light on the impact quorum-sensing systems have on biofilm formation in several bacteria. As a common theme, quorum-sensing systems appear to frequently control biofilm structuring processes, which may result in more or less extended biofilms, depending on the specific conditions (70). Agr in staphylococci controls the two main biofilm structuring and dispersal factors described above, PSMs and proteases, with the control of *psm* genes being exceptionally direct and tight (8, 88, 89). As a result, biofilms of *agr* mutants grow in an unstructured and extended fashion, as shown for both *S. aureus* and *S. epidermidis* (74, 90), and applying the extracellular autoinducing peptide signal of the Agr quorum-sensing system results in biofilm dispersal (78). However, it remains poorly understood which mechanisms lead to the spatial and temporal heterogeneity of Agr expression that is observed in biofilms (74) and which are a theoretical prerequisite for the Agr-mediated biofilm structuring effect. Finally, the autoinducer-2 quorum-sensing system, which remains less well investigated in staphylococci, represses biofilm formation in an *ica*-dependent manner (91, 92). Both quorum-sensing systems thus affect biofilm formation negatively but using different mechanisms.

The prototype of the Sar paralogue family of regulators, SarA, impacts biofilm formation via regulation of Agr, as well as in an Agr-independent manner (93–96). The strong regulatory impact of SarA on protease production appears to play a preeminent role in this effect (97), and this, historically, was how the biofilm effect of *S. aureus* proteases was discovered. Furthermore, SarA positively controls *ica*

transcription in both *S. aureus* and *S. epidermidis* (94, 96), while its paralogue SarZ appears to have opposite effects in the two species—positive in *S. epidermidis* and negative in *S. aureus* (98, 99). Generally, which environmental signals stimulate Sar expression is not known, and therefore the biological context of biofilm regulation by Sar paralogues remains poorly defined.

Sigma factors are transcription initiation factors that provide promoter recognition specificity to RNA polymerase (100). The "alternative" sigma factor SigB is expressed during the stationary growth phase and environmental stress and is involved in controlling manifold aspects of staphylococcal physiology and virulence. SigB regulation of biofilm formation in *S. epidermidis* biofilms was reported to occur by an impact on *ica* transcription via SigB dependence of the *icaR* promoter (101), and in *S. aureus* possibly via SarA-dependent protease regulation (102, 103). However, other studies found no impact of SigB on biofilm formation in *S. aureus* and *S. epidermidis* (96, 104).

IN VIVO ROLES OF STAPHYLOCOCCAL BIOFILM FACTORS

The recognition that microbes grow in biofilms in nature as well as during many types of infection revolutionized microbiology in the second half of the previous century. However, in comparison to the wealth of *in vitro* biofilm studies, biofilm microbiology has not yet widely included *in vivo* experimentation to understand mechanisms of biofilm-associated infection and determine whether general principles established *in vitro* have *in vivo* relevance. In part, this is due to the problem that animal models for biofilm-associated lung infection by most biofilm researchers' favorite model organism, *P. aeruginosa*, are extremely challenging. The situation is somewhat better for staphylococcal biofilm-associated infection, because catheter infections can quite easily be mimicked by placing a plastic device under the skin of test animals, such as mice or rabbits. Furthermore, more sophisticated models of biofilm-associated staphylococcal endocarditis are available.

Staphylococcal biofilm infection was originally associated mainly with *S. epidermidis*. Biochemical characterization of PIA and genetic approaches to find biofilm-related factors using transposon mutagenesis of *S. epidermidis* then resulted in the identification of the *ica* and *atlE* loci as important for matrix formation or initial adherence, respectively, during *in vitro* biofilm formation (28, 40). For that reason, these were the factors first assayed in animal models of biofilm-associated infection. An isogenic transposon mutant in the *ica* genes (*S. epidermidis* M10) was tested for the impact of PIA production on infection outcome in a mouse model of device-associated infection, using a subcutaneously implanted catheter, and a rat CVC-associated infection model (105, 106). In the mouse subcutaneous catheter model, the wild type produced significantly more biofilm on the catheter and a more pronounced abscess (105). In the rat model, more animals challenged with the wild-type strain developed CVC-associated infection than did those challenged with the *ica*-negative M10 strain (106). The impact of PIA and AtlE were also assayed in a different strain background in the rat CVC-associated model. Both PIA and AtlE had a significant impact on biofilm formation on the device as well as on associated bacteremia (107). Interestingly, later it was also shown that the deacetylation of PIA by IcaB is crucial for the development of biofilm-associated infection using a mouse subcutaneous catheter model (38). As for *S. aureus*, there is no direct evidence from animal infection models that would suggest a key role of PIA in biofilm-associated infection. Furthermore, one study showed that the *S. aureus* homologue of AtlE, the major autolysin Atl, does not impact biofilm-associated infection (108). These results reflect *in vitro* findings indicating that biofilm formation in *S. aureus* is mainly dependent on other factors.

Biofilm formation in *S. aureus* is believed to depend on surface proteins in a majority of strains. However, only for very few surface proteins has an impact on biofilm-associated infection been directly demonstrated using biofilm-associated infection models and deletion mutants. These include *S. aureus* Bap and protein A (Spa), for which a significant impact on pathogenesis in mouse catheter implant infection models was found (63, 109). For some other surface proteins, there is some circumstantial evidence for roles in *in vivo* biofilm formation that is derived from using antibodies. For example, human IgG recognizing ClfA was protective in a rabbit endocarditis model (110). As for *S. epidermidis*, the difficulty in producing isogenic deletion mutants has hampered research along those lines, but circumstantial evidence obtained by heterologous expression has been obtained, indicating a role of the surface protein SdrF, which is produced by a subset of *S. epidermidis* strains (111), in the initiation of experimental device driveline-related infection in mice (112). In general, the paucity of experimental *in vivo* evidence underlining the importance of surface proteins in biofilm-associated infection may be due to their pronounced functional redundancy. More recently, an *ex vivo* approach was taken to investigate biofilm formation during PJI. Dastgheyb et al. used synovial fluid obtained during surgery from uninfected human joints. Using the Nebraska transposon bank, which contains a copy of every nonessential gene in *S. aureus*, they identified ClfA, ClfB, FnBPA, and FnBPB, as well as characteristically low Agr activity and PSM concentration in synovial fluid as driving forces of the extensive formation of antibiotic-resistant biofilms seen in PJI (113–115).

In vivo information on biofilm structuring factors is available for the PSMβ peptides of *S. epidermidis*, which have been shown to drive dispersal and systemic dissemination from an implanted device in a mouse model (47). Mutants in the *psmα*, *psmβ*, or *hld* (encoding δ-toxin, now classified as a PSM) loci of *S. aureus* show the same effect, with that of a triple *psmαβhld* mutant being comparable to that of an *agr* mutant (74). However, at least in the case of α-type PSMs (PSMα peptides, δ-toxin), these outcomes may be influenced also by the cytolysis-mediated role of PSMs in immune evasion (116). Which role proteases play in biofilm-associated infection remains largely undefined. With proteases presumably having multiple roles in infection, their specific role in *in vivo* biofilms is difficult to define. In a recent study using the USA300 strain LAC, a deletion mutant in all ten protease genes did not reveal a significantly changed bacterial load on the device in experimental implanted device infection in mice (117). Similarly, *S. aureus nuc1* and *nuc2* mutants do not have a significant *in vivo* effect during biofilm-associated infection (85), casting doubt also on the role of eDNA in *in vivo* biofilms.

STAPHYLOCOCCAL BIOFILM FORMATION AS AN IMMUNE EVASION AND ANTIBIOTIC RESISTANCE MECHANISM

In vivo biofilm formation is subject to several factors that are specifically due to the *in vivo* environment, such as, most notably, interaction with innate host defenses, in addition to interaction with antibiotics during antibiotic therapy. Innate

host defenses consist primarily of phagocytes, such as neutrophils and macrophages, and AMPs, which are a part of the intracellular killing mechanisms phagocytes employ (118). AMPs are also produced in the skin, where they are secreted to control skin-colonizing or -infecting bacteria (119). Secreted AMPs may thus also form part of the host's defenses on subcutaneously placed catheters (Fig. 3).

Biofilm formation, *per se*, has long been known to provide resistance to attacks by phagocytes, which are impaired in penetrating through the biofilm matrix (120, 121). Similarly, the biofilm matrix may be impermeable to certain AMPs and antibiotics. On the other hand, some can readily penetrate, which is likely dependent on the AMP's or antibiotic's chemical features (122). It has been estimated that biofilms provide 10 to 1,000 times increased tolerance to antibiotic effects (123). One antibiotic that has been shown to be exceptionally active against biofilms and is often proposed to treat biofilm infections is rifampin (124). However, resistance to rifampin can develop quickly during treatment (125). Interestingly, recent *in vivo* research indicates that specific other antibiotics, such as ceftaroline, are more active against *S. aureus* biofilms than those commonly used in the clinical setting (126). Decreased antibiofilm efficacy of antibiotics whose penetration is not decreased is due to the specific physiology of cells in a biofilm. For example, the reduced proliferative and metabolic activity of biofilm cells makes them more tolerant to antibiotics that target those processes, such as cell wall-targeting antibiotics (e.g., beta-lactams) or antibiotics that target DNA or protein synthesis (127). Finally, biofilms have been shown to contain more so-called persisters, dormant cells which are indifferent to antibiotics, compared to the majority of the bacterial population, an effect that enables this subset of cells to withstand antibiotic concentrations far above the MIC (128).

In addition to those general effects, staphylococcal biofilms show specific alterations in physiology compared to planktonic cells, which dampen inflammation and the innate immune response. First, Agr as a regulator of many toxins, which have proinflammatory effects, shows limited expression in biofilms (74, 90). However, whether this effect has *in vivo* consequences remains to be shown directly. In support of that notion, many *S. aureus* and *S. epidermidis* isolates obtained from chronic and device-associated infections are functionally Agr-negative (90, 129). It appears as if phenotypically or genotypically Agr-negative isolates have selective advantages during chronic infection, of which the mechanistic underpinnings still need to be elucidated.

Second, *S. aureus* biofilms have been shown to reduce inflammatory effects, such as phagocyte influx. Specifically, *S. aureus* biofilms in murine biofilm-associated infection appear to skew the immune response away from a microbicidal phenotype by circumventing locus-specific pathogen recognition pathways (130)—a finding in line with reduced Agr activity. Furthermore, during experimental PJI, *S. aureus* biofilms stimulate the influx of myeloid-derived suppressor cells, resulting in reduced phagocyte influx (131), and human PJIs are associated with myeloid-derived suppressor cells (132). Finally, cyclic di-AMP, released by cell lysis, has been shown to stimulate a type I interferon-mediated anti-inflammatory effect in biofilms (133). However, it is not clear whether these immune evasion mechanisms are specific to a biofilm infection as opposed to other *S. aureus* infection

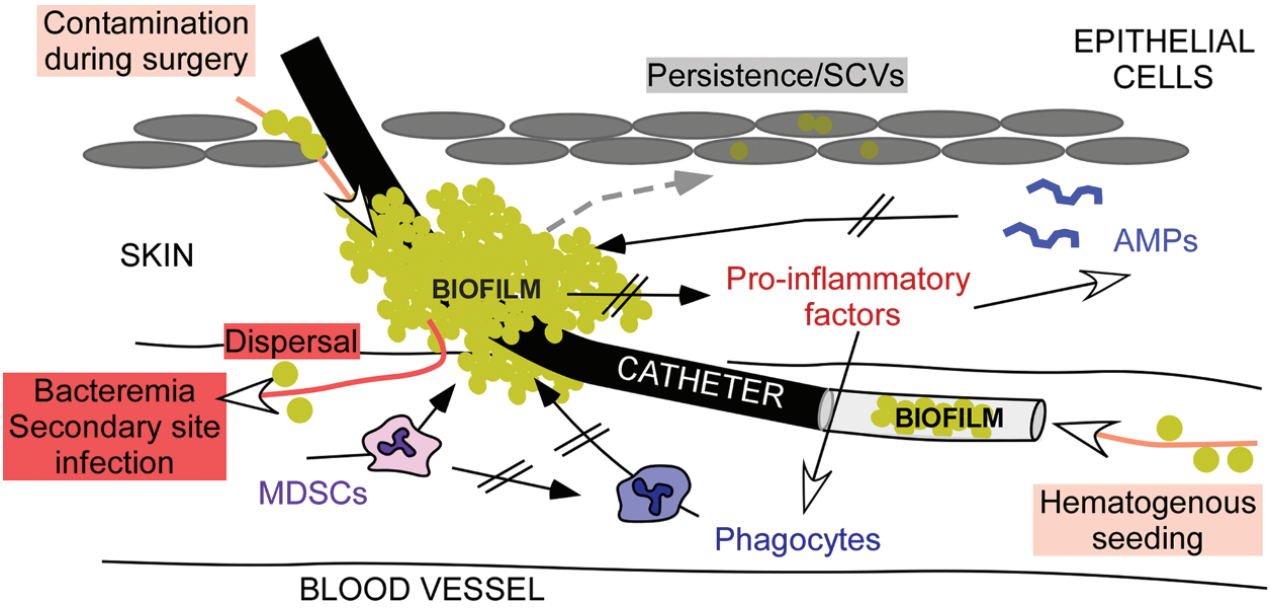

FIGURE 3 Staphylococcal biofilm-associated infection on medical devices. Mechanisms underlying staphylococcal device-associated infection are depicted in an exemplary fashion for an intravascular catheter-associated biofilm. Many of those are still hypothetical. Biofilm formation on a catheter may originate from bacteria introduced as a contamination during surgery/catheter insertion; those are believed to initiate biofilms on the catheter outside. Alternatively, biofilms in the lumen of the catheter can originate from bacteremia and other infection sites due to hematogenous seeding from those sites. Compared to planktonic growth, biofilms secrete fewer proinflammatory factors, which normally cause considerable responses by innate host defenses, such as phagocyte influx and AMP production. In addition to eliciting fewer such responses, the biofilm matrix provides a shelter from AMPs and phagocyte intrusion. *S. aureus* biofilms also attract myeloid-derived suppressor cells (MDSCs), which add to decreasing inflammatory responses, particularly phagocyte influx. Finally, internalization of bacteria, for example, by epithelial cells, can produce SCVs, which are prone to persist and cause recurrent infections.

types, or in the case of cyclic di-AMP release, occur *in vivo*. Somewhat in contrast, it has also been shown that in a long-lasting murine biofilm infection, downregulated responses in regulatory T cells (Tregs) during later stages of the infection provide for an unrestrained inflammatory response (134).

Some prominent biofilm matrix molecules have been described to promote immune evasion mechanisms independently of their role in matrix formation. PIA in its deacetylated form provides resistance to neutrophil phagocytosis and killing by AMPs (38). Possibly, this activity is responsible for the effects PIA has shown in non-biofilm-associated experimental infection (135). The *S. aureus* Bap protein, in addition to promoting adhesion, prevents *S. aureus* internalization by epithelial cells (136). This contrasts with fibronectin-binding proteins, which have long been known to facilitate such internalization (137). Which role internalization and potential intercellular persistence in nonprofessional phagocytic cells have in biofilm-associated infection still needs to be investigated in more depth. There is evidence indicating that the formation of small-colony variants, cells with severely reduced metabolism, contribute considerably to such persistence (138).

THERAPEUTIC STRATEGIES FOR STAPHYLOCOCCAL BIOFILM-ASSOCIATED INFECTIONS

Biofilm infections remain extremely resistant to antibiotic therapy. Currently, there are no alternatives, and excision and replacement of an infected device are often the only remedy. In the following, some strategies to develop alternative biofilm therapeutics will be presented. Most of them are still in the preclinical stage.

Antimicrobial Peptides

With most antibiotics not being efficacious against biofilm cells due to their mode of action that only targets active cell processes, one strategy focuses on developing bactericidal antibacterial compounds. In the center of this approach are AMPs, most of which work by forming pores in the bacterial membrane (139). However, AMPs are subject to a series of resistance mechanisms that are based on the barrier function of the biofilm matrix in addition to more specific mechanisms, such as efflux pumps and AMP repulsion. Furthermore, staphylococci have learned to sense the presence of AMPs during their co-evolution with humans and react with efficient countermeasures (140, 141).

Material Alterations

Many attempts have been made to deal with the adhesion of bacteria to medical devices by altering the surface to lower adhesive features or by coating the device surface with antibacterial compounds (142). The latter are mostly antibacterial metals, such as silver or copper, in addition to antibiotics or AMPs. Such optimized devices, mainly catheters, are in clinical use and have had some success; however, biofilm formation still happens, and it appears impossible to completely inhibit adhesion by altering device surface composition. Unfortunately, once adhesion is accomplished, altered device surfaces do not impact further biofilm growth. One reason for the limited success of altering device surfaces is the abovementioned fact that they are prone to being covered by human matrix proteins, to which bacteria attach independently of the device surface.

Vaccines

So far, there is no working vaccine for *S. aureus*, even for non-biofilm-associated infections; many have argued that development of an *S. aureus* vaccine is inherently difficult (143). It has been proposed that vaccine approaches for biofilm infections be designed depending on which antigens are present in the biofilm mode of growth (144), but no such attempts have been actively pursued. There appears to have been some preclinical success with anti-PIA antibodies, as shown in an *S. aureus* periprosthetic osteomyelitis rat model (145). As for *S. epidermidis*, there has been success using immunization with the surface protein SesC in a subcutaneous foreign body in a rat model (146). However, vaccination against *S. epidermidis* as a beneficial part of the skin microbiota is generally debatable. Furthermore, the many positive results from antistaphylococcal vaccine experiments in animals have so far never resulted in a vaccine that works in humans.

Bacteriophages and Lysins

Bacteriophage therapy is controversial for several reasons, but it has the advantage of having a bactericidal mechanism and thus not being subject to the efficacy-lowering bacterial physiology of biofilms or persister cells (147). Then again, cell surface-located bacteriophage receptor molecules may not be accessible in the biofilm matrix. However, in several cases, bacteriophages have proven efficacious against *in vitro* staphylococcal biofilms. For example, the bacteriophages φIPLA-RODI and φIPLA-C1C reduced biofilms of *S. aureus* and *S. epidermidis in vitro* (148). Bacteriophage K is also often proposed as an antistaphylococcal biofilm agent (149, 150). Furthermore, bacteriophage lysins may represent a means to enzymatically disrupt biofilms, such as bacteriophage lysin CF-301 (151, 152). *In vivo* efficacy of bacteriophages or bacteriophage lysins against *Staphylococcus* biofilm-associated infection still needs to be demonstrated.

Biofilm-Degrading Enzymes

The idea to enzymatically disrupt staphylococci in biofilms for treatment is not limited to bacteriophage-derived lysins. Lysostaphin, a lysin produced by *Staphylococcus staphylolyticus*, is used in the laboratory to digest staphylococcal cells and has been investigated intensely as an antistaphylococcal agent (153). It has also been shown to work against *in vitro S. aureus* biofilms, an effect that could be enhanced when used together with antibiotics (154–156). Notably, lysostaphin eradicated *S. aureus* in a catheter-associated infection model in mice when applied through the catheters (157). *S. epidermidis* shows increased resistance to lysostaphin due to the different composition of the pentapeptide bridge in peptidoglycan, the target of lysostaphin (158). Another enzyme-based potential therapeutic strategy consists of applying matrix-degrading enzymes. Dispersin B is a PIAse produced by *Actinobacillus actinomycetemcomitans* (159). It has been shown to degrade staphylococcal biofilms *in vitro* that are dependent on PIA, thus, predominantly *S. epidermidis* biofilms (160, 161). Other matrix-degrading enzymes, such as proteases, have also been proposed to treat biofilm infections (78, 154), a strategy obviously also dependent on the mode of biofilm matrix formation. The *in vivo* efficacy of biofilm matrix-degrading enzymes still needs to be shown.

Quorum-Sensing Blockers

Finally, quorum-sensing blockers are often proposed for biofilm infections; however, due to the biofilm-structuring

and -dispersing effect of the Agr quorum-sensing system, this approach appears counterproductive in staphylococci. Nevertheless, one needs to consider that severe and life-threatening conditions, such as bloodstream infections, often only arise after dispersal from a biofilm. For those, quorum-sensing blockers or other approaches targeting aggressive virulence factors, such as toxins, may be invaluable. Anti-toxin antibodies show great promise in that regard (162).

CONCLUDING REMARKS

Biofilm formation in staphylococci remains a serious clinical problem due to the enormous and continued difficulties in treating staphylococcal biofilm-associated infections. Therefore, mechanisms of staphylococcal biofilm formation have received much attention over the last decades, and many important results, for example on staphylococcal biofilm genetics and regulation, have been achieved using *in vitro* setups of biofilm development. However, it has become clear that biofilm-related *in vitro* observations are often not transferable to the *in vivo* level, with the *in vivo* situation differing in substantial aspects, such as the interaction of host matrix proteins and immune defenses. With the interest in staphylococcal biofilm formation clearly stemming from the involvement of staphylococci in infections, there should be a more pronounced focus on the in-depth evaluation of biofilm formation in an *in vivo* context in the future. This is equally imperative in preclinical research on potential antibiofilm therapeutics, which currently often lacks this crucial aspect. Such approaches should contain more animal models, which can be optimized to better reflect human biofilm-associated infection, and *ex vivo* research using human cells, particularly immune cells. The increasing recent interest in the genetics and immunology underlying the asymptomatic colonization of human skin and mucous surfaces, which can be seen as proceeding in a biofilm-like fashion, will also be of great value to gain a comprehensive understanding of staphylococcal biofilm physiology in the commensal and infectious states.

Fulminant Staphylococcal Infections

YVES GILLET, THOMAS HENRY AND FRANCOIS VANDENESCH

44

INTRODUCTION

Fulminant infections are not clearly defined in the field of staphylococcal infections. According to Wikipedia, "fulminant" is a descriptor, especially used in the field of medicine, for any event or process that occurs suddenly and escalates quickly and is intense and severe to the point of lethality, i.e., it has an explosive character. The word comes from Latin *fulminare*, to strike with lightning. For staphylococcal infections in which, despite the fact that *Staphylococcus aureus* is considered a commensal, progression may be devastating in many circumstances, it appears pertinent to add to this definition the notion of an unexpected event leading to a "thunderstorm in a quiet blue sky." Hence, fulminant staphylococcal infection indicates an explosive, intense, and very severe infection occurring in a patient whose previous condition and antecedent would never have suggested any anticipation of life-threatening development. Considering this definition, fulminant is an adjective that could be associated with several staphylococcal infections, including necrotizing pneumonia, necrotizing fasciitis, and to some extent toxic shock syndrome and infective endocarditis (IE). In the three former diseases, toxin production plays a major role, whereas in the latter (fulminant presentation of IE), association with any particular toxinic profile has never been demonstrated.

STAPHYLOCOCCAL NECROTIZING PNEUMONIA

The role of *S. aureus* in pneumonia has been known for decades, but staphylococcal pneumonias are rare, representing only 2% of community-acquired pneumonia in adults (1). Until the end of the 20th century, *S. aureus* was thought to be responsible for community-acquired pneumonia in two main circumstances: first, in respiratory diseases of adults, *S. aureus* pneumonia is observed mainly in the elderly and/or associated with underlying conditions such as immunodepression, cancer, diabetes, or chronic respiratory disease. *S. aureus* is also a major cause of exacerbation in cystic fibrosis. Moreover, *S. aureus* is responsible for 20 to 30% of health care-associated respiratory infections, particularly ventilator-associated pneumonias (2). In such situations, no specific staphylococcal virulence factors are clearly associated with staphylococcal pneumonia, and the main issue for the clinician is to manage methicillin-resistance and multidrug resistance, which are common in hospital-acquired cases. These staphylococcal pneumonias are often severe, but it is always difficult to determine the role of the intrinsic virulence of *S. aureus* or the patient's underlying condition in the potentially unfavorable evolution. The second presentation of severe staphylococcal pneumonia used to be observed only in very young children, aged less than 1 year (3). This disease was commonly described as a bilateral multifocal round-shaped pneumonia with bullous formations in lung parenchyma, leading sometimes to the appellation "bullous pneumonia," considered in children as pathognomonic of *S. aureus* (4). Pleural effusion was common, as was combined pleural empyema and pneumothorax secondary to rupture of bullous lesions in the pleural cavity (5). This severe presentation was associated with a high case-fatality rate, from 10 to 23% (3, 6). Although most cases in the years 1960 to 1970 were associated with the phage type 80-81, now known to encompass strains encoding the Panton-Valentine leukocidin (PVL) (7), no specific staphylococcal virulence factor was identified in staphylococcal pleuro-pneumonia of young children (7). For partially unknown reasons, staphylococcal pneumonia almost disappeared in children in developed countries at the end of the 20th century, whereas it was still commonly described in low-income areas. Nevertheless, despite the undeniable severity of staphylococcal pneumonia, fulminant presentations as defined above were considered very rare, and evolution toward a fatal outcome was usually attributed to underlying conditions rather than to staphylococcal virulence. However, case reports and even small series of fulminant staphylococcal pneumonia were sporadically reported in older children and young adults, but the basis of the severity in these cases has remained unknown.

The first step in understanding how virulence factors impact the severity of staphylococcal pneumonia was reached in 1999, when Lina et al., studying a collection of 172 strains referred to the French National Reference Center for Staphylococci (*Centre National de Référence des Staphylocoques*), showed that 85% of the strains isolated from severe community-acquired pneumonia harbored *luk*S-PV and *luk*F-PV genes, together encoding a rare (less than 5% of strains in Europe) (8) staphylococcal exotoxin: the PVL (9). The clinical presentation of these pneumonias was very unusual in view of their severity (lethality, >75%) but also in view of their epidemiology and symptoms: the cases were observed in young immunocompetent patients but not in very young ones, and most of the patients showed signs of pulmonary necrosis with massive airway bleeding. The complete clinical and biological characterization of this particular form of staphylococcal pneumonia in humans and

doi:10.1128/microbiolspec.GPP3-0036-2018

its link to the presence of *pvl* genes was achieved by a prospective comparison between PVL-positive and PVL-negative strains causing community-acquired pneumonia (10). As prospective surveillance continued in France, features associated with severity and mortality were identified (11). Hence, a rare but severe presentation of staphylococcal pneumonia was described and named "staphylococcal necrotizing pneumonia" (SNP). The main clinical characteristics of this disease can be summarized as:

- Occurrence in most cases in young immunocompetent patients, without an antecedent or underlying condition.
- Preceding flu-like illness, with documentation of influenza virus infection in some cases.
- Rapidly progressive bilateral pneumonia, without bullae, evolving toward severe hypoxemia and pulmonary edema and leading to acute respiratory distress syndrome.
- High frequency of airway hemorrhages, massive in some cases.
- Initial leukopenia.
- High case-fatality rate despite young age and absence of underlying preconditions. For the fatal cases, death occurs promptly after the onset of the disease (median survival time, 4 days).
- Unusual pathologic findings on lung necropsy: necrotic destruction of the entire respiratory epithelium, from larynx to alveoli in some cases, without polymorphonuclear infiltrate. Diffuse alveolar damage with hemorrhagic infiltration.

In the comparative study of community-acquired staphylococcal pneumonia based on toxin profiling (12), all the cases matching the above description of necrotizing pneumonia were caused by PVL-positive strains, whereas bilateral pneumonia caused by PVL-negative strains was commonly seen in the elderly and was associated with underlying preconditions. In PVL-negative cases, fulminant evolution was not observed, and leukopenia, airway bleeding, and signs of lung necrosis were absent. These differences suggest that PVL and likely other pore-forming toxins play a central role in the pathophysiology of necrotizing pneumonia.

Since its first description in 2002, (SNP) has been reported worldwide (13–17), and in all cases, the causal strains, despite their genetic diversity and lack of clonality, harbored the *pvl* genes on various prophages (reviewed in reference 18), which is presumably responsible for their dissemination among unrelated strains. Moreover, the finding that previously published cases of fulminant staphylococcal pneumonia had clinical presentations very similar to the "typical" features of SNP (19, 20) may indicate that this disease, although not formally recognized, had been encountered for many years and should not be considered an emerging entity. A particular situation concerning SNP is observed in the United States, where the description of SNP coincided with the emergence of the USA300 community-associated methicillin-resistant *S. aureus* (CA-MRSA) lineage; indeed, almost all the reported cases in the United States were due to USA300 (17, 21, 22). This particular lineage restriction in the United States led to confusion in the understanding of the determinant of severity associated with SNP. First, methicillin resistance was thought to be a major determinant of severity, presumably by inducing a delay in initiation of appropriate antibiotics. However, it has now been demonstrated that methicillin resistance *per se* is not associated with higher mortality in SNP (23) and, despite probable overreporting of cases due to MRSA, more than 70% of the cases of SNP in Europe are due to methicillin-susceptible *S. aureus* strains belonging to distinct lineages. Second, the restriction to USA300 leads to an overestimation of the role of this clone's specific virulence factors. An enhanced production of alpha-hemolysin (24, 25) or phenol-soluble modulin (25, 26) and the presence of Arginine Catabolic Mobile Element (ACME), which is strongly associated with USA300 (27), were therefore suspected to be major determinants of severity in SNP, minimizing the potential role of other virulence factors such as PVL (28). However, the low prevalence of *pvl* genes in strains circulating in Europe (8) and the absence of clonality of infection strains presented a unique opportunity to determine whether or not PVL was associated with severity and poor outcome of staphylococcal pneumonia (29). Apart from the epidemiological association of PVL with the severity of community-acquired pneumonia (10, 13), other features suggest that PVL contributes to the severity of SNP: interestingly, the most typical clinical and biological features associated with SNP, i.e., leucopenia and airway hemorrhages, although they are not fully specific, are strongly associated both with its severity and with the known biological effect of PVL. Hence, leucopenia is probably the result of the lytic effect of leukotoxins on polymorphonuclear (PMN) cells. Leucopenia is associated with mortality in various studies (11, 16, 17), and we have shown that the association of leukopenia with death is "dose-dependent": when the total leucocyte count was above 3 giga elements/liter at hospital admission, survival was observed in >75% of cases, whereas less than 20% of the patients survived when their leucocyte counts were <3 giga elements/liter (11). Airway hemorrhage is associated with poor prognosis too and is a direct consequence of the massive necrosis of the respiratory epithelium, likely due to the direct and indirect leukotoxic properties of PVL and not observed in other staphylococcal pneumonias.

Animal models are required to fully understand the complex interactions between *S. aureus*' virulence factors, host susceptibility, and severity. The model should reproduce the phenotype observed in humans with necrotic hemorrhagic lesions and pulmonary edema. The first model of necrotizing pneumonia was developed in BALB/c mice with nasal instillation of high inoculum (30). Necrotic lesions were observed, but survival of the infected mice was impaired only when overexpressing *pvl* on multicopy plasmids. Other studies in mice failed to demonstrate any role for PVL in severity and even to induce necrotic lesions (24). It is now widely accepted that PVL is poorly active toward murine leucocytes while being highly cytotoxic toward human and rabbit leucocytes (31). The identification of human C5aR and CD45 as the receptors for LukS-PV and LukF-PV, respectively, at the surface of phagocytes offered a molecular explanation for the lack of relevance of mouse models for the study of PVL-associated pathogenesis (31–33). Indeed, due to polymorphisms between mice and humans, neither LukS-PV nor LukF-PV bind to murine C5aR1 and murine CD45, resulting in PVL being inactive in mice. In contrast to murine C5aR1, rabbit C5aR1 is compatible with LukS-PV, and rabbit PMN cells are highly susceptible to PVL, making this species a relevant animal model for studying the role of PVL in SNP.

Diep et al. developed a convincing rabbit pneumonia model using inocula 10-fold lower than those previously used in mice (34). In this model, nasal instillation of a PVL-positive CA-MRSA USA300 strain is associated with activation of PMN cells and alveolar macrophages, leading to the direct destruction of PMN cells by PVL and intense production of inflammatory mediators, particularly interleukin 8

(IL-8). These mediators attract more and more PMN cells, whose PVL-induced lysis and degranulation liberates proteases and oxidative products. These toxic components provoke vasodilatation, pulmonary edema, and cellular lesions, leading to hemorrhagic necrosis of the pulmonary epithelium (34), mimicking the pathology observed in human necropsies. The central role of PMN cells in the pathogenesis of lesions observed in SNP is emphasized in this model by the absence of Il-8 production, pulmonary edema, and necrotic lesions in neutropenic rabbits exposed to a high concentration of PVL (34). Alveolar macrophages and lung epithelial cells may play a key role in the initiation of inflammation since PVL not only lyses PMN cells directly but also triggers IL-1β release in human alveolar macrophages, which in turn stimulates the massive secretion of the neutrophil-attracting chemokines, IL-8 and monocyte chemotactic protein-1, by lung epithelial cells (35). Interestingly, this inflammatory pathway is amplified by the release of pathogen- and damage-associated molecular patterns from dying neutrophils, possibly explaining the fulminant nature of SNP (36). Of note, the PSMalpha3, beta-, gamma-, and delta-hemolysins and LukDE synergize with PVL to amplify IL-1β release, indicating that these factors cooperate with PVL to trigger inflammation (35). Another issue in deciphering the complex pathophysiology of necrotizing pneumonia is to determine the putative role of influenza virus in the infection. Epidemiological links appear in many studies (11, 17, 22, 37, 38), but interactions between both pathogens remain hypothetical. However, two distinct mechanisms are probably involved: first, influenza infection may favor *S. aureus* attachment, causing epithelial lesions which expose basal layers of mucosae with matrix components to which *S. aureus* adheres (39, 40). Second, animal experiments indicate that influenza may play a role in PMN cell recruitment in the lungs, triggering inflammatory signals (41, 42). Considering the central role of PMN in necrosis induction and the near absence of PMN cells in normal lungs, it is tempting to hypothesize that this PMN recruitment is a key point for necrosis induction mediated by PVL (41).

Altogether, fulminant *S. aureus* pneumonia occurring in patients without known predisposing factors is strongly associated with PVL-producing strains, and most *in vitro* and animal model data reveal that this observation is beyond simple association. However, two major issues remain to be addressed: first, even if the prevalence of the *pvl* genes is low in the general population (8), the carriage rate of *S. aureus* in humans is sufficiently important so that millions of people are exposed to PVL-producing strains; yet the incidence of fulminant *S. aureus* pneumonia remains extremely low, i.e., 30 to 50 cases per year in a 60-million-inhabitant country like France in which there should be roughly 1 million carriers of PVL-positive *S. aureus* (CNR annual report, http://cnr-staphylocoques.univ-lyon1.fr/). It is thus tempting to speculate that factors other than PVL and/or a genetic predisposition to PVL are required for the development of these fulminant presentations of pneumonia. Susceptibility to *S. aureus* infections can be linked to specific human mutations. Rare mutations affecting the Toll-like receptor/IL-1 receptor pathway, the IL-17 pathway, and the NADPH oxidase pathway are strongly associated with recurring or severe *S. aureus* infections (for review see reference 43). Two genome-wide association studies have been performed to identify genes influencing *S. aureus* diseases, highlighting several candidates (44, 45). However, so far, no specific polymorphism has been associated with the development of fulminant *S. aureus* pneumonia. The contributing role of other virulence factors and toxins is another issue to be explored. Indeed, not all fulminant *S. aureus* necrotizing pneumonias are caused by PVL-producing strains, suggesting the involvement of other potentially necrotizing toxins such as alpha-toxin, gamma-hemolysins, or LukGH that are present in most *S. aureus* strains (8, 46). Indeed, alpha toxin is most likely the major pore-forming toxin in *S. aureus* and is known to contribute to the severity of *S. aureus* pneumonia and other infections (47), while the gamma-toxin HlgCB, which targets the C5aR on myeloid cells, as does PVL (48), could be a major contributor. Under what circumstances these toxins could determine fulminant pneumonia remains to be explored, but large variations in the expression of these toxins *in vivo* (49) is an important parameter to be considered.

The existence of staphylococcal lung infection, due to a proven "toxinic" strain, which secretes a large amount of PVL or some other pore-forming toxin, is not necessarily associated with a fulminant course even when clinical evidence of necrosis is observed. Hence, especially in young children, PVL-positive strains are predominant in staphylococcal pneumonia, in both the United States and in Europe and are associated with necrotic abscesses and pleural effusion (50, 51), but in these studies, symptoms of fulminant necrotizing pneumonia were rarely observed and mortality was <5%. In fact, the description of most of the cases matches the classic presentation of staphylococcal pleuro-pneumonia of young children, often caused by the notorious 80-81 epidemic strain, which probably produced PVL, and an unresolved challenge is to understand why in some cases, PVL-positive *S. aureus* lung infection provokes fulminant lung necrosis, whereas in other cases, necrosis is limited to abscess formation, and the outcome is far less devastating. Differential levels of virulence factor expression including that of the core-genome-encoded pore-forming toxins or patient heterogeneity regarding toxin susceptibility may contribute to these differences, but these explanations remain largely hypothetical. Another hypothesis involves the pathophysiology of lung infections. Lung invasion can be secondary to the hematogenous spreading of septic emboli from a distant infection focus; however, *S. aureus* can also directly reach the lung via the inhalation route. In the first case, necrotic effects would involve predominantly conjunctive lung tissue, and the necrotic lesion would be a localized abscess; in cases of inhalation, necrotic lesions should be more diffuse and should involve the respiratory epithelium directly, leading to major and prompt alteration of respiratory function. Currently, this distinction is purely theoretical, although some evidence from the rabbit model favors this pathophysiological model (52).

TOXIC SHOCK SYNDROME

Toxic shock syndrome (TSS) is another rare disease that matches (in some instances) our definition of fulminant staphylococcal infection. TSS was described in 1978 in seven children aged 8 to 17 years (53). Despite the severity of the disease, *S. aureus* was isolated only from mucosal sites, while blood, cerebrospinal fluid, urine, and other potential infectious sites remained sterile, leading a toxin-mediated phenomenon to be suspected. Despite the fact that similar cases had been previously described, J.K. Todd was the first to describe these cases as a specific clinical entity. A few years after the initial description, the United States faced an "outbreak" of TSS in young women who presented typical and often severe forms of TSS during their menses (54–56). This presentation was identified as menstrual TSS (mTSS)

and was initially attributed to the use of hyper-absorbent tampons, but it became rapidly apparent that all kinds of tampons could be involved (57). More recently, mTSS was associated with other devices, such as menstrual cups (58). After the withdrawal from the market of the incriminated tampons and information campaigns about this syndrome in the United States, the incidence of mTSS dramatically fell (although mTSS did not disappear), and TSS not associated with menstruation was therefore "rediscovered" (59). The nonmenstrual forms of TSS (nmTSS) are quite similar in their clinical presentation but lead to higher mortality rates (60). nmTSS are usually associated with a staphylococcal deep-seated focus of infection (61), whereas menstrual cases are associated with vaginal carriage (60).

The clinical features of TSS have been remarkably consistent since the initial description and are associated with several nonspecific features, the combination of which leads to the diagnosis. TSS is thus diagnosed in the face of a rapidly deteriorating condition associate with an infectious syndrome, with muco-cutaneous involvement and hemodynamic failure (61). At the initial stage, the patient presents with a flu-like syndrome associated with fever, headache, chills and muscle pain, sore throat, and often diarrhea (62). Even if they are observed in a young woman during menses, none of these symptoms nor their association are specific, and although not clearly documented, some cases spontaneously resolve by the end of the menstruation and the removal of the tampon (Y. Gillet, unpublished data). A few hours after, in a case progressing toward true TSS, the patient presents with a generalized cutaneous rash, which is sometimes described as "sunburn-like," but even if it may be itchy, the rash is usually not painful (63). The clinical aspect of the cutaneous eruption is not specific but usually involves the extremities with local edema and redness. Such involvement of palms and soles, unusual in other diseases (i.e., in viral rashes), may point toward the diagnosis of TSS. Finally, if the patient survives, rash is followed 10 to 15 days after the onset of the disease by a spectacular desquamation typically involving the whole palms and soles. Concomitant with the rash, mucosal involvement is constant but may be delayed a few days. Lips are dry and bright red, the tongue is red with a "strawberry" aspect, and the eyelids become inflammatory with a bilateral conjunctivitis without purulent exudate (61, 64). Genital mucosae are inflammatory too, usually without purulent discharge. Simultaneously or rapidly after the onset of the rash, the patient's general status worsens and hemodynamic failure appears. As with other infectious shock syndromes, the mechanisms of hypotension are multiple: dehydration due to diarrhea, hypovolemia caused by capillary leakage, and vasodilatation and lowering of cardiac output secondary to direct cardiac dysfunction (63). In the most severe cases, the physiological compensation for circulatory insufficiency may provoke intense vasoconstriction of the skin, leading the erythematous eruption to be unapparent. Diagnosis is particularly difficult in such situations and is often delayed until hemodynamic improvement reveals the rash (Y. Gillet, unpublished data). Moreover, although hypotension is by definition required for the diagnosis of TSS, there are many different clinical presentations in terms of severity, from simple malaise with orthostatic hypotension to refractory shock unresponsive to remediation, even if prompt, and leading to multiorgan failure (61). These potential marked differences in terms of intensity of the hemodynamic failure are unfortunately not always taken into account in studies and may result in misinterpretation, especially in the field of treatment strategies. Obviously, less severe cases are more likely to be self-limited, whereas severely ill patients should benefit more from specific intervention. Therefore, one should keep in mind that the acronym TSS embraces a large diversity of diseases, from self-limited to life-threatening, with only the latter falling into the above definition of fulminant disease. Nevertheless, as mentioned before, none of the symptoms of TSS could be considered specific, and the diagnosis is based on the criteria (65) listed in Table 1.

Interestingly, the presence of *S. aureus* is not required according to the CDC's criteria, since very severe TSS can be observed during *Streptococcus pyogenes* infections with only subtle clinical differences from nmTSS (66).

Despite the above well-defined criteria and the fact that TSS is a reportable disease in many states in the United States (67), the incidence of TSS is not precisely known. Some cases are unrecognized either because they are not severe enough and are self-limited or because of extreme severity leading to prompt death before recognition of the syndrome. However, the incidence in the United States is estimated to be from 1 to 3 per 100,000 inhabitants (56, 59). The incidence is 2-fold higher in women between 13 and 24 years old, and menstrual forms represent 54% of the identified cases (59).

In both mTSS and nmTSS, staphylococcal exotoxins with superantigenic properties are involved. mTSS and, to a lesser extent, nmTSS, are "true toxin-mediated diseases" (toxinoses), meaning that all the observed symptoms can be explained by the action of the exotoxins, without involvement of other staphylococcal virulence factors. *S. aureus* can produce 24 exotoxins with superantigenic properties (68),

TABLE 1 Case definition of staphylococcal TSS

Clinical criteria
Body temperature >38.9°C (102.02°F)
Systolic blood pressure <90 mmHg
Diffuse macular erythroderma
Desquamation (especially of the palms and soles) 1–2 weeks after onset
Involvement of three or more organ systems:
Gastrointestinal (vomiting, diarrhea)
Muscular: severe myalgia or creatine phosphokinase level at least twice the upper limit of normal for laboratory
Mucous membrane hyperemia (vaginal, oral, conjunctival)
Kidney failure (serum creatinine >2 times normal)
Liver inflammation (bilirubin, Aspartate Aminotransferase (AST), or Alanine Aminotransferase (ALT) > 2 times normal)
Low platelet count (platelet count <100,000/mm^3)
Central nervous system involvement (confusion without any focal neurological findings)
Laboratory criteria
Negative results of the following tests, if performed:
Blood, throat, and cerebrospinal fluid cultures for bacteria (besides *S. aureus*)
Serology for *Rickettsia* infection, leptospirosis, and measles
Case classification
Confirmed: All six of the criteria above are met (unless the patient dies before desquamation can occur)
Probable: Five of the six criteria above are met

but most cases of TSS are due to the following four of them, in decreasing order of incidence: toxic shock syndrome toxin-1 (TSST-1), *Staphylococcus* enterotoxin A (SEA), SEC, and SEB (59). The structure of TSST-1 is remarkable by the presence of a peptidic loop dedicated to intraepithelial transportation by a hypothetical carrier and conferring to TSST-1 its unique ability to cross the mucosal barrier (69). Therefore, TSST-1 is associated with >90% of mTSS (59, 60), whereas it is present in only 50% of nmTSS (59). Mucosal lesions induced by staphylococcal cytolysins may also play a role in the transmucosal crossing of TSST-1 (69). Staphylococcal superantigens are active at very low concentrations and induce a polyclonal activation of T lymphocytes by mediating a direct interaction between the major histocompatibility complex class II receptor on antigen presenting cells and the Vβ chain of the T cell receptor on lymphocytes independently of the sequence of the major histocompatibility complex-loaded antigenic peptide. Interestingly, each superantigen is specifically associated with 1 to 8 of the 24 major Vβ chains that can be found in human T cell receptors (70). This "Vβ profile" may be highly specific. For instance, TSST-1 is associated solely with Vβ2 activation, whereas redundancy between different superantigens sharing the same Vβ profile (e.g., SEB and SEC activate lymphocytes sharing the same Vβ chains) is also observed (69). The number of Vβ chains involved has no known consequences in terms of strength of T cell activation. The Vβ specificity of superantigens could therefore be used as a diagnosis tool: by measuring the differential activation of T cells using flow cytometry, it is possible to formally identify the "signature" of the responsible superantigen according to their Vβ chain, allowing the confirmation of atypical cases and the indirect identification of *S. aureus* (71, 72). T cell activation by superantigens bypasses normal major histocompatibility complex-restricted antigen specificity, leading to activation of up to 20% of total T lymphocytes and thus massive cytokine release (73, 74). The resulting inflammatory pathway does not seem to differ markedly from the septic shock pathway and leads to massive production of IL-1, IL-2, IL-6, tumor necrosis factor, gamma interferon, and various chemokines responsible for the enhancement and dysregulation of the inflammatory response (75). The consequences of this cytokine storm are comparable with those observed in septic shock, with even more intense clinical effects due to the initial intensity of the inflammatory response. Moreover, superantigens upregulate the expression of Toll-like receptors 2 and 4 and thus may enhance the inflammatory response by stimulation of these receptors directly by surface-expressed lipoproteins of *S. aureus* and by endotoxins (lipopolysaccharide) translocated from intestinal flora (76, 77). This "two-hit" hypothesis may explain the observed enhanced severity of bacteremic nmTSS compared with mTSS, in which *S. aureus* is absent from the blood circulation.

Nevertheless, conditions that, *in vivo*, lead to such a massive inflammatory response were largely unknown and have been studied essentially for mTSS. *S. aureus* colonization of the vagina is observed in up to 30% of healthy women (78) and may be influenced by various factors including vaginal microbiota (79, 80). Tampons are thought to favor *S. aureus* growth by elevation of the local oxygen concentration and to enhance TSST-1 production (81–83), but considering that 1% to 6.9% of healthy women carry TSST-1$^+$ *S. aureus* during their menses (84, 85), compared to the by far lower incidence of mTSS, it is obvious that TSST-1 production is not sufficient by itself to induce TSS even in favorable conditions. As discussed above for necrotizing pneumonia, various hypotheses are being studied, including genetic predispositions leading to the absence of antibody against the toxins and/or a specific deficiency in immune responses toward superantigens in a context in which 90% of adults are naturally immunized against TSST-1 (84).

STAPHYLOCOCCAL NECROTIZING FASCIITIS

Necrotizing fasciitis (NF) is a rare and severe presentation of skin and soft tissue infection characterized by extensive necrosis of cutaneous and subcutaneous tissue down to the deep fascia and muscles. This infection is often polymicrobial (type 1 NF) with a combination of Gram-positive cocci, Gram-negative rods, and anaerobes. Type 2 NF is usually monomicrobial, classically involving *S. pyogenes*, and is associated with high mortality (86). Recently, *S. aureus*, and especially the CA-MRSA USA300 lineage, has also been recognized as being responsible for type 2 NF (87).

The clinical description of *S. aureus*-associated NF is difficult since most reports are based on retrospective studies. The presentation is thought to be similar to group A *Streptococcus*-associated cases. The classic initial presentation of NF includes severe pain of the skin out of proportion to physical examination findings. Although some patients appear ill, tenderness, erythema, and warm skin are commonly the only signs of early NF. Shock, fever, and altered mental status typically develop during the first 24 to 48 hours of disease progression but are often absent at presentation (88). Local evolution is extremely severe, with uncontrolled extensive necrosis, but due to the deep-seated localization of the necrosis, the overlying skin may be minimally affected, leading sometimes to delayed diagnosis (88). In many streptococcal cases, signs and symptoms of TSS (i.e., erythroderma) are present, whereas TSS symptoms seem less frequent in staphylococcal NF (87). Therefore, staphylococcal NF should be less severe than the group A *Streptococcus*-associated cases, although to the best of our knowledge, no comparative study exists.

Diagnosis and characterization of staphylococcal NF are thus difficult for several reasons: (i) the diagnosis of NF can only be made after surgical debridement reveals pathologic findings indicating necrosis involving fascia and muscles. These findings were confirmed in the 14 cases described in Los Angeles, CA, in 2004 (87) but are not always found in other reports. (ii) In cases of polymicrobial NF, especially when group A *Streptococcus* and *S. aureus* are associated, it is almost impossible to determine which bacterium (or both) is the culprit in terms of severity and, in some cases, it appears possible that one bacterium overwhelms another one, leading to misinterpretation of strain-associated virulence. In relation to this, a recent study revealed that of 35 cases with *S. aureus* and/or Gram-negative bacteria as the only cultured pathogens from swab samples, 21 (60%) had beta-hemolytic *Streptococcus*-confirmed infections and 6 (17%) had probable beta-hemolytic *Streptococcus* disease (89). (iii) *S. aureus* is well known for its ability to induce necrotic skin and soft tissue infection, and PVL-producing strains such as USA300 are associated with primary necrotic cutaneous abscesses (9, 90, 91) involving hair follicles (92). Therefore, severe necrotic skin lesions are common with CA-MRSA (93), and in most cases, the disease description does not fulfill the criteria for necrotizing fasciitis and corresponds to common cutaneous abscesses. Because of these difficulties, staphylococcal NF is less well known than the other fulminant infections described above, but some general differences could be underlined: necrotizing pneumonia and TSS usually occur

in young and previously healthy individuals and appear to be linked to a specific, but to date hypothetical, complex combination of staphylococcal virulence factors and host predisposition. In the case of NF, patients are older (median age, 50 years), and an underlying condition predisposing nonspecifically to bacterial infection is present in most cases. Hence, diabetes is present in 43 to 53% of cases (87, 94), intravenous drug use in 21%, and immunodepression, HIV infection, and cancer each in 7% of cases (87). Thus, the specific virulence profile of the causative staphylococcal strain remains difficult to ascertain in NF.

BACTEREMIA AND INFECTIVE ENDOCARDITIS

S. aureus bacteremia can occasionally present as a fulminant infection, notably when associated with a deep focus of infection. The most frequently reported deep infectious foci are endovascular foci including infective endocarditis (IE) and central nervous system, bone and joint, soft tissue, and intra-abdominal/pelvic infections. *S. aureus* IE occurs in 5 to 25% of *S. aureus* bacteremia (95–98) and is one of the most rapidly progressive etiologies of IE with the worst outcome, often associated with destruction of cardiac valves (99–101). In a study enrolling 2008 consecutive adult bacteremic patients, meningitis (IE, 59%), persistent bacteremia at 48 hours (IE, 25%) and C-reactive protein of >190 mg/liter (IE, 15%) were independently associated with IE (98). The criteria for severe sepsis or septic shock were met in 30% of *S. aureus* bacteremia without IE (overall in-hospital mortality rate, 24%) and in 51% with IE (overall in-hospital mortality rate, 35%).

Numerous *S. aureus* virulence factors (mostly but not exclusively surface-associated proteins) have been shown, from *in vitro* and/or animal studies, to contribute to the pathogenesis of IE. These include clumping factor A-B, fibronectin-binding protein A-B, collagen-binding protein, SdrD/E, the surface factor promoting resistance to oxidative killing, protein A, coagulase, vWFbp (102–107), and superantigenic toxins such as SEA, SEG, and TSST-1 (108, 109). However, with the exception of SEA, which has been specifically associated with septic shock in the course of bacteremia (110), none of these factors have been specifically associated with fulminant progression and worse outcome in either bacteremia or IE in epidemiological studies. The multifactorial nature of *S. aureus* bacteremia severity is reflected in the observation that higher antibody levels against Hla, delta-toxin, PVL, SEC-1, and PSM-α3 may protect against sepsis in patients with invasive *S. aureus* infections (111). Conversely, certain lineages of *S. aureus*, such as clade 3 of CC30, have been associated with attenuated virulence in hematogenous infections (112), likely because of a stop-codon mutation in the major core-genome-encoded pore-forming toxin (alpha-toxin), reduced transcription of the agr effector RNAIII (113), and the expression of a phenol-soluble modulin variant with attenuated toxic and chemotactic activities (114). Interestingly, there is apparently a higher propensity of low-toxicity isolates to cause bacteremia (115).

THERAPEUTIC ASPECTS OF FULMINANT STAPHYLOCOCCAL INFECTIONS

By definition, fulminant staphylococcal infections are potentially lethal and therefore should be managed according to the guidelines of the sepsis survival campaign, i.e., prompt initiation of bactericidal antibiotics, massive fluid remediation, correction of organ failures, and continuous monitoring of objectives (116). However, despite uncertainties about the pathophysiology, fulminant staphylococcal diseases may require specific management due to the involvement of staphylococcal exotoxins. These toxins are produced when bacteria reach a high density, owing to the regulation of their production by quorum-sensing systems. In addition, necrotic lesions prevent adequate antibiotic diffusion at the site of infection. For these two reasons, surgical drainage of any accessible lesions should be systematically undertaken. Moreover, therapeutic approaches targeting toxin production are recommended in TSS (117) despite the lack of strong clinical evidence of efficacy. Furthermore, evidence from animal models and limited clinical series indicates that intravenous immunoglobulins, by their ability to broadly neutralize toxins, have a strong potential to limit casualties in fulminant infections (118, 119). Further, to assess the therapeutic potential of toxin-neutralization strategies in fulminant *S. aureus* infections, studies including larger cohorts and utilizing specific antitoxin monoclonal antibodies (46) remain to be performed. Finally, most fulminant *S. aureus* infections are associated with unleashed inflammation, suggesting that adjunctive immunosuppressive therapies might be beneficial to limit mortality and aftereffects. Yet, based on decades of failed trials involving sepsis, the efficacy of specific immuno-interventions in fulminant *S. aureus* infection remains elusive. Importantly, due to fulminant development of the disease conditions, the choice of an appropriate therapeutic regimen should be made immediately—there is no "second chance." In almost all cases this difficult decision has to be made before any bacteriological documentation, emphasizing the need for advanced knowledge of clinical presentations and severity-associated symptoms to avoid potentially deleterious choices, which are always critical, especially because the diseases are so rare.

Staphylococcus aureus Colonization of the Human Nose and Interaction with Other Microbiome Members

CLAUDIA LAUX, ANDREAS PESCHEL AND BERNHARD KRISMER

45

INTRODUCTION

The human body offers several distinct niches for specific microbiomes, variable consortia of bacterial communities. The skin, for instance, is primarily colonized by members of the genera *Propionibacterium* (now *Cutibacterium*), *Corynebacterium*, and *Staphylococcus* (1). A similar pattern of genera is found in the human nose, which is regarded as a transition zone from the dry skin to the moist, mucoid airways (2). This rather confined area, more specifically, the region from the anterior nasal vestibule to the posterior nasopharyngeal cavity, is the favored colonization site of *Staphylococcus aureus*. While *S. aureus* is a member of the normal nasal microbiome in ca. 30% of the human population, it can also become an aggressive, life-threatening pathogen (3). Nasal carriage is a major risk factor for *S. aureus* infections. Accordingly, *S. aureus* is eradicated from the nose in at-risk patients by treatment with the antibiotic mupirocin. Interestingly, a significant percentage of humans seem never to be colonized by *S. aureus*, for reasons that are currently unknown. Increasing evidence suggests that the composition of the nasal microbiome is an important factor for the exclusion of *S. aureus* from the nose (2).

This article summarizes our knowledge of *S. aureus* nasal colonization and its interaction with other bacterial species that share the same habitat. Understanding naturally occurring *S. aureus* elimination strategies might enable the development of new eradication approaches in the future.

S. AUREUS AS A HUMAN COMMENSAL AND PATHOGEN

The preferred habitat of *S. aureus* is the anterior nares. Approximately 20% of the human population is permanently colonized by *S. aureus*, and another 20% are considered to be noncarriers. The remaining 60% of the population belong to the group of intermittent carriers (4). Although several factors that affect the *S. aureus* carrier status have been described, why only certain people are colonized remains elusive. In general, *S. aureus* occurs particularly frequently in men (5) and in women using hormonal contraception (6). Moreover, diabetic (7), hospitalized, and dialysis patients (4) are more often colonized than healthy humans, and there is a higher carriage rate during childhood compared to adulthood (8). A negative correlation exists between smoking and *S. aureus* carriage (9). Seasonal differences, such as the transition from winter to spring, and temperature and pollen or dust levels, could also affect the nasal microbiome composition (10). Host genetics appear to have only a moderate impact on the shape of the microbiome (11).

S. aureus possesses an extensive arsenal of virulence factors and, therefore, the clinical manifestations of *S. aureus* diseases are diverse and range from rather mild soft skin and tissue infections to severe and life-threatening infections, such as pneumonia, osteomyelitis, endocarditis, and sepsis (12). Although nasal colonization by *S. aureus* is asymptomatic, it increases the risk of invasive infections, especially in immunocompromised and hospitalized patients (4, 13). Analysis of infecting strains revealed that it is usually the nasal strain of a patient that is responsible for subsequent infections (13, 14). Therefore, decolonization of nasal *S. aureus* serves as a very efficacious measure for prevention of invasive infections (13). Since *S. aureus* transmission from the nose to other parts of the body occurs mainly via hand contact, *S. aureus* usually disappears also from other body sites when it is eliminated from the nose (15, 16).

The high risk of *S. aureus* carriers to infection justifies widely applied mupirocin treatment to eradicate *S. aureus* from the nares of patients. Mupirocin interferes with the synthesis of bacterial proteins by reversibly binding to bacterial isoleucyl-tRNA (17). Application of a mupirocin ointment twice a day for 5 consecutive days typically leads to eradication of *S. aureus* from the nose and to a reduced risk of invasive *S. aureus* infections (14, 17). The success rate of mupirocin treatment reaches approximately 90%, yet resistance is increasing, reaching up to 30% in some parts of the United States. Hence, new antimicrobial compounds for *S. aureus* decolonization are urgently needed (17, 18). Recolonization by *S. aureus* frequently occurs a few weeks after the end of mupirocin treatment, probably as a result of *S. aureus* cells using the posterior vestibula as a hidden reservoir, which can hardly be reached by mupirocin treatment (19–21).

Resistance to several common antibiotics has increased in *S. aureus* in the past decades. Resistance to the entire class of β-lactam antibiotics, including methicillin, characterizes the epidemic methicillin-resistant *S. aureus* (MRSA) strains. However, multidrug-resistant MRSA strains, which have acquired resistance to additional antibiotics, such as erythromycin, clindamycin, ciprofloxacin, tetracycline, or mupirocin, have also been observed (22). MRSA infections used to be acquired in hospitals by patients and are called

doi:10.1128/microbiolspec.GPP3-0029-2018

hospital-associated MRSA infections. However, in the past decade, increasing numbers of MRSA infections have been acquired outside the health care system by emerging MRSA clones referred to as community-associated MRSA. Many community-associated MRSA clones are much more virulent and transmissible than hospital-associated MRSA clones (23).

DIVERSITY OF THE HUMAN NASAL MICROBIOME

In addition to the genus *Staphylococcus*, which belongs to the phylum *Firmicutes*, the nasal microbiome also contains members of other phyla, in particular, *Actinobacteria* and *Proteobacteria*. Within these phyla, the genera *Corynebacterium*, *Propionibacterium*, *Staphylococcus*, and *Moraxella* are most common in the human nose (24). Other genera are less frequently found (11). Interestingly, the nasal cavities are also colonized by various anaerobic species (19).

To classify different microbiome compositions, seven community state types (CSTs) were defined according to the dominance of specific nasal species, genera, or families. CST1 is dominated by *S. aureus*, and CST2 is defined by the major occurrence of *Enterobacteriaceae*, such as *Escherichia* spp., *Proteus*. spp., and *Klebsiella* spp. *Staphylococcus epidermidis* dominates CST3, whereas *Propionibacterium* spp. are major colonizers in CST4. *Corynebacterium* is the dominating genus of CST5, and *Moraxella* spp. are most prevalent in CST6, whereas CST7 is defined by the predominance of *Dolosigranulum pigrum*. The most common nasal CST is CST4, followed by CST3 and CST1, whereas CST6 is the least prevalent (Table 1). Although the conspicuous presence of various species or genera defines the CSTs, these species can also be identified at lower abundances in other CSTs (11). Comparing the microbiome compositions at various body sites, it is obvious that the nasal bacterial composition overlaps with those of the oral cavity and skin and can therefore be regarded as a bridge between the microbiomes of these two body sites (24, 25).

Human skin areas with mostly dry, sebaceous, or moist properties differ in the abundance of bacterial microbiome members, while the core species are largely the same (1). It remains unclear if the individual differences in the skin microbiomes can also be attributed to specific CSTs. *S. epidermidis*, *Staphylococcus capitis*, *Staphylococcus hominis*, and *Staphylococcus warneri* are the most abundant coagulase-negative staphylococci (CoNS) on the skin (1). *S. aureus* also occurs transiently on the skin of healthy humans, especially in skin areas of the axillae and perineum (26, 27). Notably, the skin of atopic dermatitis patients is often permanently colonized by *S. aureus* on inflamed and non-inflamed skin parts (28).

CoNS not only colonize the human skin; they can also occasionally be detected in the nose (29, 30). Only *S. epidermidis* is a core microbiome member of both the skin and nose (29). In general, the nasal microbiome is less dense and less diverse than, for instance, the gut microbiome (31, 32). *S. epidermidis* is particularly prevalent on moist areas of the body, such as the axillae, inguinal and perineal areas, toe tissue, and conjunctiva, and is also a common resident of the anterior nares (29). In addition, a variety of other CoNS occupy specific regions of the skin. *S. hominis* and *Staphylococcus haemolyticus* are often found in the axillae and pubic areas (29). *S. capitis* can be preferentially isolated from the sebaceous glands on the forehead and scalp (29) and is also found on the skin and in the nares (33). Whereas *Staphylococcus auricularis* is part of the external ear microbiome, *Staphylococcus saprophyticus* often colonizes the rectum and genitourinary tract (29). *Staphylococcus lugdunensis* is also part of the human skin flora and is particularly prevalent in the pelvic and perineal regions, the groin, the axillae, and in the nail bed of the first toe. *S. lugdunensis* has been isolated from the human nose at an incidence rate of 10 to 26% (19, 29, 34, 35). *S. warneri* is typically found at a lower percentage than other CoNS in the nares and on the skin, preferably on the head, arms, and legs (33). Compared to the other CoNS, *S. lugdunensis* and *S. saprophyticus* are considered species with slightly higher pathogenicity (29).

Compared to species such as *S. epidermidis*, which can be present in the nose with multiple strains simultaneously, nasal *S. aureus* isolates typically belong only to one specific clone (36, 37). Notably, the number of *S. aureus* cells, which can be cultivated from carriers by nasal swabbing, varies from only a few to more than 10^7 per swab (38). Attempts to distinguish persistent from intermediate carriers by a single nasal swab indicated that the detection of more than 10^3 *S. aureus* organisms CFU/swab corresponds to a high probability of persistent carriage (39).

The anterior nares are regarded as the primary habitat of *S. aureus* (4), but a recent study showed that this species can be isolated with an even higher incidence from deeper (posterior) areas of the nasal cavity, suggesting that the posterior vestibule or the entire nasal vestibule may be the principle habitat of *S. aureus* (19). Further studies indicated that *S. aureus* can penetrate into the nasal tissue of healthy humans, and individual cells could be visualized even at the stratum basale of the nasal epithelium, which differs in structure between the anterior and posterior areas (40, 41). While the anterior nares are characterized by a keratinized, stratified squamous epithelium, the posterior nares are

TABLE 1 Community state types of the human nose[a]

Community state type	Dominated by	Prevalence (%)
CST1	*S. aureus*	12.4
CST2	*Enterobacteriaceae*, e.g., *Escherichia* spp. (11), *Proteus* spp. (11), *Klebsiella* spp. (11)	9.0
CST3	*S. epidermidis*	22.5
CST4	*Propionibacterium* spp., e.g., *P. acnes* (88)	28.7
CST5	*Corynebacterium* spp., e.g., *C. accolens* (88), *C. pseudodiptheriticum* (88), *C. propinquum* (88)	11.2
CST6	*Moraxella* spp., e.g., *M. lacunata* (88), *M. nonliquefaciens* (88)	5.6
CST7	*Dolosigranulum pigrum*	10.7

[a]Seven major community state types were defined according to the abundance of dominant nasal bacterial species, genera, or families (11).

defined by pseudostratified, columnar ciliated epithelial cells (2, 41). In the anterior vestibule, the moist squamous epithelium on the septum adjacent to the nasal ostium harbors the highest number of *S. aureus* cells. By contrast, CoNS prefer the skin of the nasal septum and the anterior, hair-covered epidermal portion of the lateral wall (5).

METABOLISM IN THE HUMAN NOSE

The nose is an environment with a very low nutrient supply, which might be the reason for the low species diversity of this habitat. Human nasal secretions contain sodium chloride at concentrations found also in other body fluids and small amounts of potassium, magnesium, and phosphate, but they are low in potential nutrients such as sugars, amino acids, and other major building blocks (30). Based on the composition of nasal secretions, a synthetic nasal medium (SNM3) was established that enabled the efficient growth of *S. aureus*, whereas CoNS did not steadily grow in SNM3 (30). This finding indicates that *S. aureus* is better adapted to life in the human nose than many CoNS, which may use the human nose only as a temporary, but not preferred, habitat. *S. aureus* and many other nasal bacteria, such as *S. epidermidis*, *Finegoldia magna*, *Propionibacterium acnes*, and *Streptococcus pyogenes*, secrete proteases that degrade human proteins, such as albumin, lactoferrin, mucin, cytokeratin 10, and hemoglobin. These proteins are present in considerable amounts in human nasal secretions and might serve as nutrient sources for various bacteria (42–44). It is likely that secretory proteases produced by a specific bacterial strain generate peptides and amino acids that can be utilized by many other microbiome members and may have a broad impact on microbiome metabolism.

MECHANISMS OF NASAL EPITHELIAL ATTACHMENT

Efficient attachment mechanisms are a prerequisite for bacterial nasal colonizers to remain in tight contact with epithelial cells and resist clearance by mucociliar movement. *S. aureus* binds to fully keratinized, dead desquamated cells of the anterior nasal cavity and adheres also to live ciliated cells in the posterior nasal cavity. *S. aureus* uses different adhesion mechanisms depending on the specific epithelial characteristics at different parts of the nares (45–48).

The cell wall glycopolymer wall teichoic acid (WTA) mediates the initial attachment of *S. aureus* to epithelial cells, and WTA is crucial for *S. aureus* nasal colonization (41, 47, 49). WTA-deficient *S. aureus* mutants are limited in their ability to bind to nasal epithelial cells. In addition, mutations in the *dltABCD* operon, leading to a loss of D-alanine modification of WTA, also exhibit diminished epithelial binding capacities (47, 49). Similarly, the modification of WTA with *N*-acetylglucosamine (GlcNAc) in α- or β-configuration is essential for efficient binding to nasal epithelial cells, and a lack of WTA glycosylation significantly abolished the ability of *S. aureus* to colonize cotton rat nares *in vivo* (50).

The scavenger receptor class-F member 1 (SREC1) on nasal epithelia in the posterior nasal cavity is a target for the WTA of *S. aureus* and allows *S. aureus* binding to epithelial cells (46). The charged zwitterionic properties of the ribitol-phosphate repeating units of WTA are essential in SREC1 binding (51). The loss of the D-alanine modification of the WTA significantly reduces the SREC1 binding.

The adherence of *S. aureus* to the nasal epithelium is also mediated by cell wall-anchored proteins, which are involved in long-term persistence within the anterior nasal cavity. *S. aureus* expresses a variety of cell wall proteins, which belong to the group of MSCRAMMs (microbial surface components recognizing adhesive matrix molecules) (41). MSCRAMMs such as clumping factor B (ClfB), iron-regulated surface determinant A (IsdA), and serine-aspartate repeat-containing protein D (SdrD) play an important role in nasal colonization by *S. aureus*.

ClfB is a fibrinogen-binding protein produced by *S. aureus* that binds to the matrix proteins cytokeratin 10 and loricrin. These proteins are exposed on human squamous epithelial cells (48, 52, 53). IsdA, which is involved in heme uptake and iron acquisition (54), is expressed during human infections and is responsible for nasal colonization and survival of *S. aureus* on the skin. Similar to ClfB, IsdA interacts with cytokeratin 10 and loricrin, as well as with the extracellular matrix protein involucrin (48, 55). SdrD mediates adhesion to the human squamous epithelium by binding to desmoglein 1, a desmosomal cadherin that is mainly expressed by the epidermis and mucosa (56, 57) (Fig. 1). The connective function of desmoglein 1 is required for the epidermis to maintain its integrity and structure (57). In addition, the surface proteins SdrC and SasG promote adhesion to squamous epithelium cells, but their binding partners are still unknown (45, 58). Interfering with glycopolymer-receptor interaction might become a new strategy for controlling *S. aureus* colonization in the nose (46). Furthermore, ClfB could represent an ideal target molecule for new decolonization strategies (53). In this context, ClfB can be considered a promising component for the development of a vaccine that would also reduce nasal colonization by *S. aureus* (59).

S. epidermidis colonizes the human nose at a higher frequency than *S. aureus*. In contrast to *S. aureus*, *S. epidermidis* has a different WTA structure, and adhesion proteins related to ClfB, IsdA, SdrD, and SdrC, are absent. Therefore, it remains unclear how *S. epidermidis* accomplishes adhesion in the nose (2, 60).

BACTERIAL COMPETITION

Bacteria from habitats with a limited nutrient supply such as the skin and nose have developed mechanisms to increase their fitness in competition with other microbiome members. Competition between bacterial species can be direct or indirect. Direct inhibition can be achieved, for instance, through production of antimicrobials, whereas indirect inhibition may occur via competition for nutrients or modification of living conditions (61).

Many nasal *Staphylococcus* isolates produce antimicrobial substances against bacterial competitors at an unexpectedly high frequency (84%), with *S. epidermidis* as the most frequent producer of antimicrobial activity (62). Importantly, production of many of the antibacterial activities is strongly enhanced or exclusively detectable under specific environmental stress conditions which are present in the human nose, such as hydrogen peroxide release and iron limitation (62). Antimicrobial substances, also called bacteriocins, are categorized into various groups and subgroups (63). Many *Staphylococcus* isolates are producers of lantibiotics, ribosomally synthesized antimicrobial peptides characterized by the presence of the thioether amino acids lanthionine and methyllanthionine. A variety of lantibiotics have been described for *Staphylococcus* strains (64). Epidermin (*S. epidermidis*) (65), Pep5 (*S. epidermidis*) (66), epilancin K7 and 15X (*S. epidermidis*) (67, 68), epicidin 280 (*S. epidermidis*) (69), staphylococcin C55 (*S. aureus*) (70), various nukacins (*S. warneri* [71], *S. epidermidis* [62], and *S. hominis* [72]), and lantibiotic-α and -β (*S. hominis*) (73), were documented. In

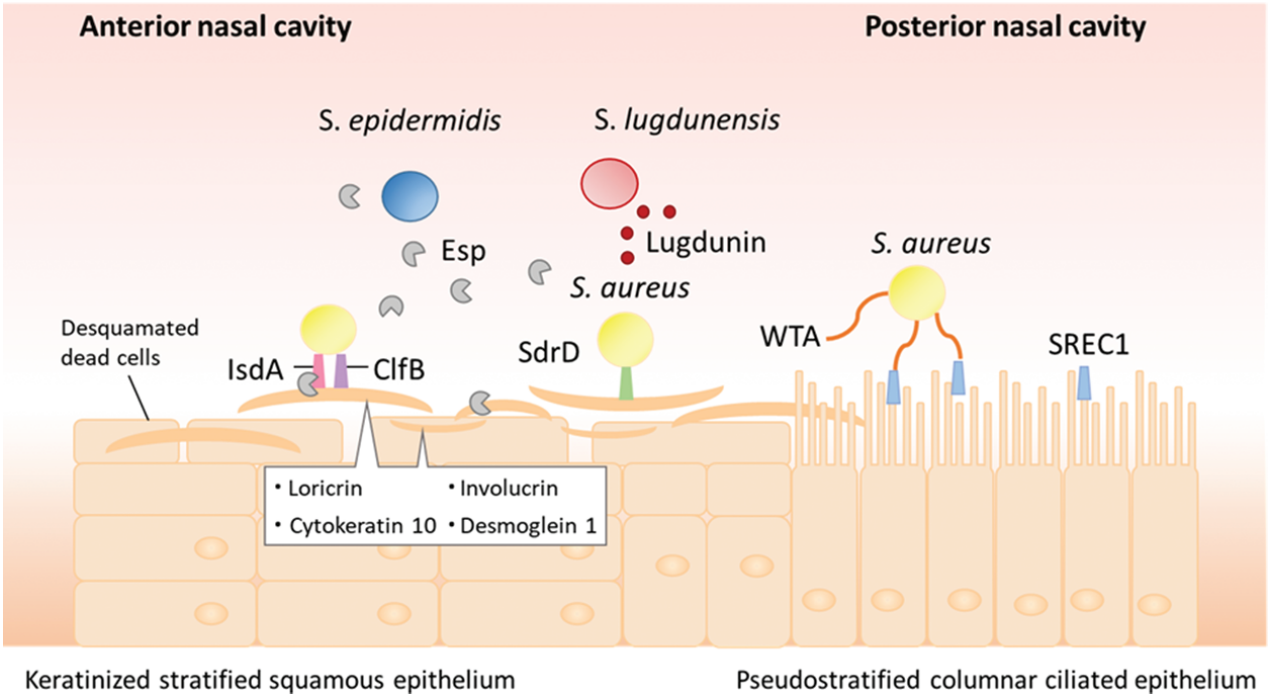

FIGURE 1 Attachment mechanisms of *S. aureus* in the human nasal cavity. The anterior and posterior parts of the human nose are lined by different types of epithelial cell, which require alternative bacterial adhesion mechanisms. For the keratinized stratified squamous epithelium in the anterior nasal cavity, *S. aureus* predominantly uses cell wall-attached surface proteins (MSCRAMMs) (2, 41). In contrast, the primary attachment in the posterior area, composed of a pseudostratified columnar ciliated epithelium, is mediated by specific interaction of the cell-wall linked wall teichoic acid (WTA) with the scavenger receptor class F member 1 (SREC1) (41, 46). The corneocytes (desquamated epithelial cells) in the anterior nasal cavity contain high levels of the proteins loricrin, cytokeratin 10, and involucrin (55). *S. aureus* can express a variety of cell wall proteins, which bind to these matrix proteins. The *S. aureus* adhesin clumping factor B (ClfB) binds to cytokeratin 10 and loricrin (48, 52), whereas the iron-regulated surface determinant A (IsdA) can also interact with involucrin (55). In addition, the *S. aureus* serine-aspartate repeat-containing protein D (SdrD) mediates adhesion to human squamous epithelial cells by binding to desmoglein 1 (56). Some *S. epidermidis* isolates secrete an extracellular serine protease (Esp), which inhibits *S. aureus* colonization by degradation of the surface proteins IsdA and SdrD and host receptors (77, 78). In addition, *S. lugdunensis* can prevent nasal colonization of *S. aureus* by producing the cyclic thiazolidine-containing peptide antibiotic lugdunin (35).

addition, putative lantibiotic-biosynthetic gene clusters were found in the genome of *S. capitis*, which share homology with the biosynthetic systems of epidermin/gallidermin and the nonlantibiotic bacteriocin epidermicin (74). Lantibiotics are usually exclusively active against Gram-positive bacteria but often show no activity against *S. aureus* (62, 71). It is rather uncommon that nasal *S. aureus* is severely affected by lantibiotic-producing CoNS. Interestingly, a systematic analysis of *P. acnes* isolates revealed a frequent capacity to inhibit *S. epidermidis* (75). No compound has been identified that could explain this inhibitory activity; however, the genomes of various *P. acnes* strains encode a putative thiopeptide-biosynthetic gene cluster that is similar to those for antimicrobially active siomycin and berninamycin, which might explain the inhibitory effect (76).

A recent study showed that secretion of the extracellular serine protease Esp by *S. epidermidis* can efficiently inhibit *S. aureus* colonization. Artificial inoculation of Esp-secreting *S. epidermidis* to the nasal cavities of human volunteers was sufficient to eradicate *S. aureus* (77). Nasal colonization of *S. aureus* is probably abolished by Esp via the degradation of both bacterial adhesive surface proteins IsdA and SdrD and host receptor proteins (78). Although most *S. epidermidis* isolates produce Esp and some are producers of lantibiotics, there is no clear correlation of the absence of *S. aureus* with the presence of *S. epidermidis* (20, 64, 77).

Nasal *S. lugdunensis* can prevent colonization by *S. aureus* by producing an unusual antimicrobial compound termed lugdunin, which is a novel, cyclic thiazolidine-containing peptide antibiotic (35). The lugdunin gene cluster is encoded on the *S. lugdunensis* chromosome and is present in almost all *S. lugdunensis* strains. Lugdunin is generated by nonribosomal peptide synthetases. It has bactericidal activity against *S. aureus* and other Gram-positive bacteria, and it was shown to be active *in vivo* in animal models. Analysis of nasal microbiomes of hospitalized patients revealed that *S. lugdunensis* colonization is associated with a 6-fold reduced risk of *S. aureus* carriage in the nose, suggesting that lugdunin or lugdunin-producing commensals could become useful for the prevention of *S. aureus* colonization and infection.

Streptococcus spp. mainly occur in the oropharynx but can also be found at low frequency in the nostrils (79). Importantly, *S. pneumoniae* can modify the nasal habitat by releasing hydrogen peroxide, which induces the SOS response in *S. aureus* and activates DNA repair mechanisms as well as resident prophages. Subsequently, phage-produced lytic enzymes destroy *S. aureus* cells (80, 81). Hence, *S. pneumonia* is negatively correlated with nasal *S. aureus* carriage (82, 83).

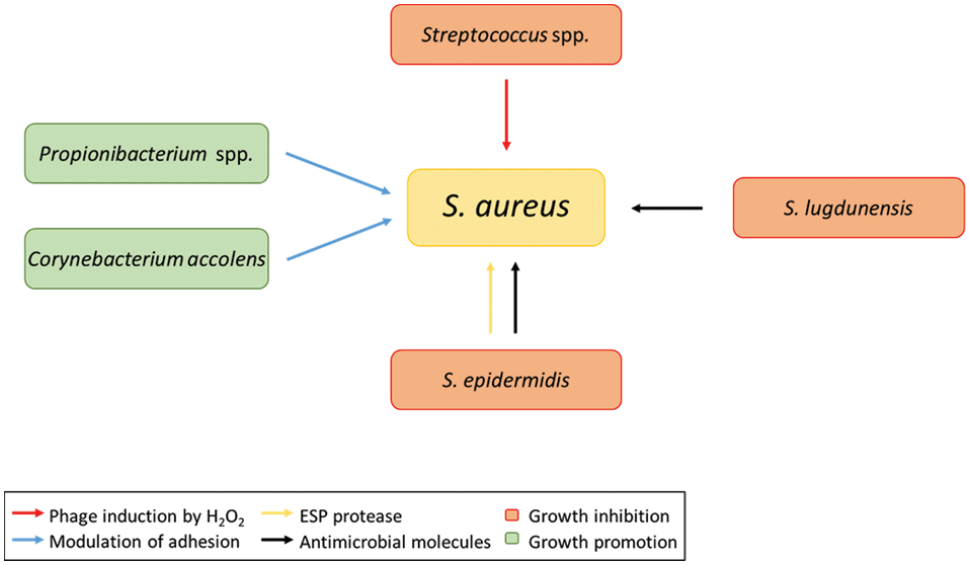

FIGURE 2 Established interactions between nasal bacteria. *C. accolens* and *Propionibacterium* spp. can promote the colonization by *S. aureus* (green boxes) by modulation of its adhesive capacities (20, 85) (blue arrows), while specific clones of *S. epidermidis*, *S. lugdunensis*, and *Streptococcus* spp. can lead to *S. aureus* growth inhibition (orange boxes). Some *S. epidermidis* isolates secrete high levels of extracellular serine protease (Esp), which inhibits *S. aureus* nasal colonization (77) (yellow arrow). In addition, *S. epidermidis* and *S. lugdunensis* can impede *S. aureus* colonization by producing antimicrobial molecules (35, 64) (black arrows). *S. pneumoniae* can release hydrogen peroxide, which leads to prophage activation in *S. aureus* along with phage-mediated lysis of *S. aureus* cells (80, 81) (red arrow).

An ambivalent correlation between *Corynebacterium* spp. and *S. aureus* was reported. While *Corynebacterium accolens* often occurs together with *S. aureus*, *Corynebacterium pseudodiptheriticum* is associated with the absence of *S. aureus*. A mutualistic relationship between *C. accolens* and *S. aureus* might rely on the joint mobilization of nutrients promoting the growth of these strains. In contrast, the competitive interaction between *C. pseudodiptheriticum* and *S. aureus* interferes with *S. aureus* colonization. Thus, the presence of *C. accolens* or *C. pseudodiptheriticum* might become a useful predictor of the propensity for nasal *S. aureus* carriage (20). A bacterial strain replacement study highlighted that nasal inoculation of persistent *S. aureus* carriers with a *Corynebacterium* sp. can lead to complete eradication of the pathogen in more than 70% of the probands (84).

Nostril- and skin-associated *Propionibacterium* spp. release coproporphyrin III, a porphyrin metabolite that promotes the aggregation and nasal colonization of *S. aureus* (85) (Fig. 2). A negative association with *S. aureus* carriage was reported for *Simonsiella* spp., *D. pigrum*, and *F. magna*, which are also regular members of the nasal microbiome (11, 31). The particular sensitivity of *D. pigrum* to a multitude of *Staphylococcus* isolates suggests that *D. pigrum* can only be present when no bacteriocin-producing *Staphylococcus* is in the same habitat (62).

COMPETITION BY INDUCTION OF HOST DEFENSE

In addition to the above-described competition scenarios, the human host can also impact the composition of the nasal microbiome. *S. aureus* expresses surfactant-like phenol-soluble modulin peptides, which mobilize proinflammatory lipoproteins from the staphylococcal cytoplasmic membrane. These lipoproteins activate the Toll-like receptor 2 and, consequently, lead to inflammation (86). The resulting inflammatory response in the nasal epithelium provokes the production of antimicrobial peptides. Although these hardly affect *S. aureus*, with its intrinsic immune evasion factors, they impair growth of other nasal commensal bacteria (5, 87).

CONCLUSION AND OUTLOOK

The mechanisms of microbiome-mediated exclusion of *S. aureus* from the human nose are probably multifactorial. It is likely that in addition to the processes described above, other factors are involved. It will be important to further investigate which other antimicrobial substances are produced by nasal commensals and which other strategies are used in their competition with *S. aureus* for nutrients and adhesion sites. New findings on nasal colonization may clarify why 20% of the human population is permanently colonized by *S. aureus*, while a similar percentage is never colonized. A better understanding could be helpful for developing new *S. aureus* eradication approaches that protect against recurrent *S. aureus* nasal colonization.

Staphylococcus aureus in Animals

ANDREAS F. HAAG, J. ROSS FITZGERALD AND JOSÉ R. PENADÉS

46

INTRODUCTION

The genus *Staphylococcus* currently comprises 81 species and subspecies (https://www.dsmz.de/bacterial-diversity/prokaryotic-nomenclature-up-to-date/prokaryotic-nomenclature-up-to-date.html), and most members of the genus are mammalian commensals or opportunistic pathogens that colonize niches such as skin, nares, and diverse mucosal membranes. Several species are of significant medical or veterinary importance. *Staphylococcus pseudintermedius* (1) is a leading cause of pyoderma in dogs and is considered to be a significant reservoir of antimicrobial resistance factors for the genus (2, 3). *S. pseudintermedius* is very similar to *Staphylococcus intermedius* and can be distinguished from other coagulase-positive staphylococci by positive arginine dihydrolase and acid production from β-gentiobiose and D-mannitol (4) or by using a multiplex-PCR approach targeting the nuclease gene *nuc* (5). *Staphylococcus saprophyticus* is the second leading cause of uncomplicated urinary tract infections (6). While *Staphylococcus epidermidis* is a normal component of the epidermal microbiota, it is a leading cause of biofilm contamination of medical devices (7). The most promiscuous and most significant human pathogenic staphylococcal species is *Staphylococcus aureus*, which is the causal agent of a variety of disease symptoms that can range from cosmetic to lethal manifestations. *S. aureus* is distinguished from most members of the genus by its abundant production of secreted coagulase, an enzyme which converts serum fibrinogen to fibrin and promotes clotting. However, the *S. intermedius* group and some strains of *Staphylococcus lugdunensis* have coagulase activity (5, 8, 9).

Despite the prevalence of literature characterizing staphylococcal pathogenesis in humans, *S. aureus* is a major cause of infection and disease in a plethora of animal hosts, leading to a significant impact on public health and agriculture (10). Infections in animals are deleterious to animal health, and animals can act as a reservoir for staphylococcal transmission to humans. While about 20 to 30% of the human population carries *S. aureus*, the prevalence of *S. aureus* varies from host species to host species, and up to 90% of chickens, 42% of pigs, 29% of sheep, and between 14 and 35% of cows and heifers are carriers (11, 12). The economic importance of various animal species strongly determines the abundance of available literature on the subject, and as such, it is not surprising that *S. aureus* colonization and infection have only been superficially investigated in wild animals. Nevertheless, *S. aureus* has been isolated from a plethora of wildlife sources such as red squirrels (exudative dermatitis) (13), black bears (endocarditis) (14), zebras (cutaneous granuloma) (15), raccoons (botryomycosis) (16), dolphins (pyogenic meningoencephalitis) (17), harbor seals (systemic infections) (18), black rhinoceroses (skin lesion and sepsis) (19), boars (nasal carriage) (20, 21), rhesus macaques (nasal carriage) (22), great apes (nasal carriage and sepsis) (23), chaffinches (healthy carriage) (24), mallards (sepsis) (25), red deer, griffon vultures, and Iberian ibex (carriage) (21).

Animal isolates of *S. aureus* have been reported to exhibit distinct phenotypic properties that vary depending on the host of origin, and six biotypes have been described: human, β-hemolytic human, bovine, caprine, avian-abattoir, and non-host specific. These biotypes have, by and large, withstood the application of sophisticated characterization methods; isolates from different hosts, characterized by multilocus enzyme electrophoresis, cluster together, suggesting host specificity and a limited ability of strains to be transmitted from one host species to another (10). These observations were further corroborated by genotyping methods such as pulsed-field gel electrophoresis, and strains belonging to specific biotypes grouped in the same or closely related pulsotypes (26).

DNA sequence-based approaches such as multilocus-sequence typing (MLST) (27) have been extensively used to analyze population structures. At present, more than 3,300 sequence types isolated from more than 4,700 *S. aureus* samples have been collated in the MLST reference database (http://saureus.mlst.net/). The database contains isolates from a range of species, with human strains predominating by a large margin. Nevertheless, MLST showed that some clonal complexes (CCs) are predominant in, and associated with, specific hosts. In particular, it was shown that animal-associated strains belonged to specific clonal lineages, whereas human strains did not (28, 29). Today we know that 87% of *S. aureus* isolates from colonization and infections in humans represent 11 widely disseminated clonal complexes: CC1, CC5, CC8, CC12, CC15, CC22, CC25, CC30, CC45, CC51, and CC121. Clonal complexes CC8, CC15, CC22, CC30, CC45, CC30, CC45, and the rarer clonal complexes CC80 and CC152 are primarily associated with isolates from humans (30). MLST-based phylogenetic analysis provided the first long-term picture of the evolution of both human and animal strains (31, 32) and indicated that *S. aureus* has coevolved with its human host over a long time and that it had acquired the ability to infect animals on multiple

doi:10.1128/microbiolspec.GPP3-0060-2019

occasions via human-to-animal host jumps. These host jumps eventually led to specific strain lineages spreading and adapting within new animal hosts (32). Animal to human host jumps have also been documented (33) but are less frequent. Additionally, a number of methicillin-resistant *S. aureus* (MRSA) strains with low host specificity attributed to CC130 and CC398 have emerged over the past decades.

The main clonal complexes associated with ruminants are CC97, CC133, CC522, and CC151, while clonal lineage sequence type 385 (ST385) is mainly represented by isolates from poultry (30, 34–38). Comparative analyses of the genomes of methicillin-susceptible *S. aureus* (MSSA) isolates attributed to ST5 from humans and poultry and of MSSA/MRSA of CC398 revealed that the livestock subpopulations of these clonal complexes originated from ancestral populations in humans (39–41). In contrast, human-associated isolates of the ST97 lineage were clearly shown to have originated from ruminants (33). *S. aureus* colonization or infection in companion animals is usually caused by human-related genotypes (42), yet some colonization factors can determine host specificity (38).

S. aureus has colonized diverse animal species following host-switching events and subsequent adaptation through acquisition and/or loss of mobile genetic elements (MGEs) as well as further host-specific mutations, allowing it to expand into new host populations (Fig. 1, Table 1). Close contact between animals and humans can facilitate host-switching events, and there is a significant body of evidence indicating that the beginning of animal domestication in the Neolithic period (10,000 to 2,000 BC), as well as the increased industrialization of livestock farming, provided a platform for animal-to-human transmission of pathogens (43). While host jumps are generally accompanied by the acquisition or loss of larger MGEs, not all host jumps are associated with such large-scale events. Recently, Viana et al. showed that single amino acid substitutions in the *dltB* gene were sufficient to confer infectivity of human ST121 isolates for rabbits (44). Overall, *S. aureus* can readily cross species barriers and infect new hosts. This ability is largely associated with the large proportion of MGEs in the *S. aureus* genome and its capacity to exchange these through contact with its environment. The animal host can provide reservoirs for new virulence traits and antibiotic resistances, and the increased contact between humans and animals through industrialized agriculture coupled with its globalization necessitate tight monitoring of pathogenic animal *S. aureus* strains to understand the development and spread of staphylococcal lineages.

In this article, we will be giving an overview of *S. aureus* in animals, how this bacterial species was, and is, being transferred to new host species, and the key elements thought to be involved in its adaptation to new ecological host niches. We will also highlight animal hosts as a reservoir for the development and transfer of antimicrobial resistance determinants.

S. AUREUS IN RUMINANTS

S. aureus, next to *Escherichia coli* and several streptococcal species such as *Streptococcus uberis*, and *Streptococcus agalactiae*, is a major cause of mastitis in dairy cows and incurs a significant economic loss to the dairy industry. Mastitis in dairy cows results in reduced yields, the need for veterinary intervention, and the loss of milk that has to be discarded due to either pathogen or antibiotic contamination. If treatment of the udder is unsuccessful, the animal is often culled. *S. aureus* is associated with both clinical and, more commonly, subclinical mastitis, both of which frequently result in persistent and recurrent infections with a low cure rate after antibiotic therapy (45). Mastitis leads to the influx of leukocytes into the udder, and various thresholds for leukocyte numbers have been established for categorizing good milk quality. Taking cow milk as an example, milk with more than 200,000 leukocytes per ml is considered to be infected, and in the European Union when more than 400,000 cells per ml are found, the milk is deemed unfit for human consumption. Apart from the considerable economic losses incurred through *S. aureus*-derived mastitis, mammary gland infections pose a considerable public health problem. *S. aureus* can be shed from infected glands, and most staphylococcal isolates from dairy milk possess genes encoding enterotoxins. Thus, contamination of bulk milk can lead to food poisoning from fermented raw milk products (46, 47).

S. aureus can be found in healthy cows (carriers) on the teat skin, nasal cavity, and rectum (11). However, the main reservoirs in a dairy herd are infected udders and teat skin. Infected animals can shed bacteria through their milk, and transmission occurs primarily from udder to udder during milking via contact with contaminated milking machines, farmer's hands, or contaminated bedding (48). Other environmental transmission routes are less frequent; although *S. aureus* can survive in the environment for some time, it requires animal colonization to ensure its survival.

The majority of bovine infections worldwide are caused by a subset of specific, bovine-adapted *S. aureus* strains (28). The substantial genetic variation between different lineages (49, 50) suggests that there might be lineage-specific differences in the molecular mechanisms involved in *S. aureus* pathogenesis.

Animal microbiota provide a reservoir of antibiotic resistance genes that can be acquired from their ecological niches and selected for by the use of antibiotics in agriculture. The ability of some animal-adapted *S. aureus* strains to colonize and infect humans can give rise to the development of new epidemic clones with hitherto uncharacterized virulence capacity (32). This becomes particularly clear in strains of the CC97 lineage, which is one of the major clones associated with bovine mastitis (28). Moreover, an increased number of bovine-to-human transmissions has been reported in recent years (37, 51, 52). A closer analysis revealed that at least two CC97 subclades for human infection had emerged that originated in bovine-to-human host jumps and had thereafter spread through the human population (33). This provided further evidence that animals can provide a reservoir for the development of new *S. aureus* clones that can rapidly spread from animal to human and then through the population. Richardson et al. recently showed, using genomics-based approaches, that cows are a major reservoir for reinfection of humans, and multiple host-switching events, both human-to-cow and cow-to-human, have occurred over the past 3,000 years (43).

Bovine *S. aureus* isolates of the CC8 lineage closely resemble human isolates, and Resch et al. used this observation to further study the genetic basis of host adaptation (53). They compared a total of 14 CC8 isolates from cows with subclinical mastitis, 9 CC8 isolates from colonized or infected human patients, and 9 isolates belonging to typical bovine lineages (CC389, CC71, CC151, CC504, and CC479). They observed that CC8 isolates segregated into a unique group that was separate from typical bovine CCs and that within this group isolates segregated into three subgroups. The main segregating parameter was the content of MGEs within the individual strains, and they showed that strains of the mixed human-bovine isolate clusters contained

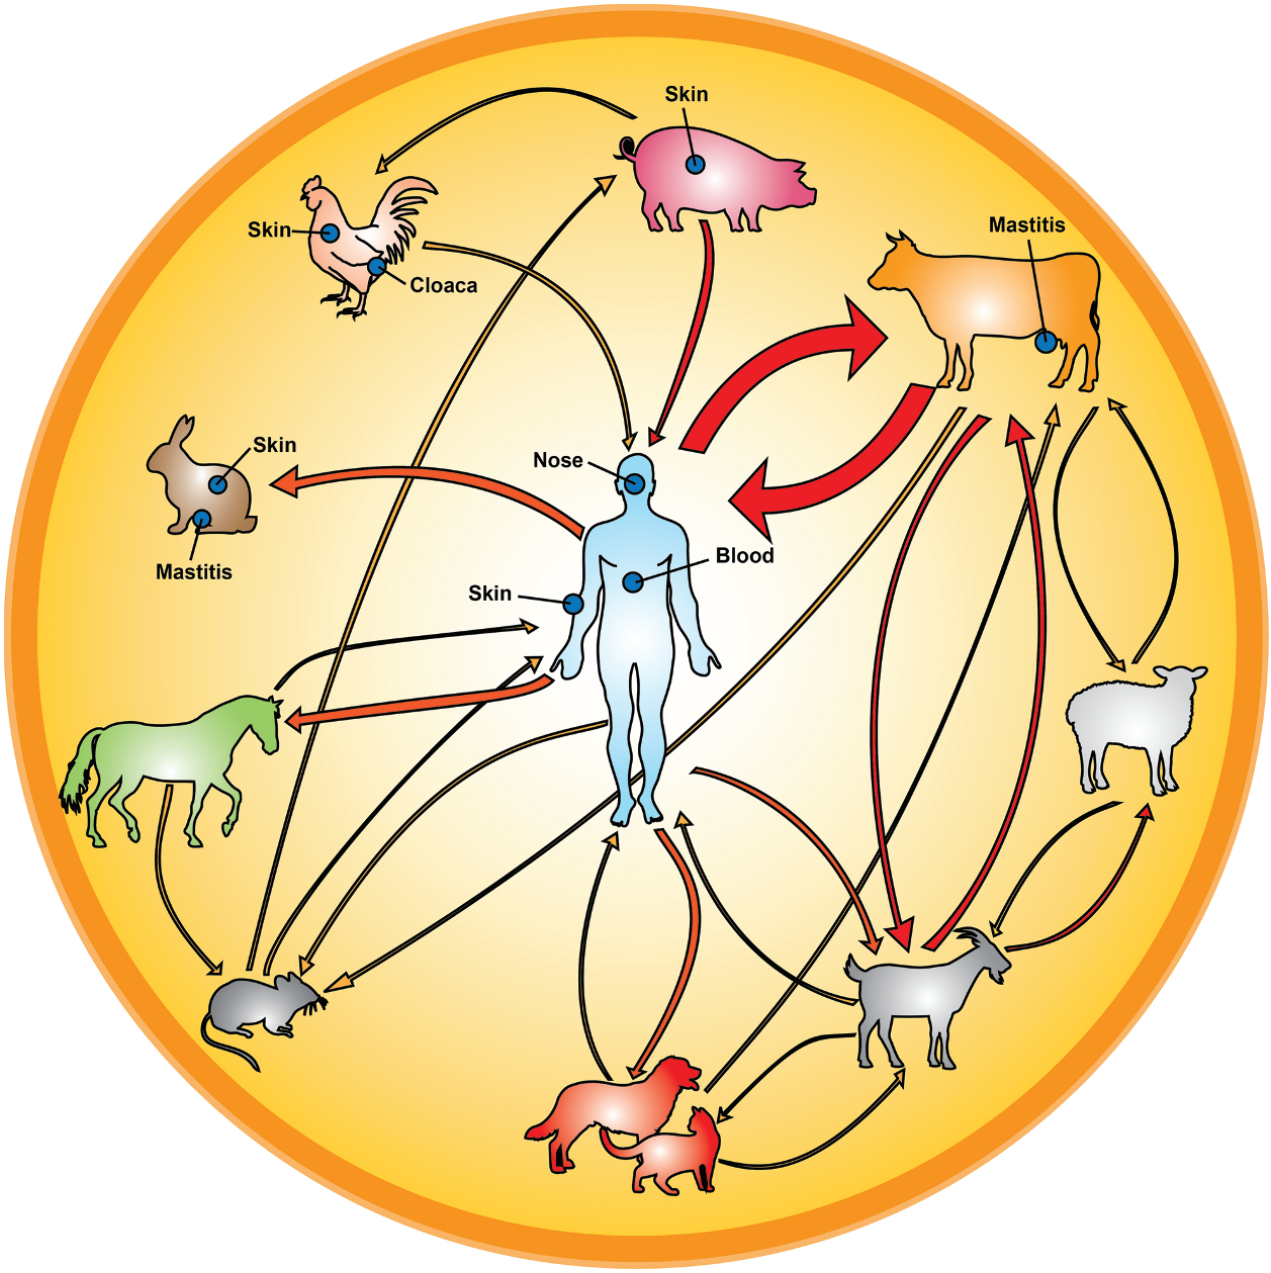

FIGURE 1 Humans act as a major hub for *S. aureus* host jumps. *S. aureus* has been isolated from a plethora of vertebrates and has undergone multiple series of host jumps. A major exchange hub is humans that interact with domesticated livestock and companion animals. Arrow thickness indicates the frequency of host jumps, with colors from yellow to red indicating their likelihood. Figure adapted from reference 43.

β-hemolysin converting prophages. Conversely, the bovine isolates were devoid of this phage and harbored an additional, new non-*mec* staphylococcal cassette chromosome containing an LPXTG-surface protein with similarity to proteins present in environmental bacteria, often found as milk contaminants (53).

Bar-Gal et al. compared pheno- and genotypic characteristics of bovine isolates from Israel, Germany, the United States, and Italy using a Bayesian phylogenetic comparison of several key genes (*nuc*, *coa*, *lukF*, and *clf*A) and *spa* and *agr* typing, followed by CC assignment, and assessed the presence of a broad range of virulence factors and antimicrobial resistance genes (54). This analysis enabled them to cluster different isolates according to their host of origin. Sheep and goat isolates generally showed lower variability and fewer CCs compared to bovine isolates. Within the bovine clade, the authors described two subclades in which isolates matched strains found in Israel or other countries. Their data therefore corroborate other studies suggesting staphylococcal coevolution with its respective host and might indicate the existence of multiple host jumps by bovine *S. aureus* strains that have occurred in diverse geographical locations (54). Overall, the authors found that 27 virulence-associated factors showed a different prevalence in bovine compared to

TABLE 1 Selected staphylococcal elements associated with specific hosts

MGE	MGE-associated determinants putatively involved with virulence/resistance/host specificity[a]	Reference(s)
Human		
ΦSa3 (β-hemolysin converting phage)	*sea*, *sep*, *scn*, *chp*, and *sak* genes encoding staphylococcal enterotoxin A and P, staphylococcal complement inhibitor, chemotaxis inhibitory protein and plasminogen activator staphylokinase, respectively	43
MGE	Type I restriction modification system	43
Ruminant		
SaPIbov	Staphylococcal enterotoxin C (*sec*-bovine) and L (*sel*), toxic shock syndrome toxin *tst* (TSST-1)	171, 172
Enterotoxin gene cluster	Gene cluster encoding 5 enterotoxins (*seg*, *sei*, *sem*, *sen*, *seo*)	171, 173
Not described	Superantigen-like proteins encoded by *ssl07* and *ssl08*	54
SaPIbov4	vWbp with ruminant-specific activity	63
Non-*mec* staphylococcal cassette chromosome	LPXTG-surface protein	53
SCC-*mec*C	*mec*C	79
Equine		
ΦSaeq1	Contains immune modulators with equine-specific activity *scn* gene encoding staphylococcal complement inhibitor	163
	*luk*PQ genes encoding the bipartite leukocidin PQ	162
SaPIeq1	Encodes vWbp able to coagulate equine and ruminant plasma	63
Porcine		
Plasmid	SCC*mec*	43
Plasmid	Resistance to heavy metals	43
SaPI-S0385	Composite of SaPI5 and SaPIbov1 Unique region at 3′ end encoding extracellular proteins with similarity to staphylococcal complement inhibitor and vWbp	146
Avian		
ΦAvβ (β-hemolysin-converting phage)	Putative ornithine cyclodeaminase 38% amino acid identity to ornithine cyclodeaminase made by *Bacillus cereus* HMM match to ornithine cyclodeaminase/mu-crystalin family (PF02423) Putative membrane protease 27% amino acid identity to Plnl (membrane-bound protease of CAAX family) made by *Lactobacillus plantarum*; HMM match to CAAX amino terminal protease family	40
ΦAv1	Ear-like protein *ear* previously identified in pathogenicity islands SaPI1, SaPI3, SaPI5, and SaPImw2 *ear* encodes β-lactamase-like protein	40
SaPIAv	Putative virulence region Novel hypothetical proteins in accessory region A3 where virulence genes such as *tst* and *eta* are located in other SaPIs SAAV_0806: signal peptide, 1 transmembrane helix SAAV_0810: signal peptide, 4 transmembrane helices May suggest role as membrane transporter	40
pAvX	Thiol protease ScpA 99.5% amino acid identity to ScpA (GenBank accession no. AB071596) previously identified among chicken isolates from Japan Suggested role in poultry dermatitis Lysophospholipase 42% amino acid identity to a lysophospholipase encoded by *Bacillus clausii* Bacterial phospholipases are known virulence factors implicated in disease pathogenesis	40

goat and sheep isolates. The authors noted a higher rate of strains carrying capsule type 8 in sheep and goat isolates compared to cow isolates, where both capsule types 5 and 8 were approximately equally distributed. Superantigen genes *ssl07* and *ssl08* were found in almost all bovine strains (>93%) but were present in less than 44% of sheep and goat strains. Strikingly, all bovine strains carried the *hysA2* gene encoding hyaluronate lyase, while only 48% of goat and sheep strains did. Cow strains showed a higher prevalence of leukocidins D and E, while leukocidins F-P83 and LukM appeared to be more prominent in goat and sheep strains (54). As noted above, infection of the mammary glands triggers the influx of large numbers of leukocytes that are deployed to fight off the infection. Leukocidins play an important role in bovine mastitis and can kill immune cells (leukocytes), thus protecting the pathogen (55–59). In agreement with this, the *lukF*/*lukM* genes are associated with the most prevalent CCs found in mastitic cattle (CC151, CC479, CC133, some CC97, and most CC522) (60). Leukocidins show different specificities for immune cells (particularly phagocytic cells) of various hosts through recognition of different host cell receptor alleles, and this can be related to the formation of hybrids among the different LukF and LukS paralogs. The leukocidins LukMF′ and LukPQ are mainly associated with zoonotic disease and found among animal-derived *S. aureus* strains (61). Several additional virulence factors located primarily on MGEs, such as superantigens (62) and ruminant-specific alleles of the von Willebrand factor-binding protein (vWbp) (63), have also been found to be strongly associated with bovine hosts (43).

S. aureus strains in ruminants appear to be undergoing a significant amount of DNA exchange leading to the emergence of hybrid clones. A recent study by Spoor et al. (64) showed that the CC71 lineage of livestock-associated (LA) *S. aureus* strains evolved from an ancestor belonging to the major bovine lineage CC97. The authors showed that multiple large-scale import and recombination events involving other *S. aureus* lineages occupying the same ruminant niche had occurred and that these affected a 329-kb region surrounding the chromosomal origin of replication. These recombination events resulted in allele replacement and either loss or gain of genes influencing host-pathogen interactions. In particular, the CC71 lineage acquired factors involved in innate immune evasion and bovine extracellular matrix adherence. The ability to take up and integrate large DNA segments from environmental staphylococcal strains highlights the pathogen's capacity for rapid evolution and adaptation.

In small ruminants, *S. aureus* is a major cause of mastitis and septicemia, by infections that may have a thromboembolic origin (65). These infections can also be secondary to parasite infestation, which allows *S. aureus* of the normal skin flora to enter the bloodstream (66) and in lambs can lead to fatal toxemia or to chronic disease with organ dissemination and abscess formation. In goats, staphylococcal infection can be secondary to parapox virus infection, leading to chorioptic mange or contagious pustular dermatitis (67). Morel's disease in sheep and goats is caused by a subspecies of *S. aureus*, *S. aureus* subsp. *anaerobius*, which primarily affects young animals. The disease is manifested through the formation of abscesses in superficial lymph nodes usually located in the mandibular region. This disease is thought to be caused by a single bacterial clone worldwide (ST1465), which has undergone long-term adaptation and is restricted to small ruminants (68).

MRSA in animals was first isolated from the milk of dairy cows with mastitis in Belgium in the early 1970s (69) and has since then been isolated from cows around the globe (70–76). MRSA strains harbor an MGE known as SCC*mec*, containing the *mec* gene, which codes for an additional penicillin binding protein that has low affinity for β-lactam antibiotics and therefore mediates resistance to nearly all compounds of this antibiotic class (besides ceftobiprole and ceftarolin). The mainly pig-related LA-MRSA CC398 has also been isolated from bovine udder infections (77), altogether in line with the elevated host promiscuity of this CC. Several cattle-associated MRSA lineages (ST130, ST425, and ST1943) that had previously been thought to be bovine-restricted have been recently isolated from human disease or carriage in Europe (78). Moreover, a newly identified *mec* determinant, named *mec*C (also known as $mecA_{LGA251}$), which shares 70% homology with *mec*A, was identified among MRSA strains of CC130, CC705, and ST425 recovered from cattle and humans (79). The *mec*C allele is associated with a unique SCC*mec* element designated SCC*mecXI* and is thought to be present in about 1.4% of bovine *S. aureus* isolates in as many as 2.8% of herds.

A recent study investigated the molecular profile of *S. aureus* strains isolated from bovine mastitis in the Shanghai and Zhejiang areas of China (80). The study identified a total of 19 sequence types, with the dominant ones being ST97, ST520, ST188, ST398, ST7, and ST9. The majority of isolates were found to be methicillin-sensitive (198/212), with ST97 being the predominant lineage among MSSA strains and ST9-MRSA-SCC*mecXII* the most common MRSA clone. The study revealed that the molecular virulence profiles of different lineages differed significantly. The predominant lineage causing bovine mastitis in eastern China was the MSSA ST97, but there was some indication that toxigenic MRSA ST9 lineages were also present, and it was suggested that their spread and distribution should be monitored in the future. ST9-MRSA strains containing the SCC*mecXII*

cassette have also been identified in nasal swabs from live pigs in China (80–82), and in isolates from humans in Taiwan (83). These strains were shown to have a specific MGE profile encoding vWbp on an SaPIbov4-like pathogenicity island (83). vWbps are responsible for the activation of host prothrombin and the formation of fibrin strands, thereby promoting the development of infectious lesions. SaPI-borne vWbps are distinct from their genomic homologs and have been shown to be responsible for the coagulation of ruminant plasma (63) and may therefore have an important role in the animal host specificity of *S. aureus*. The vWbp variants encoded by the SaPIbov4-like pathogenicity island shared only between 67 and 93% protein sequence identity with the previously characterized SaPI-vWbp (63). Nevertheless, they were able to coagulate bovine and caprine plasma. However, the ability of these vWbps to coagulate human plasma was not assessed in the study (83).

In a study investigating the prevalence of MRSA strains in contaminated milk and dairy products in southern Italy, 8.3% of all isolates (40/484) were methicillin resistant. Of these MRSA strains, the most prevalent sequence types in this study were ST152 (67.5%) followed by ST398 (25%), ST1 (5%), and ST5 (2.5%) (84). Additionally, 92.5% (37/40) and 5% of isolates harbored SCC*mec* type V and Iva, respectively, while 2.5% of isolates (1/40) harbored a not-further-defined methicillin resistance determinant.

MRSA of CC130, which has recently gained attention, carries *mec*C instead of *mec*A and is primarily associated with ruminants and wildlife that share the same habitats, suggesting that there might be mutual exchange of strains (85). The *mec*C gene is also found in the dairy-associated lineage ST425, which causes mastitis in cows. Both CC130 and ST425 isolates have been isolated from human infections (79, 86, 87).

S. AUREUS IN RABBITS

Staphylococcal infection causes substantial economic losses in commercial cuniculture, and clinical signs of *S. aureus* infection are present in more than 60% of rabbitries (88, 89). Infection of rabbits with *S. aureus* is associated with suppurative dermatitis, abscesses, pododermatitis, and mastitis (90–93), with chronic mastitis being the main reason for culling diseased animals in rabbitries (88, 91). Most chronic staphylococcal infections in rabbits are caused by the ST121 lineage; less common lineages, such as ST96, can also be involved (94, 95). Infection of mammary glands with ST121 strains resulted in elevated levels of granulocytes and reduced numbers of B cells, T cells, $CD4^+$ T cells, and $CD8^+$ T cells compared to mammary glands infected with ST96 strains (96). The authors of the study suggested that this observation might be explained by strain-specific differences in host interactions leading to altered perception by the host's immune system. However, further studies will be required to verify this hypothesis.

Among *S. aureus* strains isolated in rabbitries, two main strain types were initially classified, according to their virulence, into high-virulence strains with the capacity to rapidly spread through entire flocks and low-virulence strains that cause more limited infections (97). In accordance with this, high- and low-virulence strains can induce either severe or mild symptoms, respectively, in a rabbit skin infection model, indicating the presence of either different virulence factors or differences in virulence factor expression levels (98). Interestingly, most low-virulence strains could be grouped into poultry or human biotypes, whereas high-virulence strains were members of a mixed biotype that produced β-hemolysin and showed no staphylokinase activity (99). Classical high-virulence strains belong to the biotype "mixed CV-C" and are sensitive to phages 3A/3C/55/71 of phage group II, suggesting a clonal origin of these high-virulence strains (100). Subsequent molecular typing studies found that the majority of high-virulence strains belonged to ST121 and to a lesser extent to ST425 with *agr* types 4 and 2, respectively (95).

Viana et al. analyzed a total of 178 strains from chronic mastitis in rabbits that presented with a range of disease manifestations including abscesses, suppurative mastitis with a lobular pattern, cellulitis, and mixed lesions. The majority of isolates belonged to the high-virulence ST121 (166/178), with sequence types 398, 96, 45, 1, DVL879, and SLV9 (7, 1, 1, 2, 1, respectively) comprising the rest. However, disease symptoms could not be correlated to any specific genotype or sequence type (94). Rabbit isolates are significantly different from those found in humans and ruminants, suggesting the presence of host-specific factors selective for rabbit-specific sequence types (93). The phylogenetic origin of the ST121 lineage was eventually traced back to a human-to-rabbit host jump approximately 40 years ago (44). Comparative analysis of the accessory genomes of ST121 strains showed that the majority of human strains contained MGEs which encode potent toxins involved in human disease pathogenesis, such as Panton-Valentine leukocidin and exfoliative toxins, and all except one contained a β-hemolysin-converting phage (Φ*Sa*3) encoding the human-specific immune evasion cluster. None of the rabbit strains contained Panton-Valentine leukocidin- or exfoliative toxin-encoding MGEs, indicating that these were dispensable for *S. aureus* infection of rabbits (44). Interestingly, the rabbit strains did not contain any MGEs that were unique to rabbit *S. aureus*, indicating that the acquisition of rabbit-specific MGEs was not required to cause infection. Instead, the authors found that single nonsynonymous mutations at the 5′ end of the *dltB* gene were sufficient to confer rabbit infectivity in human ST121 strains. DltB is an integral membrane protein encoded by the *dltABCD* operon that is likely responsible for the translocation and incorporation of D-alanine into teichoic acids and lipoteichoic acids in *S. aureus* (101). However, Viana et al. (44) showed that neither the D-alanine nor the bacterial cell wall composition was altered in in strains harboring the rabbit-infective *dltB* mutants. This suggests an additional function for DltB during rabbit infections, and the authors propose that DltB, a member of the membrane-bound O-acetyltransferases that transfer organic acids, typically fatty acids, to hydroxyl groups, has a role in signaling that could be responsible (44). Rabbit-associated *S. aureus* strains therefore appear to be representatives of infective strains that require little adaptation to jump between humans and rabbits, and further studies will be required to determine how these relatively recent epidemic strains have evolved.

Rabbitries endeavor to prevent *S. aureus* infection by limiting the introduction of new animals and by reducing contact between rabbit flocks. Unfortunately, antibiotic treatments, disinfection of cages and environments, and vaccinations have so far proved inefficient in eliminating *S. aureus* infections in rabbitries (97). Consequently, culling of entire flocks followed by thorough disinfection of the cages is the only efficient strategy for dealing with *S. aureus* epidemics in cuniculture.

S. AUREUS IN CHICKENS AND OTHER POULTRY

The growth of commercial poultry farming has provided a fertile field for staphylococcal infections and zoonotic

transfer (102). *S. aureus* is among the leading causes of bacterial infections in poultry (10), causing a wide range of diseases including septic arthritis, subdermal abscesses, gangrenous dermatitis, and septicemia (103). As with other hosts, staphylococcal strains associated with poultry cluster into specific clonal complexes that appear to have either evolved together with their avian host or adapted after zoonotic transmission. For example, CC385 has so far been identified only among avian hosts, whereas strains of CC5 and CC398 have been isolated from chickens, humans, and other mammals (39, 104, 105). One of the predominant staphylococcal lineages causing disease in the poultry industry is CC5 (40, 103). Dissemination of CC5 into chickens involved a single transmission from a human approximately 40 years ago (40) followed by a significant number of genetic recombination events leading to host adaptation. At least 44 recombination events in 33 genes have accumulated in poultry isolates, and another 47 genes were found to be more frequent in poultry compared to human isolates. Interestingly, many of these genes were common among chicken isolates from other CCs, indicating that horizontal transfer of these genes between CCs may have a potential role in host adaptation (102). On a phenotypic level, these genetic alterations contribute to *S. aureus* adaptation to poultry hosts, and poultry isolates show enhanced growth at 42°C (the core body temperature of the adult chicken [106]) and greater erythrocyte lysis on chicken blood agar for chicken compared to human isolates (102). Conversely, most human isolates but only around half of the chicken isolates were able to lyse human erythrocytes (102). The improved growth of chicken isolates at 42°C is thought to be related to two poultry-associated genes (SAAV_0062 and SAAV_0064) that share more than 85% nucleotide identity with genes important for growth at elevated temperatures, including *dnaK* and *dnaE* (102).

Furthermore, the host jump from humans to poultry was also accompanied by genetic changes such as the loss of several genes involved in human disease pathogenesis and the acquisition of avian-specific MGEs (40). For example, the poultry strain ED98 had acquired two prophages, two plasmids, and a SaPI, and these MGEs are widely distributed among avian but completely absent from human strains (40). A similar observation has been made with bovine-adapted strains (107).

Plasmids can confer virulence traits and antibiotic resistances (pT181, pT127, pC194, pC221, pC223, and pUB112) (108) and can contribute to the spread of disease. Such plasmids are present in *S. aureus* isolates causing a variety of difficult to treat chicken diseases (102, 103, 109). A recent study focused on identifying bottlenecking and drift-related genetic changes, and on separating them from genetic changes conferring advantages in the poultry niche, and on showing adaptation to the avian host over time (102). By sampling a total of 191 isolates from diseased chickens from the United Kingdom, United States, and the Netherlands, they confirmed that the major staphylococcal lineage in these infections was CC5 and that human and chicken isolates within CC5 clustered in distinct subgroups (102). They further identified an increased recombination frequency within the CC5 poultry isolate relative to human isolate genomes and a tight clustering of chicken isolates once recombination events were compensated for. Changes in chicken-derived genomes localized within 33 genes and consisted of 196 substitution and 44 recombination sites. Forty-seven genes were more frequently present in CC5 chicken isolates compared to human isolates, with 38 of these being shared among CC5 and CC1 and 41 genes shared between CC5 and CC398 poultry isolates. All 47 poultry-associated genes were present in strains of the CC385 lineage. Recombination regions in poultry isolates were associated with both the core genome and plasmids, and many clustered within three distinct genomic regions comprising genes with putative roles in heat shock response, hemolysis, adhesion, mobile elements, and transposons. Furthermore, a total of 58 poultry-associated genes and genetic elements were predicted to be involved in the transfer of MGEs containing genes with predicated function as transposases, in conjugation as well as pathogenicity islands and two hotspot regions containing phage-related elements (102).

Several genes that have so far been found only in poultry isolates are implicated in increased pathogenicity in chickens (41, 110). These include *scpB*, encoding a putative cysteine protease (staphostatin A) (40, 111), which is found on an avian disease-associated plasmid (pAvX) in CC5 and CC385 strains (112). The CC385 lineage has been isolated from various wild and reared birds, suggesting that it has had long-term avian host restriction (40, 43).

MULTIHOST CC398: A MELTING POT AND RESERVOIR FOR VIRULENCE AND RESISTANCE DEVELOPMENT

MRSA strains of the CC398 complex have been studied in detail. This lineage is likely derived from a human MSSA clone that successfully jumped into pigs, where it acquired methicillin resistance and changes to its accessory genome (39). Despite these changes, it has retained the ability to infect humans, and it has been found in other animals, suggesting that CC398 strains are more promiscuous infecting agents than other CCs (43). CC398 is the main lineage of LA-MRSA strains in Europe, whereas other lineages have been isolated frequently in other geographical areas (113–115). CC9 LA-MRSA isolates are predominantly isolated in Asia, whereas CC398 and CC5 are relatively common in North America (116). Methicillin resistance is conferred by the acquisition of SCC*mec* elements that contain various *mec* genes. Presently, at least 13 structural types of SCC*mec* are known (30, 79–83).

The proportion of *S. aureus* infections caused by MRSA increased significantly from the end of the 1980s until 2000 worldwide (30). MRSA infections of humans could be initially grouped into either health care-associated (HA) or community-associated (CA) MRSA based on epidemiological criteria (117). HA-MRSA and CA-MRSA strains can be differentiated by their structural and functional genomic traits (118). However, these epidemiological criteria have become increasingly blurred because HA-MRSA strains have been found within the community and CA-MRSA strains were identified as the causative agents in the hospital setting (119, 120). In addition to these two categories of MRSA, animals can act as a reservoir for the development and transmission of so-called LA-MRSA strains that have been found to cause infections within the human community. All three MRSA types differ from each other in their genotypes and associated genotypic traits, allowing for a clear segregation into specific lineages associated with specific origins of the pathogen.

In pigs, *S. aureus* usually does not cause much disease; skin infections in pigs are typically caused by *Staphylococcus hyicus* and have only been occasionally documented to be caused by *S. aureus* (67, 121, 122). Consequently, *S. aureus* had not been monitored extensively in pigs. However, it has recently been realized that pigs represent a major reservoir for MRSA, after all.

CC398-MRSA and CC398-MSSA staphylococcal strains were first identified among pig farmers in France (122, 123). While CC398 MRSA strains rapidly spread among pigs and other livestock, they are considered to spread only infrequently beyond animals and personnel in direct contact with infected animals (124–126). Most LA-CC398 strains are resistant to β-lactams, macrolides, lincosamides, streptogramins, tetracyclines, and in part to fluoroquinolones as well as to cotrimoxazole. They are susceptible to glycopeptides, daptomycin, tigecycline, rifampicin, fusidic acid, fosfomycin, and with few exceptions also to linezolid (30). Initial studies suggested a possible human origin for LA-CC398 that was transferred to pigs and subsequently acquired methicillin resistance driven by the pressure of antibiotics in animal feed (39). However, a more recent analysis indicated that both human MSSA and LA-CC398 emerged in parallel around 1970 (127).

The CC398 lineage is the most commonly detected MRSA lineage among European livestock and thus was given the name LA-MRSA, with *spa* types t011, t034, and t108 being the most prevalent among the LA-MRSA CC398 strains (128, 129). CC398 MRSA strains are nontypable by *Sma*I pulsed-field gel electrophoresis (130), comprise only a small set of *spa*-types, and harbor a novel *Sau1-hsdS1* type 1 restriction-modification system (131). LA-MRSA isolates typically carry SCC*mec* type IVa or V, which are different from those carried by other MRSA genotypes commonly found in community and health care settings (132). They often exhibit coresistance to many non-β-lactam antimicrobials (e.g., macrolide [70%], trimethoprim [65%], gentamicin [14%], ciprofloxacin [8%], and trimethoprim-sulfamethoxazole [4%]), including those commonly used in animal production (133). The majority of CC398 LA-MRSA isolates do not produce toxins such as Panton-Valentine leukocidin or enterotoxins (134). Following the reduction in cost of next-generation sequencing approaches, further characterization of *S. aureus* CC398 isolates has been possible through the increased availability of whole-genome sequencing data for this CC, allowing more detailed insight into CC398's host adaptation (see sections below).

There is frequent transmission of CC398 LA-MRSA between livestock and farmers (135–139) and, until recently, strains of this lineage were rarely found outside this group (125). However, a rising number of cases of MRSA CC398 have recently been observed in humans within the health care environment (140). These findings show a strong epidemiological link with livestock contact (124). The origin of LA-CC398-MRSA is believed to be a human MSSA strain harboring the Φ*Sa*3 phage. This phage carries a so-called immune evasion cluster that encodes many human-specific immunomodulatory factors, including the *sea*, *sep*, *scn*, *chp*, and *sak* genes (encoding staphylococcal enterotoxin A and P, staphylococcal complement inhibitor, chemotaxis inhibitory protein, and plasminogen activator staphylokinase, respectively) and integrates within the *hlb* gene (141). The *hlb* gene encodes a sphingomyelinase known as β-toxin or β-hemolysin, which can lyse sheep erythrocytes. The factors encoded in the Φ*Sa*3 phage specifically interfere with the human immune response (142, 143), and about 90% of clinical human-derived isolates contain the Φ*Sa*3 phage within their genome (141). Given that the immunomodulatory factors encoded in Φ*Sa*3 specifically target human immune factors, it is not surprising that the Φ*Sa*3 phage is missing from the genomes of CC398 lineages adapted to livestock (30, 39). In general, porcine LA-MRSA CC398 lacks the Φ*Sa*3 phage and is *mec*A positive, while human-specific CC398 is *mec*A negative and Φ*Sa*3 positive (144, 145).

Studies indicate that the adaptation of CC398 to its host is connected to the loss and/or acquisition of MGEs, including Φ*Sa*3, since the major changes that were revealed in these studies occurred within the CC398 accessory genome (134, 146). In particular, a new staphylococcal pathogenicity island (SaPI-S0385) was identified in strain S0385 that appears to be a composite of the 5′ sequence of SaPIbov1 (up to and including the excisionase gene) and SaPI5 (packaging module) and contains a unique region at its 3′ end encoding two putative extracellular proteins with similarity to staphylococcal complement inhibitor and vWbp, respectively. Both proteins also have a conserved homologue in the core genome of S0385, but no studies have been performed to determine whether these conferred advantages to *S. aureus* within the porcine host (146).

In parallel, animal-independent human colonization and infection by CC398 MSSA strains has occurred and spread worldwide with a particularly high incidence rate in China, where this clone accounts for almost 20% of skin and soft tissue infections (147).

While CC398 has spread successfully among pigs in Europe, CC9 is the most commonly isolated lineage in farmed pigs in South-East Asia (82). Strains belonging to this CC are genetically distinct from strains of the CC398 lineage, and their genome is consistent with an independent zoonotic event leading to its emergence. CC9 MSSA strains colonize humans, and transmission between humans and pigs has been reported in the United Kingdom (122). The characterized CC9 isolates were deficient in the type IV restriction modification system, which poses a major restriction barrier for the acquisition of foreign DNA. Loss of the type IV restriction modification system has been observed in *S. aureus* strains prone to acquire the *van*A gene from enterococci conferring vancomycin resistance (148). Furthermore, two novel transposon-like elements containing genes with a high degree of similarity to genes from coagulase-negative staphylococci or enterococci have been identified in CC9 strains but so far have not been found in *S. aureus* strains belonging to other lineages (82). Overall, these observations might suggest that the newly emerged LA-CC9 strains could have an enhanced capacity for the uptake of foreign DNA. However, experimental verification remains to be provided. In line with this observation, the analyzed CC9 strains contained SCC*mec* type XII cassettes with a class C2 *mec* and *ccr*C gene complex (82). Such CC9 strains have also been isolated from cattle in China (81). The genes encoded by the SCC*mec* type XII elements are similar to genes found in coagulase-negative staphylococci, which could represent a potential source of this element. The CC9 MRSA strains thus represent a significant threat to humans as well as livestock, owing to their apparent ability to acquire novel genetic elements and their propensity for interspecies transmission.

MRSA IN COMPANION ANIMALS: CATS, DOGS, AND HORSES

Generally, MRSA strains of companion animals differ from those in livestock and meat production animals. *S. aureus* strains isolated from companion animals are mainly of human origin and are passed between human owners and their animals (38, 149–151). Dogs and cats are not typically colonized by *S. aureus* but, rather, form transient associations that can on occasion lead to severe infections (38, 152). MRSA infections in companion animals are predominantly skin and soft tissue infections; previous antibiotic treatments of human owners, the number of antimicrobial courses, the number of hospitalization days, implant devices, surgical

interventions, and contact with humans who have been previously hospitalized are major risk factors to these animals (153, 154). Overall, these risk factors are similar to those defining HA-MRSA infections in humans (155).

S. aureus MRSA strains isolated from horses and from humans in close contact with horses differ from those spread throughout the human population. A CA-MRSA clone (CC8) was isolated from horses in Canada and was well adapted to the animal host (156). In Europe, CC398 MRSA strains have also been isolated from horses, and horse-to-human transmission has been shown (157, 158). MRSA was first reported in horses in 1999 during a 13-month outbreak in a veterinary teaching hospital in Michigan. These were horses that had undergone surgical procedures and were subsequently infected with MRSA that appeared to have originated from colonized surgical staff (159). MRSA has since then been detected among horses in Europe, the United States, and Asia (160). Consistent with the risk factors, disease presentation in horses mirrors that observed in humans in the clinic. Skin and soft tissue MRSA infections, bacteremia, septic arthritis, osteomyelitis, implant-related infections, metritis, omphalitis, catheter-related infections, and pneumonia have all been reported in horses (160). MRSA infections in horses have been linked to strains carried by clinical personnel (CC1, CC254, and CC398), and nasal colonization of veterinarians, veterinary personnel, and students were also observed, indicating transmission to or from humans (161).

The main CC isolated from horses is CC8, and equine isolates are distinct from human strains of the general population but not from strains isolated from close-contact personnel. A recent study has shown that equine CC8 isolates acquired a phage encoding a novel equine allele of the staphylococcal inhibitor of complement (*scn*) as well as an equine-specific form of the bi-component leukocidins, LukPQ (43, 162, 163). Acquisition of antibiotic resistance determinants influences the clustering of equine and pig isolates, suggesting a role for the acquisition of resistance in host adaptation (43). Adaptation to horses also involves the acquisition of SaPI-encoded paralogues of the vWbp able to coagulate equine plasma (63). Since phages are required for the activation of SaPIs (164), it will be interesting to see whether the newly identified horse-specific phage is also able to activate and transfer this horse-specific SaPI.

MONKEYS IN SUB-SAHARAN AFRICA

Studies of species to species transmission of *S. aureus* have largely focused on LA transmission, yet nonhuman primates are readily colonized by *S. aureus* in captivity and in the wild (165). In a recent study, Senghore and colleagues investigated the transmission of *S. aureus* from humans to green monkeys in The Gambia (166). The study revealed multiple anthroponotic transmissions of *S. aureus* from humans to green monkeys and the emergence of a monkey-associated clade of *S. aureus* approximately 2,700 years ago. Development of this monkey-associated clade was accompanied by the loss of the Φ*Sa3* phage carrying genes known to play important roles in human colonization. More recent anthroponotic transmissions included well-characterized human lineages and are thought to be the result of human encroachment on monkey habitats. However, the authors did not observe any monkey to human transmission (166). Nonhuman primates (and bats) in sub-Saharan Africa are colonized by the related but distinct staphylococcal species *Staphylococcus argentus* and *Staphylococcus schweitzeri*. While *S. schweitzeri* was isolated from monkeys from all study sites, no transmission of these strains to humans was observed. In contrast, human-associated *S. aureus* sequence types (ST1, ST6, ST15) were detected in domestic animals and nonhuman primates, indicating a human-to-monkey transmission in the wild (165).

S. AUREUS HOST SWITCHING AND THE ROLE OF MGES

A recent study by Richardson et al. used a population-genomic approach to better characterize how *S. aureus* adapts to multiple different hosts and causes colonization and disease (43). The study found that humans act as a major hub for the pathogen for both ancient and recent host-switching events leading to the emergence of endemic livestock strains. Cows were shown to be the most frequent recipient of *S. aureus* host jumps but also appeared to be the main animal reservoir for reinfection of humans and the emergence of animal-derived human epidemic clones (33, 43). The study identified 14 host jumps from humans to cows (median number of host jumps per tree as distributions from all subsamples and trees in the study) dating back as early as 2000 BC to as recently as 2012 AD. Cows were also shown to act as a source of *S. aureus* for small ruminants such as goats and sheep. A pan-genome-wide association analysis identified host-specific accessory gene pools specific for birds, pigs, and horses. Accessory genomes from human, cow, sheep, and goat strains also clustered in a host-specific manner but exhibited greater diversity in gene content. The authors suggested that these differences might have been caused either by a range of cryptic host niches occupied by the pathogen or because the time elapsed since the host-switching event had been too short to allow sufficient diversification to result in the clear separation of human and ruminant accessory genome clusters. Alternatively, specific gene sets or combinations of gene sets might confer a more generalist host tropism. However, it was noted that clustering in equine and pig isolates was influenced by the acquisition of host-specific antimicrobial resistance determinants. Host-switching events were shown to be correlated with the acquisition via horizontal gene transfer of host-niche-specific genetic elements that confer selective advantages to the pathogen for survival within the new host. The study identified a total of 36 distinct MGEs (including predicted plasmids, transposons, *S. aureus* pathogenicity islands, and prophages). For instance, the β-hemolysin-converting phage Φ*Sa3*, which encodes modulators of the human innate immune response, was primarily associated with human strains, whereas several pathogenicity islands contain ruminant-specific superantigens or vWbps where associated with ruminants (62, 63). Conversely, equine isolates were shown to contain a prophage, integrated in the lipase precursor gene (*geh*), encoding equine-specific alleles of the staphylococcal inhibitor of complement (*scn*) and a bi-component leukocidin LukPQ (Table 1) (162, 163). The study also identified numerous previously uncharacterized MGEs. A novel plasmid SCC*mec* element encoding resistance to heavy metal ions (a common pig-feed supplement) was linked to human-to-porcine host-switching events. Furthermore, *S. aureus* isolates from animals acquired several gene clusters encoding bacteriocins that would enable them to compete with the resident bacterial flora. Interestingly, the MGEs in *S. aureus* pig isolates showed an increased guanine-cytosine content and reduced codon-adaptation index that indicated a distinct genealogical origin for these MGEs which may be related to pathogenicity islands identified in the pig-associated zoonotic pathogen *Streptococcus suis* (43). Host-switching events are therefore accompanied by the rapid

acquisition of MGEs that confer the capacity for survival within a new host niche, mainly by targeting the host's innate immune response. Acquisition of resistance to antimicrobials and heavy metals allows the pathogen to survive under high selective pressures; subsequent positive selection via point mutations or recombination (102) acts on the core genome to modify metabolic pathways and to further adapt *S. aureus* to its new host.

S. aureus host adaptation was found to coincide, depending on the host, with both gain and loss of gene function. While avian strains contained a higher proportion of functional genes compared to strains from other host species, ruminant strains showed an increase in pseudogenes. Many of these pseudogenes in ruminants were found to be associated with nutrient transport, including carbohydrates, and could indicate metabolic remodeling in response to distinct nutrient availability. *S. aureus* was shown to further adapt to its host niche in response to the availability of distinct nutrients. The authors showed that strains isolated from dairy cattle exhibited an enhanced ability to utilize lactose as a carbon source, supporting the concept that *S. aureus* undergoes genetic diversification in response to the nutrients that differ in availability in different niches (43).

The study also revealed that staphylococcal antibiotic and heavy metal resistance genes are unevenly distributed among isolates from different animal hosts and showed a clear correlation to antibiotic usage practices within medicine and agriculture. For example, human, pig, and ruminant isolates harbored a collection of key resistance determinants that were absent in avian isolates, in line with antimicrobial usage practices (43).

The acquisition of specific MGEs and core genome mutations plays a crucial role in *S. aureus* host adaptation (40, 44, 63). For instance, the presence/acquisition of MGEs not found in human strains could be clearly associated with host jumps from humans to avian and porcine hosts (39, 40, 43). Host-specific functional effectors of *S. aureus* pathogenicity such as leukocidins, superantigens, and vWbps are frequently located on MGEs (61, 162, 163, 167–170).

CONCLUSIONS

In the past decades an increasing number of studies have demonstrated that *S. aureus* is able to colonize and infect a plethora of different hosts. While *S. aureus* can cause severe infections in some animals, others show less severe symptoms and are mainly colonized, acting as a staphylococcal reservoir for human reinfection. This is particularly true for *S. aureus* lineages found in pigs and dairy cows. Due to the use of specific antibiotics and growth-enhancing supplements, these strains have acquired mechanisms of resistance to these agents from various environmental sources. Current farming practices make farm animals ideal breeding grounds for the development and/or acquisition of new resistance mechanisms that can spread into the community and pose a significant risk to the human population. There is an ever-increasing amount of data detailing host-switching events for *S. aureus*, with humans acting as the major exchange hub for strain lineages. These data highlight the ability of *S. aureus* to function as a multihost pathogen and to evolve and adapt to new hosts. The ability of *S. aureus* to readily adapt to new environments and rapidly take up new genetic material via horizontal gene transfer makes the bacterium a most versatile colonizer that is able to spread into new niches. Moreover, it can also rapidly adapt to new stresses and antibiotics with the result of an ever-continuing arms race between *S. aureus* and humankind.

Antibiotic Resistance and the MRSA Problem

MARTIN VESTERGAARD, DORTE FREES AND HANNE INGMER

47

INTRODUCTION

Staphylococcus aureus gives rise to a variety of infections, and treatment of these relies on antibiotics. A number of antibiotics are used to treat staphylococcal infections (Table 1), and they target major bacterial processes including cell wall synthesis, translation, transcription, and DNA synthesis. However, resistance to antibiotics is a growing problem, and treatment failures are associated with enormous human and medical costs. Antibiotic resistance arises by several different mechanisms, such as altered drug targets, enzymatic drug inactivation, increased efflux of antimicrobial compounds, and altered drug accessibility (1), and the spread of resistance is aided by a multitude of mobile genetic elements (reviewed in 2–4). Although resistance has been observed for essentially all compounds, individual strains resistant to all drugs have not appeared. Yet resistance still poses treatment challenges, as exemplified by vancomycin. Fully resistant strains of which are rare, but the more common intermediately resistant (VISA) strains are associated with more severe infections and longer duration of treatment compared to susceptible strains despite the fact that they only display a minor increase in the MIC of vancomycin. This highlights the problem that we only have limited knowledge of how resistance genes and mutations affect the overall biology of resistant strains and of the impact of resistance on pathogenesis. In this article, we focus on the biology of antibiotic resistance in *S. aureus* and on the behavior of resistant strains, and we conclude with a description of some of the new therapeutic approaches that in the future may become treatment options for infections with antibiotic-resistant staphylococci.

CELL ENVELOPE ACTIVE AGENTS

Beta-Lactam Antibiotics

History and mode of action

Alexander Fleming's observation that the growth of *S. aureus* can be inhibited by a contaminating mold led to the groundbreaking discovery of penicillin and initiated the antibiotic era. In the past 75 years beta-lactams have been the most important class of antibiotics for the treatment of *S. aureus* infections. However, even before penicillin was marketed, some *S. aureus* strains were in possession of a powerful resistance mechanism in the form of beta-lactamases. Carried by plasmids (5), the beta-lactamase gene spread rapidly and soon obviated penicillin as the first line of treatment for *S. aureus* infections. As a consequence, in the following years, several hundred antibiotics of four structural subclasses, penicillins, cephalosporins, monobactams, and the more powerful carbapenems, were developed and marketed. The ability of *S. aureus* to become resistant to almost all of these through the acquisition of a single genetic element, the staphylococcal cassette chromosome *mec* (SCC*mec*), giving rise to the notorious methicillin-resistant *S. aureus* (MRSA) strains, is beyond doubt the major resistance concern. The amount of scientific literature covering the epidemiology of MRSA and beta-lactam resistance mechanisms is overwhelming. Nonetheless, important knowledge gaps still exist, as will be highlighted below.

All beta-lactam antibiotics possess the defining four-membered beta-lactam ring that is essential for the biological activity of these compounds. Early work on the mechanism of action of penicillin culminated in the discovery that penicillin inhibits cross-linking of peptidoglycan, the central component of bacterial cell walls (6). In Gram-positive bacteria, the cell wall is composed of glycan chains of *N*-acetylglucosamine and *N*-acetylmuramic acid that are heavily cross-linked by pentapeptides (UDP-MurNAc-penta). Each precursor component is synthesized in the cytoplasm and transported to the division septum of the growing cell, where the structural similarity between penicillin and D-alanyl-D-alanine (D-ala-D-ala) residues of newly synthesized UDP-MurNAc-penta, allows penicillin to inhibit crosslinking of peptidoglycan by acting as a substrate analog (6). The enzymes mediating transpeptidation of peptidoglycan strands, the target of penicillin, were hence designated penicillin binding proteins (PBPs). The binding of beta-lactams to PBPs leads to formation of long-lasting acyl-enzyme complexes, thereby essentially blocking the transpeptidase activity of these enzymes. The realization that penicillin reduces peptidoglycan cross-linking led to the classical model explaining penicillin-mediated cell lysis as a consequence of a mechanically weakened cell wall incapable of withstanding the high internal osmotic pressure (7, 8). The killing effect of beta-lactam antibiotics, however, has turned out to be much more complex, and the downstream effects of blocking transpeptidation that lead to cell death remain an unsolved mystery (8). In staphylococci, the killing mechanism has been shown to be highly cell cycle dependent, and it has been proposed that a mis-coordination in the spatial and temporal deposition of peptidoglycan during cell division leads to cell death and that cell lysis and cell death may be two separate events

doi:10.1128/microbiolspec.GPP3-0057-2018

TABLE 1 Antibiotics used against *S. aureus*

Agent class	Agent (examples)	Molecular target	Reference(s)
Cell envelope			
β-lactams (penicillinase sensitive)	Ampicillin, amoxicillin	Penicillin-binding proteins	276
β-lactams + β-lactamase inhibitors	Amoxicillin + clavulanate	Penicillin-binding proteins	276
β-lactams (penicillinase resistant)	Oxacillin, nafcillin	Penicillin-binding proteins	276
Cephalosporins	Ceftaroline	Penicillin-binding proteins	58
Carbapenems	Imipenem	Penicillin-binding proteins	277
Glycopeptides	Vancomycin, teicoplanin	MurNac pentapeptide	278
Lipoglycopeptides	Dalbavancin, telavancin	MurNac pentapeptide and cell membrane	110, 112
Phosphonic acid	Fosfomycin	Enoylpyruvate transferase (MurA)	125
Lipopeptide	Daptomycin	Cell membrane	130
Protein synthesis			
Oxazolidinones	Linezolid, tedizolid	50S ribosomal subunit	279, 280
Macrolides	Erythromycin	50S ribosomal subunit	281
Streptogramins	Quinupristin, dalfopristin	50S ribosomal subunit	282
Lincosamides	Clindamycin	50S ribosomal subunit	283
Chloramphenicols	Chloramphenicol	50S ribosomal subunit	284
Pleuromutilins	Retapamulin	50S ribosomal subunit	194
Aminoglycosides	Gentamicin	30S ribosomal subunit	198
Tetracyclines	Tetracycline, doxycycline	30S ribosomal subunit	208
Glycylcyclines	Tigecycline	30S ribosomal subunit	210
Pseudomonic acid	Mupirocin	Isoleucyl-tRNA synthtase	224
Fusidic acid		Elongation factor G	285
DNA replication			
Fluoroquinolones	Ciprofloxacin, moxifloxacin	DNA gyrase, topoisomerase IV	237
Transcription			
Rifamycins	Rifampicin	RNA polymerase	244
Metabolism			
Trimethoprim		Dihydrofolate reductase	286
Sulfonamides	Sulphamethoxazole	Dihydropteroate synthetase	286

(9, 10). Similar to other bacteria, *S. aureus* possesses several PBPs that in addition to providing transpeptidase activity seem to fulfill distinct functions in coordinating peptidoglycan synthesis (see below). Because different classes of beta-lactams target individual PBPs with variable affinity, this may explain why different beta-lactams introduce various morphological changes (10). Hence, the molecular events underlying the bactericidal effects of beta-lactam antibiotics may depend on the affinity of the specific compounds for the various PBPs.

Resistance

Penicillin-resistant *S. aureus* isolates emerged shortly after penicillin was introduced for clinical treatment of bacterial infections (11), and less than 2 decades later, about 80% had become resistant to penicillin through acquisition of the *blaZ* gene encoding the enzyme beta-lactamase, which inactivates penicillin by hydrolyzing the critical beta-lactam ring (12). The *blaZ* gene is part of a transposable element that can either be integrated into the chromosome or be located on large conjugative plasmids that, in addition to *blaZ*, often harbor resistance to mercury and other heavy metals as well as additional antibiotic resistance genes (13–16). Today as many as 99% of clinical *S. aureus* strains are resistant to penicillin, underscoring the adaptive power of *S. aureus* when exposed to a strong selective pressure such as antibiotics (1).

In response to the worldwide spread of penicillin-resistant *S. aureus*, semisynthetic penicillinase-resistant beta-lactams such as, first, methicillin and, later, oxacillin were developed for clinical use. Methicillin was introduced into clinical practice in 1961, and later the same year, the first clinical MRSA isolates were identified in a UK hospital (1, 17). MRSA strains are resistant to methicillin through horizontal acquisition of the *mec*A gene encoding PBP2a, an alternative transpeptidase with low affinity for most beta-lactam antibiotics, hence conferring resistance not only to methicillin but to virtually all members of the large class of beta-lactams. Despite the broad resistance provided, and even though methicillin is no longer used clinically, MRSA has remained the preferred designation for *mec*A-positive isolates.

The *mec*A gene is present on a family of structurally complex genetic elements designated SCC*mec* that often carry additional genes conferring resistance to other antibiotics and harmful substances such as heavy metals (18, 19). Several lines of evidence suggest that SCC*mec* evolution occurred in the *Staphylococcus sciuri* group, a primitive group

of *Staphylococcus* species that are frequent colonizers of the skin of domestic animals (20–23). PBP2a is very similar to the native PBPs encoded by species belonging to the *S. sciuri* group, but the evolution of the *mecA* ancestor gene into a resistance determinant required numerous genetic changes (23). Consistent with this finding, it seems to be the widespread use of penicillin and other first-generation beta-lactams in the years prior to the introduction of methicillin which selected for *S. aureus* strains carrying the *mecA* resistance determinant (24). A novel genetic determinant, *mecC*, encoding a transpeptidase enzyme with only 63% identity to *mecA*-encoded PBP2a, was recently described (25). Interestingly, *mecC*, similar to *mecA*, seems to have evolved in animal-adapted lineages of *S. aureus*, emphasizing the importance of the animal staphylococci as a reservoir of resistance genes that can potentially contribute to the evolution of antibiotic-resistant human pathogens (26).

The SCC*mec* element

SCC*mec* elements are highly diverse in their structural organization and genetic content, with sizes varying from approximately 20 kb to >60 kb (27). They share a modular structure with two essential gene complexes, the *mec* complex, consisting of *mecA* plus its regulators (*mecR1* and *mecI*), and the *ccr* complex, encoding recombinases of the invertase/resolvase family that mediate site-specific integration of the element (18). The element has a single chromosomal integration site (designated *attB*) located downstream of the *rlmH* gene (previously *orfX*), encoding an rRNA methyltransferase (28). The SCC*mec* elements additionally carry a highly variable number of insertion sequences, transposons, and plasmids inside the so-called joining regions J1 to J3 (also known as junkyard regions). Support for SCC*mec* as a mobile genetic element was provided by the finding that different staphylococcal strains harbor identical SCC*mec* elements (29, 30), but it was only recently that *in vitro* transfer of SCC*mec* by transducing phages or conjugative plasmids was finally demonstrated (31–34). Epidemiological data likewise support the idea that acquisition of SCC*mec* elements by methicillin-susceptible *S. aureus* (MSSA) strains is a relatively rare event (35, 36), and restriction modification barriers between major MRSA clones are thought to limit transfer (37). Thus, the primary spread of MRSA seems to occur via clonal expansion of a relative low number of epidemic clones.

SCC*mec* typing in the epidemiology of MRSA

The structural differences between the *mec* and *ccr* gene complexes form the basis for SCC*mec* typing, a PCR-based typing method that is used worldwide for epidemiological surveillance of MRSA (see 38 for details). To date, 11 SCC*mec* types have been identified (27). Early hospital-acquired MRSA isolates such as the archaic MRSA strain COL typically harbor large SCC*mec* elements belonging to type I, II, or III (>50 kb). In contrast, more recent strains typically possess the much smaller SCC*mec* IV (21 to 24 kb) or V (27 kb). The smaller SCC*mec* cassettes were first identified in community-associated MRSA (CA-MRSA) that emerged outside of hospitals in the mid-1990s (until then MRSA isolates were largely confined to hospitals) (15). Today, the traditional grouping of MRSA isolates into health care-associated MRSA (HA-MRSA) and CA-MRSA is losing relevance, because CA-MRSA has also become established in health care settings, and it has been suggested that these clones, which are more contagious and more virulent than the classic HA-MRSA, will replace the HA-MRSA clones over time (39).

Factors impacting resistance level

A notable feature of most MRSA isolates is that resistance to beta-lactams is expressed in a heterogeneous manner (40, 41). For these strains, populations arising from a single cell display widely different resistance levels, with the majority of cells exhibiting a low level of resistance and a minority of cells being highly resistant. While some HA-MRSA isolates exhibit high-level, homogeneous methicillin resistance, CA-MRSA isolates often exhibit low-level, heterogeneous resistance (42). Insight into the molecular mechanisms underlying this phenomenon has come from the identification of mutations that convert strains expressing low, heterogeneous resistance into homogeneous, highly resistant strains. These mutations map to genes associated with cellular stress responses, such as stringent response signaling via ppGpp and the ClpXP protease controlling the Spx stress response (42–45), indicating a close link between bacterial physiology and resistance levels.

Despite the fact that MRSA strains have become resistant to beta-lactams through acquisition of one specific resistance determinant, the *mecA* gene, clinical MRSA isolates exhibit highly variable levels of resistance: in some MRSA strains resistance is barely above that displayed by susceptible isolates (methicillin MICs <3 μg/ml), while other strains are highly resistant (methicillin MICs up to 1,600 μg/ml) (46). The mechanisms underlying these intriguing differences in resistance level remain poorly understood. In some cases, high resistance levels were attributed to increased expression of PBP2a due to duplication or enhanced transcription of the *mecA* gene (47). Two functionally similar two-component systems, BlaR1/BlaI and MecR1/MecI, control transcription of *mecA* in response to beta-lactams, and because genetic mutations are common in the regulatory elements controlling *mecA* expression, the PBP2a level varies widely between MRSA strains (see 48 for a recent review of *mecA* regulation). In several cases differences in resistance levels did not correlate to PBP2a expression, suggesting that factors other than PBP2a modulate the strain-specific level of beta-lactam resistance (46, 49, 50). Indeed, genetic screens have identified a number of auxiliary factors (also designated "fem-factors") essential for methicillin resistance that are critical for PBP2a-mediated resistance to beta-lactam antibiotics (51, 52). Examples include cell division proteins, native PBPs, and enzymes involved in the synthesis of teichoic acids and peptidoglycan precursors. In some cases, the requirements for these auxiliary factors have been explained. For example, the essential glycosyltransferase domain of the native PBP2 is needed to cooperate with the transpeptidase activity of PBP2a in the building of peptidoglycan (53). The fact that beta-lactam resistance depends on auxiliary factors opens up new possibilities for the treatment of MRSA infections, because drugs that inhibit the functions of auxiliary factors work synergistically with beta-lactams to kill MRSA (52, 54, 55).

Beta-lactams for the treatment of MRSA: future perspectives

The discovery that MRSA strains can be resensitized to beta-lactams by interfering with the activity of auxiliary factors opens up a novel paradigm in the treatment of MRSA, because drug-like leads targeted against these factors could be used in combination with beta-lactams to restore the sensitivity of MRSA to beta-lactams (56). Indeed, a combination agent strategy of pairing beta-lactamase inhibitors such as clavulanic acid with beta-lactams has proven highly successful in restoring beta-lactam efficacy against Gram-negative bacteria that have become resistant to beta-lactams

through acquisition of beta-lactamase enzymes (57). Additionally, a new generation of cephalosporins, fifth-generation cephalosporins such as ceftaroline, with efficacy against MRSA have been marketed (58). The active site of PBP2a is normally protected from beta-lactam antibiotics because it is present in a narrow, inaccessible groove. To accommodate the native peptidoglycan strand, the active site is made accessible via a conformational change regulated by an allosteric switch (59, 60). Ceftaroline binds to the allosteric site of PBP2a and thereby opens the active site for binding of a second molecule of ceftaroline that inhibits transpeptidase activity (60). Despite the short time that ceftaroline has been in clinical use, MRSA strains with reduced susceptibility to ceftaroline (obtained through mutations in PBP2a) have already been isolated (61, 62). Hence, the battle continues.

Vancomycin Resistance and VISA

History and mode of action

Although it was discovered in the late 1950s, it was not until the emergence of MRSA 30 years later that the glycopeptide vancomycin became the choice for treatment of MRSA infections (63). Since then, vancomycin has been one of the preferred drugs for treatment of MRSA infections. The target of vancomycin is the cell wall, where it binds with high affinity to the penultimate D-ala-D-ala residues of newly synthesized UDP-MurNAc-penta, thereby disrupting peptidoglycan assembly (64). Strains of *S. aureus* susceptible to vancomycin (VSSA) have MICs of <2 μg/ml, whereas intermediately resistant (VISA) strains display MICs of 4 to 16 μg/ml, and for the resistant strains the MIC is ≥16 μg/ml. Vancomycin-resistant *S. aureus* (VRSA) carries the *vanA* operon that provides the cell with two important activities, namely, the hydrolysis of the D-ala-D-ala precursors and the synthesis of the D-ala-D-lactate precursor, which cannot bind vancomycin (65). The first case of VRSA was reported in 2002, when during coinfection with *Enterococcus faecalis* a MRSA strain acquired the *vanA* operon from a conjugative *E. faecalis* plasmid and displayed a MIC to vancomycin of >1,000 μg/ml (66, 67). Fortunately, since then, only a handful of VRSA cases have been reported, and usually they involve transfer of the *vanA* operon from enterococci (68). The low prevalence of VRSA may be due to limited fitness of the *vanA*-containing enterococcal plasmids in *S. aureus* (69) or, for the MRSA strains, the incompatibility with methicillin resistance, because the *mecA*-encoded transpeptidase, PBP2a, is not able to cross-link the modified wall precursor in the VRSA wall (70). The incompatibility between glycopeptide and methicillin resistance has been termed the "seesaw" effect and can be exploited clinically (71).

Intermediate resistance

VISA strains are associated with serious clinical complications, such as prolonged hospitalization, persistent infections, prolonged vancomycin treatment, and/or treatment failure (71–75), although they appear compromised when examined in animal model systems (76). Vancomycin treatment failure has even been reported for strains with marginally decreased susceptibility and MIC break- points of 1 to 2 μg/ml, the latter being the concentration of an antibiotic, which defines whether a bacterium is susceptible or resistant to the antibiotic (77). In contrast to VRSA, VISA's reduced susceptibility to vancomycin is not due to an acquired antibiotic resistance gene but results from the accumulation of mutations leading to one or more of a number of characteristic phenotypes. These include increased cell wall thickness, cell wall changes leading to anomalous diffusion of vancomycin through the VISA cell wall, decreased negative cell surface charge, decreased autolysis, increased cell wall synthesis, and decreased peptidoglycan cross-linking resulting in high-affinity binding of vancomycin to nonamidated muropeptides (78–89). The mutations associated with VISA were recently summarized in reference 90 and often involve genes associated with (i) the cell wall stress regulon, e.g., the two-component regulatory systems *graRS*, *vraSR*, and *walRK* (*yycFG*) that stimulate expression of the *dlt* operon and *mprF*, leading to reduced negative cell surface charge and consequently less vancomycin binding; (ii) *agr* encoding the virulence regulatory quorum sensing system; (iii) *rpoB* encoding the RNA polymerase; and (iv) other transcriptional regulators or *clpP* encoding the proteolytic component of the Clp protease. There are multiple evolutionary pathways for a VSSA strain to become VISA (91), and although the number of mutations needed to display the VISA phenotype is usually less than 10 (92), it can be challenging, particularly with respect to clinical isolates, to determine the contribution of individual mutations to the VISA phenotype. In one study of the well-known VISA strain Mu50, Katayama and coworkers introduced mutations of six genes associated with decreased vancomycin susceptibility to VSSA strains and tracked the contribution (93). Importantly, all six mutated genes contributed to the VISA phenotype and were directly or indirectly involved in the regulation of cell physiology (93). In other studies, sequential tracking of strains during infection and chemotherapy has revealed a much greater number of genes involved (80, 94–96), stressing the importance of bacterial processes for the development of VISA strains.

Similar to methicillin resistance, the VISA phenotype is commonly preceded by a hetero-VISA phenotype (hVISA), where multiple mutations in hVISA strains lead to the VISA phenotype (97). Mu3 was the first hVISA to be characterized, and similar to hetero-MRSA, the hVISA phenotype is revealed as an uneven killing of a seemingly homogenous cell population. For hVISA the majority of cells have little or no resistance to vancomycin and are killed by 2 μg/ml, whereas a subpopulation survives vancomycin concentrations of >4 μg/ml and thus behaves like VISA strains (89). The hVISA strains are characterized by a thickened cell wall in the absence of mutations associated with VISA strains, and the phenotype can be triggered by exposure to nonglycopeptide antibiotics such as beta-lactams (98, 99). Interestingly, the hVISA phenotype does not develop in cells carrying a mutation in *trfA* that influences resistance to teicoplanin, another glycopeptide antibiotic (100), and encodes an adaptor of the ClpC ATPase (101) that together with the proteolytic subunit, ClpP, is responsible for the degradation of nonnative proteins (101, 102). Clinically, hVISA strains are associated with persistent infections and attenuated host immune response, and differential gene expression changes seem to underlie their development (103).

Recently, yet another VISA phenotype was discovered, termed slowVISA (sVISA), which is characterized by very slow growth, requiring 72 hours or more for colony formation, relatively high MICs (>8 μg/ml) to vancomycin, an unstable resistance profile, and colony morphology that reverts in the absence of vancomycin (104). Altered expression of the stringent response, as well as mutations in *rpoB* and *rpoC* encoding subunits of the RNA polymerase, are associated with the sVISA phenotype (105, 106). Importantly, low concentrations of mupirocin, a well-known inducer of the stringent response, enabled the isolation of stable sVISA

strains, and this approach was used to demonstrate the presence of sVISA among clinical isolates (107).

A significant challenge with the hVISA and sVISA strains is that traditional susceptibility testing does not reveal their presence. Both forms are induced by vancomycin exposure, but hVISA also arises in response to beta-lactam antibiotics, while stabilization of sVISA occurs upon induction of the stringent response—neither of which are present during susceptibility testing. A related finding was made by Haaber et al., who observed that upon exposure to the antimicrobial peptide antibiotic colistin, *S. aureus* elicited reversible and reduced susceptibility to vancomycin in the absence of genetic change (108). Collectively, these findings indicate that VISA derivatives may develop not only through mutations but also through unrelated phenotypic processes (90) and that such phenotypic tolerance could contribute significantly to the clinical failures of vancomycin chemotherapy.

Lipoglycopeptides

Mode of action

The reduced susceptibility of MRSA strains to vancomycin has called for new treatment options for MRSA infections, leading to the development of the lipoglycopeptides, telavancin, oritavancin, and dalbavancin. They are derivatives of vancomycin that have been modified by lipophilic side chains, where the heptapeptide core inhibits transglycosylation and transpeptidation reactions in cell wall synthesis and the lipophilic side chains prolong half-life and allow interactions with the cell membrane (109). While dalbavancin inhibits the late stages of peptidoglycan synthesis mainly by impairing transglycosylase activity, oritavancin and telavancin anchor in the bacterial membrane by the lipophilic side chain linked to their disaccharide moiety, disrupting membrane integrity and causing lysis (110).

Telavancin is active against both MSSA and MRSA, and it causes rapid, concentration-dependent depolarization of the bacterial plasma membrane, increased permeability, and leakage of cellular ATP and K^+ (111). It is 16- to 32-fold more active than vancomycin and displays activity against hVISA and VISA but reduced activity against VRSA (112). Dalbavancin is also active against VISA and hVISA, but strains with reduced susceptibility to vancomycin also demonstrate reduced susceptibility to dalbavancin (113, 114). Importantly, oritavancin is active against both VISA and VRSA (115). This is likely related to its ability to bind not only to the D-ala-D-ala peptidoglycan termini similar to vancomycin but also to interact with peptides near the terminal D-ala-D-ala (or D-lactate in VRSA), thus maintaining binding affinity for the modified peptidoglycan peptide termini of vancomycin-resistant organisms (116). In comparison to vancomycin; dalbavancin, oritavancin, and telavancin all have longer half-lives, which allow once daily dosing for telavancin, once weekly dosing for dalbavancin, and potentially one dose per treatment course for oritavancin (109, 117, 118).

Resistance

In general, resistance to lipoglycopeptides is remarkably rare. The long half-life of these compounds *in vivo* may contribute to this but may also provide selection for resistance at subinhibitory concentrations. In a study of telavancin, resistance development was assessed by *in vitro* passages, and only 1 out of 10 passaged MRSA clones showed increasing MIC. This was from 0.25 μg/ml to 2 μg/ml after 43 days, and subsequently, no further increase occurred (119). Resistance to dalbavancin could not be obtained by direct selection of MSSA, MRSA, or VISA strains on plates containing dalbavancin (120), whereas passaging in the presence of subinhibitory concentrations increased the dalbavancin MIC of MRSA strains by 2 or 3 dilutions (to 0.25 and 0.5 μg/ml) (120). Recently, a clinical case of decreased susceptibility to dalbavancin was reported, where the use of a dalbavancin and vancomycin therapy led to development of a vancomycin- and dalbavancin-nonsusceptible phenotype. Importantly, these susceptibility changes were accompanied by a 4-fold increase in daptomycin and telavancin MICs, although the patient did not receive treatment with these agents (121). This observation may be explained by the finding that decreased dalvabancin susceptibility was a result of mutations of *yvqF* (*vraT*), which regulates cell wall metabolism and has been implicated in the VISA phenotype (122).

Fosfomycin

Mode of action

Due to the increasing problems with antibiotic resistance, older antibiotics are being re-evaluated for clinical use to expand treatment opportunities against difficult to treat infections (123, 124). Fosfomycin is a phosphoenolpyruvate analogue that inhibits the enzyme MurA, which catalyzes the first step in peptidoglycan biosynthesis, and prevents the formation of *N*-acetylmuramic acid, which is an essential precursor for the peptidoglycan cell wall (125). Fosfomycin is minimally used for other than uncomplicated urinary tract infections. However, it generally displays good activity against MRSA and can be orally administered; hence, this antibiotic may be of clinical importance for difficult to treat *S. aureus* infections (124).

Resistance

Fosfomycin resistance can arise via enzymatic modification of the agent, reduced uptake, or target-site modifications. Enzymatic modification of the antibiotic by a thiol-*S*-transferase encoded by the *fosB* gene is a common resistance mechanism among clinical *S. aureus* isolates (126, 127). Several other enzymes, such as FosA and FosX, have been identified in other bacterial species that can modify fosfomycin, whereas in *S. aureus* only the *fosB* gene has thus far been identified (128). Reduced uptake has been characterized in *E. coli* by chromosomal mutations in two transporter systems, GlpT and UhpT, which enable fosfomycin uptake (129). Mutations in the genes encoding for GlpT and UhpT have also been identified among clinical fosfomycin-resistant *S. aureus* isolates, along with target-site modifications of MurA (127). However, the individual roles of such mutations have not been elucidated in naive strain backgrounds (127).

Daptomycin

History and mode of action

Daptomycin, a cyclic lipopeptide produced by *Streptomyces roseosporus*, was approved by the FDA in 2003 for treatment of complicated skin and soft tissue infections caused by Gram-positive bacteria, for *S. aureus* bacteremia, and in 2006 for right-sided infective endocarditis. (See 130 for an extensive review of the journey of daptomycin from drug discovery to the bedside.) Since then, daptomycin has become an important treatment option for deep-seated infections caused by MRSA (131). Daptomycin targets the cytoplasmic

membrane, but the mechanistic details underlying the bactericidal effect of this binding remain elusive (reviewed in 130). The activity of daptomycin is completely dependent on calcium ions, and it is generally accepted that the positive charge of calcium-complexed daptomycin facilitates binding and insertion of daptomycin into the cytoplasmic membrane, where it oligomerizes to form pore-like structures (130). Demonstrated downstream effects that directly or indirectly may cause cell death involve membrane depolarization, ion leakage, and delocalization of enzymes synthesizing the cell wall (130). Notably, daptomycin, in contrast to most antibiotics, has bactericidal activity even against stationary *S. aureus* cells, supporting the view that it targets a process that is essential in nongrowing cells (132).

Resistance

The development of daptomycin resistance (an official daptomycin resistance breakpoint has not been declared, and therefore the official terminology is "daptomycin nonsusceptibility," but for ease of presentation we will use the term "daptomycin resistance") in staphylococci seems to be a relatively rare phenomenon, and no trend toward increased daptomycin resistance was noted in a worldwide surveillance program (2005 to 2012) (133). Nonetheless, *S. aureus* isolates that have evolved daptomycin resistance during clinical treatment are well described (134–136). Daptomycin resistance is obtained through selection of multiple spontaneous mutations with hotspots in genes affecting the composition or charge of the cell envelope (134, 136). The clinically most significant example of this is mutations increasing the activity of the multipeptide resistance factor (MprF) that catalyzes synthesis of the positively charged lysylphosphatidylglycerol (134–138). The *mprF* mutations correlate with excess lysylphosphatidylglycerol in the cell membrane but not always with augmented positive surface charge, suggesting that electrostatic repulsion alone does not explain the improved ability to withstand daptomycin (138, 139). Other genetic changes frequently implicated in decreased tolerance to daptomycin map to *rpoB* and to genes controlling activity of the YycFG (WalRK) two-component system, which responds to perturbations in cell membrane homeostasis (94, 95, 134, 140, 141). Consistent with these genetic changes, the prevailing phenotypic changes reported for daptomycin-resistant *S. aureus* strains include increased positive charge of the cell membrane and a thickened cell wall (134, 136, 142–144). Additionally, the genetic changes associated with daptomycin resistance often correlate with decreased expression of virulence genes and altered pathogenesis of the isolates (144, 145). An intriguing explanation for this finding was proposed when it was found that mutants lacking the *agr* quorum sensing system survived daptomycin exposure by releasing membrane phospholipids, which bound and inactivated the antibiotic. Although wild-type bacteria also released phospholipid in response to daptomycin, *agr*-triggered secretion of small cytolytic toxins, known as phenol soluble modulins, prevented antibiotic inactivation (146).

PROTEIN SYNTHESIS INHIBITORS

Linezolid and Tedizolid

History and mode of action

Linezolid is an oxazolidinone that since its approval in 2000 has been used to treat nosocomial pneumonia and skin and soft tissue infections caused by both MRSA and MSSA (147). Compared to vancomycin, it has favorable pharmacokinetic properties and is applied to difficult to treat infections, including those caused by strains displaying decreased susceptibility to glycopeptides (148). Linezolid targets the ribosome by interacting with the 23S rRNA and blocks protein synthesis by preventing binding or proper placement of aminoacyl-tRNA in the peptidyltransferase center (149, 150). Linezolid also interacts with tRNA, the ribosomal protein L27, and the ribosomal-associated protein LepA (150). The general effect of linezolid on protein expression leads to reduced expression of toxins (151) and particularly reduced amounts of excreted or membrane-associated proteins (152), which likely contributes to the clinical efficacy of the drug.

Resistance

The primary activity of linezolid is binding to the 23S rRNA, and since there are five to six rRNA (*rrn*) operons in *S. aureus* (153), it was suspected that resistance development would be limited (154). However, resistance has been associated with distinct nucleotide substitutions in domain V of the 23S rRNA gene, particularly G2447T, T2500A, and G2576T, where a gradual increase in the number of mutated 23S rRNA gene copies occasionally combined with copy deletions has been associated with increased resistance levels (155–158). In particular, the first mutation appears to be rate limiting in resistance development as demonstrated in one study, where the first G2576T mutation required by far the longest time to occur (157). Subsequent acquisition of the same nucleotide exchange in the other 23S rRNA gene copies suggested that they are not independent mutational events but arise, for example, by homologous recombination or gene conversion (157, 159). Deletions or mutations in the ribosomal proteins L3 and L4 have also been associated with resistance (158, 160) and sometimes in combination with 23S rRNA mutations (147). The fitness of resistant strains obtained by *in vitro* passage decreases with increasing numbers of mutated 23S rRNA copies and resistance levels (157), but importantly, strains that carry only one mutated copy and are susceptible to linezolid are without apparent fitness defects, and the mutations are stable over extended periods of time (159). In a clinically isolated, linezolid-resistant mutant, the resistance was found to be mediated by a G2576U mutation in all five 23S rRNA copies. The resistance was not accompanied by any growth defect, and passage in antibiotic-free medium did not decrease resistance levels (161). Thus, in successfully resistant clinical strains, compensatory mutations are likely to be present.

Another mechanism by which *S. aureus* may become resistant to linezolid is through the acquisition of the ribosomal methyltransferase *cfr* gene (154, 162, 163). It methylates the A2503 in the peptidyl transferase center of the 23s rRNA (164). The *cfr* gene has been identified in a number of clonal complexes, including the livestock-associated ST398 and ST9 (165), and it is commonly associated with other mobile genetic elements (166). Importantly, the *cfr* gene is present on plasmids also in other Gram-positive pathogens, including *S. epidermidis*, from where it can be transferred to clinical MRSA strains (166, 167), highlighting the importance of the resistance gene pool present in other staphylococcal species. Fortunately, tedizolid, a second-generation oxazolidinone, retains activity against strains carrying *cfr* (168). Tedizolid is 4- to 16-fold more potent toward MRSA compared to linezolid, and this compound causes a dramatic reduction in virulence factor production (169), and resistance is still limited.

Although there are numerous reports of resistance to linezolid (147), generally >98% of *S. aureus* strains remain susceptible. In some patient groups, however, resistance is

significantly more prevalent. For example, in cystic fibrosis patients, 11% of isolates are resistant (170). Surprisingly, linezolid may also stimulate the growth of some staphylococcal strains, as demonstrated for a thymidine-dependent small colony variant of a MRSA strain isolated from the lung of a cystic fibrosis patient (171). In this strain, in the absence of any known linezolid resistance mutations or genes, the presence of linezolid greatly stimulated growth. This finding reflects the complexity and unpredictability of linezolid's effects on ribosomal functions and stresses the need for further investigations.

Macrolides, Lincosamides, and Streptogramins

History and mode of action

Macrolides, lincosamides (including clindamycin [172, 173]), and streptogramins (type A and B) (commonly abbreviated MLS) all inhibit protein synthesis by targeting the peptidyl transferase center of the 50S ribosomal subunit. Macrolides and streptogramin B bind adjacent to the peptidyl transferase center within the exit tunnel and thereby prevent elongation of the peptide chain (174). Binding of lincosamides inhibits peptide-bond formation by preventing correct positioning of the aminoacylated ends of tRNAs in the peptidyl transferase center (174). When macrolides, lincosamides, or streptogramins are used for monotherapy, they are bacteriostatic (175). However, when a type B streptogramin (e.g., quinupristin) is used together with a type A streptogramin (e.g., dalfopristin), the combination, marketed as Synercid, acts synergistically and is bactericidal against staphylococci (176).

Resistance

Resistance to macrolides, lincosamides, and streptogramin can be mediated via target-site mutation, enzymatic target-site modification, enzymatic inactivation of the antibiotic, and active efflux (177). Target-site modification occurs by acquisition of rRNA methylases encoded by *erm* genes, including *erm*(A), *erm*(B), *erm*(C), and related genes, which add methyl groups to an adenine residue in the 23S rRNA (177, 178). Also, the 23S rRNA methyltransferase, encoded by the *cfr* gene, confers resistance to lincosamides and streptogramin A, as well as oxazolidinones, phenicols, and pleuromutilins, but does not confer resistance to macrolides (179).

Ribosomal mutations in the 23S rRNA target site may cause resistance to macrolides, lincosamides, and streptogramins. As is the case for linezolid, the number of *rrn* genes limits resistance development. However, in cystic fibrosis patients treated with a macrolide, strains have been isolated that contain mutations in five of the six *rrn* genes, conferring cross-resistance to lincosamides and streptogramins (180). Mutations in the ribosomal proteins L22 (encoded by *rplV*) and L4 (encoded by *rplD*) may also contribute to the development of resistance to the MLS antibiotics (180, 181). Enzymatic inactivation of macrolides can be mediated by phosphorylases encoded by *mph* genes, and type A streptogramin resistance can be mediated by acetyltransferases (177, 182).

Staphylococci can also acquire genes encoding efflux pumps that can extrude one or more of the MLS antibiotics (183). Acquisition of the *msr*(A) gene encoding for the Msr (A) ABC transporter confers resistance to macrolides and streptogramin B, while lincosamides are not substrates for this pump (184). The plasmid-carried gene *vga*(A) encodes an ABC transporter with specificity for type A streptogramins, along with the pleuromutilin class of antibiotics (184, 185). The LmrS efflux pump can extrude macrolides and lincosamides, as well as several other classes of antibiotics (186). Finally, overexpression of the chromosomally encoded gene *mdeA* reduces susceptibility to the streptogramin virginiamycin (187).

Chloramphenicol

Mode of action

Chloramphenicol is a broad-spectrum, bacteriostatic antibiotic that interferes with protein synthesis by binding to the ribosomal 50S subunit. Chloramphenicol binds at the peptidyl-transferase center and thus inhibits peptide bond formation between the tRNAs at the A- and P-sites (174). The wide use of chloramphenicol has been hindered by its toxicity, because systemic administration of chloramphenicol is associated with irreversible aplastic anemia (188). Due to the severity of the adverse effects of chloramphenicol, it is now used primarily for topical applications, such as a treatment for staphylococcal conjunctivitis (189).

Resistance

Resistance to chloramphenicol is attributed to either enzymatic inactivation of the antibiotic, active efflux, or target-site modification. Inactivation of chloramphenicol occurs through acetylation at the C3 position via various chloramphenicol acetyltransferases, encoded by *cat* genes (190), which often are located on plasmids (191). Active efflux of chloramphenicol is mediated by the FexA (192) or LmrS efflux pump (186). Finally, chloramphenicol resistance can occur through target-site modification of the 23S rRNA at position A2503 by an rRNA methylase encoded by the gene *cfr* (164).

Pleuromutilins

History and mode of action

The pleuromutilin class of antibiotics was first described in 1951, and the first agent in this class, tiamulin, was approved for veterinary use in 1979 (193). In 2007, the pleuromutilin retapamulin was first approved for human use for treatment of skin infections caused by *S. aureus* and *Streptococcus pyogenes* (193, 194). Pleuromutilins inhibit protein synthesis by binding to the ribosomal 50S subunit at the peptidyl transferase center (174).

Resistance

Pleuromutilin resistance mechanisms include reduced binding to the target and active efflux (194). *In vitro* selected pleuromutilin resistance can be conferred by spontaneous mutations in the gene *rplC*, which encodes the ribosomal protein L3. Stepwise mutations in *rplC* confer higher levels of resistance than single mutations in the gene (195, 196). Reduced binding to the target can also occur by acquisition of the *cfr* gene (179). Pleuromutilins are also subjected to active efflux by, for example, Vga(A) (185) and related efflux systems (197).

Aminoglycosides

History and mode of action

Aminoglycosides, such as gentamicin, interfere with protein synthesis by binding to the A-site of the 16S rRNA of the 30S subunit and promote inaccurate codon-anticodon recognition that ultimately decreases fidelity of translation, leading to the generation of mistranslated proteins (198, 199). The bactericidal activity of aminoglycosides is attributed to the

production of mistranslated proteins that may incorporate into the membrane, increasing its permeability and leading to uncontrolled small molecule diffusion and eventually increased uptake of aminoglycosides (198). Aminoglycosides are rarely used as monotherapy; they may be used in combination with other agents for treatment of endocarditis (172).

Resistance

For *S. aureus*, resistance to aminoglycosides is conferred by several mechanisms, including enzymatic modification of the aminoglycoside agents, decreased uptake, and target modifications of the 30S ribosomal subunit. Active efflux of aminoglyocsides has not been reported for *S. aureus*, whereas this mechanism is common among Gram-negative pathogens (200). In contrast, enzymatic modification and inactivation of aminoglycoside agents is common among *S. aureus* clinical isolates. The aminoglycoside-modifying enzymes can be divided into three subclasses based on the chemical type of modification of the aminoglycosides (200–202).

Aminoglycoside uptake is dependent on the membrane potential, and mutants experiencing depolarization of the membrane display low-level resistance to aminoglycosides (203). On agar plates such mutants often display a small colony phenotype and hence are referred to as small colony variants (203). Aminoglycoside-resistant small colony variants are considered to be of clinical importance, because they have been associated with recurrent and persistent staphylococcal infections such as device-associated infections, bone infections, and airway infections in cystic fibrosis (204).

Plasmid-mediated 16S rRNA methyltransferases can confer a high level of resistance to various aminoglycosides by preventing binding of the aminoglycoside to the active site; however, this mechanism has been reported only among clinical Gram-negative bacteria (205). Nonetheless, an *in vitro*-generated *S. aureus* mutant containing the 16S rRNA methyltransferase gene *rmt*C on a plasmid was capable in conferring resistance to gentamicin and kanamycin (206).

Tetracyclines and Tigecycline

History and mode of action

Tetracyclines, including tigecycline, are bacteriostatic antibiotics that inhibit protein synthesis by binding to the ribosomal 30S subunit (207). Tigecycline blocks entry of aminoacyl tRNA molecules into the acceptor site of the ribosome, thus preventing incorporation of amino acids into the elongating peptide chain (174, 208).

The backbone of the tetracycline compound class is characterized by four interlocking six-carbon rings. Due to the emergence of resistance to the marketed tetracyclines, there has been continued development of new analogues that overcome common resistance mechanisms against older versions of tetracyclines (209). In 2005, the FDA approved tigecycline, which belongs to the novel antibiotic class of glycylcyclines. Glycylcyclines are derivatives of the tetracycline class of antibiotics and thus contain the four-ring carbocyclic structure, with a substitution of an *N*-alkylglycylamido group to the D-9 position. This substitution expands the spectrum of activity compared to tetracyclines and overcomes some tetracycline resistance mechanisms (210).

Resistance

Tetracycline resistance of clinical relevance has been attributed to active efflux or target-site protection (211). Active efflux is mediated via the Tet(K) and Tet(L) efflux pumps of the major facilitator superfamily by exchanging a proton for a tetracycline molecule (211). The efflux pump of Tet(K) can be encoded on plasmid pT181, which may be integrated with SCC*mec* elements of MRSA CC398 (212). A chromosomally encoded efflux pump, Tet38, confers tetracycline resistance when the repressor protein MgrA is inactivated (213).

Target-site protection is mediated via TetM or TetO determinants, which are often encoded on chromosomally located conjugative transposons. TetO and TetM bind to the elongation factor G (EF-G) binding site on the ribosome, releasing bound tetracycline from the A site in the presence of GTP (214). Strains harboring both TetK and TetM display higher MICs than strains carrying an individual gene (215) and are selected for during exposure to subinhibitory concentrations (216).

Tigecycline susceptibility is minimally affected by the presence of the tetracycline resistance determinants TetM and/or TetK in *S. aureus* (217). Tigecycline is currently not greatly burdened by resistance in clinical isolates, with only a few reports highlighting this in staphylococci (218). Among 28,278 strains from the United States, more than 99.9% isolated between 2006 and 2012 remained susceptible to tigecycline (219), whereas the susceptibility frequency in Mexico (where prescription control is limited) was down to 91% (220). Mechanisms conferring resistance to tigecycline have been investigated *in vitro* by selection of resistant mutants. Loss-of-function mutations have been identified in the transcriptional repressor *mepR*, leading to derepression of the *mepA*-encoded efflux pump (221, 222). Mutations in *mepA* itself have also been associated with reduced tigecycline susceptibility (222). Furthermore, mutations have been identified in the gene *rpsJ*, which encodes the ribosomal protein S10, that are suspected to reduce the access of tigecycline to the binding site (223).

Mupirocin

Mode of action

Mupirocin is a topical antibiotic widely used to reduce nasal carriage of MRSA and to treat skin infections. Mupirocin arrests protein synthesis by inhibiting the isoleucyl-tRNA synthetase, which is encoded by the *ileS* gene. The isoleucyl-tRNA synthetase (IleRS) catalyzes formation of isoleucyl-tRNA from isoleucine and tRNA and thereby prevents incorporation of isoleucine into protein chains (224).

Resistance

Resistance to mupirocin can arise by chromosomal mutations in the *ileS* gene. Amino acid substitutions in IleRS reduce the affinity for mupirocin and confer low-level resistance to the antibiotic (224). Resistance to mupirocin can also be conferred by acquisition of the gene *mupA*, which encodes a mupirocin-insensitive isoleucyl-tRNA synthetase (224). *mupA* is often located on plasmids that also harbor genes conferring resistance to other antibiotics of greater importance than mupirocin for treatment of *S. aureus* infections, and hence mupirocin may provide selective pressure for maintenance of nonmupirocin resistance genes (225). Recently, it was demonstrated that *mupB* confers high-level resistance, but the mechanism of resistance remains incompletely understood (226).

Fusidic Acid

Mode of action

Fusidic acid is a bacteriostatic antibiotic that inhibits protein synthesis by binding to the EF-G on the ribosome, effectively

stalling the elongation phase of translation. EF-G is encoded by the chromosomally located gene *fusA* (227). For systemic application, fusidic acid often is used in combination with other antistaphylococcal antibiotics to reduce the risk of resistance development, because fusidic acid resistance can be readily selected (227, 228). Fusidic acid has been applied as a monotherapy for topical administration, but consequently has experienced a rapid emergence of resistant variants (227).

Resistance

Fusidic acid resistance can arise due to chromosomal mutations in *fusA*, leading to reduced fusidic acid binding to EF-G due to altered protein conformation (227, 229) or mutations in *rplF* (also termed *fusE*, encoding the ribosome protein L6) (230). *rplF* mutations can be selected for using fusidic acid or aminoglycosides and may be accompanied with secondary mutations in hemin or menaquinone biosynthesis genes conferring the small colony variant phenotype (230, 231). Acquired fusidic acid resistance genes found in *S. aureus* include *fusB*, *fusC*, and *fusD* (232). By binding to EF-G on the ribosome, FusB frees stalled ribosome-EF-G-GDP complexes that form in the presence of fusidic acid, which allow the ribosomes to resume translation (233). *fusC* has been inferred to have a similar mechanism of resistance as *fusB*, based on sequence similarity (231). The *fusD* gene is associated with the intrinsic resistance of *Staphylococcus saprophyticus* to fusidic acid (232). Fusidic acid resistance genes have been identified on SCC*mec*-like elements termed SCC*far*, which lack the *mecA* gene, and these elements may contribute to the horizontal transfer of fusidic acid resistance genes (234). The *fusB* gene has also been identified on mobile elements with similarity to staphylococcal pathogenicity islands. In *S. aureus* the mobile element does not harbor any known virulence determinants, so it is termed the *S. aureus* resistance island carrying *fusB* ($SaRI_{fusB}$) (235), while in *S. epidermidis*, the *fusB* gene is located on the pathogenicity island $SePI_{fusB\text{-}857}$ (236).

INHIBITORS OF DNA REPLICATION

Fluoroquinolones

Mode of action

Fluoroquinolones are bactericidal due to the blocking of bacterial DNA replication. They have two molecular targets, where the primary target in *S. aureus* is topoisomerase IV and the secondary target is DNA gyrase. Topoisomerase IV promotes separation of intertwined daughter chromosomes following replication and is a tetramer complex consisting of two GrlA and two GrlB subunits encoded by *grlA* and *grlB*. DNA gyrase is a tetramer complex consisting of two GyrA and two GyrB subunits encoded by *gyrA* and *gyrB*, and it is essential for viability because it removes positive supercoils that accumulate during replication (237).

Resistance

Resistance to different fluoroquinolones is common, with some reporting a prevalence of up to 60% (238, 239). Due to the high prevalence of fluoroquinolone resistance and the risk of resistance developing during treatment, it is primarily recommended that fluoroquinolones be used in combination with other antibiotics (172). Fluoroquinolone resistance mechanisms include mutational changes in the target site of topoisomerase IV and DNA gyrase and increased expression of endogenous efflux pump systems (240). Target-site resistance mutations have primarily been located in the DNA gyrase gene, *gyrA*, and the topoisomerase IV gene, *grlA* (241). Combinatorial mutations in topoisomerase IV and DNA gyrase produce higher levels of resistance than a single mutation in either of the targets (242). *S. aureus* harbors three chromosomally encoded efflux pump systems, namely, NorA, NorB, and NorC, whose overexpression leads to reduced susceptibility to fluoroquinolones. The affinity of these efflux pump systems varies for the individual fluoroquinolone; e.g., NorA primarily extrudes ciprofloxacin and norfloxacin, and its overexpression can increase the MIC approximately 8-fold (243). Fluoroquinolones generally have great activity against *S. aureus*, so accumulation of multiple mutations altering the target-site and/or conferring overexpression of efflux pump systems is needed to exceed the clinical breakpoint (240).

TRANSCRIPTIONAL INHIBITORS

Rifampicin

Mode of action

The selective antibacterial activity of rifampicin is attributed to the inhibition of RNA synthesis, because it binds to prokaryotic RNA polymerases with much greater affinity than to eukaryotic RNA polymerases. The bacterial RNA polymerase is a multisubunit complex, consisting of the subunits α_2, β, β', and σ. The binding site of rifampicin is located in the β-subunit, which is encoded by the gene *rpoB* (244).

Resistance

Rifampicin-resistant mutants are readily selected (228), and resistance-conferring point mutations have been located within the *rpoB* gene. Alteration of the target decreases affinity for rifampicin and can confer a more than 10,000-fold increase in MIC (245). Rifampicin resistance mutations often confer a fitness cost, but the level of resistance is not correlated with the magnitude of the fitness cost for *in vitro* selected mutants, and rifampicin-resistant mutants from clinical isolates often carry mutations associated with low fitness costs (245). Available online tools can help to determine chromosomal *rpoB* point mutations conferring rifampicin resistance from whole-genome sequences, e.g., the Mykrobe Predictor (246). Due to the extensive risk of resistance development, treatment with rifampicin is recommended only for use in combination with a secondary antibiotic (172).

SMALL MOLECULE BIOSYNTHESIS INHIBITOR

Trimethoprim-Sulfamethoxazole

History and mode of action

Sulphonamides were the first class of antibiotics to be introduced into the clinic (in 1935). Currently, sulfamethoxazole (SMX) is the most widely used sulphonamide. Trimethoprim (TMP) was introduced in 1962 and has been used in combination with SMX since 1968 in a formulation called co-trimoxazole (247). Both of the agents interfere with bacterial metabolism by inhibiting the synthesis of folic acid, a cofactor in amino acid and nucleotide synthesis. SMX inhibits the enzyme dihydropteroate synthase, which catalyzes the formation of dihydrofolate from para-aminobenzoic acid. TMP inhibits dihydrofolate reductase (*dfrB*), which catalyzes the formation of tetrahydrofolate from dihydrofolate (247). By inhibiting two enzymes in the same metabolic pathway, it was anticipated that the risk of resistance

development would be diminished, yet a high prevalence of resistance to both agents has been reported (247).

Resistance

Resistance to SMX in clinical isolates arises from chromosomal mutations in the gene encoding the dihydropteroate synthase enzyme, which is expected to reduce the binding affinity of SMX to the target (248). Similarly, TMP resistance arises from chromosomal mutations in the *dfrB* gene encoding the dihydrofolate reductase enzyme (249). Besides chromosomally encoded TMP resistance, *S. aureus* can acquire *dfr* gene variants, *dfrA*, *dfrG*, and *dfrK*, which are less susceptible to inhibition by TMP (250). The two antibiotics are often used in combination to limit resistance development, but in patients exposed to long-term treatment with TMP-SMX, thymidine-dependent TMP-SMX-resistant small colony variants emerge (251). The thymidine-dependent small colony variants acquire mutations in *thyA* encoding for thymidylate synthase, which is essential for *de novo* thymidylate biosynthesis. Tetrahydrofolic acid acts as a cofactor for thymidylate synthase, and *thyA* mutants are therefore dependent on the uptake of thymidine or its metabolite dTMP (252, 253).

COMPOUNDS AND ALTERNATIVES IN DEVELOPMENT

The World Health Organization has classified MRSA and VRSA as "high priority" for development of new therapeutics (254). The majority of the small molecules in clinical development and those recently approved are modifications of existing chemical scaffolds. Therefore, cross-resistance to earlier versions of the antibiotics may be experienced, as was observed with the recently approved fluoroquinolone delafloxacin (254, 255). However, novel membrane-targeting antibiotics are being developed, such as the nonpeptide defensin mimetic brilacidin, which is in clinical development phase 2 (254, 256), and the antimicrobial peptide LL-37 (257). Although brilacidin is structurally different from daptomycin, the cellular effects of brilacidin are similar to those of daptomycin and LL-37. For thorough reviews on the antibiotic pipeline please see the WHO report (254) and the article by Butler and colleagues (256).

Another avenue being pursued for new clinical options is resensitizing resistant isolates by inhibiting acquired resistance mechanisms or core cellular functions needed for antibiotic resistance (258). The opportunity of expanding the spectrum of activity of polymyxins, an antibiotic class only used for treatment of infections caused by Gram-negative bacteria, has been pursued by searching for inhibitors of the ATP synthase that was identified in a genetic screen for sensitizer targets (259). Compounds affecting expression of PBP2a have also been proposed as ways to increase susceptibility of MRSA to beta-lactams, as demonstrated by the antipsychotic drug thioridazine, which decreases *mecA* and *blaZ* transcription and PBP2a expression (260). Importantly, a combination of thioridazine and dicloxacillin is active against VISA strains (261).

Alternative treatment strategies are also being explored, including but are not limited to antibodies, antivirulence therapy, bacteriophages, and vaccines (262). Two types of antibodies are being explored, namely, those binding to the pathogen to promote opsonization-mediated phagocytosis and those that neutralize virulence factors, such as toxins (263). *S. aureus* possesses a plethora of virulence factors (264), so neutralization of a single factor is generally insufficient against *S. aureus* infections; hence, cocktails of monoclonal antibodies binding to different targets are also under development (254). Antibodies are also being assessed for increasing the intracellular activity of antibiotics that display reduced activity against *S. aureus* residing inside host cells (254, 265). Here, antibody-antibiotic conjugates bound to bacteria are being opsonized by phagosomes, where intracellular proteases release the antibiotic by cleaving the antibody-antibiotic linker and thereby enable the antibiotics to gain intracellular activity and improve intracellular bacterial clearance (265).

In antivirulence therapy, the strategy is to disarm key virulence factors involved in disease progression; bacterial clearance then relies on a functional immune system or coadministered antibiotics (266). For *S. aureus*, compounds have been explored that target the *agr* quorum sensing system and suppress production of major virulence factors such as α-hemolysin by binding to either the AgrC sensor histidine kinase or the AgrA response regulator of the *agr* two-component system (267–270). Such interventions may ultimately prove to be effective against both colonization by and infection of *S. aureus* (271).

Bacteriophages (in short, phages) are viruses that specifically target bacteria; lytic phages were introduced to human medicine a century ago worldwide. With the introduction of antibiotics, the human application of phage therapy was abandoned in Western medicine but has maintained applicability in Eastern Europe, including countries of the former Soviet Union (272, 273). The difficulties imposed by antibiotic resistance have renewed the interest in phage therapy in Western medicine (274). Several phage therapies are currently being tested against *S. aureus*, with a focus on topical decolonization (275). In summary, a line of new therapeutic options are being explored, and future research will reveal their efficacy and clinical potential against infections with *S. aureus*.

Immunity to *Staphylococcus aureus*: Implications for Vaccine Development

RICHARD A. PROCTOR

48

INTRODUCTION

Most adult humans have high levels of circulating antibodies against many staphylococcal antigens, indicative of prior subclinical infections, but these antibodies are generally not protective, and clinically significant infection with *S. aureus* fails to provide protective immunity. Multiple vaccines have been developed for the prevention of *S. aureus* infections, but none were proven efficacious in the human trials reviewed in references 1–4. All of the vaccine candidates functioned well in animal models, mostly murine models, but also in rabbits and primates. The reliance on murine models can be related to the extensive data available about murine immunity. Based on the large number of failures, a reasonable conclusion is that murine immunity and human preventive immunity against *S. aureus* are significantly different. The divergence of human and murine immunity has been detailed in the recent literature (1–6).

Clearly, one major hurdle in producing an *S. aureus* vaccine is the lack of detailed information about the human protective immune response to *S. aureus* (1–4). Several vaccine candidates that target surface antigens and produce opsonizing antibodies have reached clinical trials, but they have failed to protect or attenuate infections in humans. All of these antigens produced robust humoral immunity that provided protection in animal models. These data indicate that antibodies based on opsonophagoctyic activity are not protective in humans. While these results were very disappointing, they were not entirely surprising, because patients with B cell defects do not show increased frequency or severity of *S. aureus* diseases (2–4). Information from immune defects, clinical trials, and studies of human sepsis are providing important information about the immune response to *S. aureus* in humans, underlining the importance of cellular immunity. This information is examined here.

IMMUNE DEFECTS AND RECURRENT *S. AUREUS* INFECTIONS

The inborn and acquired immune defects that increase the incidence of *S. aureus* help to define the cells and pathways that provide protective immunity, and these are summarized in Table 1. Overall, evidence is mounting that helper T (T_H) cells plus polymorphonuclear neutrophils (PMNs), dendritic cells, and macrophages are important for a protective immune response (7–14).

Vitamin D Deficiency and Dendritic Cell Failure

Patients with vitamin D deficiency have increased numbers of *S. aureus* infections (15, 16). This may relate in part to decreased bactericidal activity of their dendritic cells (17). Indeed, some strains of *S. aureus* were able to reside within bone marrow dendritic cells and macrophages because they expressed high activity of the Agr quorum-sensing system and escaped from phagosomes by producing the lytic proteins phenol-soluble modulins (18). Therefore, having adequate vitamin D levels may help dendritic cells to express maximal bactericidal activity against *S. aureus* as well as to release mediators to activate the immune system.

Mutations in NGFβ and Its Receptor NTRK1 Reduce Phagocyte Activation

Mutations causing loss of nerve growth factor β (NGFβ) or its receptor have been associated with recurrent *S. aureus* infections in humans in skin, joints, bones, and the oral cavity (19). *S. aureus* factors such as peptidoglycan, protein A, α-hemolysin, and phenol-soluble modulins stimulate macrophages through nucleotide-binding oligomerization domain-like receptors to produce NGFβ (19). NGFβ is both a chemoattractant for and an activator of phagocytes. NGFβ activation of neutrophils and macrophages results in enhanced killing of *S. aureus*. Deletion of NGFβ or its receptor NTRK1 results in more severe *S. aureus* infections in animal models (19). Of note, the ability to activate macrophages to produce NGFβ is limited to *S. aureus* because not even *Staphylococcus epidermidis* causes the release of NGFβ. Patients deficient in NGFβ demonstrate the critical importance of phagocytes in the control of *S. aureus* infections.

IRAK-4/MyD88 Deficiency

Defects in interleukin-1 receptor-associated kinase-4 (IRAK-4) or myeloid differentiation factor 88 (MyD88) impair Toll-like receptor 2 (TLR-2)-mediated and interleukin-1 (IL-1) receptor-mediated immunity such that macrophages fail to produce inflammatory cytokines such as IL-1β, IL-6, IL-8, interferons (IFNs), and tumor necrosis factor alpha (TNF-α) (20–23). Without these cytokines, there is a failure to activate a specific subset of T-helper cells known as T_H17 cells, which are critical for the activation of polymorphonuclear

doi:10.1128/microbiolspec.GPP3-0037-2018

TABLE 1 Immune defects that increase the incidence of *S. aureus* infections[a]

Immune defect	Biological basis	Clinical presentation	References
Failure of dendritic cells	Vitamin D required for activation	Recurrent and more severe infections	15, 16
Failure to activate macrophages	Mutations in NGFβ and its receptor, NTRK1	Recurrent and more severe *S. aureus* infections	19
Failure to activate PMNs	IRAK-4 or MyD88 deficiency	Failure of PMNs to kill *S. aureus*, *S. pnumoniae*, and *P. aeruginosa* despite Abs; invasive and skin infections; resolving in teenage years	20–23
Failure to differentiate naive T cells into T_H17 cells	IL-6 autoantibodies or IL-6 deficiency	Recurrent *S. aureus* infections	14
Failure of T_H17 cells to recruit PMNs	STAT-3 defect	Recurrent *S. aureus* skin and mucosal infections, starting in neonates	8, 10, 13
T-cell defects, e.g., with HIV or prednisone treatment	Reduced activation of T cells	Recurrent *S. aureus* infections, especially mucocutaneous	34–36
MAIT cell exhaustion (T cell exhaustion)	10–45% of lymphocytes Inactive after SAg exposure	Increased severity and frequency of infections in intensive care units with reduced MIAT cells	39–44, 48

[a]IRAK-4, interleukin-1 receptor-associated kinase-4; MAIT, mucosal-associated invariant T; MyD88, myeloid differentiation factor 88; NGFβ, nerve growth factorβ; STAT-3, signal transducer and activator of transcription 3; T_H17, T helper cell-17.

neutrophils (PMNs). These deficiencies manifest soon after birth with recurrent *S. aureus*, *Streptococcus pneumoniae*, and *Pseudomonas aeruginosa* infections. Prophylactic antibiotics and early aggressive antibiotic therapy are required to treat babies with these defects. While intravenous immunoglobulin is often used, with respect to pneumococcal infection, there is no correlation between the presence or absence of antipneumococcal antibodies and the occurrence of invasive pneumococcal disease in patients with these deficiencies. This demonstrates the critical importance of T_H17 cells and PMNs in the outcome, even though it is well known that anticapsular antibodies are important in host defense against the pneumococcus (20–23). Those children that survive until their teenage years have a resolution of frequent invasive infections.

IL-6 Autoantibodies

A patient described by Puel et al. with recurrent *S. aureus* infections had normal immunoglobulins, suggesting that his infections could not have been the result of immunoglobulin deficiency. Instead, this patient was found to lack the proinflammatory cytokine IL-6 due to anti-IL-6 antibodies (14). The absence of IL-6 causes an immunodeficiency state, which can be assumed to be responsible for his recurrent *S. aureus* infections. IL-6 is normally produced in response to *S. aureus* interactions with macrophages, dendritic cells, and γδ-T cells. IL-6, in conjunction with transforming growth factor β (TGF-β), helps to direct the conversion of naive CD4 T cells to T_H17 cells (24) and the proliferation of T_H1 and T_H2 cells, among many cell types (25). IL-6 is also important for blocking regulatory T cell (Treg) development and for stimulating B cells to produce antibodies (24). Overly active Tregs can produce immunosuppression by reducing T_H1 and T_H17 cellular activation of the bactericidal activity of phagocytes. On the one hand, activation of T_H17 cells is critical for the control of *S. aureus* infections (26); on the other hand, the suppression of Tregs may allow for an overly exuberant inflammatory response to *S. aureus* infections (27, 28). Indeed, loss of Tregs can result in fatal inflammatory disease (29). Thus, IL-6 plays a key role in regulating T_H17/Treg balance so as to control immunity and immunopathology.

Job's Syndrome, a T_H17/STAT3 Defect

Patients with autosomal-dominant hyper-IgE, or Job's syndrome, have dominant-negative mutations in signal transducer and activator of transcription 3 (STAT3) (8, 10, 13), and mutations in STAT3 have a strong association with frequent and severe *S. aureus* mucocutaneous infections, including staphylococcal pneumonia, empyema, and "cold" skin abscesses. STAT3 is an intracellular signal transduction factor in T_H17 cells, which links surface receptors to the activation of genes (30, 31). Activation by IL-6 of its receptor on T_H17 cells plays a key role in the differentiation of naive T cells into T_H17 cells. T_H17 cells are critical for controlling *S. aureus* infections because they release IL-17, which recruits PMNs to the site of infection and helps to activate the PMNs for killing *S. aureus* (31). A key role for PMNs in the protection from *S. aureus* infections has also been established by the observation of recurrent *S. aureus* infections in patients with chronic granulomatous disease (primary defect in the production of reactive oxygen species by their PMNs) (32). However, the role of STAT3 may extend beyond PMNs because STAT3 is also involved in expression of host antimicrobial peptides in keratinocytes (31) and in the production of Reg3γ, an antimicrobial peptide produced by respiratory epithelial cells, whereby these respiratory mucosal cells become bactericidal for *S. aureus* (33). *S. aureus* interaction with respiratory epithelial cells activates them through STAT3 for the production of Reg3γ. Thus, while STAT3 is important for controlling systemic invasion by *S. aureus* by recruiting and activating PMNs, it also plays an important role in activating mucosal and skin cells. Hence, this defect is associated with recurrent *S. aureus* mucocutaneous infections.

Corticosteroids and AIDS

Patients with reduced cell-mediated immunity have an increased incidence of *S. aureus* infections. This can be due

to an underlying disease such as systemic lupus erythematosus, AIDS infection, or the use of corticosteroids (34–37). Even moderate-dose prednisone therapy increases the risk of serious *S. aureus* infection (36). While we frequently think of viral infections as being associated with reduced cell-mediated immunity, the link to *S. aureus* infections comes from the reduced T_H17 cell-PMN axis in prednisone-treated patients (38).

Mucosal-Associated Invariant T (MAIT) Cells, Superantigens, and T Cell Exhaustion

MAIT cells represent up to 10% of T cells in blood and up to 35% in liver and some mucosal sites (39–44), and they may be considered the first T cell responders to invading bacteria because they are activated during the early stages of bacterial infection and act as a bridge between the innate and adaptive immune systems by recognizing bacterial byproducts derived from riboflavin metabolism (42). However, unlike the situation with humans, MAIT cells are infrequent in laboratory mouse strains such as C57BL6, thereby limiting the utility of murine models without humanization (39). MAIT cells have been implicated in protecting the host from multiple species of bacteria (40–42, 44, 45). However, recent studies have shown that they also respond to superantigens (SAgs), such as staphylococcal enterotoxin B (SEB), and have been identified as extremely potent and fast-acting producers of proinflammatory cytokines (39). To quote from Taylor et al. (39), "We have identified a population of innate T-like cells, called MAIT cells, as the most powerful source of proinflammatory cytokines after exposure to SAgs." In addition to being involved in immunopathogenic activity, MAIT cells may also be involved in "a novel mechanism of SAg-associated immunosuppression in humans" (39) wherein widespread activation of MAIT cells by SAgs results in their inability to respond to future challenges. Sandberg et al. (43) report that subsequent to such SAg activation, the MAIT cells remain unresponsive to stimulation with conventional bacterial antigens. This concept of immune exhaustion is supported by the observation that intensive care unit patients with reduced MAIT cells were more vulnerable to severe and subsequent bacterial infections during their stay in the intensive care unit (46). Equally, ill patients' normal MAIT numbers did not show increased bacterial infections (46). Thus, SAg-producing *S. aureus* hijacks MAIT cells by inducing the cytokine storm and leaves them functionally impaired. A mechanism for this is based on the occurrence of anergy via upregulation of inhibitory receptors such as lymphocyte-activation gene 3 (39, 44, 47).

T Cell Exhaustion is Manifested in Humans by Low Levels of IL-2

SAgs induce other modifications to T cells (see Fig. 2). A marker of T cell exhaustion is low levels of IL-2 (39, 43, 48). IL-2 production increases dramatically in SEB-challenged MAIT cells compared to conventional T cells in peripheral blood mononuclear cells (39). This is in contrast to *E. coli* exposure to MAIT cells where IL-2 was not produced (49). These observations are consistent with previous findings where SEB and other SAgs delete or anergize T cells (50, 51). Moreover, exposure of human $CD4^+CD25^-$ T cells to SEA induces proliferation and is followed by a switch to a $CD25^+FoxP3^+$ Treg phenotype that secretes IL-10 but not IL-2 (39). SEA also activates $\alpha\beta$T cells (52). SEB activates $\alpha\delta$T cells and stimulates the conversion of Treg to T_H17-like cells (11, 39, 52–57). In summary, SAgs can induce a cytokine storm, but they are also potent immunomodulators of the T cell immune response. These effects would be anticipated to change during the course of *S. aureus* sepsis.

Summary of Immune Defects and *S. aureus* Infections

In summary, the inborn and acquired immune defects that are associated with an increase in the incidence of *S. aureus* infections show that the macrophage-T cell axis is critical for the activation of phagocytes to control *S. aureus* invasive infections. Conspicuously absent is the need for opsonic antibodies for protection against *S. aureus*, because children with agammaglobulinemia do not show increased numbers of *S. aureus* infections (1–5). The innate activation of macrophages and dendritic cells, as well as the surface factors that activate complement, seem sufficient to control *S. aureus* without opsonization. On the other hand, antibodies against *S. aureus* toxins have been shown to reduce the severity and mortality of *S. aureus* toxin-mediated diseases (6, 58–61). As discussed below, staphylococcal SAgs can play a major role in the modulation of T cell development; therefore, antitoxin antibodies may be crucial in the maintenance of a balanced macrophage-T cell axis.

STAPHYLOCOCCAL SEPSIS AND CYTOKINE PRODUCTION

Some information is emerging about anti-*S. aureus* immunity that is based on studies of patients with sepsis, especially *S. aureus* bacteremia, and this is summarized in Table 2. In septic patients, the profile of cytokines produced during infection is a reflection of the cells that are activated (Table 2). Normally, interaction of invasive *S. aureus* with macrophages and dendritic cells causes the release of proinflammatory cytokines such as IL-1, IL-2, IL-6, IFN-γ, and TNF-α. This is later followed by IL-10, which downregulates the immune response. However, this normal pattern of immune response is not seen in patients that have worse outcomes from *S. aureus* sepsis. Thus, mortality is associated with dysregulation of the immune system in apparently normal individuals. As detailed in Table 2, mortality or more severe disease is associated with low IL-1, IFN-γ, and TNF-α but high IL-6 and IL-10.

A dramatic example of immune dysfunction during *S. aureus* infection came from the V710 staphylococcal vaccine trial, where increased mortality occurred in vaccinated patients (62). V710 was a recombinant *S. aureus* surface protein, IsdB (iron surface determinant protein B), and was given to subjects prior to cardiovascular surgery. Patients that received the vaccine and subsequently developed invasive *S. aureus* infection during the postoperative period showed increased mortality. The cause of the increased mortality was systemic inflammatory response wherein control of the immune response was lost. Posttrial investigation found that low levels of IL-2 were observed not only during sepsis but even before patients received the V710 vaccine (63). There was a 5-fold increased mortality in vaccinees that had low prevaccination levels of IL-2. Thus, low baseline levels of IL-2 could predict a tragic outcome when vaccinees developed a postoperative infection. These patients also showed low levels of IL-17. These unanticipated results show that excess mortality was related to a dysregulated immune response even before the vaccine was given. Because IL-2 is critical for the survival of Tregs (64), one can postulate that the loss of these cells that modulate the immune response may have played a role in the mortality of these vaccinees.

TABLE 2 Cytokines, sepsis, and survival in *S. aureus* infection

Study	Type of infection[a]	Survival or less complicated course	Death or complicated course
Söderquist et al. 1992 (84)	65 patients with sepsis	Rapidly dropping IL-6	Persistently elevated IL-6
van Dissel et al. 1998 (67)	Sepsis	High IL-1 and TNF-α with low IL-10	Low IL-1 and TNF-α with high IL-10
Rose et al. 2012 (68), Rose et al. 2017 (69)	*S. aureus* bacteremia	High IL-1 and low IL-10	Low IL-1β and IFN-ϒ; high IL-10
V710 vaccine trail Fowler 2013 (62); McNeely 2014 (63)	Invasive infections after cardiothoracic surgery	High IL-1, IL-2, and IL-17	Low IL-2 and IL-17 preoperatively and all postoperative testing
McNicholas et al. 2014 (85)	61 patients with SAB[a]	Low levels of IL-6 predict better outcome	High levels of IL-6 predict worse outcome
Gupta et al. 2016 (65)	Posttrauma sepsis (mix of bacterial pathogens)		High IL-4, IL-10, TGF-β, T_H17, and T_H17/Treg Low IL-2 and IFN-γ
Minejima et al. 2016 (66)	196 patients with SAB	Low TNF-α and IL-10; low IL-17A in all patients	High TNF-α and IL-10; low IL-17A in all patients
Chantratita et al. 2017 (86)	327 patients with SAB	Low IL-6 and IL-8 had less respiratory failure	High IL-6 and IL-8 had more respiratory failure

[a]SAB, *S. aureus* bacteremia.

IL-2 is complex in that it produces both pro- and anti-inflammatory effects by downregulating T_H17 but upregulating T_H1 cells. Although increased numbers of T_H17 cells were found in *S. aureus* sepsis in several studies (9, 65), this is usually not accompanied by an increased blood concentration of IL-17 (12, 62, 65, 66) and may help to explain why IL-17 levels were low in clinical studies when one would anticipate higher T_H17 activity. It also raises the possibility that T_H17 cells may act locally rather than systemically (Fig. 1).

The data outlined in Table 2, suggesting that immune dysregulation correlates with more severe disease and mortality, are considered here. IL-1 is released from macrophages and dendritic cells (among other cells) when *S. aureus* is first met while invading tissues (12). However, patients that show low levels of IL-1 have worse outcomes during invasive *S. aureus* infections (67–69). Of the many functions that IL-1 has, perhaps a very important one for invasive *S. aureus* infections comes in directing T_H17 differentiation and activation (70), because T_H17 cells are critical for protection against *S. aureus* infections (10, 13). Therefore, it is striking that patients with *S. aureus* circulating in their bloodstream and interacting with macrophages would fail to produce IL-1, and this is an obvious sign of immune dysregulation.

Another cytokine released early in the course of *S. aureus* infection is IL-2 (71), and low levels have correlated with poor outcomes (62, 65). Broadly speaking, IL-2 ± TGF-β reduces inflammation by directing reduction of T_H1, T_H2, and T_H17 differentiation and increasing Treg expansion (72). The importance of IL-2 in directing cells toward a moderated inflammatory response is underscored by the increased deaths in patients receiving the V710 *S. aureus* vaccine (62), wherein low prevaccination IL-2 levels correlated very strongly with a systemic inflammatory response syndrome (SIRS) response in these patients when an invasive *S. aureus* infection occurred. Moreover, IL-2 levels remained low during the infection. These observations are consistent with data from Gupta et al. (65), who studied sepsis in trauma patients, wherein death was associated with low level of IL-2 in culture supernatant of peripheral blood mononuclear cells from these patients. Of course, severe trauma itself causes changes in the immune response, so the immune dysregulation noted in this study is less clear cut than in the *S. aureus* vaccine study.

Also consistent with the IL-2 data for immune dysregulation are the observations from several studies that strongly correlate high levels of IL-10 with poor outcomes (65, 67–69). IL-10 downregulates the inflammatory response to *S. aureus* invasion. The increased mortality suggests that the balance between pro- and anti-inflammatory responses is incorrect. *S. aureus* itself may actively alter this balance by stimulating production of IL-10 directly. Quantitatively, *S. aureus* interactions with monocytes and macrophages via TLR-2 interactions produce 4- to 20-fold more IL-10 than interactions with dendritic cells (58). Thus, more IL-10 is produced during bacteremia than in cutaneous infections. While the downregulatory effects following interactions of *S. aureus* ligands with the TLR-2 on T cells, monocytes, macrophages, and dendritic cells may be critical for balancing the host response to SAgs (73–76), overly vigorous suppression of the immune response may lead to continued bacteremia, whereas inadequate suppression may result in death due to SIRS. Engagement of TLR-2 on macrophages can also produce the proinflammatory cytokine, IL-1, but in dendritic cells IL-2 is produced. IL-2 production is needed for the development and maintenance of Tregs, which suppress immune responses produced by T_H17 cells (56). In some cases, T_H17 cells, which are not thought of as IL-10 producers, can convert to IL-10 production when given a second *S. aureus* challenge (70), which might relate to the first challenge being vaccination and the second challenge being invasive infection (63). Hence, the inhibitory activity of IL-2 on T_H2 and T_H17 cells and stimulatory activity on Treg cells might be lost when IL-2 levels are low during sepsis and allow for increased IL-10 production. High IL-10 would decrease PMN activation and killing of *S. aureus* (70, 77–81), reduce T_H17 proliferation (78, 82), and reduce Treg activity (78, 82, 83). A balance between too low and too high IL-10 levels in response to *S. aureus* infections has been suggested as needed

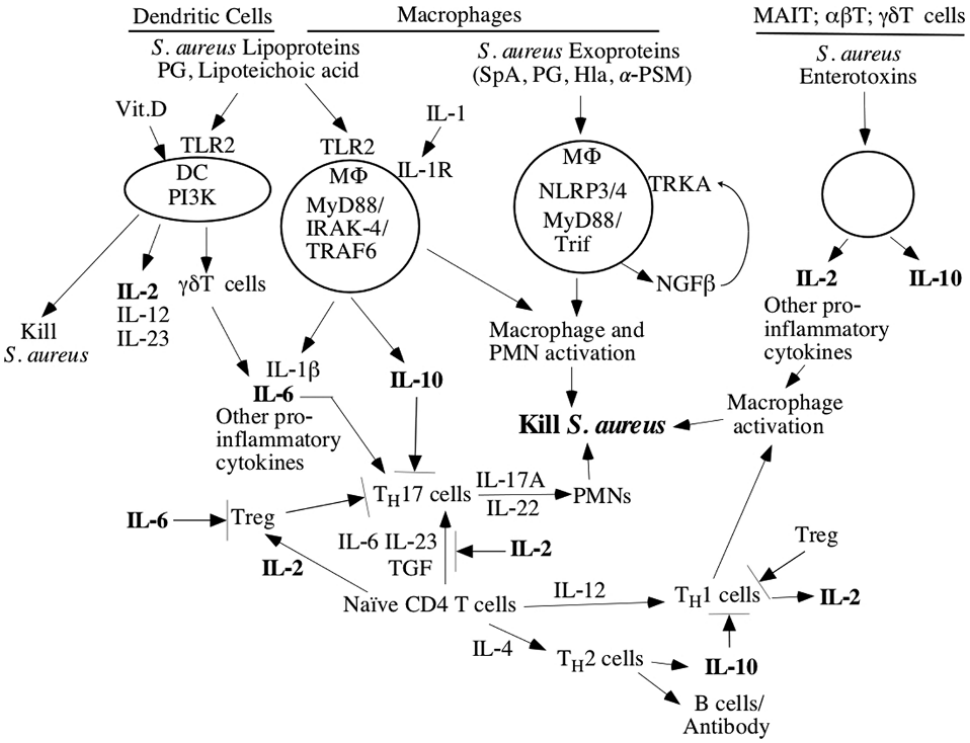

FIGURE 1 Model for human immunity to *S. aureus* based on immune defects and cytokines in sepsis.

to avoid an overly vigorous response (SIRS) or an incomplete activation (persistent bacteremia) (78, 82, 83).

Another consistent finding is that persistently elevated IL-6 correlates with death and/or with another worse outcome with *S. aureus* sepsis (84, 85, 86). IL-6 is produced by macrophages and dendritic cells shortly after *S. aureus* products bind to TLR-2 (14, 24, 27, 30, 81). IL-6 causes differentiation of naive T cells into T_H17 and regular Tregs into proinflammatory Tregs that produce IL-17, IFN-γ, and TNF-α (14, 24, 27, 56). Thus, persistently elevated IL-6 may be linked to an overactive proinflammatory response that damages the host more than it protects it.

Finally, noninterleukins have also been examined during *S. aureus* sepsis in humans. Low levels of IFN-γ correlate with death (65, 68, 69). Early interactions of *S. aureus* with macrophages via TLR-2 lead to IFN-γ release (83). Similarly, when *S. aureus* interacts with dendritic cells via TLR-2, this results in dendritic-cell-mediated activation of T_H1 and γδT cells to produce IFN-γ (18, 87). IFN-γ activates macrophages to kill *S. aureus* (83). MAIT cells can also produce IFN-γ after interactions with SEB (39). Clearly, low levels of IFN-γ might result in poor clearance of *S. aureus* by macrophages. Of interest, immunization of C57Bl/6 mice with killed *S. aureus* resulted in CD4 T-cell-dependent production of high IFN-γ levels with *S. aureus* bacteremia challenge that produced death (88). This provides another example where human and murine immunology diverge.

In contrast to IFN-γ levels, TNF-α levels yielded inconsistent results because high levels of TNF-α were associated with increased (66) or decreased (67) mortality from *S. aureus* bacteremia. TNF-α is important for activation of phagocytes, but it has also been associated with SIRS and death. More studies will be needed to sort this out. Nevertheless, the available studies of cytokine release during *S. aureus* sepsis provide strong evidence for immune dysfunction that leads eventually to death or more severe disease.

IMMUNE DYSREGULATION AND DEATH

Immune dysregulation, either over- or under-activation, of the immune response can be associated with mortality and/or more severe disease. This raises the question of why so many humans have a nonprotective response to *S. aureus* infections that is clearly related to immune dysregulation. We are familiar with *Mycobacterium leprae* and *Trypanosoma cruzi* as causing immunosuppression of the host, and hence one hypothesis is that the balance between the host and *S. aureus* has become lost. This might be due to the production of superantigens (SAgs) that can alter the responses of antigen-presenting cells and T cells (39, 43, 47, 50–53, 57, 74, 89–96). Observations from these papers are summarized in Fig. 2 and are offered as enterotoxins redirecting T cell differentiation. For example, SEB has many interactions with the human immune system. SEB can cause Tregs to develop a T_H17 phenotype and to produce TGF-β (91). The TGF-β enhances naive T cells to differentiate into T_H17 cells, and it inhibits T_H2 cell activation. SEA, SEB, and SEE can activate T_H1 and MAIT cells as superantigens that result in massive macrophage activation and toxic shock (39, 43, 46, 47, 49). After such activation, the T cells and MAIT cells down-regulate and fail to respond to further stimulation, leaving the host immunocompromised for days to weeks (39, 46). In addition, SAgs can even inhibit the primary interactions between staphylococcal products and TLR-2 (89, 90). Thus, SAgs have a very large number of interactions with the human immune system, especially T cells and macrophages (Fig. 2). Notably, cutaneous infections and vaginal toxic shock syndrome with *S. aureus* do not reliably provoke

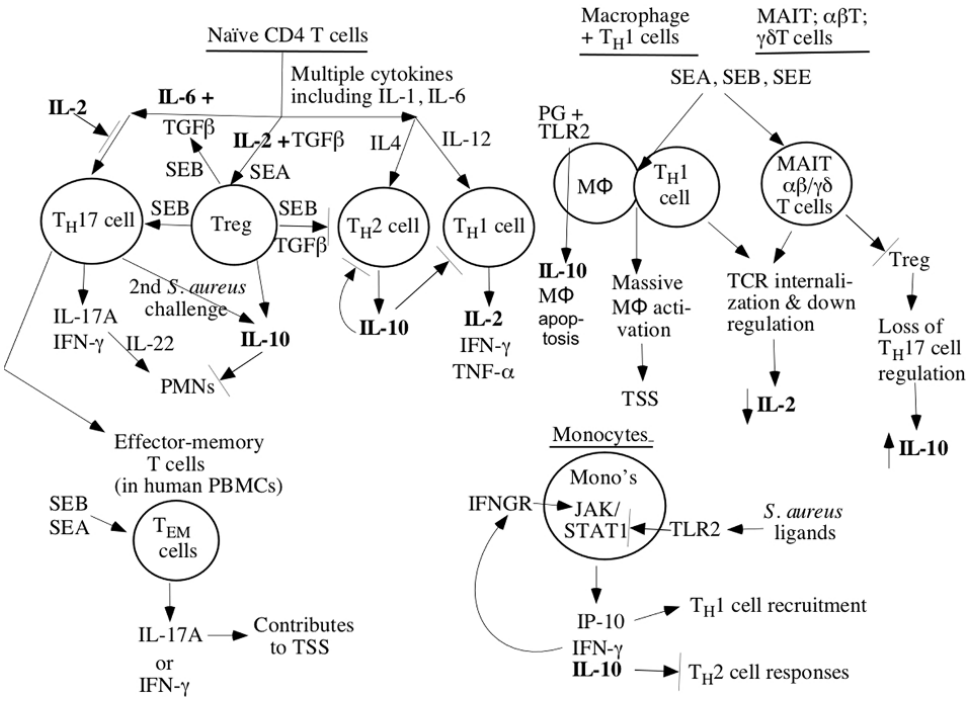

FIGURE 2 *S. aureus* enterotoxin modifications of immune response.

durable, protective immune responses (58, 97), thereby opening the possibility for SAgs and other toxins to influence the immunity response; yet seemingly, they have provoked no immune response. These interactions may underlie failures of humans to respond with protective immunity against *S. aureus* because continued exposure to SAgs is not inhibited without the presence of antitoxin antibodies.

COMMENTS ON THE MODELS

Gaps exist in our knowledge of the construction of the models of human immunity against *S. aureus* presented in Fig. 1 and 2, but these generate testable hypotheses. A major breakthrough for the development of an *S. aureus* vaccine that could prevent disease and death, or at least reduce the severity of infections, would be the discovery of a biomarker. Examples of vaccine biomarkers are anti-hepatitis B viral surface antigen and antimeningococcal capsular antibodies whose presence correlates with protection from infection. Our lack of a biomarker that predicts protection from *S. aureus* infections relates directly to our lack of understanding of protective immunity against *S. aureus*. Many successful bacterial vaccines against *S. pneumoniae*, *H. influenzae*, *Neisseria meningitidis*, and *Clostridium tetani* have been developed when the mechanism of immune protection was known and a biomarker was followed during clinical trials.

While cytokines provide some indication of which cells are activated, the precise cells being activated are not defined because cytokines can be produced by multiple cells and pathways. There is limited information concerning the timing and precise pathways in *S. aureus* human infections, which are not well replicated by murine models (1, 4, 6, 59, 60, 88). Moreover, cytokines may be released just locally, not systemically, so blood levels are not helpful. Finally, the relative balance between T cell subsets may be critical to the outcome. For example, our current state of knowledge does not allow us to know whether T cell exhaustion, reduced action of Tregs, or overactivation of T_H17 cells cause death with multiorgan failure during invasive *S. aureus* infections. In addition, the immune reactions to cutaneous/mucosal invasion versus systemic (bacteremic) infection are probably distinct, wherein γδT and T_H17 cells (IL-17A) are more important for skin and respiratory infections, whereas T_H1 (IFN-γ) responses are more important for survival during bacteremia (12, 98–100). We can see that sustained high levels of IL-10 correlate with death from *S. aureus* infections, yet it is not clear whether this is due to oversuppression of the immune response or a manifestation of the host attempt to reduce an overly exuberant immune response. When human peripheral blood mononuclear cells were differentiated into dendritic cells by culturing with granulocyte-macrophage colony-stimulating factor + IL-4, they produced a primarily T_H1/T_H17 stimulatory response, whereas when they were differentiated with macrophage colony stimulating factor, this triggered primarily an IL-10 response in response to TLR-2 activation by peptidoglycan or lipoteichoic acid (101). Hence, it is conceivable that the high levels of IL-10 during persistent *S. aureus* bacteremia come from continued activation of macrophages; however, it is also conceivable that the high levels of IL-10 downregulate the immune response needed to clear the bacteria.

Similarly, the data from the V710 vaccine trials, wherein low prevaccination IL-2 was strongly associated with SIRS, could be due to be overexpansion of or overly active T_H17 cells, e.g., by reduced Treg activity and loss of suppressive effects on T_H17 cells. Another hypothesis that springs out of Fig. 2 is that some patients may have T cell exhaustion and altered immune response due to colonization with superantigen-producing *S. aureus* strains (especially SEB), which can downregulate T cell receptors (92). For example, if superantigens led to MAIT cell downregulation, then low levels of IL-2 might prime the host for poor Treg and high T_H17 responses when *S. aureus* invasion occurred. It would be anticipated that these patients might be colonized with

SEB-producing strains, lack anti-SEB antibodies, and have low levels of IL-2. Low levels of IL-2 result in reduced Treg and increased T_H17 activity, perhaps adding to an imbalanced immune response to invasive *S. aureus* infections as seen in the V710 clinical vaccine trial. Finally, patients with immunodeficiencies tend to have local infections that rarely develop spillover bacteremia (102), but we have little knowledge about the factors involved in protection from primary *S. aureus* bacteremia. Contrasting the immune responses to bacteremia to cutaneous infections may shed light on the context for T cell activation.

The models for human immune responses to *S. aureus* are really hypotheses (Fig. 1 and 2), and much more detail is needed about the types of T cells being activated, the balance between T cell types, the timing of T cell activation and inactivation, the impact of antibodies, and the correlations to outcomes. Given the multiple possible interpretations of changes in cytokines, a detailed analysis of the types of T cells produced, their state of activation, the time course of activation, and the relative balance between the different T cell subsets prior to and during *S. aureus* invasive infections should shed light on which pathway(s) are critical for immunity to *S. aureus* infections. In addition, prospective data on the types of antibodies being produced (opsonic versus toxin-neutralizing), especially during *S. aureus* bacteremia versus cutaneous infections, that are correlated with outcome will help to inform us about the relative value of these antibodies. Animal models do not substitute for human data. This basic knowledge will be critical as *S. aureus* vaccine trials are designed because patients should be stratified in future clinical trials to evaluate the impact of therapeutic interventions.

SUMMARY OF HUMAN IMMUNITY AGAINST *S. AUREUS*

Cell-mediated immunity seems to be critical for the prevention and resolution of invasive *S. aureus* infections, but an imbalance in this immunity may also produce SIRS and death or an inadequate protective response with prolonged bacteremia and death. This dysregulation is likely at the heart of mortality and severe disease in humans. Antitoxin antibodies may also come into play in reducing the severity of *S. aureus* infections, but these antibodies might also address superantigen-induced immune dysregulation. Thus, while changing intrinsic T cell responses may be therapeutically difficult, monoclonal antibodies against superantigens may have utility in addressing dysfunctional immune responses to *S. aureus*. The models above are hypotheses for examining, and potentially dramatically improving, the immune response to and safety of *S. aureus* vaccines.

Nonconventional Therapeutics against *Staphylococcus aureus*

CAROLINE M. GRUNENWALD, MONIQUE R. BENNETT AND ERIC P. SKAAR

49

INTRODUCTION

Staphylococcus aureus is one of the most important human pathogens, causing a variety of diseases, including skin and soft tissue infections, osteomyelitis, endocarditis, surgical site infections, pneumonia, and sepsis. In recent decades, the treatment of staphylococcal infections has become increasingly difficult as the prevalence of multidrug-resistant strains continues to rise. Penicillin-resistant *S. aureus* emerged in the 1940s, followed by the appearance of methicillin-resistant *S. aureus* (MRSA) in 1961 (1, 2). Subsequent introduction of new antibiotics has been followed by reports of resistance (3). With increasing mortality rates and medical costs associated with MRSA and other drug-resistant strains, there is an urgent need for alternative therapeutic options (4). Therefore, considerable effort has been put forth to identify and develop novel *S. aureus* treatment strategies as alternatives to conventional antibiotics.

PREVENTION AND DISRUPTION OF BIOFILM FORMATION

Biofilms are multicellular, three-dimensional aggregates of bacteria embedded in a matrix composed of polysaccharides, extracellular DNA, proteins, and/or lipids and are formed as an adaptation to environmental stress. *S. aureus* biofilms are notorious for causing chronic infections due to their ability to adhere to living tissues and implanted medical devices (artificial heart valves, catheters, joint prosthetics, etc.), as well as their inherent recalcitrance to antibiotics (5–7). These biofilm-related infections lead to increases in morbidity, mortality, and health care costs, with infected devices often requiring surgical removal. However, antibiotic resistance is adaptive because biofilm-associated resistant bacteria revert to their planktonic susceptible phenotype as they disperse from the established biofilm (8). Thus, considerable effort has been put forth to identify effective antimicrobials that specifically treat *S. aureus* biofilms.

The biofilm extracellular matrix serves as a protective physical barrier that shelters the resident bacteria against antibiotics and host immune defenses. Therefore, approaches to disrupt the matrix by enzymatically degrading the chemical components have been investigated. DNase I-mediated degradation of extracellular DNA appears to be effective in disrupting early *S. aureus* biofilms, and treatment with trypsin or proteinase K disrupts the protein components of the biofilm matrix (9–12). Likewise, dispersin B, a glycoside hydrolase produced by the periodontal pathogen *Actinobacillus actinomycetemcomitans*, is able to break down the polysaccharide components of staphylococcal biofilms and can promote antibiotic penetration, resulting in synergistic killing when combined with the antibiotics cefamandole nafate or triclosan (13–15). However, a number of clinical strains are capable of forming polysaccharide-independent biofilms, and thus *S. aureus* susceptibility to dispersin B can vary widely among strains (16, 17). Additional glycoside hydrolases, α-amylase and cellulase, and lysostaphin, a glycine endopeptidase produced by *Staphylococcus simulans* that cleaves the pentaglycine bridge in the staphylococcal cell wall, have also been shown to significantly reduce the matrix biomass of *S. aureus* biofilms *in vitro* (18, 19). Although these *in vitro* results are promising, the application of exoenzymes as therapeutic drugs may be limited due to the possibility of protein-induced inflammatory responses in the host, toxicity, or immunity. Alternatively, these enzymes could be employed in an approach similar to an "antibiotic lock," where a high concentration is applied to catheter lumens to prevent catheter-associated *S. aureus* infections (12, 20). The efficacy of this strategy was demonstrated when implanted jugular vein catheters in mice preinstilled with lysostaphin provided complete protection against *S. aureus* infection compared to untreated catheters (21).

The release of planktonic cells has been shown to result in increased susceptibility to antimicrobials; thus, combining molecules that induce biofilm dispersal with traditional antibiotics could be another viable strategy to eradicate *S. aureus* infections (22). One such candidate is *cis*-2-decenoic acid, a fatty acid produced by *Pseudomonas aeruginosa* that causes an increase in planktonic bacteria released by *S. aureus* biofilms (23). Although the mechanism by which this occurs is not understood and further studies are needed to confirm these findings, it does suggest that *cis*-2-decenoic acid could be utilized as a dispersal agent. Moreover, *S. aureus* produces a number of endogenous dispersal agents, including the surfactant-like molecules phenol soluble modulins (PSMs). PSMs are intrinsically inflammatory and cytolytic for neutrophils, so repurposing PSMs into therapeutic dispersal agents seems questionable. However, due to the fact that PSMs are key to proper biofilm formation (24, 25), interference with PSM production or secretion could prove to be

doi:10.1128/microbiolspec.GPP3-0047-2018

an effective approach to inducing dispersal of *S. aureus* biofilms and enhancing antibiotic killing (26).

Targeting bacterial iron metabolism through the use of chelators and gallium-based therapeutics has been demonstrated to effectively disrupt staphylococcal biofilms (27). Iron is crucial for a variety of cellular processes, including DNA synthesis, energy production, respiration, and biofilm formation, and thus is a potential target for antistaphylococcal therapeutics (28). Due to their structural similarity, gallium is able to serve as an iron analog. In a "Trojan horse" strategy, gallium complexes are imported into the cell through bacterial iron uptake systems, where once inside, gallium competes with iron by binding to iron-dependent enzymes and molecules. This results in disruption of vital iron-dependent activities, including respiration, DNA synthesis, biofilm production, and bacterial proliferation (27). Gallium nitrate [$Ga(NO_3)_3$] has been shown to be effective at reducing bacterial biofilms *in vitro*, and mice treated with gallium maltolate had significantly lower bacterial burdens 48 hours post-treatment in a burn wound model of *S. aureus* infection (29, 30). However, not all gallium-based molecules exhibit antimicrobial effects. Conjugation of gallium to the *S. aureus* siderophore staphyloferrin A failed to effectively inhibit MRSA (31).

Recently, a combination therapy of synthetic gallium-based heme analogs and a metal chelator have shown promise as effective antimicrobials against *S. aureus* biofilms. Heme bound to hemoglobin is the most abundant source of iron within the host and is the preferred iron source for *S. aureus* (32). The metalloporphyrin gallium-protoporphyrin IX (GaPP) is capable of mimicking heme and thus facilitating its uptake (33). Once inside the cell, GaPP can be substituted for heme in heme-containing enzymes, including cytochromes, catalases, and peroxidases, disrupting vital cellular processes (33). *In vitro* studies indicate that treatment with the iron chelator deferiprone and GaPP results in significant reduction of methicillin-susceptible *S. aureus* (MSSA) and MRSA biofilms (34). Similar antimicrobial activity was also observed against biofilms formed by small colony variant *S. aureus* strains, which are linked to increased antibiotic tolerance and resistance (35). Moreover, this combination therapy has the ability to potentiate antibiotic-mediated killing, so combining current antimicrobials with gallium could be a promising strategy for the treatment of biofilm infections (36).

Although current data indicate that GaPP-mediated treatments may prove to be efficacious for abolishing *S. aureus* biofilms, the possibility of cytotoxicity due to interference with host iron metabolism should not be entirely discounted. Loss of cell viability and increased lactate dehydrogenase production, a biomarker for cellular cytotoxicity and cytolysis, have been observed in a number of mammalian cell lines when exposed to high concentrations of GaPP (33, 34, 37). However, concentrations of GaPP that induced cytotoxicity were considerably higher than those needed to significantly inhibit *S. aureus* biofilms (33, 35). Moreover, no health effects or changes in behavior were observed in mice given a single intraperitoneal dose of GaPP (25 to 30 mg/kg) followed by a daily dose (10 to 12 mg/kg) of GaPP given for an additional 4 days (33). This suggests that with optimized dosing of GaPP-based therapeutics, host toxicity could be avoided without compromising GaPP antimicrobial activity.

Antimicrobial peptides (AMPs) have been increasingly recognized for their antibiofilm properties. AMPs are typically small cationic peptides that exhibit a range of antimicrobial and immunological properties. One of the first recognized AMPs with antimicrobial activity against *S. aureus* biofilms was the human cathelicidin peptide, LL-37 (38). This peptide displays bactericidal activities against a wide range of Gram-positive and Gram-negative pathogens by disrupting the bacterial membrane (39). LL-37 synthetic derivative OP-145, when integrated into a medical device coating, was shown to prevent *S. aureus*-induced implant-associated infections in rabbits (40). Moreover, OP-145 has been successfully used in a clinical phase 2 trial for the treatment of chronic otitis media (41). Another LL-37 derivative, SAAP-148, demonstrated significant efficacy against MRSA, where treatment led to complete eradication of established biofilms *in vitro*, as well as *in vivo* in a murine wound model (42). Furthermore, cotreatment of the AMPs IB-367 and BMAP-28 with antibiotics was shown to be highly effective at treating catheter-associated infections, suggesting that AMPs could also be used to potentiate antibiotic killing of *S. aureus* biofilms (43, 44).

Another innovative attempt to effectively eradicate *S. aureus* biofilms includes the use of small-molecule inhibitors. A variety of small molecules with activity against *S. aureus* biofilms *in vitro* have been identified, including aryl rhodanines, d-amino acids, benzimidazole, and metal chelators (12, 45–47). An inhibitor of the essential *S. aureus* protein RnpA (RNP1000) significantly reduced the number of biofilm bacteria in an *in vitro* catheter model and protected against lethal systemic *S. aureus* infection in mice (48). These results are encouraging and suggest that small molecules that exhibit strong antibiofilm activities *in vitro* could be potent antimicrobials. However, very few small-molecule biofilm inhibitors have been tested in animal models, and thus, the ability of these compounds to treat *S. aureus* infections is not yet well defined.

INHIBITION OF VIRULENCE BY TARGETING QUORUM SENSING

Virulence factor production in *S. aureus* is regulated by quorum sensing (QS), a cell-to-cell communication mechanism bacteria use to regulate gene expression in response to cellular density. The *S. aureus* QS system is under the control of the accessory gene regulator (*agr*) system, and activation of the *agr* system by an accumulation of auto-inducing peptide leads to activation of the *agr* regulatory network that controls the expression of virulence factors by RNAIII, the major effector for downstream virulence expression and biofilm dispersal (10, 49–51). Inhibiting QS prevents the production of QS-regulated toxins such as delta-toxin, staphylococcal enterotoxin C, and Panton-Valentine leukocidin, thus restricting *S. aureus*' ability to evade the host immune system, kill host cells, and disseminate (52). Moreover, targeting virulence systems such as QS, rather than systems critical for bacterial survival, may exert less selective pressure for the development of resistance compared to using traditional antibiotics.

A number of synthetic and natural QS quenchers have been evaluated for their efficacy against MSSA and MRSA. Biaryl hydroxyketones were shown to successfully inhibit QS by preventing the interaction between the AgrA transcriptional regulator and the P3 promoter, which drives the transcription of the RNAIII master virulence regulator (53). Follow-up studies with synthesized biaryl hydroxyketones demonstrated that compound F12 was capable of reducing MRSA-induced rabbit erythrocyte hemolysis by 98% *in vitro* (54). In a *Galleria mellonella* insect larvae infection model, F12 treatment led to increased larval survival from 12 hours in untreated controls to 42 hours, and combining biaryl hydroxyketones with the β-lactam antibiotics cephalothin or

nafcillin, both of which MRSA is resistant to, further increased larval survival (55). However, in a murine wound infection model, compounds F12 and F1 promoted only modest increases in wound healing, and there were no significant differences in wound bacterial burdens between treatment groups (55). This suggests that the success of biaryl hydroxyketones to treat MRSA may be highly dependent on the infection model utilized, and therefore it has yet to be proven that biaryl hydroxyketone inhibition of QS will be an effective drug development strategy.

Additional ArgA-targeting molecules include the synthetic small molecule savarin and the natural product ω-hydroxyemodin. Savirin, which is capable of blocking *S. aureus* QS, attenuates *S. aureus* in a murine skin lesion infection model (56). Importantly, extensive passage of *S. aureus* in the presence of savarin does not lead to the development of resistance. ω-Hydroxyemodin, a polyhydroxyanthraquinone isolated from the fungus *Penicillium restrictum*, successfully reduced inflammatory cell recruitment and cytokine production and promoted bacterial cell clearance in a murine model of *S. aureus* skin infection (57, 58). Both molecules show promise for skin and soft tissue infections, but it is unknown if these molecules will be effective in other infection models.

Another promising QS inhibitor is ambuic acid, a fungal small-molecule metabolite that selectively inhibits *S. aureus* auto-inducing peptide production (59). Treatment with ambuic acid resulted in decreased lesion size and reduced weight loss in a murine model of *S. aureus* skin and soft tissue infection (59). Furthermore, plant-derived QS inhibitors such as hamamelitannin and its associated derivatives, ajoene, and cinnamaldehyde exhibit potent killing against *S. aureus* biofilms alone or in combination with antibiotics (60–66).

Pursuing additional components of the staphylococcal QS regulatory network could be an alternative option for development of QS-targeted therapeutics, but further research into the molecular mechanisms of QS regulation is needed. Another biofilm and virulence regulatory locus, staphylococcal accessory regulator (*sar*), is a promising target because it is thought to perform an opposing role to *agr* in *S. aureus* biofilm formation (45, 67–69). Overexpression of *sar* can inhibit biofilm production in some *S. aureus* strains; however, other studies demonstrated that *sarA* facilitates the expression of *agr* (67, 68). Although it is clear that the *agr* and *sar* systems are important regulators of *S. aureus* biofilm activities, a better understanding of the roles and relationships between *agr* and *sar* and how modulators of *agr* or *sar* affect *S. aureus* QS signaling, virulence factor production, and biofilm formation will be necessary to advance the development of drugs targeting QS.

BACTERIOPHAGE-BASED THERAPY

Bacteriophages (phages) have evolved to be the ultimate bacteriocidal agents. Phages are viruses that infect bacteria and multiply via a lytic cycle in which the phage particle attaches to the host, injects its genomic material, and manipulates the host machinery, resulting in intracellular phage multiplication. The cycle is complete when the bacterial cell is lysed, releasing multiple phage progeny. The antimicrobial power of lytic phages against staphylococcal infections was recognized as early as the 1920s, but with the discovery of antibiotics, phage therapy quickly fell out of favor in Western medicine (70–72). However, with the rise of multidrug-resistant bacteria, the use of phage-based therapies as an alternative to antibiotic treatment has garnered renewed interest from the medical and research communities.

A number of factors make phage therapy an attractive therapeutic strategy for *S. aureus* infections. Highly conserved components of the cell wall, such as teichoic acids, serve as phage receptors in *S. aureus*; thus, the likelihood of developing resistance to this type of therapy is reduced, and strains that do develop resistance often exhibit a reduction in virulence or fitness (73). The highly specific nature of phages results in only targeted bacteria being infected and subsequently killed, which prevents the disruption of the resident microbiota and morbidities associated with microbiota dysbiosis (74, 75). Moreover, phage therapy eliminates the potential for toxicity that is associated with many antibiotics, and many phages are capable of targeting multiple strains, including both MRSA and MSSA (76–80).

The efficacy of phage therapy has been explored for a wide range of *S. aureus* diseases, including skin and soft tissue infections, sepsis, pneumonia, and osteomyelitis, utilizing animal models with relatively good success (76, 79–88). An early report examining *S. aureus* skin infections in rabbits demonstrated that simultaneous subcutaneous administration of LS2a phage and *S. aureus* prevented abscess formation in 88% of the rabbits treated (81). Abscess size and bacterial burdens were also shown to significantly decrease compared to untreated infected controls in a dose-dependent response (81). A similar outcome was observed in skin lesions of mice infected with MRSA and injected intraperitoneally with SATA-8505 phage, but in this case lesion size failed to decrease despite a reduction in bacterial burdens (79). Phages have also been shown to protect against lethal doses of *S. aureus* (76, 82). Matsuzaki et al. demonstrated that intraperitoneal treatment with φMR11 phage led to complete protection against an *S. aureus* systemic infection, whereas untreated mice exhibited a mortality rate greater than 90% 24 hours postinfection (76). Phage levels rapidly increased within the blood stream and remained high until 6 hours postinfection, coinciding with a drop in bacterial burdens below detectable limits (76). Moreover, phage therapy has been shown to be effective against chronic *S. aureus* infections. Intravenous injection of M^{sa} phage suspension into mice that were systemically infected with a low dose of *S.* aureus 10 days *a priori* resulted in a significant drop in organ bacterial counts to below the limit of detection compared to infected untreated control mice (82). Combined, these studies provide clear evidence that phages are able to multiply and kill *S. aureus in vivo*, leading to disease reduction. *S. aureus* biofilms on indwelling medical devices and in the sinonasal cavity are notoriously difficult to eradicate, so some phage studies have focused specifically on the treatment of biofilms. Multiple groups have demonstrated that lytic phages are capable of significantly reducing biofilm biomass *in vitro*; however, it is still unclear if this is the case *in vivo* (89–91). Recently, Drilling et al. described a significant reduction in *S. aureus* biofilm mass in the frontal sinuses of sheep that were flushed with a cocktail of *S. aureus*-specific phages compared to those treated with heat-inactivated viruses (92, 93). Moreover, bacteriophage treatment significantly reduced *S. aureus* colonization of an indwelling catheter compared to controls in a rabbit model (94). Although these results are encouraging, questions about the efficacy of phage therapy for biofilm-associated infections, particularly in relation to biofilms in less accessible body sites, such as those coating joint prosthetics or artificial heart valves, have not been extensively addressed. In a single study using a rat orthopedic implant infection model, local injection of phage significantly decreased *S. aureus* colony-forming units and biofilm thickness on the implant compared to the control (95).

Pretreating the surface of such devices with a coating of phages may also prevent *S. aureus* medical device colonization and subsequent disease. Studies examining phage-coated orthopedic implants in mice saw a significant reduction in bacterial adherence to the device (96) and bacterial load in adjoining tissues (97). Combined, these studies suggest that phage therapy could be applicable to a number of *S. aureus* biofilm-associated diseases, and phage prophylaxis could help prevent *S. aureus* infections of indwelling medical devices.

A few attempts have been made to turn phages into drug delivery systems to increase the efficacy of *S. aureus* treatments (98–102). Bacteriophage 75 complex was used to administer a photosensitizer to *S. aureus* cells, which significantly enhanced MRSA and MSSA killing when exposed to red light *in vitro* (102). Additional reports describe the use of phages to transfer the antibiotic chloramphenicol to *S. aureus* cells, but bacterial growth was only partially inhibited due to limitations of drug-loading capacity caused by the drug's hydrophobicity (100, 101). Although the concept of manipulating phages into highly specific drug transfer systems is appealing, additional research is needed to further develop this strategy and determine if it could be applicable to the wide breadth of *S. aureus* disease presentations.

At this time, clinical use of therapeutic phages is limited to European countries and the former Soviet Union (71, 103–105). No formal regulations or standards for phage therapy in these countries exist, so well-documented clinical trials including robust controls are lacking (104). Therefore, it is difficult to come to any definitive conclusions, as well as to confidently assess the risks associated with these treatments in humans (106, 107). Nevertheless, multiple reports have described positive clinical outcomes associated with phage therapy for a wide range of *S. aureus* diseases in humans, including respiratory, circulatory, orthopedic, and soft tissue infections (71, 105, 108–110). These clinical reports, taken together with the growing body of literature on *in vitro* and *in vivo* studies, demonstrate that phage therapy could be a feasible strategy for treating *S. aureus* infections.

However, it should be noted that phage therapy is not without potential pitfalls. Due to the high specificity of phages, one significant drawback can be a narrow spectrum of sensitive strains. This issue can be circumvented by selecting polyvalent phages, i.e., those with the capability to infect a large set of strains within a species or combining multiple phages into a therapeutic cocktail (78, 111, 112). Additionally, the health risks associated with *S. aureus* phage therapy are poorly defined. In most cases no adverse effects have been reported, but it is not unforeseeable that a sudden influx of phage or the release of bacterial toxins due to lysis could stimulate a robust inflammatory response (70, 103, 113). Immune induction could also lead to the production of antibodies and subsequent clearance of phages, significantly reducing the efficacy of the treatment (114). Moreover, as viruses are replicating biological agents, it would be extremely difficult to standardize commercial production for clinical use. Nonetheless, the potential of phage therapy may outweigh the drawbacks in the face of increasing staphylococcal antibiotic resistance, and therefore it warrants continued consideration.

STAPHYLOLYTIC ENZYMES AS THERAPEUTICS

The antimicrobial potential for lytic enzymes was first appreciated by Alexander Fleming upon the discovery of the eukaryote-derived cell wall hydrolase, lysozyme; however, more recently, the staphylolytic enzyme lysostaphin, an endopeptidase that cleaves the pentaglycine crosslinking bridges of peptidoglycan, has garnered much attention as a potential antimicrobial agent (115). Since the identification of the enzyme, a growing body of literature indicates that lysostaphin is effective at targeting MSSA, MRSA, and vancomycin-resistant *S. aureus*, as well as *S. aureus* biofilms (19, 116–120). Treatment with lysostaphin systemically or as a material coating has shown promise for eradication of *S. aureus* infections *in vivo* using several animal models (121–123). Moreover, application of lysostaphin reduced *S. aureus* nasal carriage in humans, with no reported toxicity. This suggests that lysostaphin treatment may also be an effective decolonization strategy (124).

Recombinant phage-derived lysins have also been demonstrated to be highly effective antimicrobials *in vitro* and *in vivo* (125). During the lytic phage cycle, viral peptidoglycan hydrolases (endolysins) are produced to facilitate the release of progeny virions by degrading the bacterial cell wall (126). Phage endolysins are particularly attractive as alternative antimicrobial candidates due to a high degree of species and strain specificity (127).

Additionally, endolysins have evolved to bind and cleave highly conserved structures in the cell wall without necessitating intracellular transport of the enzyme, thus decreasing the potential for resistance development and avoiding mechanisms that play a role in conventional antibiotic resistance (e.g., active efflux from the cell) (128). Staphylococcal endolysins can differ significantly at the amino acid sequence level, which is also reflected in their diversity of enzymatic and antibacterial properties (129, 130). Combinations of endolysins have been shown to provide a synergistic treatment effect and would also help decrease the chance of resistance development (131–133). Moreover, recombinant endolysin proteins have the potential to be mass produced for clinical use.

A variety of endolysins and their antistaphylococcal activity have been characterized, with many identified as being highly effective at clearing *S. aureus in vivo* (128). MV-L, originally derived from the staphylococcal phage φMR11, was the first phage endolysin tested in an animal model. These early studies demonstrated that MV-L is capable of killing multiple strains of *S. aureus in vivo*, including those with vancomycin and methicillin resistance (134). Since then, additional endolysins with potent lytic activities against drug-resistant strains of *S. aureus* have been identified, including LysK, an endolysin derived from bacteriophage K, and the LysK derivatives PlyGH15, ClyH, ClyS, CHAPk, and SAL-1 (83, 135–139). Unlike MV-L, where lytic activity is limited to only *S. aureus* strains, LysK has a much broader spectrum of antimicrobial activity that includes the ability to lyse coagulase-negative staphylococci (112). CHAPk, an engineered, truncated version of LysK, has an even broader lytic spectrum that includes members of the *Streptococcus* and *Micrococcus* genera (137).

Numerous reports indicate that endolysins have the potential to be highly effective against skin and soft tissue *S. aureus* infections. Intranasal treatment with MV-L successfully eliminated *S. aureus* in the nares of mice, and similar nasal decolonization outcomes were observed in mice administered CHAPk orally or intranasally (134, 137). Intranasal inoculation with the engineered endolysin fusion protein ClyS resulted in a 2-log reduction in colony-forming units 1 hour postinfection of mice intranasally infected with MRSA (136). In a murine skin infection model, bacterial loads were significantly reduced when ClyS was topically applied compared to mice treated with mupirocin, a com-

monly prescribed antibiotic for the topical treatment of *S. aureus* skin infections, and untreated controls (140). Additionally, endolysin MR-10 combined with the antibiotic minocycline significantly reduced the mortality rate and healing time in a murine burn wound model (141).

Endolysins also hold promise as effective therapeutics against more severe *S. aureus* infections. Mice infected intraperitoneally with MRSA were 100% rescued when MV-L was administered intraperitoneally 30 minutes postinfection. Similar outcomes were observed in mice systemically infected with MRSA and treated intraperitoneally with endolysins phi11, LysK, 80α WMY, and 2638A (129). After 2 days, 100% of the endolysin-treated mice survived, whereas only 25% of vehicle-treated mice survived (129). LysGH15 and SAL-1 have also been shown to be effective against systemic MRSA infections (83, 138). Moreover, intravitreal injection of the engineered endolysin Ply187 significantly reduced bacterial burdens in the eye and preserved retinal function in a murine model of endophthalmitis (50). However, delays in treatment time can significantly reduce the efficacy; thus, endolysin-based therapies may need additional optimization to ensure that they are effective against the most severe *S. aureus* diseases (134).

Recent attempts have been made to enhance the stability and delivery of endolysins utilizing nanoparticles. Nanoparticles containing CHAPk and lysostaphin in the thermoresponsive polymer poly(N-isoporopylacrylamide) allowed for the controlled release of the enzymes upon reaching 37°C (142). Moreover, complexing LysK in polycationic polymers enhanced enzyme stability and lytic activity (143). Nanotechnology could prove to be an effective way to enhance endolysin-based therapies and ensure stability at both storage and physiological temperatures.

Notably, the first generation of staphylococcal phage endolysin-based antimicrobial products is already on the market, and clinical trials are underway for endolysin-based drugs. Staphefekt XDR.300 is an antiseptic solution that is effective against MSSA and MRSA on human skin and is incorporated into a series of creams and gels sold under the Gladskin brand name by the company Micreos Human Health BV (Netherlands). These skin products are for the treatment of skin conditions with an infectious component, such as acne, rosacea, eczema, and skin irritation, and contain the active ingredient Staphefekt. SAL200 is a therapeutic formula containing the endolysin SAL-1, a well-characterized homolog of LysK derived from the *S. aureus* phage SAP-1 (138, 144). It is the first to have undergone a good laboratory practice-compliant safety evaluation including single and repeated dose toxicity and organ function studies in rats and dogs, as well as further pharmokinetics and safety testing in monkeys (145, 146). SAL200 has been shown to be well tolerated with limited side effects observed in these studies. Recently, SAL200 was intravenously administered to healthy male humans as part of a phase 1 clinical trial (147). No serious adverse effects were observed for any of the participants, but there were reports of mild headache, fatigue, and myalgia (147). Additionally, a phase 2 clinical trial is underway for CF-301, an antistaphylococcal endolysin derived from a prophage originally isolated from *Streptococcus suis* (148, 149). Previous work has demonstrated CF-301 to be highly effective at eradicating *S. aureus* biofilms, including biofilms enriched for the more resistant small-colony variants, and it was more effective than antibiotics for the treatment of septicemia in a murine infection model (150, 151). In light of these developments, endolysin-based therapies are likely to be clinically applied in the near future.

RNA GUIDED NUCLEASES

The natural bacterial defense system known as clustered, regularly interspaced, short palindromic repeats (CRISPR) and CRISPR-associated (Cas) genes enables bacteria to recognize and degrade foreign DNA and can serve as an effective, programmable tool for genome editing (152, 153). The Cas9 endonuclease found in the type II CRISPR/Cas system uses a 20-nucleotide small-RNA guide to specify the site of DNA cleavage (154). Recent studies have demonstrated that reprograming Cas9 to target bacterial genomic sequences can result in effective cell killing (155, 156). Therefore, it may be possible to create highly specific, programmable antimicrobials by exploiting the CRISPR system.

Only recently has the antimicrobial power of CRISPR/Cas systems been tested experimentally (157–159). Bikard et al. generated phagemids encoding the packaging site and *rinA*, *terS*, and *terL* genes from the staphylococcal φNM1 bacteriophage with the CRISPR/Cas9 system that were capable of selectively killing *S. aureus* strains depending on the guide RNA sequence provided (158). Application of a phagemid containing RNA-guided Cas9 specific to the methicillin resistance gene, *mecA*, to a mixed culture of MRSA and MSSA strains resulted in a significant reduction in the proportion of MRSA from 50% (pretreatment) to 0.4% (posttreatment), with no differences observed in treated MSSA cells or either strain treated with nonspecific Cas9 targets (158). Similar outcomes were observed when phagemids were topically applied in a murine skin colonization model. Mice colonized with a mixture of kanamycin-resistant and kanamycin-sensitive *S. aureus* saw a significant reduction in kanamycin-resistant but not kanamycin-sensitive cells when treated with RNA-guided Cas9 targeting the kanamycin resistance gene *aph* (158). These results suggest that programming Cas9 nuclease to be a sequence-specific antimicrobial could be an effective treatment strategy, particularly against drug-resistant *S. aureus* infections, or as a decolonization strategy to selectively eliminate *S. aureus* without disturbing the rest of the host's microbiota.

Effective drug delivery remains a significant hurdle to implementation of CRISPR-based antimicrobials (160). As mentioned in the previous section, bacteriophage delivery systems are associated with a number of drawbacks, not limited to reduced host range, poor penetration to areas of infection, and possible adverse health effects. A few attempts have been made to circumvent these issues, including genetically modifying phage tail protein sequences to increase host range and conjugating the CRISPR/Cas9 system to nanoparticles to eliminate the use of the virus altogether (159, 161). Kang et al. described a nonviral delivery system in which CRISPR/Cas9 machinery was covalently modified with the cationic polymer branched polyethylenimine to form a CRISPR nanocomplex (159). These nanocomplexes significantly reduced the growth of MRSA strains *in vitro* compared to the native CRISPR/Cas complex, but their efficacy against *S. aureus* infections *in vivo* remains untested (159). Additional studies examining the use of nanoparticles and other alternative delivery systems are warranted. Future efforts will need to focus on engineering and refining CRISPR/Cas antimicrobial delivery systems, as well as validating these strategies utilizing animal models.

PHOTODYNAMIC THERAPY

Photodynamic therapy (PDT) is a treatment method combining photosensitizers, visible light, and oxygen to induce cell death. Photosensitizers accumulate in the targeted cells,

and upon illumination with light of a specific wavelength, become activated from a ground state to an excited state. The energy produced during excitation is transferred either to a cellular substrate and then to oxygen to form several reactive oxygen species (ROS) (type I mechanism) or directly to molecular oxygen to form a highly reactive singlet oxygen (type II mechanism) (162). Various biomolecules are affected during this process, specifically proteins, nucleic acids, and unsaturated lipids, resulting in irreversible damage and cell death (163, 164). In some cases, the direct mechanism of cytotoxicity has been investigated, which depending on the photosensitizer and its subcellular location, can be attributed to inactivation of enzymes, damage to the cell membrane, or indirect damage to the chromosome (164–168).

Historically, PDT was applied to treat various forms of cancer, but over the past two decades PDT has emerged as an alternative modality for the treatment of localized microbial infections. The nonselective nature of PDT and nonspecific damage triggered by ROS ensures that the development of antimicrobial resistance is unlikely (169–171). Perhaps even more importantly, the effectiveness of PDT against *S. aureus* is independent of a strain's antibiotic resistance profile; thus, PDT treatments can be applied to treat both MSSA and MRSA (172). Moreover, since PDT is exclusively used to treat localized infections, the risk of host cell toxicity and disruption of the microbiota is greatly minimized compared to the use of systemic antibiotics.

A key factor dictating the success of PDT-mediated treatment of *S. aureus* is the selection of a suitable photosensitizer. Consideration should include the propensity of the photosensitizer to preferentially target bacterial cells over host cells, solubility, a long light wavelength absorption band, and high generation of ROS (173). Most antimicrobial photosensitizers tested are organic, aromatic dyes, namely porphyrins, chlorines, phthalocyanine, rose bengal, phenothiazines, and acridines (174). Although a number of photosensitizers have been approved for use in humans, only a select few have been applied clinically to treat microbial infections. These include methylene blue, toluidine blue O, neutral red, PP904 phenothiazium dye, and protoporphyrin IX formed from the porphyrin precursor 5-aminolevulinic acid (ALA) or the ALA-methyl ester, methyl aminolevulinate (175).

Depending on the light source, duration of exposure, and photosensitizer used, PDT can be highly effective at reducing both MSSA and MRSA numbers *in vitro* (166, 172, 176–180). For example, combining 50 μg/ml toluidine blue O and a 15-minute exposure to an 632.8-nm HeNe laser resulted in complete eradication of 8 MRSA isolates, and PDT treatment with aluminum disulfonated phthalocyanine was shown to effectively inactivate 16 epidemic MRSA strains (181, 182). Similar outcomes were observed for the treatment of *S. aureus* biofilms, where PDT treatment with the photosensitizer hypericin significantly reduced biofilm viability (92 to 99%) in all 22 MRSA strains tested (180).

The effectiveness of PDT has also been explored for a number of animal models of localized *S. aureus* infections. In parallel with what is observed *in vitro*, PDT can be highly successful at eradicating *S. aureus* within the host; however, this is greatly dependent on the photosensitizer, light source, and duration of exposure chosen (183). Nonetheless, PDT has been shown to effectively deplete bacterial levels and decrease wound healing time in superficial skin infections using murine skin abrasion and burn wound models, as well as to reduce bacterial burdens in deeper soft tissue abscesses (184–189). Using fiber-optic light delivery systems, PDT treatment has been quite effective against *S. aureus* osteomyelitis in rats (190–193). Administration of the photosensitizer toluidine blue and a red diode laser resulted in an immediate bacterial reduction of 97% within the bone tissues of *S. aureus*-infected rats that was maintained for at least 30 days following treatment (190); moreover, significantly less bone destruction was observed when rats were treated with either toluidine blue or another photosensitizer, Napheophorbide, and the corresponding laser lights (190, 193). Additionally, increased accumulation of neutrophils and bacterial clearance was observed in mice treated with PDT in a murine *S. aureus* septic arthritis model (194, 195).

Despite the nonspecific nature of PDT's ROS-induced killing, PDT sensitivity and resistance levels can vary widely among *S. aureus* strains. A recent study comparing MSSA and MRSA strain susceptibilities to PDT inactivation using protoporphyrin arginate, toluidine blue O, and ALA found that resistance to PDT was independent of antibiotic resistance or virulence profile (196). Moreover, the study also demonstrated that the same bacterial strain could be categorized as PDT sensitive or resistant depending on the photosensitizer used (196). Coupling PDT treatment with ALA and antibiotics has been shown to enhance bacterial killing compared to PDT alone, but this synergistic effect is not necessarily enough to overcome strain differences in PDT resistance (197–199). Although the mechanism that confers strain-dependent resistance to PDT has not yet been fully elucidated, polymorphic differences in the *agr* locus and Agr system functionality have been shown to correlate with *S. aureus* sensitivity to PDT (200, 201). Continued research into the molecular markers that predict strain responses to photo-inactivation will aid in the development of more effective treatment modalities in the future. One significant issue with PDT-based therapies is the potential for ROS to inflict harm on neighboring host cells. Thus, a significant challenge in PDT development is to identify mechanisms in which pathogenic bacteria are efficiently inactivated without damaging the surrounding host tissue. Improving the selectivity of photosensitizers has been an area of intense research within the antimicrobial PDT field. Modification of photosensitizers via antibody conjugation, attachment of peptides, and use of bacteriophage delivery systems have been used to enhance the specificity of antimicrobial PDT (102, 202–204). Moreover, targeting bacteria-specific structures has also been proposed. The addition of two phenothiazinium photosensitizers (EtNBS-COOH) to the side chains of cephalosporin resulted in an enzymatically activated photosensitizer, whereby activation was reliant on the cleavage of the lactam ring by beta-lactamase (205). This novel approach of targeting the antimicrobial resistance mechanism itself resulted in very little nonspecific photosensitizer uptake by host cells *in vitro* (205). Small-molecule activation of the coproporphyrinogen oxidase (CgoX), an enzyme essential for heme biosynthesis and specific to Gram-positive organisms, induced accumulation of the phototoxic heme precursor coproporphyrin III in *S. aureus* and upon light exposure led to a reduction of bacterial burdens *in vitro* and in a murine model of skin and soft tissue infections (206).

Nanotechnology has also been applied to enhance the efficacy of antimicrobial PDT by improving photosensitizer solubility, photochemistry, and photophysics and targeting the pathogen (207, 208). Covalent conjugation of a photosensitizer to a nanostructure or encapsulation in engineered nanoparticles, such as liposomes, micelles, chitosan nanoparticles, and carbon nanotubules, has been proposed to heighten PDT-mediated killing of microbes

(207). Nanostructures with cationic charges have been shown to increase the specificity of PDT photosensitizers due to increased binding to the negatively charged microbial membranes (209). Many photosensitizers are insoluble and tend to aggregate, and thus, nanoparticle-based delivery helps to improve the lethality of PDT via increasing the concentrations of photosensitizer absorbed by the targeted bacterial cells (207, 208, 210). Moreover, some nanoparticles, such as gold, can potentiate PDT by exerting a photothermal effect when exposed to light or, as is the case with silver, have intrinsic antimicrobial properties of their own (208, 211). Additional advantages of using nanoparticles include increased photosensitizer resistance to photobleaching and inactivation, generation of higher concentrations of locally produced ROS resulting in more damage to the targeted bacteria, and low immunogenicity (207, 212).

Another chief obstacle for the advancement of PDT technologies is the limited penetration of light into tissues. Several approaches have been employed to overcome this limitation. Major advancements in fiber optics and microendoscopic technology have allowed PDT to be used with interstitial, endoscopic, intraoperative, or laparoscopic light delivery systems (213). This allows light to be delivered to almost any body site in a minimally invasive manner. Moreover, optical clearing with harmless substances such as glycerol that match the refractive index of tissues can dramatically reduce the effects of tissue scattering of light during PDT (214). Light application with a 2-photon short-pulsed laser has also been shown to result in deeper photopenetration of tissues compared to traditional continuous wave lasers or light sources.

At this time, antimicrobial PDT is predominately applied to treat dental and dermatological infections, but clinical use of antimicrobial PDT has been documented for the treatment of oral infections, acne vulgaris, burn wound infections, and skin ulcers (175). However, clinical trials testing the efficacy of PDT specifically for the treatment of *S. aureus* infections in humans are few. In a randomized, double-blind, placebo-controlled phase 2 trial by Mannucci et al., patients with chronic leg ulcers or chronic diabetic foot ulcers that were treated with a gel containing the photosensiziter RLP086 and 689-nm red light had a significant reduction in total microbial load, with no significant adverse effects reported compared to the placebo-treated group (215). Additionally, a clinical trial in Vancouver, Canada, found that surgical patients that received intranasal PDT during preoperative care had significantly reduced levels of nasal carriage and a 42% reduction in postsurgical site infection rate compared to a 4-year historical average (216). This study led to the development and commercial release of the PDT-based decolonization system MRSAid (Ondine Biomedical, Inc., Vancouver, Canada), which has been approved for clinical use in Canada and is pending approval in the European Union. In the United States, a clinical trial sponsored by the University of Rochester investigating PDT-based treatment of deep tissue bacterial abscesses is expected to be completed by the end of 2018 (217). With the rapid pace at which PDT technologies continue to evolve, it is expected that more clinical trials and PDT-based products will appear in the near future.

ANTIBODIES AND ANTIBODY CONJUGATES

S. aureus expresses many immune evasion and virulence factors that may be potential candidates for antibody therapies and vaccine development. Unfortunately, previous efforts at immunotherapies have failed, due in large part to the functional redundancies of these evasion factors, which is further aggravated when only one antigen is targeted. There have been a number of failed passive immunotherapies against different targets, including lipoteichoic acid (Pagibaximab), clumping factor A (Veronate), capsular polysaccharide (Altastaph), and α-hemolysin (Salvecin, MEDI4893) (218–221). Currently, the development of a promising human monoclonal antibody therapy for the treatment of *S. aureus* bacteremia, 514G3, is ongoing. 514G3 was isolated from the immune repertoire of a healthy human donor and targets the *Staphylococcus* protein A (222). In early 2017, a double-blind, placebo-controlled, phase 1/2 clinical trial of 514G3 involving more than 50 patients in the hospital setting (223) was completed. Another monoclonal antibody treatment against *S. aureus*, ASN100, was developed by Arsanis, Inc., and targets α-hemolysin, Panton-Valentine leukocidin, leukocidin ED, leukocidin GH, and γ-hemolyins AB and CB (224, 225). ASN100 was developed especially to treat patients on respirators who are at risk of developing *S. aureus* pneumonia. The endpoints of a phase 1 trial were met, and a phase 2 clinical trial has been scheduled (226).

SUMMARY

Unfortunately, antibiotic-resistant microorganisms continue to become more and more prevalent, threatening public health and placing a significant economic burden on the health care system. To eliminate drug-resistant infections, novel and effective therapeutic options are desperately needed. Many innovative strategies for alternative drug development are being pursued, including disruption of biofilms, bacteriophage-derived antimicrobials, antistaphylococcal vaccines, and light-based therapies. While many compounds and methods still need further study to determine their feasibility, some are quickly approaching clinical application and may be available in the near future.

SECTION 4

The Listeriae

Section Editor: **Daniel A. Portnoy**

Listeriosis and *Listeria monocytogenes* are of interest to a broad range of investigators, including food microbiologists, clinicians, immunologists, medical microbiologists, and cell biologists. While *L. monocytogenes* remains one of the leading causes of mortality from food-borne infections in the United States, it has emerged as an excellent model system to study basic aspects of bacterial pathogenesis and cell-mediated immunity. Indeed, for over five decades, immunologists have exploited the *L. monocytogenes* model to study cell-mediated immunity, and much of our current understanding of cell-mediated immunity has derived from the murine model of listeriosis. It may be true that more is known about the murine response to *L. moncytogenes* than to any other bacterial pathogen; however, it should be noted that the vast majority of these studies have used an intravenous or intraperitoneal route of inoculation, and the relevance of these studies to the natural, oral route of infection is not always clear. Newly developed animal models, including pregnant guinea pigs and transgenic mice, are sure to have a vital impact during the next few years. *L. monocytogenes* has also been utilized as a live, attenuated recombinant vector for the development therapeutic vaccines for cancer immunotherapy. During the past few years, clinical trials have shown promising results.

L. monocytogenes has also emerged as a model system for studying basic aspects of intracellular pathogenesis. Many genetic techniques have been developed, including transposon mutagenesis, allelic exchange, reporter systems, inducible gene expression, integration vectors, and transducing phages. The completion of multiple genome sequences and the subsequent development of transcriptomics have resulted in the identification and characterization of many novel determinants of pathogenesis. The combination of Listeria genomics with mouse genomics, along with an extensive battery of genetic and cell biological tools, should make the next few years truly exciting.

Epidemiology and Clinical Manifestations of *Listeria monocytogenes* Infection

WALTER F. SCHLECH

50

EPIDEMIOLOGY

Listeria monocytogenes is a Gram-positive motile facultative anaerobe that inhabits a broad ecologic niche (1–3). With selective media it can be readily isolated from soil, water, and vegetation, including raw produce designated for human consumption without further processing (4, 5). Newer chromogenic media may offer some advantages in the detection of contaminated foodstuffs (6, 7). Surface contamination of meat and vegetables is relatively common, with up to 15% of these foods harboring the organism. In addition, the organism is a transient inhabitant of both animal and human gastrointestinal tracts (8–10), and intermittent carriage suggests frequent exposure. The gut is the source for the organism in invasive listeriosis when it occurs, and the virulence factor ActA may promote carriage (11). The organism is psychrophilic and enjoys a competitive advantage against other Gram-positive and Gram-negative microorganisms in cold environments, such as refrigerators. It may also be amplified in spoiled food products, particularly when spoilage leads to increased alkalinity. Feeding of spoiled silage with a high pH has resulted in epidemics of listeriosis in sheep and cattle (12).

Several large foodborne outbreaks of listeriosis in humans have parallels to epidemic listeriosis in animals. The first proven foodborne outbreak occurred in Canada in 1980 to 1981 and was caused by ingestion of contaminated coleslaw (13). Subsequently, many other foodstuffs have been implicated in both small and large outbreaks, including unpasteurized and pasteurized cheeses (14–22), pasteurized milk (23, 24), butter (25), various fruits and vegetables (26–30), and several meat products (31–35) (Table 1). A large outbreak of listeriosis with over 900 cases and 200 deaths was reported from South Africa in 2017-2018. The source was a contaminated processed meat called "polony" (36). Recent evidence suggests that hospitalized patients are also at risk of acquiring invasive listeriosis (37). Tracking listeriosis cases and creating linkages to food products is now dependent on typing isolates using pulsed field gel electrophoresis and whole-genome sequencing, which have largely replaced older methods such as serotyping (38, 39). Uncertainty exists as to why outbreaks of listeriosis occur in human populations, although the 50% infective dose in sporadic disease is probably high. Enhancement of organism-specific virulence factors may play a role in epidemic disease, although all isolates of *L. monocytogenes* have the ability to produce all the virulence factors characteristic of the species.

Recent evidence has suggested that sporadic cases of listeriosis are also foodborne. Case-control studies of sporadic listeriosis cases in the absence of epidemic disease have implicated food products, including cold meats, turkey franks, and delicatessen-type foods, as vehicles for the development of sporadic invasive listeriosis in humans (40).

Our current understanding of the epidemiology of human listeriosis suggests that the organism is a common contaminant of food products and that ingestion of small numbers of *L. monocytogenes* occurs frequently in human populations. In one prospective study, a rate of 5 to 9 exposures per person-year was estimated (41). Amplification of the organism in biofilms or on food products undergoing processing but not pasteurization and kept at cold temperatures allows overgrowth of *L. monocytogenes*. Subsequent ingestion of large numbers of the organism may overwhelm innate host-defense systems in the gastrointestinal tract, liver, and spleen with subsequent development of invasive disease. The annual rate of sporadic listeriosis in Europe (42–44) and North America (45) is usually <1/100,000 population per year, and the disease is costly in both human (46) and economic terms (47). Sporadic listeriosis appears to be more common in the spring and summer months. This could be explained by seasonal variations in the types of food products eaten by human populations, with higher-risk products eaten in the warmer months. In addition, data suggest that preexisting damage to the gastrointestinal mucosa by other microorganisms, such as those that are associated with viral gastroenteritis, may allow translocation of *L. monocytogenes* from the gastrointestinal tract with subsequent development of invasive disease (48). These viral pathogens often have seasonal patterns that overlap with those of invasive listeriosis.

Demographic data from surveillance studies indirectly revealed several host-specific risk factors for invasive listeriosis (49, 50). Infection is most commonly seen in the first 30 days of life or in patients older than 60. In the first instance, the fetus is infected during maternal sepsis with *L. monocytogenes* or from perivaginal and perianal colonization of the mother by transition through the birth canal. Host defense against listeriosis is impaired in those infants with underdeveloped macrophage and cell-mediated immune function, and invasive listeriosis is more likely to occur if

doi:10.1128/microbiolspec.GPP3-0014-2018

TABLE 1 Some foods implicated in published reports of foodborne listeriosis

Dairy products	Fruits and vegetables	Meat products	Fish products
Pasteurized whole milk	Coleslaw (cabbage)	Delicatessen foods (deli meats)	Tuna salad
Chocolate milk	Lettuce	Pâté	Smoked fish
Mexican-style cheese	Corn	Uncooked hot dogs	Shrimp salad
Soft cheese (different types)	Rice salad	Turkey franks	
Hard cheese	Strawberries	"Rillettes"	
Goat cheese	Cantaloupes	Pork tongue in aspic	
Ice cream	Nectarines	Pork pie	
Fresh cream	Salted mushrooms	Beef	
	Alfalfa tablets	Jellied pork	
	Apples	Cooked ham	
	Blueberries	Foie gras	
	Stone fruit	Ox tongue	
	Sprouts	Undercooked chicken	

colonization of the liver, respiratory tract, or gastrointestinal tract has occurred.

The increased risk of invasive listeriosis in older patients reflects the increasing incidence of immunosuppressive conditions, such as solid tumors and hematologic malignancy, in this age group. Control of early infection in humans and in animal models is highly dependent on an intact gastrointestinal mucosa and effective macrophage function in the liver, spleen, and peritoneum following bacterial translocation from the gastrointestinal tract. Both these protective events can be impaired by the primary disease or by chemotherapy or radiation-induced damage. In addition, treatment of malignancy and the use of immunosuppressive agents with a specific effect on cell-mediated immune function, such as corticosteroids or cyclosporin A (51), predispose to invasive infection by diminishing *L. monocytogenes*-specific host responses that occur after the initial phase of infection. The recent proliferation of biologic treatments with immune modulators such as tumor necrosis factor-alpha inhibitors has also contributed to increases in invasive listeriosis (52–54).

The cell-mediated immune response to *L. monocytogenes* is impaired in pregnant women (55) and, with the decreased gastrointestinal motility (56) seen in pregnancy, may predispose to invasive listeriosis and subsequent transplacental infection of the infant. This results in "early-onset" listeriosis characterized by the delivery of an often premature and severely ill infant. Spontaneous recovery of the mother from *Listeria* sepsis normally occurs following delivery of the infant, although if recognized prepartum, appropriate antibiotic therapy can save the infant.

In "late-onset" listeriosis, the infant is infected through maternal gastrointestinal carriage of *L. monocytogenes* without sepsis, and the infant is infected during transition through a colonized birth canal. In these cases, clinical disease in the infant develops 7 to 14 days later. Direct cutaneous invasion is unlikely, and it is believed that aspiration of the organism into the respiratory tract or swallowing of the organism by the infant may occur during the incubation period. A unique outbreak of neonatal listeriosis in Costa Rica has been described: the vehicle was *L. monocytogenes*-contaminated mineral oil used to clean infants after delivery from healthy mothers, with cross contaminations of shared mineral oil (57). The index case was infected through the placental route of maternal-fetal transmission. Pregnancy-associated listeriosis has been recently reviewed (58, 59).

Several large outbreaks of a febrile gastroenteritis syndrome have further highlighted the importance of *L. monocytogenes* as a foodborne pathogen. In these outbreaks, with an average incubation period of approximately 24 h, attack rates (up to 72%) were much higher than those reported for outbreaks of invasive listeriosis. The reported vehicles for these more typical foodborne infections have included shrimp (60), rice salad (61), chocolate milk (24), corn salad (62), ready-to-eat meats (63, 64), jellied pork (65), and fresh cheese (15). The foods implicated were usually heavily contaminated (>10^9 CFU/ml of *L. monocytogenes*), and the amount of food ingested appeared to correlate with infection, suggesting that the high attack rates are not related to enhanced intrinsic virulence of the particular infecting strain of *L. monocytogenes*. A hospital-acquired outbreak of gastroenteritis has also been described from contaminated meat jelly (66).

While a predisposition to invasive listeriosis is seen in patients with malignancy or organ transplant, human immunodeficiency virus (HIV) infection is also an important risk factor in sporadic listeriosis (67). Earlier studies have reported that attack rates for invasive listeriosis in HIV-positive patients that were 500- to 1,000-fold greater than those in the general population. However, reductions in invasive listeriosis cases in HIV infection has been brought about by widely promulgated dietary recommendations to prevent foodborne illness and by the use of prophylaxis for *Pneumocystis jiroveci* pneumonia, primarily trimethoprim-sulfamethoxazole, to which *L. monocytogenes* is susceptible. Further reductions in HIV-associated cases may be due to better and more widespread antiretroviral therapy (68). Reductions in the overall incidence of listeriosis in non-HIV-positive patients may also be attributed to distribution of dietary recommendations to populations at risk, including pregnant women, patients with malignancies, and organ transplant recipients (69). Perhaps more importantly, the decreased incidence of listeriosis may be due to the promotion of guidelines to promote universal awareness of the problem in the food-processing industry, which has undertaken hazard analysis at critical control point (HACCP) (70–72) and microbial risk assessment (73, 74, 141) programs to reduce contamination of foods with *L. monocytogenes* as well as with other foodborne pathogens such as *Salmonella* spp., *Campylobacter* spp., and *Escherichia coli*. These activities have provided increased protection in the face of increased public demand for fresh, unprocessed food products that may not have been cooked or pasteurized and that by definition present a greater degree of risk for foodborne illness.

In addition to hazard analysis at critical control point programs, regulatory agencies have aggressively pursued the control of *L. monocytogenes* contamination of food. The U.S.

Food and Drug Administration has a zero-tolerance policy for *L. monocytogenes* in its industry sampling programs (75). Other countries have adopted less stringent guidelines, allowing a small amount of contamination ($<10^2$ CFU/g) to strike a balance between protection of public health and needless condemnation of otherwise edible food products. While invasive listeriosis may be more common in some countries in Europe than in the United States, it is not clear whether these differences can be attributed to less stringent standards in Europe that allow more *L. monocytogenes* in the food supply. The debate continues between zero tolerance advocates and those supporting a risk-assessment approach to *Listeria* contamination of food (76). However, these measures have not led to decreases in the incidence of *L. monocytogenes* infections in the developed world (77).

CLINICAL DISEASE DUE TO *L. MONOCYTOGENES*

A wide variety of clinical syndromes have been associated with *L. monocytogenes* infection in both animals and humans (Table 2). The earliest descriptions of *L. monocytogenes* sepsis were described in an epizootic affecting South African rodents (78) and in laboratory colonies of rabbits (79). One distinguishing characteristic of infection in rabbits was the production of monocytosis in blood, which suggested the species name *monocytogenes*. A monocytosis-producing antigen has been described as a virulence factor of *L. monocytogenes* (80), but monocytosis in the peripheral blood is not a characteristic of infection in humans.

Many wild and domesticated animals are subject to invasive listeriosis. Animals acquire the organism from the environment through grazing, amplified by fecal contamination of soil and vegetation. Specific syndromes with parallels in human disease have been recognized in animals. In New Zealand in the 1930s, Gill (81) described "circling disease," a rhombencephalitis of sheep that may effect flocks fed spoiled silage. *L. monocytogenes* has also been implicated as a cause of abortion and prematurity in ruminants. Intravenous and oral models of *L. monocytogenes* infection in rodents can duplicate the illness seen in the natural state in animals, including maternal sepsis and abortion (82).

TABLE 2 Some clinical syndromes associated with *L. monocytogenes* infection

Neonatal meningitis
Meningoencephalitis in adults
Rhombencephalitis
Sepsis (bacteremia) in infants or adults
Native or prosthetic valve endocarditis
Spontaneous bacterial peritonitis
Septic arthritis
Biliary tract disease
Hepatitis
Liver abscess
Cutaneous infections (in animal workers)
Endophthalmitis
Febrile gastroenteritis
Continuous ambulatory peritoneal dialysis peritonitis
Osteomyelitis

The clinical syndromes associated with listeriosis in humans were discovered later. Neonatal listeriosis was initially described in postwar Europe in premature septic newborns in East Germany (83). This description of early-onset listeriosis was followed by reports of neonatal meningitis (late-onset listeriosis) occurring later in the postpartum period. *L. monocytogenes* as a cause of meningitis in neonates is third to group B streptococci and *E. coli* in the developed world (84, 85). The use of antibiotic prophylaxis to prevent group B streptococcal infection may also have reduced cases of neonatal listeriosis (86). In less-developed countries, Gram-negative meningitis with *E. coli* or *Salmonella* spp. is more common, but *Listeria* meningitis still occurs.

PREGNANCY-ASSOCIATED LISTERIOSIS

Pregnant women are at high risk of infection, and occult or overt bacteremia can result in chorioamnionitis producing early-onset neonatal listeriosis (58). These infants have characteristic clinical features, including prematurity, sepsis at birth, fever, a diffuse maculopapular cutaneous eruption, and evidence of significant hepatic involvement with jaundice (87). The mortality rate of early-onset listeriosis, even with treatment, is very high, and stillbirth is also common in this setting. Autopsy findings in cases of early-onset listeriosis show significant chorioamnionitis in placental remnants and granulomas in multiple organs, particularly the liver and spleen, in infected infants. The original descriptions from East Germany characterized the entire syndrome as "granulomatosis infantiseptica." (83).

The mothers of these septic infants may be asymptomatic but commonly have flu-like or pyelonephritis symptoms before the early onset of labor, and their blood cultures are frequently positive for *L. monocytogenes*. Symptoms in the mother include fever, chills, and malaise, which resolve spontaneously following delivery of the infected infant and placenta (87). Anecdotal case reports suggest that early treatment of the mother who has *Listeria* sepsis can prevent transplacental infection or treat the fetus *in utero*, with subsequent delivery of a normal uninfected infant (88). Unfortunately, this usually only happens when a community-based outbreak of *L. monocytogenes* has been identified and physicians are aware of the problem in a particular geographic region through public health alerts.

Late-onset neonatal meningitis due to *L. monocytogenes* has the typical features of the same syndrome caused by other organisms in this setting, including fever, irritability, bulging fontanelle, and meningismus (89). These symptoms usually develop 1 to 2 weeks following delivery. The mother has usually had an uncomplicated pregnancy, delivery, and postpartum course with no signs of sepsis. The clinical syndrome usually dictates a lumbar puncture, and the cerebrospinal fluid (CSF) in 50% of the cases reveals the organism by Gram's stain. CSF cultures are usually positive, although the organism may be isolated simultaneously or only from the blood in some cases. The CSF shows other characteristics of bacterial meningitis, including a high polymorphonuclear leukocyte count, elevated protein, and low glucose with a decrease in the CSF-serum glucose ratio.

ADULT MENINGOENCEPHALITIS

L. monocytogenes is an uncommon cause of bacterial meningitis in adults. There are two major clinical presentations. The first is a typical subacute bacterial meningitis characterized by fever, headache, and neck stiffness (90). Because the organism is not commonly seen on Gram's stain of CSF,

and because the cell counts are lower than in other forms of bacterial meningitis, an initial diagnosis of viral meningitis is commonly made before culture of the organism from CSF or blood. The onset of the syndrome can occur over several days, unlike meningococcal or pneumococcal meningitis, which have more abrupt onsets. During epidemics of foodborne listeriosis, *Listeria* meningitis can occur in apparently healthy individuals of all ages. In sporadic disease, patients more commonly have obvious defects in cell-mediated immune function that predispose them to listeriosis.

The second form of central nervous system listeriosis in adults is a rhombencephalitis that has features characteristic of the same illness in animals, described as circling disease (91). Fever, headache, nausea, and vomiting occur early, with signs of meningeal irritation less commonly present. Subsequently, patients develop multiple cranial nerve abnormalities accompanied by cerebellar dysfunction, including ataxia. Fever may not be present in up to 15% of patients, which makes the diagnosis more difficult and more suggestive of noninfectious disorders. CSF pleocytosis may be minimal, and the organism is rarely seen on Gram's stain. The diagnosis is established by culture of CSF or blood. Magnetic resonance imaging is the best diagnostic study and frequently demonstrates typical multiple microabscesses of the cerebellum and diencephalon (Fig. 1). The mortality rate in this condition approaches 50%, and despite treatment, residual morbidity, including permanent cranial nerve palsies and ataxia, may persist.

L. monocytogenes can also be responsible for cerebritis or typical brain abscess in the supratentorial region (92). In these cases the typical rhombencephalitic symptoms due to microabscesses are absent. Host risk factors reflecting immune deficiency are commonly seen in these cases as they are in *Listeria* sepsis.

LISTERIA SEPSIS

Listeria sepsis, or bacteremia without central nervous system involvement, represents one-third of adult cases of invasive listeriosis. The symptoms are nonspecific but usually include fever and chills. As noted above, in pregnant women *Listeria* sepsis often masquerades as pyelonephritis or "flu" (87). The diagnosis is often established in retrospect following delivery of an infected infant. In nonpregnant adults, *Listeria* sepsis almost always occurs in patients with malignancy, organ transplant, or other immunocompromised states (93–95). In these settings, the presentation is also nonspecific and mimics sepsis with other Gram-positive and Gram-negative pathogens. The mortality rate for *Listeria* sepsis in these series is 25 to 30%.

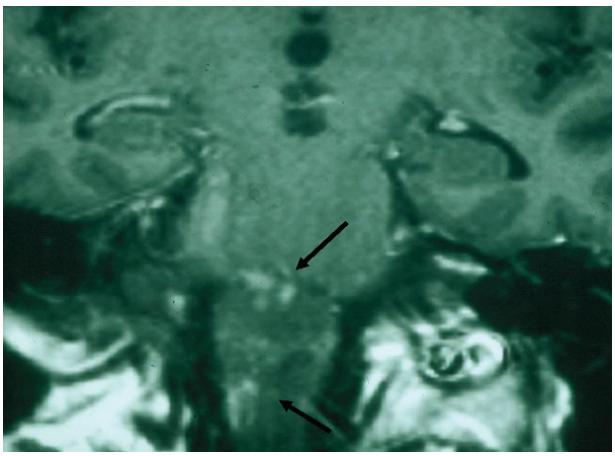

FIGURE 1 Computed tomography scan from a 72-year-old male with *Listeria* rhombencephalitis. The arrows point to multiple microabscesses.

OTHER CLINICAL SYNDROMES

Cutaneous Listeriosis

Cutaneous listeriosis is an occupational hazard of veterinary workers exposed to infected amniotic fluid or placental remnants that are removed from the birth canal of animals (96–98). Occasionally, cutaneous infection, including conjunctivitis, has been seen in laboratory workers (99). Cutaneous listeriosis is characterized by low-grade fever and multiple papulopustular lesions of the skin from which the organism can be isolated. Its appearance is similar to the rash seen in infants with early-onset disseminated listeriosis. In adults, the condition may resolve spontaneously without treatment, but the infection itself should be entirely preventable with appropriate gloving and other protective wear.

Bacterial Endocarditis Caused by *L. monocytogenes*

Bacterial endocarditis presumably follows transient bacteremia from a gastrointestinal source, with subsequent establishment of endovascular infection on an abnormal heart valve. *L. monocytogenes* is an uncommon cause of native valve endocarditis, and over 50% of cases that have been described involve prosthetic valves (100–102). Infection with *L. monocytogenes* is usually found as part of the late prosthetic valve endocarditis syndrome. Diagnostic criteria for *Listeria* endocarditis include the presence of a prosthetic valve with or without vegetation and continuous bacteremia with *L. monocytogenes*. Septic emboli and abscess formations in other organs are relatively frequent. In native valve endocarditis, *L. monocytogenes* can sometimes follow previous episodes of streptococcal bacterial endocarditis or other valvular heart disease. Patients with malignancy, diabetes, steroid therapy, and renal and liver transplantation have been described with *Listeria* endocarditis. Their presentation is nonspecific for *L. monocytogenes* and includes prolonged fever, chills, and ultimately, signs of congestive heart failure. Septic embolization occurs in two-thirds of patients, and aortic and mitral valve involvement are most common. *L. monocytogenes* can also cause arterial infections that involve prosthetic abdominal and aortic grafts or native abdominal aortic aneurysms (103). The mortality of this condition approached 40% before 1985 but has been reduced to 12% with better recognition and surgical management.

Hepatitis and Liver Abscess Due to *L. monocytogenes*

L. monocytogenes has been described as a cause of acute hepatitis in several case reports (104). It occurs as acute onset of fever and jaundice accompanied by positive blood cultures for *L. monocytogenes*. The diagnosis is usually unsuspected. Severe disease with death has been described, and autopsy or liver biopsy generally reveals microabscesses and occasionally granulomas similar to those seen in severe early onset neonatal disease. Predisposing factors include cirrhosis and liver transplantation (105), although *Listeria* hepatitis can occur in a normal host.

Solitary and multiple liver abscesses with fever are also described (106, 107). Bacteremia occurs in half of these patients. Predisposing factors include diabetes mellitus,

transplantation, cirrhosis, and alcoholism. Aspiration of the abscess demonstrates the organism. The mortality rate is 50%, and postmortem examination often reveals abscesses in other organs as well. Patients with multiple abscesses appear to do worse than those with a solitary abscess.

Listeria Peritonitis

L. monocytogenes can also cause isolated episodes of peritonitis (108, 109). It is most commonly seen in patients undergoing continuous ambulatory peritoneal dialysis (110), and the organisms are isolated from the dialysate or from blood culture. The organisms presumably cause infection through translocation from the gastrointestinal tract in patients who have ingested the organism with food. This complication is extremely rare and represents <1% of all cases of continuous ambulatory peritoneal dialysis peritonitis. It can also cause spontaneous bacterial peritonitis in advanced liver disease with ascites (111–113). The mortality rate is low, and laboratory and clinical features are typical of spontaneous bacterial peritonitis due to other organisms. The organism can rarely cause this disease in patients who have undergone liver transplantation.

Biliary Tract Infections

Recent reports have seen *L. monocytogenes* emerge as a biliary tract pathogen (114, 115, 142). Retrograde infection from contaminated food is the likely source. The organism is resistant to bile, and this may play some role in the pathogenesis of biliary disease. Most cases also have medical comorbidities, including immunosuppression from corticosteroid use or newer biologic agents to treat the underlying conditions. A number of deaths have been reported, often due to inappropriate antibiotic therapy.

Musculoskeletal Infection

L. monocytogenes is a very uncommon cause of osteomyelitis (116–118). Reports of *Listeria* osteomyelitis emphasize the role of diabetes mellitus or leukemia as predisposing factors, particularly when long-term corticosteroids are administered. Relapses have been described despite effective antibiotic therapy. Septic arthritis due to *L. monocytogenes* appears to be more common than bone infection, and rheumatoid arthritis appears to be a frequently associated condition. Low-dose methotrexate therapy may predispose to this infection. Infection may follow joint injection with corticosteroids. Infection has been described in prosthetic hips and knees as well as in native joints (119, 120). The organism can also cause vertebral osteomyelitis with epidural abscess (121). With prolonged antibiotic therapy, medical treatment alone, as opposed to removal of the prosthetic joint, may be successful. Deaths are rare and are normally due to the underlying disease.

Gastroenteritis

A febrile gastroenteritis syndrome has been described for listeriosis (15, 24, 25, 60–64, 143). Gastrointestinal prodromal symptoms, such as diarrhea or abdominal pain, have been common in large outbreaks of foodborne adult listeriosis, but sepsis and meningoencephalitis have been the usual presenting syndromes. Population-based attack rates for invasive listeriosis have been low in this setting. In *Listeria* gastroenteritis, a more typical foodborne illness occurs with high attack rates (up to 72%) among the individuals exposed to the vehicle of infection. Large numbers of organisms in the contaminated food may be responsible.

Most patients are well before development of the infection. While bacteremia has occurred in some patients, primary symptoms are diarrhea, fever, fatigue, chills, and myalgias occurring 24 h following exposure. This incubation period is considerably shorter than the 3- to 4-week period for more usual forms of invasive listeriosis.

Pregnant women appear to be more likely to have sepsis in these outbreaks. Isolation of *L. monocytogenes* with selective media from stool has been rare, but serologic tests have been used to help define the extent of the outbreaks. In the outbreaks reported to date, rice salad, shrimp salad, chocolate milk, corn, deli meats, and fresh cheese have been the reported vehicles, and high colony counts of the organism (up to 10^9 CFU/g) appear to be present in the contaminated food. Invasive listeriosis can also be a result of loss of gastrointestinal integrity due to other gastrointestinal tract pathogens such as *Shigella* spp. (122) or to presumed viral gastroenteritis (48). This may account for some sporadic and epidemic cases of *Listeria* sepsis and meningoencephalitis.

DIAGNOSIS OF LISTERIOSIS

Diagnosis of all forms of *L. monocytogenes* infection depends on isolation of the organism from a normally sterile site, usually blood or cerebrospinal fluid. Gram's stain of specimens of sterile spinal fluid, peritoneal fluid, or joint aspirates occasionally, but unpredictably, reveals Gram-positive coccobacilli, characteristic of *L. monocytogenes*. In some forms of central nervous system infection, particularly rhombencephalitis, several samples may have to be obtained to isolate the organism. Focal neurologic findings that are characteristic of rhombencephalitis should prompt computed tomography or magnetic resonance imaging scanning. The finding of multiple microabscesses in the hindbrain is highly suspicious for *Listeria* rhombencephalitis, and empiric treatment for listeriosis should be started.

In situations where antibiotic therapy has already been administered, isolation of the organism from a nonsterile site may support a diagnosis of listeriosis. In pregnant women, stool or vaginal cultures may be positive when selective media for *L. monocytogenes* are used for culture. In febrile gastroenteritis syndromes, where traditional pathogens have not been isolated using standard media, culture of the stool with selective media for *L. monocytogenes* may also demonstrate the organism.

Direct detection of PCR products such as the HlyA from *L. monocytogenes* in CSF and other fluids has been studied. Sensitivity appears to be low but might be useful in patients already on treatment for listeriosis where cultures are negative (123, 124).

TREATMENT OF LISTERIOSIS

L. monocytogenes remains susceptible to most β-lactam antibiotics, with the exception of cephalosporins, to which the organism is usually resistant (125–127). Because newer cephalosporins are commonly used for the treatment of nonspecific sepsis syndromes or for the empiric treatment of bacterial meningitis, specific therapy for listeriosis may be delayed for some patients. Empiric therapy for bacterial meningitis with ampicillin is recommended for older adults but may not be necessary for children beyond the neonatal period (128). When listeriosis is a likely diagnosis, the use of ampicillin or, in penicillin-allergic patients, vancomycin provides empiric coverage for *L. monocytogenes* until the diagnosis is made by culture.

A combination of ampicillin and gentamicin is the current therapy of choice for all forms of listeriosis (129, 130).

However, some data suggest that this combination is not useful and could be harmful (131). There has been a trend toward increasing resistance to penicillins (127). Ampicillin is not bactericidal for *L. monocytogenes*, and *in vitro* and *in vivo* data suggest that an additive or synergistic effect with gentamicin may improve the outcome (132). No randomized, controlled clinical trials of therapy in humans have been carried out, however.

Trimethoprim-sulfamethoxazole, with or without the addition of rifampin, is an alternative treatment regimen that has been recommended. Early "step-down" to oral trimethoprim-sulfamethoxazole has been successful in several cases (133). In one retrospective study, the combination of amoxicillin and cotrimoxazole was found to be more effective than ampicillin and gentamicin (134). High-level resistance to trimethoprim has been recognized, however (127, 135). New quinolones may also be effective, but data are limited to *in vitro* studies (136, 137). Rifampin is active against *Listeria*, but resistance has been found in cases of prosthetic joint infection (138, 139). For central nervous system infection, dexamethasone and phenytoin have been suggested as possible treatment adjuncts (140).

Trimethoprim-sulfamethoxazole has also been used as a prophylactic agent against a number of microorganisms, including *P. jiroveci*, in patients with HIV infection and in patients undergoing chemotherapy for leukemia or lymphoma. This drug would be effective in protecting against *L. monocytogenes* infections. The use of prophylaxis has been temporally associated with a decrease in the incidence of listeriosis in these compromised hosts in combination with dietary guidelines that have been issued for these patients in recent years (68).

The duration of treatment for invasive listeriosis has not been studied. Relapses appear to be uncommon, and 2 to 3 weeks of therapy with ampicillin and gentamicin is sufficient for most forms of listeriosis. Rhombencephalitis with abscess formation in the central nervous system may require more prolonged therapy, but data are not available that support treatment beyond 4 weeks (129, 130).

Innate and Adaptive Immune Responses during *Listeria monocytogenes* Infection

SARAH E. F. D'ORAZIO

51

INNATE IMMUNITY

Mammalian hosts have multiple, redundant ways to rapidly respond to the presence of infection. These innate immune mechanisms are triggered within minutes to hours after infection. Although they are not microbe specific, they do contribute to limiting exponential growth of *L. monocytogenes* and may even reduce bacterial dissemination to secondary infection sites. The role of these rapid immune responses can be clearly demonstrated by examining bacterial loads in various inbred strains of laboratory mice, with CFU burdens differing by 100- to 1,000-fold within the first few days of infection (1, 2). This difference has been attributed largely to multiple innate immune mechanisms, and both the prototypic susceptible strain (BALB/c) and highly resistant C57BL/6 mice can induce robust $CD8^+$ T cell responses and eventually clear sublethal doses of *L. monocytogenes*. Weak or delayed innate immunity allows *L. monocytogenes* to replicate exponentially for several days and thus is a major determinant of disease severity. The innate immune responses generated during the first few days of infection are also critical for proper induction of the adaptive immune mechanisms that lead to immunological memory (3–5).

In humans, *L. monocytogenes* is transmitted by ingestion of contaminated ready-to-eat food products. The attack rate during documented outbreaks can be high, with up to 75% of affected individuals experiencing symptoms of gastrointestinal disease (6–9). However, fewer than 20% of those people had intestinal disease severe enough to require hospitalization, and fewer than 5% had positive blood cultures. These observations suggest that orally acquired *L. monocytogenes* bacteria face several anatomic or innate immune bottlenecks that can severely limit systemic spread and the onset of life-threatening bacteremia or meningoencephalitis. The widely used i.v. infection model, which is meant to mimic systemic listeriosis, has the disadvantage that it completely bypasses the gut phase of infection. Oral infection of mice can be inefficient and much less reproducible than i.v. infection (10); however, technological advances involving humanized mice (11, 12) and mouse-adapted bacterial strains (13, 14) led to the development of a highly reproducible foodborne infection model (10, 15). Because these developments occurred only recently, little has been done at this point to assess host immune responses following oral transmission of *L. monocytogenes* (16). Therefore, the paradigms highlighted in this article come primarily from studies using the i.v. model, unless noted otherwise.

Triggering of Innate Immune Receptors

Innate immune recognition of microbes occurs through a variety of pattern recognition receptors (PRRs) expressed by mammalian cells. Engagement of these receptors initiates signaling cascades that lead to expression of cytokines and chemokines that shape the local microenvironment and dictate the type of immune response that ensues. PRRs have different patterns of cellular localization (e.g., at the cell surface, on phagosomal membranes, in the cytosol) and exhibit differential expression in various cell types. Thus, innate immune recognition of *L. monocytogenes* varies depending on the cell types the bacteria interact with during each phase of infection. Even within a single cell, bi-phasic recognition of *L. monocytogenes* may occur as extracellular bacteria are rapidly sensed by PRRs expressed at the host cell surface, while invasive bacteria may not maximally trigger cytosolic sensors until a few hours later (17). There is significant redundancy among innate immune sensing mechanisms, with multiple receptors able to recognize microbial ligands at each cellular location. Most of these signaling pathways have been studied in isolation, and the net effect of signaling through multiple receptors is not well understood.

The earliest opportunity for innate immune recognition of naturally acquired *L. monocytogenes* occurs at the surface of intestinal epithelial cells that line the gut lumen. InlA-mediated uptake results in rapid translocation across intestinal epithelial cells without escape from membrane-enclosed vacuoles (18), so we would expect to find that only PRRs at the surface or in vacuoles are triggered initially. After reaching the underlying lamina propria, myeloid-derived cells such as monocytes, macrophages, and dendritic cells (DCs) encounter primarily extracellular bacteria (19); as described below, cytosolic invasion is likely to occur only in tissue-resident macrophages. Later in the infection, *L. monocytogenes* may reinvade intestinal epithelial cells from the basolateral side (20), and in this case, escape from vacuoles and cytosolic replication may occur.

Extracellular *L. monocytogenes* at the cell surface

The major families of PRRs expressed at the cell surface are Toll-like receptors (TLRs), which recognize highly

doi:10.1128/microbiolspec.GPP3-0065-2019

conserved microbial components found in all bacteria, and C-type lectin receptors, best known for detecting fungal cell wall components. Broad evidence for a significant role for TLR in recognition of *L. monocytogenes* comes from the use of MyD88-deficient mice that lack the signaling adaptor used by most TLR proteins. MyD88$^{-/-}$ mice have at least 1,000-fold increased bacterial burdens compared to wild-type mice (21), and the 50% lethal dose in these animals is decreased by at least three logs (22). Six members of the TLR family (TLR1, TLR2, TLR4, TLR5, TLR6, and TLR11) are expressed at the cell surface, but the two receptors most involved in recognition of *L. monocytogenes* are TLR2 and TLR5.

TLR2 is expressed on a variety of cell types, including intestinal epithelial cells (23) and CD8$^+$ T cells (24, 25), but it is expressed at the highest level on myeloid-derived phagocytes (26, 27). TLR2 binds lipoteichoic acids and lipoproteins found in bacterial cell walls (28). Although it was originally thought that TLR2 could also detect *L. monocytogenes* peptidoglycan, it was later shown that thorough removal of all traces of lipoteichoic acid and other lipoproteins abrogated sensing by TLR2 (29). The receptor forms heterodimers with other TLR proteins, and this results in recognition of specific subsets of lipoproteins. For example, TLR2-TLR1 complexes recognize triacylated lipopeptides, and TLR2-TLR6 detects diacylated lipoproteins (30). TLR2 dimers recruit MyD88 and TIRAP adaptors which activate a signaling cascade that leads to NF-κB activation and the expression of several proinflammatory cytokines such as interleukin-6 (IL-6), tumor necrosis factor alpha (TNFα), and IL-12 (31). TLR2$^{-/-}$ mice had significantly reduced levels of serum cytokines 24 hours postinfection (22). However, only modest effects of TLR2 deficiency were noted during the later stages of infection (21, 32). TLR2-deficient macrophages internalized fewer *L. monocytogenes* organisms, but there appeared to be little effect on subsequent growth of the bacteria that did reach the cytosol (33, 34). Thus, TLR2 appears to contribute to early recognition of *L. monocytogenes* but is not absolutely required for clearance during the systemic phase of infection.

TLR5 binds flagellin, the structural subunit of bacterial flagella, and is expressed on the basolateral surface of intestinal epithelial cells (35, 36). In the mouse, a subset of intestinal CD11b$^+$ DCs also expresses high levels of TLR5, but most myeloid-derived phagocytes found in other tissues do not (37, 38). TLR5-deficient mice were generated by two groups (39, 40) and have been used to study infection with a variety of Gram-negative flagellated bacterial pathogens. *L. monocytogenes* has peritrichous flagella, but most strains downregulate expression of flagellin at 37°C. However, Way et al. showed that *L. monocytogenes* reference strain 10403s and 20% of the clinical isolates they tested did, in fact, express *flaA* at 37°C, and those bacteria were sensed by TLR5-transfected HeLa cells (41). Furthermore, *flaA* mutant *L. monocytogenes* had a defect in persistence and dissemination in orally infected mice compared with flagellated bacteria (42). These observations suggest that TLR5 is likely to contribute to early recognition of infection following oral transmission and rapid MyD88-mediated production of IL-6 and TNFα in the gut.

The C-type lectin receptor family of proteins is well known for detecting β-glucans expressed by fungi, but more recent work indicates that these receptors are also involved in sensing bacteria and viruses. Chen et al. showed that CLEC5A, a C-type lectin expressed primarily on myeloid-derived cells, was important for innate immunity against *L. monocytogenes* (43). Infection of bone marrow-derived macrophages from CLEC5A$^{-/-}$ mice resulted in decreased IL-1β secretion, and neutrophils from these mice had a defect in killing *L. monocytogenes in vitro*. The authors suggested that *L. monocytogenes* may simultaneously interact with both TLR2 and CLEC5A on the cell surface and that coactivation of the two signaling pathways enhances proinflammatory responses.

L. monocytogenes in phagocytic or endocytic vacuoles

After invading mammalian cells, *L. monocytogenes* resides briefly in phagocytic or endocytic vacuoles before escaping to the cytosol. Cytosolic invasion occurs within 30 minutes in macrophages (44), leaving little time for bacterial products to be sensed by vacuolar PRRs. However, there are circumstances in which *L. monocytogenes* can replicate slowly within vacuoles (45). Leber et al. measured the transcriptional response to vacuolar *L. monocytogenes* by analyzing mRNA expressed in bone marrow-derived macrophages during infection with listeriolysin O (LLO)-deficient bacteria that were unable to escape to the cytosol. They found that the vacuolar response was completely dependent on MyD88 (46), a result that is consistent with sensing only through TLR molecules that are internalized from the cell surface (e.g., TLR1, TLR2, TLR5, or TLR6) or recruited to vacuoles (TLR9). TLR9 detects unmethylated CpG DNA, a motif that is common in bacterial and viral genomes but rare in mammalian cells. Most subsets of DCs, macrophages, and B cells respond to treatment with synthetic CpG oligonucleotides, and plasmacytoid DCs, in particular, express very high levels of TLR9. Stockinger et al. infected TLR9-deficient mice with a lethal dose of *L. monocytogenes* and found no difference in the survival curve compared to that of wild-type mice (47).

Cytosolic *L. monocytogenes*

Intracellular sensing of microbes is a critical function of the innate immune system because commensal bacteria rarely access the host cell cytosol, so detection of microbial components here typically indicates a pathogenic infection. Cytosolic PRRs that sense *L. monocytogenes* can be divided into two large groups: microbial cell wall components and surface proteins are detected by Nod-like receptors (NLRs), and nucleic acids are sensed by either cyclic GMP-AMP synthetase (cGAS)/STING (stimulator of interferon genes) (cyclic dinucleotides), AIM2-like receptors (AT-rich double-stranded DNA [dsDNA]), or retinoic acid-inducible gene 1 (RIG-I)-like receptors (RNA). More than 20 members of the NLR family have been identified to date (48), and cytosolic *L. monocytogenes* can be sensed by several of these proteins. Nucleotide-binding oligomerization domain 1 (NOD1) and NOD2 both detect dipeptide components of bacterial peptidoglycan (49) and are widely expressed by most cell types. Sensing of cytosolic *L. monocytogenes* by either of these receptors activates NF-κB and leads to increased transcription of proinflammatory chemokines (e.g., CXCL2) and cytokines (e.g., IL-6, TNFα). *L. monocytogenes* can avoid detection by NOD1 via the action of PgdA, a deacetylase that modifies *N*-acetylglucosamine residues (50). However, NOD2 appears to be a key PRR for sensing cytosolic *L. monocytogenes*, particularly in the gut. NOD2 deficiency resulted in decreased expression of several antimicrobial peptides in the ileum of infected mice (51) and a reduction in DUOX2-dependent reactive oxygen species production in Caco-2 cells (52). A lack of NOD2 signaling in the gut altered the course of infection, increasing bacterial burdens in orally infected mice, but Nod2$^{-/-}$ mice infected by the intravenous route showed no differences compared to wild-type mice (51).

Cytosolic recognition of bacterial nucleic acids generally leads to the production of type I interferons (IFNαβ). STING is a signaling adaptor that links cytosolic recognition of damaged DNA by cGAS or viral DNA by DDX41 to the (interferon regulatory factor 3) IRF3-dependent transcription of IFNαβ (53, 54). However, STING can also directly sense cyclic di-nucleotides such as c-di-GMP or c-di-AMP (55). These molecules serve as second messengers in bacteria, and for *L. monocytogenes*, c-di-AMP is required for growth in the host cell cytosol (56–58). STING is most highly expressed in myeloid cells and was not found in hepatocytes (59). STING-deficient mice have a blunted type I IFN response but had no differences in bacterial burdens compared to wild-type mice (60, 61). Thus, STING-mediated recognition of cyclic dinucleotides is not absolutely required for innate immune recognition of cytosolic *L. monocytogenes*. However, Archer et al. measured cytokine secretion by macrophages lacking both STING and the TLR adaptor MyD88 and found that the cells made very little IFNβ, IL-12, TNFα, or IL-6 in response to infection (60). RIG-I is generally thought of as a sensor of viral doubled-stranded RNA, and it may also detect small RNAs secreted by actively growing cytosolic *L. monocytogenes* (62). Triphosphorylated RNA released into the cytosol triggered IFNβ expression in a RIG-I-dependent manner in epithelial cells but not in bone marrow-derived myeloid phagocytes (63). In contrast, no role could be demonstrated for the cytosolic RNA sensor MAVS in the induction of type I IFN (64).

Another possible intracellular detection system for *L. monocytogenes* could be TLR10. Much less is known about TLR10 than about other TLRs, and its ligand has not been clearly defined. Regan et al. did an RNA interference screen in *Listeria*-infected human cell lines HT-29 and THP-1 and found that small interfering RNA silencing of TLR10 led to decreased chemokine (CCL20 and IL-8) production and increased intracellular CFU (65). There is no murine homolog for TLR10 (it is a pseudogene in mice), so confirmatory *in vivo* studies using a mouse model of listeriosis are not possible.

Inflammasomes

Many members of the NLR family act as scaffolds for the assembly of unique cytosolic protein complexes called inflammasomes. *L. monocytogenes* can be sensed by multiple inflammasomes. Although each is activated by a different stimulus, all inflammasomes recruit and activate the caspases needed for either secretion of IL-1β and IL-18 or gasdermin-mediated pyroptosis, an inflammatory type of cell death (66, 67). Early work using bone marrow-derived macrophages and human peripheral blood mononuclear cells showed that *L. monocytogenes* was sensed by both NLRP3 (Nalp3) and NLRC4 (Ipaf) (68–71); however, neither of these inflammasomes is essential for protection against infection. NLRP3 is activated by a variety of stimuli but is not constitutively expressed in most resting cells; TLR or NOD signals are required to induce NF-κB-dependent transcription of the gene (67, 72). The secreted proteins p60 and LLO have both been associated with activation of the NLRP3 inflammasome (70, 73), but NLRP3-deficient mice do not have increased bacterial burdens in the spleen or liver 24 hours after i.v. challenge (74). NLRC4 is activated by cytosolic flagellin, but most *L. monocytogenes* strains downregulate the expression of flagella at 37°C. *Listeria* strains engineered to secrete heterotypic flagellin in the cytosol readily activated the NLRC4 inflammasome and were severely attenuated *in vivo* compared to wild-type *L. monocytogenes* (75, 76).

Unlike most inflammasomes that activate caspases, the output of NLRC5 activation is maximal expression of major histocompatibility complex I (MHC-I) genes (77). Two groups showed that *Nlrc5*$^{-/-}$ mice have decreased CD8^{+} T cell responses and significantly higher *L. monocytogenes* burdens than wild-type mice (78, 79). It is not yet clear which cell type is critical for sensing infection or what component of the bacteria is recognized by NLRC5. Neiman-Zenevich et al. recently showed that intracellular infection also indirectly activated the NLRP1B inflammasome by reducing intracellular ATP levels in infected RAW264.7 macrophage-like cells (80). Prior to this study, the only known activator of the NLRP1B inflammasome was anthrax toxin. *L. monocytogenes* can also activate (aim2-like receptors) ALR-dependent inflammasomes (69, 81). It was known that chromosomal DNA was released into the host cell cytosol during *L. monocytogenes* infection (82), and it is now clear that this dsDNA can be sensed by AIM2-like receptors. Like NLRP3, AIM2 expression also requires a signal for induction, but the priming occurs through type I IFN signaling rather than TLR or NOD-mediated NF-κB signaling (83). Studies using macrophages from various knockout mouse strains suggest that caspase-mediated secretion of IL-1β and subsequent cell death by pyroptosis depends mainly on the AIM2 inflammasome rather than NLRP3 or NLRC4 (84, 85).

Portnoy and colleagues have argued that caspase-mediated pyroptosis is actually rare in macrophages infected with wild-type *L. monocytogenes* (4). However, it is clear that inflammasome-mediated cleavage and secretion of IL-18 occur during infection. For example, Schmidt and Lenz showed that the N-terminal domain of p60 could stimulate release of IL-1β and IL-18 from myeloid phagocytes without triggering pyroptosis (73). Seminal work by Shao's lab has made clear that cell death triggered by inflammatory caspases is completely dependent on expression of one or more isoforms of gasdermin, thus providing a mechanism to explain caspase-mediated cytokine secretion in the absence of cell death (86, 87). Further studies will be required to assess the levels of gasdermin expressed in the various cell types encountered by *L. monocytogenes in vivo*. It is also possible that there are negative regulators of innate immune sensing that can dampen inflammatory responses. Anand et al. showed that NLRP6-deficient mice were highly resistant to lethal challenge and had reduced bacterial burdens following intraperitoneal inoculation (88). Caspase-1 activation was unaffected in these animals, but higher numbers of circulating polymorphonuclear neutrophils (PMNs) and monocytes were observed in their blood than in the blood of wild-type mice. This suggests that activation of the NLRP6 inflammasome functions to dampen the proinflammatory signals that release myeloid phagocytes from the bone marrow. NLRP6 is highly expressed in neutrophils but is also found in macrophages, DCs, and epithelial cells (88). Given the large size of the NLR family, it is possible that additional negative regulators will be identified in future studies.

Chemokine and Cytokine Production

The primary output of innate immune signaling pathways is the expression and subsequent secretion of inflammatory mediators that can either act locally or accumulate in the blood and act systemically. Chemokines are small chemoattractant molecules that induce migration of innate immune cells and infiltration of infected tissues, and cytokines are small proteins that alter the behavior of other cells of the immune system. We know that cytosolic invasion of

L. monocytogenes in bone marrow-derived macrophages induces a different profile of cytokine expression compared with bacteria that remain phagosomes (46, 89). This is also true for infection of intestinal epithelial cells such as the human Caco-2 cell line (90). In both cases, the molecular basis for differential cytokine expression is the triggering of distinct innate immune sensing pathways that leads to activation of various transcription factors such as NF-κB, IRF3, or STAT3. In this section, proinflammatory mediators and effector cytokines will be discussed in the approximate order in which they are produced during *L. monocytogenes* infection.

Chemokines attract immune cells to sites of infection

A key function of the innate immune system during bacterial infection is to trigger the release of granulocytes from the bone marrow and to direct migration of circulating neutrophils (PMNs) to infectious foci. Sensing through either TLRs or NODs leads to NF-κB-dependent expression of IL-6, CXCL2 (previously called MIP-2), and CXCL8 (also called IL-8 in humans or KC in mice), and all of these molecules act as chemoattractants for neutrophils. Ebe et al. first showed that a hepatocyte cell line could produce both CXCL2 and CXCL8 within 1 to 2 hours of infection and that treatment of mice with neutralizing antibodies against either of these molecules modestly inhibited PMN infiltration in the liver (91). Later studies showed that cytosolic invasion was required to induce CXCL8 secretion in either human umbilical vein endothelial cells or HEK293 cells (92). Other cell types are slower to induce chemokine secretion. For example, CXCL8 expression peaked at 24 to 48 hours in primary human monocyte-derived macrophages, whether the cells were infected with *L. monocytogenes* or treated with synthetic TLR2 ligands (93).

IL-6 is produced by both myeloid-derived phagocytes and epithelial cells within 0.5 to 3 hours after infection, and the responding cell types with the highest levels of IL-6 receptor on the cell surface are PMNs, monocytes, macrophages, T cells, and hepatocytes (90, 94–97). The need for IL-6 early in infection was demonstrated by the studies of Liu et al., who showed that administration of recombinant IL-6 could protect mice if it was given 4 hours prior to infection, but not if given 24 hours after infection (94). Mice lacking IL-6 are highly susceptible to listeriosis and fail to trigger the release of neutrophils from bone marrow into the blood (98, 99). A recent clinical report described the case of a rheumatoid arthritis patient being treated with anti-IL-6 receptor monoclonal antibody therapy (tocilizumab) who developed meningoencephalitis, one of the more severe forms of systemic listeriosis (100). Inflammatory monocytes and macrophages respond to the presence of IL-6 by increasing expression of CD38, a surface protein that facilitates phagocytosis (101). However, *L. monocytogenes* may have evolved mechanisms to limit the induction of IL-6 *in vivo*. Personnic et al. showed that infection with strains lacking the surface protein InlH induced greater IL-6 production in both spleen and liver without detectable changes in other cytokine levels (102), suggesting that InlH may interact with innate immune cells to dampen the IL-6 response.

Recruitment of monocytes occurs shortly after neutrophil infiltration and is driven primarily by the production of chemokines CCL2, CCL3, and CCL7. CCL2 (also called MCP-1) was produced in the spleen and liver within 1 to 3 hours after i.v. infection (103, 104). CCL7 (also known as MCP-3) was found in blood, liver, and kidney within a similar time frame, with peak levels occurring at 48 hours postinfection (105). Only *L. monocytogenes* organisms that were actively secreting LLO induced chemokine expression in these studies; cytosolic localization of c-di-AMP is the likely stimulus, because STING-deficient mice produced less CCL2 and CCL7 (59). Both of these chemokines bind to the same receptor, CCR2, which is highly expressed on monocytes. Monocytes that lack CCR2 remain sequestered in the bone marrow and do not migrate to sites of infection (106). The overlapping but nonredundant functions of these two chemokines is evidenced by the observation that $CCL2^{-/-}$ and $CCL7^{-/-}$ mice are more susceptible to infection, but neither mouse strain is as susceptible as receptor-deficient ($CCR2^{-/-}$) mice (105). CCL3 (also known as MIP-1α) attracts a variety of leukocyte cell types and is a member of the C-C subfamily of chemokines that all share a common receptor (CCR5). Neither $CCL3^{-/-}$ nor $CCR5^{-/-}$ mice had a defect in bacterial clearance compared to wild-type animals, suggesting that sensing of this subfamily of chemokines is either not necessary or can be easily compensated for by other chemokines during primary infection (107, 108). However, mice treated with anti-CCL3 antibody were much more susceptible to reinfection with *L. monocytogenes* (109). Work by the group of Gregoire Lauvau has shown that CCL3 produced by memory T cells during secondary challenge is indirectly required for TNFα-mediated reactive oxygen species-dependent killing of *L. monocytogenes* by inflammatory myeloid phagocytes (110).

Type I interferons can have either proinflammatory or anti-inflammatory effects

IFNα and IFNβ (commonly referred to as type I IFNs) are produced in response to cytosolic invasion by *L. monocytogenes* (89). Macrophages and DCs are the primary producers of type I IFN, with peak expression in the spleen, liver, or mesenteric lymph nodes occurring approximately 24 hours postinfection (47, 111, 112). Secreted IFNα and IFNβ bind to a common type I interferon receptor (IFNAR). Type I IFN signaling leads to a distinct profile of interferon-stimulated genes 4 to 8 hours after infection of bone marrow-derived macrophages (17), and similar profiles of interferon-stimulated genes have been observed in the blood or spleens of infected mice (113). Most of the transcriptional response to cytosolic bacteria could be reconstituted by transfecting macrophages with *L. monocytogenes* genomic DNA; however, coadministration of muramyl dipeptide to trigger NOD2 signaling did amplify the response (46). The overall proportion of extracellular versus intracellular bacteria in a given tissue is likely to be important since TLR2-mediated signaling can suppress STING/RLR-mediated (RIG-I like receptors) induction of type I IFN (114). Mice that lack the IFNAR have dysregulated infiltration of innate immune cells with an increase in PMNs and a decrease in monocytes 24 hours after intraperitoneal infection (115).

Type I interferons were initially identified as antiviral molecules (116), and secretion of modest amounts of IFNαβ is likely to be important for the initiation of cell-mediated immune responses against all intracellular pathogens. However, excessive production of type I IFN during bacterial infection can promote anti-inflammatory effects such as T cell apoptosis (117), decreased TNFα production (118), downregulation of IFNγR (119), and increased secretion of IL-10 (120, 121). Early studies of $IFNAR1^{-/-}$ mice infected intravenously indicated that sensing of type I IFN was detrimental to the host, since the knockout mice were more resistant to *L. monocytogenes* (118, 122), but more recent work suggests that the magnitude of the type I IFN response depends on the route of bacterial transmission. Kernbauer et al. found that IFNAR-deficient C57BL/6N mice were more susceptible than wild-type mice to *L. monocytogenes*

delivered by intragastric inoculation (123). However, Pitts et al. saw no difference in CFU burdens in wild-type and IFNAR-deficient mice that were infected by the natural feeding route (113). In that study, foodborne transmission of *L. monocytogenes* resulted in significantly reduced IFNβ secretion in the spleen, and no anti-inflammatory effects were observed. Thus, the net effect of IFNαβ production appears to differ depending on the local concentration and the cellular context in which the cytokines are sensed, and the robust type I IFN response previously observed in the spleen may be an artifact of the i.v. model.

Type III interferons (IFNλ1, IFNλ2, IFNλ3, and IFNλ4) are a recently identified family of proteins that respond to different stimuli (TLR ligands) (124) and bind to a different receptor than type I IFN but have a similar functional output of interferon-stimulated genes. Intestinal epithelial cells induced expression of IFNλ within 6 hours of *L. monocytogenes* infection (125). IFNλ binds to a heterodimeric receptor composed of IL-28Rα and IL-10β chains, but unlike IFNAR, the complex is not expressed in hematopoietic cells; it is found primarily on epithelial cells and possibly hepatocytes (126). Given the cell tropism of the IFNλ receptor, it is tempting to speculate that type III IFN is an important component of tissue-specific innate immunity at mucosal surfaces. However, it has been difficult to study the role of type III interferons *in vivo* because two of the IFNλ genes are pseudogenes in mice, and the IFNλ receptor genes are not highly expressed in mouse liver (127). In cell culture, cytosolic *L. monocytogenes* secretes LntA, which translocates to the host cell nucleus and interacts with the chromatin repressor BAHD1 to prevent silencing of interferon-stimulated genes (128). Although it seems counterintuitive for an intracellular bacterium to promote expression of genes involved in innate immunity, one possibility is that IFN signaling can also lead to cell cycle arrest, prolonging the intracellular replication niche (129).

IL-1β is a pyrogen with pleiotropic functions in innate immunity

IL-1 was the first cytokine to be identified, and the original function ascribed to it was induction of fever during infection (130). Fever is part of the early response to *L. monocytogenes* in murine models. Murapa et al. used temperature transponder microchips implanted in the abdominal cavity to show that i.v.-infected mice had a 2°C increase in body temperature that peaked approximately 2 days postinfection (131). However, it is now clear that IL-1 is also involved in modulating neutrophil influx, prostaglandin synthesis, and Th17 T cell responses. IL-1α is constitutively expressed in many cell types and does not require any additional processing to bind to the IL-1 receptor (IL-1R) (132). In contrast, IL-1β is induced by CLEC5A and TLR2 signaling in myeloid phagocytes and is expressed as an inactive proform that must be cleaved by caspase-1 (43, 133, 134). IL-1β does not have a classic secretion signal, and it is not yet clear how it is released from the cell. One possibility is that membrane pores formed when inflammatory caspases activate gasdermin-mediated pyroptosis allow for cytokine release, but other mechanisms have also been proposed (135, 136). *In vivo*, IL-1 did not reach detectable levels in serum during systemic listeriosis, but it was produced locally in the spleen and liver with peak levels occurring 2 to 4 days postinfection (137). Neither IL-1β$^{-/-}$ mice nor IL-1R$^{-/-}$ mice generated on a resistant C57BL/6 background showed a defect in CFU burdens or survival compared to wild-type controls (138, 139). However, antibody-mediated blockade of the receptor in susceptible strains such as BALB/c or SCID mice decreased neutrophil influx (140) and increased bacterial burdens by 50- to 100-fold (137, 141). Thus, IL-1 can enhance innate resistance to listeriosis but is not absolutely required for bacterial clearance.

IL-12 and IL-23 promote the development of proinflammatory T cell responses

The IL-12 gene family consists of five cytokine subunits: p19, p28, p35, p40, and EBI3. Heterodimeric complexes of these proteins form bioactive cytokines: IL-12 (p35 + p40), IL-23 (p19 + p35), IL-27 (p28 + EBI3), and IL-35 (p35 + EBI3) (142). Of these four cytokines, IL-12 is by far the best studied during *L. monocytogenes* infection. IL-12 is produced by phagocytes and is triggered when surface-exposed TLRs encounter either live or heat-killed *L. monocytogenes* (143–145). Secreted IL-12 induces natural killer (NK) cells, NKT cells, and memory phenotype CD8$^+$ T cells to express IFNγ (146–148). If IL-18 is also present, the two cytokines act synergistically to induce IFNγ secretion (22, 146). Using a mouse model with a conditional knockdown of the IFNγ receptor, Lee et al. showed that CD8α$^+$ DCs were an important source of IL-12 that initiated IFNγ responses in the spleen within the first 24 hours of infection (149). However, soon after that, the large number of infiltrating Ly6C^{hi} monocytes become the primary source of IL-12 in the spleen. Although IL-12 levels peak within 12 hours of infection (145), ablating IL-12 does not typically result in changes in bacterial burdens until 3 days postinfection or later (149–151). This highlights the fact that IL-12-dependent IFNγ production is important for shaping the ensuing inflammatory response and generating Th1-type T cells, but IL-12 does not play a direct role in early innate immune clearance of *L. monocytogenes*.

IL-23 is also secreted by phagocytes in response to *L. monocytogenes* infection (152) and is best known for promoting the generation of Th17 cells, a subset of CD4$^+$ T cells that enhance clearance of extracellular bacteria and fungi. In the absence of IL-12 and type I IFN, IL-23 can also drive CD8$^+$ T cells to lose their cytotoxic capacity and begin producing IL-17 (153). A Th17-type inflammatory response could be important during the intestinal phase of infection, when most *L. monocytogenes* organisms are found in the extracellular compartment (19). In fact, Disson et al. recently showed that when *L. monocytogenes* translocated across M cells in the gut mucosa, CX$_3$CR1^{int} "MP" cells rapidly produced IL-23 (154). MP cells are a functionally plastic cell type that shares properties with both macrophages and DCs (155). Increased output of IL-23 in the gut resulted in secretion of IL-22 and IL-17 by innate lymphoid cells (ILCs), which in turn, induced mesenchymal stromal cells to express IL-11 (154). A previous study had found no role for IL-11 in systemic infection (156), but inclusion of IL-11 in the cytokine milieu of the small intestine apparently induced an epithelial response that included increased proliferation, less goblet cell maturation and mucus production, and a decrease in accessible E-cadherin (154). Together, these responses may cause a blockade of InlA-mediated uptake in intestinal villi, which could help to explain why *L. monocytogenes* can persist in the gut lumen for several days after initial clearance from the underlying lamina propria (2). Using the i.v. infection model, p19$^{-/-}$ mice (unable to produce IL-23 but producing normal levels of IL-12) had reduced infiltration of monocytes in the spleen and fewer neutrophils in the liver, leading to increased bacterial burdens in both organs (157, 158). Sieve et al. also reported that splenocytes from p19$^{-/-}$ mice treated exogenously with IL-23 showed a significant reduction in IL-12-dependent IFNγ secretion (159). This

suggests that IL-23 might directly antagonize IL-12 and, thus, serve as a key factor that regulates the switch between Th1 or Th17-type inflammatory responses.

Effector cytokine TNFα is required for direct bacterial killing

TNFα is essential for clearance of *L. monocytogenes*. Mice that lack either the cytokine itself or one of its cognate receptors (TNFR1, also known as p55, and TNFR2, also known as p75) are highly susceptible to either systemic (160–164) or oral (165) *L. monocytogenes* infection. The importance of the TNFα response is also readily observed in humans. TNFα inhibitors are commonly used to reduce chronic inflammation in rheumatoid arthritis and ulcerative colitis patients, and several case reports suggest that this therapy leaves the patients susceptible to developing the more severe forms of systemic listeriosis (166–168). TNFα is produced by a variety of cell types including macrophages, a subset of TNF and nitric oxide synthase-producing myeloid cells referred to as "TipDCs" (169), and effector $CD8^+$ T cells. Secretion can be induced by triggering MyD88-dependent TLR (22) or by the presence of the chemokines IL-6 and CCL3 (109, 170), but a maximal, sustained response requires cytosolic localization of *L. monocytogenes* (104, 171). In the spleens of mice, TNFα was first detected at 24 hours postinfection, and the concentration peaked at 3 days (137). TNFα signaling in conjunction with IFNγ activates macrophages, pushing them toward an inflammatory "M1" phenotype while suppressing the alternatively activated "M2" phenotype (172). Activated macrophages produce increased reactive oxygen species and inducible nitric oxide synthase and display enhanced killing of intracellular *L. monocytogenes* (173, 174). TNFα produced by effector T cells may also have direct killing effects. White and Harty found that perforin-deficient $CD8^+$ T cells killed target cells displaying the appropriate antigen-loaded MHC-I molecules using a TNFα-dependent mechanism (175). Although TNFα is clearly an important cytokine for initiating a proinflammatory, Th1-type immune response, excess production can be detrimental. Murapa et al. showed that heat shock factor 1-deficient mice produced higher levels of TNFα and were significantly more susceptible to infection than wild-type animals (131).

IFNγ stimulates the expression of hundreds of genes and is essential for protective immunity

IFNγ, also known as type II interferon, is a critical cytokine for clearance of intracellular bacterial pathogens such as *L. monocytogenes* and is involved in both the innate and adaptive phases of the immune response. Signaling through the IFNγ receptor activates the JAK-STAT pathway and results in transcriptional regulation of hundreds of genes which are collectively known as interferon-regulated genes (176). Many of these genes are involved in innate immunity and result in increased effector functions such as phagocytosis, production of proinflammatory cytokines, and the production of reactive oxygen and nitrogen intermediates. In addition to enhancing the killing function of phagocytes, IFNγ can increase expression of costimulatory molecules and MHC, resulting in enhanced priming of T cells. Badovinac et al. also showed that the presence of IFNγ can alter the immunodominance hierarchy of specific antigenic epitopes that are processed and presented to T cells (177). For additional information about the specific activities of IFNγ during listeriosis, please see the extensive review by Dussurget et al. (126).

Mice that lack the IFNγ gene are highly susceptible to listeriosis (178), and patients with mutations in the receptor IFNγR1 are prone to develop recurrent infections with intracellular bacteria, including *L. monocytogenes* (179, 180). Furthermore, innate resistance to either orally transmitted or systemic listeriosis, which varies among different laboratory strains of mice, correlates with both the timing and the magnitude of the IFNγ response (181). Serum levels of IFNγ peak at 24 to 48 hours after i.v. infection. Although this important cytokine can be secreted by a variety of cell types (182, 183), the relevant cellular sources are likely to vary throughout the course of infection depending on the localization of infectious foci of bacteria. For example, shortly after i.v. infection, most *L. monocytogenes* organisms in the spleen are found in the red pulp, where they colocalize with NK cells and $CD169^+$ marginal zone macrophages (184). If memory $CD8^+$ T cells are present, they also localize to the red pulp and begin producing IFNγ within 6 hours of infection (185). However, within 24 hours, most of the bacteria have moved to the T cell zone of the spleen, where they encounter primarily DCs and naive T cells (184, 186).

Early IL-10 production may contribute to host susceptibility

IL-10 is an immune-suppressive cytokine with pleiotropic functions that can dampen Th1-type inflammation. Many cell types can produce IL-10 after recognition of bacterial motifs by either MyD88 or (TIR domain containing adaptor-Inducing interFeron beta) TRIF-dependent PRRs (187), but the downstream effects of IL-10 expression vary depending on the time and place that the cytokine is secreted. During the later stages of infection, secretion of IL-10 has an important regulatory function to limit pathology caused by excessive inflammation. For example, γδ T cells produce IL-10 and help to prevent immune-mediated tissue damage in the liver. In mice lacking γδ T cells, TNFα-secreting effector $CD8^+$ T cells persisted in the liver instead of contracting normally once *L. monocytogenes* was cleared, and this resulted in hepatic necrosis (188). NK cells also begin to secrete IL-10 midinfection, as discussed in greater detail below, but robust production of IL-10 early during infection seems to underlie known differences in host innate resistance to *L. monocytogenes*. Pasche et al. observed that gender-specific differences in serum IL-10 concentrations 3 days postinfection correlated with the enhanced susceptibility of females compared to males in certain mouse strains (189). Neonates also have increased serum IL-10 compared to adults early after infection with *L. monocytogenes* (190), and this likely contributes to their enhanced susceptibility compared to adults. In neonatal mice, IL-10 was rapidly produced by both macrophages and dendritic cell precursors (190, 191).

IL-10-deficient mice were more resistant to *L. monocytogenes* infection than wild-type mice and displayed differences in bacterial burdens in the spleen and liver as early as 2 days postinfection (192, 193). Two groups have shown that subsets of regulatory B cells are major producers of IL-10 and that mice lacking these B cells had decreased bacterial loads in the spleen (194, 195). However, it is possible that this early IL-10 response is an artifact of the i.v. model, which results in a large bolus of bacteria all reaching the spleen within just minutes of inoculation (196). Emil Unanue's group has shown that i.v. injection of *L. monocytogenes* induces a robust type I IFN response that leads to massive lymphocyte apoptosis and a concomitant increase in IL-10 production by phagocytes in the spleen (120, 197, 198). Their studies suggest that IL-10 production is integral to creating a proliferative niche in the spleen that allows *L. monocytogenes* to grow exponentially during the first few days of infection. In contrast, Pitts et al. did not see an increase

in T cell death or enhanced IL-10 production in the spleen following oral infection, even when the spleens had bacterial burdens that were similar to those of i.v.-infected mice (113). This suggests that transmission by the oral route, which involves several bottlenecks before reaching the spleen, does not trigger rapid IL-10 production by phagocytes and B cells. Further work will be required to determine if the age- or gender-specific differences in rapid IL-10 production that have been described also occur following natural foodborne transmission in either susceptible mice or humans.

Activation of the Complement System

The complement system is a complex network of soluble proteins present in blood and other body fluids (199). Activation of the complement cascade could aid in the innate immune response to *L. monocytogenes* in three ways: (i) by generating the anaphylatoxins C3a and C5a, which are strong chemoattractants for PMNs, (ii) by generating the opsonin C3b to promote internalization of microbes by phagocytes, and (iii) by direct killing via the C5b-9 membrane attack complex. Gram-positive bacteria such as *L. monocytogenes* are thought to be somewhat resistant to lysis via the membrane attack complex because the thick peptidoglycan layer of the cell wall prevents efficient insertion of C5b-9 proteins (200). However, the cell wall fraction of *L. monocytogenes* does activate complement, most likely via the alternative pathway, and if *Listeria*-specific antibodies bind to the bacteria, the classical pathway will also be activated, resulting in the production of many cleavage products, including C3a, C3b, and C5a (201–204).

The complement mechanism that has been most extensively investigated during listeriosis is promoting uptake by myeloid phagocytes. In the presence of serum from naive mice, C3b-laden bacteria were readily taken up by cells that express the complement receptor CR3 (205). CR3-mediated internalization occurred more frequently in activated macrophages and was associated with bacterial killing (206). Rosen et al. showed that treatment with antibodies specific for CR3 resulted in large increases in CFU burdens and death in mice infected with a dose that is normally sublethal (207). Tissue-resident phagocytes such as Kupffer cells in the liver often express little CR3; however, they do express abundant complement receptor of the immunoglobulin superfamily (CRIg). CRIg binds C3b and iC3b fragments and mediates clearance of opsonized particles from the blood (208). Signaling through CRIg promotes rapid phagocytosis by macrophages and some DCs and induces the subsequent formation of autophagosomes (209). Thus, even *L. monocytogenes* bacteria that are able to escape from phagocytic vacuoles in these cells may be killed by autophagy. Indeed, CRIg-deficient mice had a 100-fold increase in circulating *L. monocytogenes* in the blood compared to wild-type mice (208).

Activation of complement via the alternative pathway also leads to the formation of C3a and C5a fragments, particularly in myeloid-derived cells (monocytes, macrophages, DCs, neutrophils, basophils, and eosinophils). C57BL/6 mice lacking the receptor for either of these anaphylatoxins ($C3aR^{-/-}$ or $C5aR^{-/-}$) were significantly more susceptible to *L. monocytogenes* infection as evidenced by higher CFU burdens and decreased survival (210, 211). In both of these studies, the receptor deficiency led a decrease in innate immune cell infiltration in the spleen at 3 days postinfection. The A/J mouse, an in bred strain that naturally lacks the C5 component of complement, was also moderately more susceptible to *L. monocytogenes* infection (212, 213). These results suggest that complement activation and the production of both C3a and C5a is necessary for optimal chemotaxis of inflammatory phagocytes during *L. monocytogenes* infection.

Recent studies suggest that complement may also have other novel functions during listeriosis. Verschoor et al. found that C3-opsonized *L. monocytogenes* in the bloodstream rapidly associated with platelets and then colocalized with $CD8\alpha^+$ DCs in the spleen (214). In the liver, Kupffer cells also used CRIg to recognize platelet-bound bacteria (215). The authors of these studies proposed that this complement- and platelet-dependent mechanism of clearance is slower than the rapid killing that occurs when phagocytes use scavenger receptors to mediate uptake of bacteria. This would allow for additional time for *L. monocytogenes* antigens to be presented to lymphocytes, thereby promoting adaptive immunity. Complement activation may also directly affect T cells. Nakayama et al. showed that proliferation of both $CD4^+$ and $CD8^+$ T cells was diminished in C3-deficient mice, indicating that complement had a role in promoting optimal expansion of T cells (216). However, Tan et al. found that memory $CD8^+$ T cells were maintained at higher levels in $C3^{-/-}$ mice (217). This suggests that complement may be involved in the contraction phase of the T cell response, although additional studies will be required to understand the exact roles of the various C3 cleavage fragments.

Infiltration of Inflammatory Cells

L. monocytogenes derives its species name from the robust monocytosis first observed in infected rabbits (218), and this feature is replicated in both oral and systemic mouse models of listeriosis (219, 220). Systemic mediators produced during infection generally increase both progenitor development and the release of mature leukocytes from the bone marrow. These circulating cells traffic to sites of infection and, upon recognition of *L. monocytogenes*, begin to secrete additional cytokines that can alter the local microenvironment, shaping the ensuing immune response. This section discusses innate immune cells in the approximate order in which they either infiltrate infectious foci or become activated during the course of infection.

Neutrophils (PMNs) are first responders that directly kill *L. monocytogenes*

During infection, PMNs downregulate expression of CXCR4, a receptor that promotes retention in the bone marrow, and upregulate expression of the receptor CXCR2, which can sense the chemokines CXCL1 and CXCL2 (221, 222). Within just 30 minutes of i.v. inoculation, circulating PMNs begin to infiltrate the *L. monocytogenes*-infected liver, with peak numbers occurring by 4 hours postinfection in C57BL/6 mice (223). This rapid recruitment appears to be at least partially dependent on formyl peptide receptors (FPRs). Murine neutrophils have a low affinity for fMet-Leu-Phe, the prototypic formylated peptide that is commonly used to stimulate human PMNs. However, murine PMNs have strong affinity for other N-formylated peptides derived from *L. monocytogenes* (224). In mice deficient for either FPR1 or FPR2, peak neutrophil recruitment is delayed until 8 hours postinfection, and in doubly deficient mice that cannot sense formylated peptides at all, the total number of PMNs that infiltrate the liver is greatly reduced (223). These results suggest that formylated peptides derived from the N-terminus of *L. monocytogenes* proteins drive much of the early chemotaxis of neutrophils into the liver, although other signals, such as leukotriene B4 and complement component C5a, are also likely to play a role in PMN recruitment. During

sublethal infection, serum granulocyte colony-stimulating factor levels increase, and enhanced granulopoiesis in the bone marrow replenishes lost PMNs. However, in mice challenged with a lethal dose, extensive triggering of PRRs on cells in the bone marrow leads to the depletion of PMN progenitors (225).

Granulocyte colony-stimulating factor-deficient mice have severe neutropenia and when challenged with *L. monocytogenes* have increased bacterial burdens in both the spleen and the liver compared to wild-type animals (226). Likewise, early studies using antibody-mediated depletion of neutrophils suggested that PMNs were critical for limiting *L. monocytogenes* growth during the first few days of infection (227–232). However, the antibodies used in those studies (clone RB6-8C5) were subsequently shown to bind both Ly6G (a surface marker specific for PMNs) and Ly6C (a protein expressed by both PMNs and monocytes). Two more recent studies using newer antibodies with a validated Ly6G specificity (clone 1A8) confirmed that depletion of PMNs resulted in significantly increased bacterial burdens in the liver but not the spleen (233, 234). A third report found no role for neutrophils (235); however, in that study the anti-Ly6G antibodies were administered at the time of infection, rather than as a pretreatment, so it is possible that some PMNs rapidly infiltrated the liver and killed *L. monocytogenes* before the antibodies could deplete the cells. *L. monocytogenes* is not an obligate intracellular pathogen, but the ability to invade host cells and spread from cell to cell to avoid extracellular immune defenses is thought to be the primary virulence strategy during infection of mammalian hosts. However, it is clear that at any given point in time, a significant number of extracellular bacteria are also present in the tissues (19). The ability of PMNs to directly kill those bacteria before they can establish an intracellular niche is likely to be critical for limiting exponential replication of *L. monocytogenes*.

PMNs are abundant in human blood but account for only 15% of circulating leukocytes in mice (236, 237). This, along with the ease of access to large volumes of peripheral blood from human donors, probably explains why most *in vitro* studies of PMN function have used human cells. In mice, bone marrow is a good source of morphologically mature PMNs that release both primary and secondary granules upon stimulation (238, 239). Incubation of human PMNs with either live *L. monocytogenes* or purified LLO caused the cells to degranulate and enhanced production of both leukotrienes and reactive oxygen species (240). This process occurred rapidly, because the granules fused with the plasma membrane before the PMNs had even completed engulfment of the bacteria (241). Arnett showed that matrix metalloproteinase-8 was responsible for the rapid degradation of LLO, leaving *L. monocytogenes* within a phagosome from which it could not escape. Similar results were found in murine PMNs, where a small number of *L. monocytogenes* bacteria were able to persist intracellularly for a short period of time without replicating (242). Pitts et al. demonstrated that murine PMNs use both oxidative and nonoxidative mechanisms to kill serum-opsonized *L. monocytogenes* and that there were no intrinsic differences in the killing ability of PMNs harvested from either susceptible BALB/c mice or resistant C57BL/6 mice (242). However, the level of extracellular superoxide dismutase produced does seem to affect the ability of murine PMNs to kill internalized bacteria (243, 244).

In addition to being laden with granules that allow for rapid degradation of engulfed bacteria, PMNs may also serve other functions in immunity. For example, Yin et al. found that a subset of neutrophils in the spleen was secreting IFNγ 18 hours after *L. monocytogenes* infection (183). This suggests that PMNs can also contribute to the early innate cytokine response to infection. Tvinnereim et al. also reported that depletion of neutrophils reduced $CD8^+$ T cell activation, implicating neutrophils as a source of antigen that could be cross-presented by $CD8\alpha^+$ DCs (245). Unfortunately, those studies were performed with the Ly6G/Ly6C cross-reactive antibodies, so it is not yet clear if PMNs or monocytes were the critical cell type. There is a growing awareness that neutrophils are not homogenous, but it is not yet clear whether there are distinct subsets of dedicated PMNs with different functions or if different states of differentiation exist within one population of cells (246). As this field advances, it will be exciting to see if neutrophils are also involved in regulating other aspects of immunity during listeriosis.

Monocytes patrol tissues and migrate to draining lymph nodes and the spleen

Monocytes were long thought of as simply the circulating blood precursors for tissue macrophages, but we now understand that there are several subtypes of monocytes and that these cells serve both regulatory and antimicrobial functions during infection (247, 248). One regulatory function of monocytes may be to prevent excessive activation of PMNs which could lead to increased tissue damage. Boyartchuk et al. showed that 24 hours after *L. monocytogenes* infection, the number of infiltrating PMNs in the liver was similar in both BALB/c and C57BL/6 mice (249). However, 1 day later, the livers of the more susceptible BALB/c mice still had predominately neutrophilic infiltrates, but the infectious foci in the more resistant C57BL/6 mice were surrounded by monocytes. In mice treated with an anti-CR3b antibody, monocytes did not properly organize into granuloma-like foci in the livers, and increased bacterial burdens were observed (207). Antibodies administered after monocytes had already appeared at the site of infection had much less effect, which suggests that the recruitment of monocytes to neutrophilic infectious foci is critical for limiting exponential growth of *L. monocytogenes*. Monocytes may be uniquely suited to serve a regulatory role because they are more efficient at infiltrating sites of infection where tissue damage already exists. Velásquez et al. used multiphoton intravital microscopy to show that by 3 days postinfection, foci of *L. monocytogenes* in the liver were no longer perfused by blood, yet monocytic cells were still able to enter the foci, while other cell types only accumulated at the periphery (250). These observations are all consistent with the idea that recruitment of monocytes is important for shifting the environment toward a resolving type of inflammation.

Expression of Ly6C distinguishes the two major subsets of monocytes in mice: $Ly6C^{lo}$ cells patrol endothelial surfaces and are functionally equivalent to $CD14^{lo}CD16^+$ cells in humans, while $Ly6C^{hi}$ cells ($CD14^{hi}CD16^-$ cells in humans) are typically thought of as inflammatory monocytes, and these are the cells that increase in number substantially during infection (248, 251, 252). Inflammatory monocytes express high levels of the chemokine receptor CCR2 and are released from the bone marrow during infection in response to the presence of CCL2, CCL7, and CCL12 in the blood (106). Shi et al. reported that recruitment from the bloodstream and subsequent trafficking to infectious foci in the liver was chemokine-independent and instead relied on interactions with CD11b, CD44, and ICAM-1 that were induced near sites of infection (253). However, Jin et al. found that STING-deficient mice had diminished serum

levels of CCL2 and CCL12 during infection and that this led to decreased migration of monocytes to the liver but not the spleen (59). In the spleen, efficient recruitment of Ly6C^{hi} monocytes depends, at least in part, on interactions with CX3CR1 and requires secretion of IL-23 (157, 254). As the infection proceeds, monocyte recruitment declines, perhaps due to negative feedback from IL-10 produced by NK cells (255).

It is difficult to discuss the antimicrobial effector functions of monocytes without acknowledging the confusion that has existed in the field regarding the origin and function of macrophages and DCs (256), since monocytes have been reported to differentiate into both of these cell types. An emerging consensus suggests that activated Ly6C^{hi} monocytes can differentiate into either effector monocytes, monocyte-derived DCs that partially resemble conventional DCs (cDCs), and monocyte-derived phagocytes that resemble tissue-resident macrophages. Although the plasticity of monocytes is widely understood, some debate still exists concerning whether inflammatory cues or the intrinsic properties of precursor subsets determine functional phenotype (257, 258). Regardless, the transcriptional profiles and cell surface phenotypes that are currently being used to distinguish various subsets of monocyte-derived cells are much more extensive and complex than those that were typically used in earlier studies. Therefore, it can be hard to attribute previous results obtained using only a few surface markers to one of these newly defined subsets. Despite this limitation, it is clear that monocytes and monocyte-derived effector cell types have microbiocidal functions that are involved in *L. monocytogenes* clearance. Serbina et al. were the first to show that a subset of Ly6C^{hi} monocytes rapidly secreted TNFα and increased output of nitric oxide (169). Ly6C^{hi} monocytes can also produce high levels of reactive oxygen species, but this seems to be more important during secondary infections.

Another possible function for monocytes during infection is the transport of microbes from one part of the body to another. It is now clear that some subsets of monocytes can migrate through tissues and transport antigen to draining lymph nodes without differentiating into tissue-resident cells (259, 260). However, *L. monocytogenes* does not efficiently invade monocytes. Using a flow cytometric approach, Jones et al. found that the majority of cell-associated *L. monocytogenes* bacteria in either the gut lamina propria or mesenteric lymph nodes (MLNs) were adhered to Ly6C^{hi} monocytes (220). However, they were unable to demonstrate intracellular growth or survival of *L. monocytogenes* in either bone marrow-derived cultured monocytes or Ly6C^{hi} monocytes harvested from the lymph nodes of mice and infected directly *ex vivo*. Likewise, Shi et al. found that very few monocytes in the livers of i.v.-infected mice harbored viable *L. monocytogenes* (253). Drevets et al. published a series of reports demonstrating that association of *L. monocytogenes* with monocytes could promote entry into the brain during systemic listeriosis, but they also failed to identify significant numbers of viable gentamicin-resistant bacteria within these cells (261, 262) Therefore, monocytes appear to be a major cell type that interacts with *L. monocytogenes* during the innate immune response, but they do not serve as an intracellular growth niche.

Macrophages serve as an intracellular growth niche until activated by IFNγ

Tissue macrophages are not technically an infiltrating cell type but are included here because both monocyte-derived and tissue-resident macrophages are involved in the early, innate immune response to *L. monocytogenes*. Resident macrophages are thought to derive from embryonic progenitors that seed tissues during development. They are imprinted with characteristics specific to a given tissue and self-renew throughout the lifespan of the host (263). Resident macrophages differ phenotypically and functionally from monocyte-derived macrophages found in the spleen or lymph nodes, although there is still confusion regarding the extent to which monocyte-derived cells can acquire the properties of tissue-resident cells. Many published *in vitro* studies that examined the interaction of *L. monocytogenes* with macrophages used either transformed cell lines (e.g., J774 or RAW264) or bone marrow-derived macrophages. Culturing bone marrow yields a homogenous population of cells that most closely resembles an early differentiation state of a macrophage, but the cultures generally lack the heterogeneity of macrophage subsets that have been observed *in vivo* (256). Regardless, these cells have been extraordinarily useful for delineating the stages of the *L. monocytogenes* intracellular life cycle since they support extensive bacterial growth in the cytosol (264). Indeed, bone marrow-cultured cells become permissive for intracellular proliferation of *L. monocytogenes* as soon as they start transitioning from a monocyte to a macrophage, as indicated by decreased surface expression of Ly6C and increased CD64 (220).

As the innate immune response to infection proceeds and high levels of proinflammatory cytokines are produced, macrophages become activated and induce multiple killing mechanisms that destroy *L. monocytogenes*. In macrophages pretreated with IFNγ, *L. monocytogenes* was destroyed within phagocytic vacuoles and did not escape into the host cell cytosol (265). TNFα alone did not have the same effect but could synergize with IFNγ to enhance bacterial killing. During primary infection, a major killing mechanism that activated macrophages use is the production of reactive nitrogen intermediates (266). However, during secondary infection, memory T cells are available to rapidly produce CCL3, and this induces phagocytes to produce increased levels of TNFα and reactive oxygen species, and reactive nitrogen intermediates are no longer required (109, 267). Antimicrobial peptides produced by epithelial cells or neutrophils can also contribute to phagosomal killing of *L. monocytogenes* in macrophages. Arnett et al. showed that extracellular α-defensins that were engulfed during phagocytosis blocked phagosomal escape and intracellular proliferation of *L. monocytogenes* in human macrophages (268). Macrophages are professional antigen-presenting cells (APCs) and, thus, are capable of processing and presenting peptide epitopes derived from *L. monocytogenes* proteins in both the MHC-I pathway (for bacteria that reach the host cell cytosol) and the MHC-II pathway (for bacteria killed within phagocytic vacuoles). However, as described below, DCs are thought to be the most efficient APCs involved in priming naive T cell responses.

Following i.v. infection, *L. monocytogenes* is filtered from the blood by specialized subsets of macrophages in the spleen and liver. Two types of macrophages in the marginal zone of the spleen initially engulf the bacteria: highly phagocytic CD209b^{+} marginal zone macrophages and CD169^{+} marginal metallophilic macrophages (186, 269, 270). Both populations of cells appear to restrict intracellular growth of *L. monocytogenes*, although this has not been studied extensively. Selective depletion of marginal zone macrophages and marginal metallophilic macrophages results in the rapid spread of bacteria into the red pulp of the spleen instead of containment within the marginal zone (186, 269). By

24 hours postinfection, *L. monocytogenes* typically moves to the T cell zone in the white pulp of the spleen (184). Perez et al. recently suggested that transfer of *L. monocytogenes* from infected $CD169^+$ macrophages to migratory DCs may facilitate this process (186). Outside of the marginal zone, most macrophages resemble monocyte-derived $CD64^+/F4/80^+$ cells, and it is likely that these cells represent the primary intracellular growth niche in the spleen. In the liver, tissue-resident Kupffer cells also capture *L. monocytogenes* circulating in blood. Kupffer cells are critical for limiting early replication of *L. monocytogenes* in the liver (91, 269), but the mechanism may not involve internalization of the bacteria. Gregory et al. suggested that *L. monocytogenes* did not invade Kupffer cells and that neutrophils recruited to the liver were responsible for killing extracellular adherent bacteria (271). More recently, Blériot demonstrated that Kupffer cells exposed to *L. monocytogenes* rapidly died by necrosis, triggering a Th1-type inflammatory response that recruited monocytes to the infected liver (272). There is also a population of $CX3CR1^{hi}Tim4^-$ macrophages in the liver that is distinct from Kupffer cells (273). These cells patrol the lining of the liver and can engulf any *L. monocytogenes* that may disseminate from the peritoneal cavity. Like other tissues, the gut also has specialized subsets of macrophages that reside either in the lamina propria or the muscularis externa as well as a population of $CX3CR1^{int}$ myeloid phagocytes referred to as MPs that seem to have functional plasticity (274). Interactions between these subsets of cells and *L. monocytogenes* following oral infection have not yet been extensively studied. In one recent report, Disson et al. argued that InlA-dependent invasion of the gut mucosa was immunologically "silent," while uptake via M cells triggered $CX3CR1^{int}$ myeloid phagocytes to produce IL-23 (154). If *L. monocytogenes* organisms disseminate to the brain, they encounter specialized resident macrophages known as microglia. Microglia support intracellular replication of *L. monocytogenes*, and infection induces high-level expression of TNFα, but other inflammatory responses are suppressed in the brain (275).

Antigen-laden DCs migrate to draining lymph nodes to activate T cell responses

cDCs derive from a dedicated precursor in the bone marrow and depend on both the transcription factor Batf3 and the growth factor Flt3 ligand for terminal differentiation (276). Monocytes can also differentiate into $CD11c^+$ cells that resemble cDCs, but there is still debate about the nomenclature of monocyte-derived cells. High expression of CD11c was long used as a defining surface marker for DCs, but we now know that CD11c can be expressed on many myeloid cell types, particularly those that reside outside of lymphoid tissue. Furthermore, the *in vitro*-cultured, bone marrow-derived $CD11c^{hi}$ cells commonly referred to as DCs in the published literature more closely resemble macrophages (277, 278). Both DCs and macrophages express the costimulatory molecules needed to prime naive T cell responses, and both cell types can process and present peptide antigens bound to either MHC-I or MHC-II, but DCs are thought to be the primary cell type that stimulates an initial T cell response. The key functional property that distinguishes DCs from macrophages is their superior ability to traffic to the areas where naive T cells reside in the white pulp of the spleen or the T cell zone of lymph nodes. The migratory nature of DCs allows for acquisition of antigens at sites of infection and transport to lymphoid tissue, but it may also promote dissemination of bacterial pathogens such as *L. monocytogenes*.

Waite et al. used multiphoton intravital imaging to examine the interactions of *L. monocytogenes* with cell types in the subcapsular sinus of the spleen (196). They found that within just minutes, *L. monocytogenes* colocalized with $CD11c^+$ cells that actively extended dendrites towards the bacteria. As early as 9 hours after infection, *L. monocytogenes*-associated DCs begin to move from the marginal zone of the spleen to the periarteriolar sheath (279). Verschoor et al. showed that C3-opsonized bacteria that had associated with platelets in the bloodstream were the microbes preferentially targeted by $CD8\alpha^+$ cDCs in the spleen (214). Association with cDCs appears to be a critical step in colonization of the spleen, since mice depleted of DCs have significantly lower bacterial burdens at 24, 48, and 72 hours postinfection (234, 280). Edelson et al. showed that *L. monocytogenes* failed to move to the white pulp of the spleen in Batf3-deficient mice that lacked $CD8\alpha^+CD103^+$ cDCs (234). This suggests that *L. monocytogenes* that remain in the marginal zone can readily be cleared by macrophages and that exponential growth of *L. monocytogenes* does not happen until cDCs transport the bacteria to the white pulp of the spleen. Once there, DCs form clusters with T cells at the border of the T and B cell zones in the spleen (281). Batf3-deficient mice also have decreased bacterial burdens in the liver following infection with either *L. monocytogenes* or *Listeria ivanovii* (234), but exactly how hepatic $CD103^+$ DCs promote infection in the liver is not yet clear.

Muraille et al. intravenously injected heat-killed *L. monocytogenes* into mice and found that the bacteria were rapidly filtered by the spleen but remained in the marginal zone and red pulp (282). This suggests that active invasion of DCs and cytosolic escape of the bacteria may be required for transport to the white pulp. Multiple studies have used flow cytometric approaches to attempt to identify *L. monocytogenes*-infected subsets of cells in the spleen directly *ex vivo* (278, 280, 282–285). Although the gating strategies used in each study varied somewhat, in the aggregate, this body of work provides evidence that rare DCs do contain live intracellular *L. monocytogenes*. However, when Jones et al. isolated $CD103^+$ and $CD103^-$ cDCs from the MLNs of naive mice and infected the cells directly *ex vivo*, they found no increases in gentamicin-resistant bacteria over time and, instead, observed that the number of live intracellular *L. monocytogenes* bacteria had decreased by 8 hours postinfection (278). Likewise, Westcott et al. found that *L. monocytogenes* did not efficiently escape the phagosome in bone marrow-derived $CD11c^{hi}$ cells (286, 287). Since we know that *L. monocytogenes* organisms do begin growing exponentially once they reach the white pulp of the spleen, there could be a mechanism whereby intracellular *L. monocytogenes* can exit from infected cDCs, or it is possible that only the adherent extracellular bacteria transported by DCs would be able to replicate in the white pulp.

cDCs are more efficient than macrophages at "cross-priming" T cells, a process in which dead or dying cells are phagocytosed and antigens contained within these cells are processed and presented to T cells (288). Thus, cDCs could prime T cells that recognize epitopes from either secreted or nonsecreted proteins expressed by *L. monocytogenes*, even if cDCs themselves are not productively infected with live replicating bacteria (289). All professional APCs, including DCs, can be activated by $CD4^+$ T helper cells through interactions between the costimulatory molecule CD40 expressed on the DC and CD40 ligand (CD40L or CD154) expressed on the T cell. However, in the case of *L. monocytogenes* infection, direct activation of cDCs by exposure to

bacterial microbial associated molecular patterns (MAMP) is sufficient, and $CD4^+$ T cell help is not required to stimulate cDCs to prime $CD8^+$ T cell responses (290). Peak costimulatory molecule expression on splenic dendritic cells occurred 24 to 48 hours after i.v. infection (285). Activated cDCs produce proinflammatory cytokines such as IL-12 and IL-18 (74, 149).

NK cells are a major source of early IFNγ but rapidly switch to production of IL-10

NK cells are protective during many viral infections, so it was a logical assumption that NK cells might also be protective during infection with an intracellular bacterial pathogen such as *L. monocytogenes*. Activated NK cells secrete IFNγ and can directly lyse infected cells if they do not sufficiently engage inhibitory receptors due to low MHC-I expression or if they express high levels of stress-induced host or microbial proteins (291). The p60 autolysin secreted by *L. monocytogenes* indirectly promotes activation of NK cells by a mechanism that involves contact with an infected DC and sensing of IL-18 independent of IL-12 secretion (74, 292, 293). Multiple studies have shown that NK cells are a major source of the early IFNγ produced during listeriosis (146, 182, 255, 294). Early work also envisioned a role for NK cells in the lysis of infected hepatocytes to release intracellular bacteria so they could be cleared by inflammatory phagocytes (295, 296). However, several studies that examined the effect of NK cell deficiency found either little difference in CFU burdens compared to NK-replete animals or significantly increased resistance to *L. monocytogenes* infection (255, 297–299). These results suggested that NK cell activation may actually be detrimental to the host during listeriosis.

Perona-Wright et al. clarified that NK cells have an important regulatory function during infection with *L. monocytogenes* or other pathogens that cause systemic disease (300). Using IL-10 reporter mice, they found that approximately 80% of the NK cells circulating in peripheral blood expressed IL-10 4 days postinfection. They argued that IL-10 production was triggered when a high enough serum concentration of IL-12 was achieved and suggested that this might represent a negative feedback mechanism to prevent extended inflammation and tissue damage during systemic infection. Clark et al. confirmed these findings and further showed that most NK cells stopped producing IFNγ fairly early during infection and began secreting IL-10 instead (255). Depletion of NK cells in IL-10-deficient mice had no effect on bacterial burdens, suggesting that NK-mediated susceptibility was due to secretion of this immune suppressive cytokine rather than a lack of immune stimulatory IFNγ. Mice lacking NK cells did have significantly lower serum levels of IFNγ 24 hours postinfection (255); however, there are a wide variety of other cell types that can be induced to secrete IFNγ during the first few days of infection (182). Early IFNγ levels vary between different strains of mice (181), and the balance of IFNγ produced by these other cell types compared to the level of IL-10 produced by NK cells is likely to have a key role in determining overall susceptibility to infection.

Lymphocytes can also provide protective function during first few days of infection

Lymphocytes mediate the adaptive immune response to infection and are generally thought to require specific antigen stimulation and several days of differentiation before they acquire effector function. One of the hallmarks of adaptive immunity is that lymphocytes can acquire memory and respond rapidly upon secondary exposure, allowing innate and adaptive immune responses to work synergistically within just a few days of infection. However, even in a naive host that has never encountered *L. monocytogenes* before, two different groups of lymphoid cells can respond rapidly in an antigen-independent manner and are therefore part of the innate immune response. The first group of cells are bona fide T lymphocytes that have acquired a memory phenotype without encountering the specific antigen recognized by their T cell receptor (TCR). The second group, termed innate lymphoid cells (ILCs), are tissue-resident cells found in both lymphoid and nonlymphoid organs that resemble lymphocytes but do not express a functional T cell or B cell receptor (301).

Memory phenotype or "virtual memory" $CD8^+$ T cells express high levels of surface markers such as CD44 and CD122 that define memory T cells, but they are found in naive or even germ-free animals that have no known prior exposure to specific antigen (302–304). Early studies showed that IL-12 and IL-18 produced in response to cytosolic invasion of *L. monocytogenes* activated these T cells to rapidly secrete IFNγ within 16 to 24 hours of infection (181, 294, 305–308). Adoptive transfer of virtual memory cells can provide significant protection against *L. monocytogenes* challenge, particularly for the subset of cells that express the chemokine receptor CXCR3 (304, 305, 309). Inbred mouse strains differ with respect to the number of virtual memory cells that can be detected, and the absolute number of virtual memory T cells present in the spleen correlates directly with innate resistance to systemic listeriosis (146, 181). These cells are not just found in mice; Bou Ghanem et al. showed that 85% of human blood donors had circulating memory phenotype T cells that rapidly produced IFNγ after incubation with *L. monocytogenes* (147). High levels of IFNγ would certainly promote clearance of infection by activating phagocytes to kill internalized *L. monocytogenes*. However, the sustained presence of IFNγ produced by innate T cells may also be important for stimulating the programmed death ligand-1 on naive T cells to promote their continued expansion following antigenic stimulation (310).

Another population of lymphocytes involved in innate immunity during *L. monocytogenes* infection is NKT cells, a small subset of T cells that share features of both NK cells and T cells. Most express a TCR that comprises an invariant Vα chain and diverse β chains that recognize several types of lipid antigens instead of peptide. Like memory phenotype T cells, NKT cells are a significant source of IFNγ during the first few days after *L. monocytogenes* infection (146, 294). It is important to note that these cells can express CD8, so they can be misidentified as classical $CD8^+$ T cells if NK1.1 is not used as an additional surface marker (148). NKT cells may be part of a complex feedback mechanism with dendritic cells. Lee et al. showed that TNFα activated NKT cells to secrete IFNγ, which caused $CD8\alpha^+$ cDCs to secrete IL-12 (149). IL-12, IL-15, and IL-18 have all been implicated in the activation of both NK cells and NKT cells (311).

ILCs have been classified into three groups (ILC1, ILC2, and ILC3); however, there is still considerable confusion regarding these cells because they seem to have functional plasticity (312). They are activated by exposure to MAMPs and to "danger" signals released from the cytosol of host cells (DAMPs) and they help to coordinate innate immune responses by secretion of specific cytokines. Disson et al. recently reported a role for ILCs in the intestinal lamina propria of mice orally infected with *L. monocytogenes* (154). They found that bacteria that translocated across specialized

M cells in the gut triggered ILC3 to secrete IL-17 and induced ILC2 to secrete IL-22, and that the dual presence of these two cytokines induced mesenchymal stromal cells to express IL-11. IL-11 had no apparent role in systemic listeriosis (156), but inclusion of this cytokine in the milieu of the small intestine induced an epithelial response that decreased accessible E-cadherin expression (154). These observations suggested that M cells and ILCs work together to provide a sentinel function that ultimately leads to a decrease in further invasion of *L. monocytogenes* in intestinal villi.

Mast cells

Mast cells are granulocytes loaded with secretory granules that are best known for their role in allergic responses. Other physiologic functions have also been attributed to mast cells, but these findings are somewhat controversial because the studies used either a transformed human cell line (HMC-1) or c-kit mutant mice with pleiotropic effects besides mast cell deficiency (313). Mast cells can be activated by a variety of stimuli, leading to degranulation and the local production of chemokines and cytokines that could be important for mobilization of PMNs during early listeriosis. In fact, c-kit specific-antibody-mediated depletion of mast cells resulted in increased bacterial burdens and significantly fewer PMNs infiltrating the spleens and livers of mice (314). Mast cells were also an apparent source of IL-6 *in vivo* (315) and may even be involved in direct antigen presentation to $CD8^+$ T cells (316). *In vitro* studies using HMC-1 cells suggest that *L. monocytogenes* can activate mast cells in an LLO-dependent manner (317). Although the bacteria did not appear to be readily internalized by HMC-1 cells, infection did cause a reactive oxygen species burst and a release of extracellular DNA similar to neutrophil extracellular traps (318). Together, these preliminary reports suggest that mast cells could play a role in innate immunity against *L. monocytogenes*, but further work will be needed to confirm this idea.

ADAPTIVE IMMUNITY

Innate immune responses alone can clear small doses of *L. monocytogenes* and can limit exponential growth in resistant hosts such as C57BL/6 mice. However, an efficient adaptive immune response is required to achieve sterilizing protective immunity. This is readily apparent in animal models such as SCID or RAG-deficient mice, where small differences in CFU burdens observed at early time points grow by orders of magnitude at 10 days postinfection, and the bacteria are never cleared (319, 320). Indeed, in humans, it is deficiencies in adaptive immunity that are associated with high mortality in immunocompromised populations such as neonates and the elderly (321, 322). The primary virulence strategy of *L. monocytogenes* during systemic infection is thought to be using actin-based motility to spread from cell-to-cell, avoiding the extracellular milieu, so it is intuitive that cytotoxic $CD8^+$ T cells are the crucial lymphocyte population needed for clearance (323, 324). As outlined below, $CD4^+$ T cells and B cells play supporting roles but are important for efficient generation of long-lasting memory cells. Because the i.v. model of listeriosis is highly reproducible, immunologists have long used this model system to study the basic biology of $CD8^+$ T cells, and this has been reviewed recently elsewhere (325, 326).

Activation of a naive T cell in the spleen or draining lymph node requires three signals that must be recognized in a specific sequence. A requirement for multiple signals ensures that T cells will not become activated in the absence of danger that indicates the presence of either microbes or tissue damage. Signal 1 occurs when an epitope-specific TCR engages with its cognate antigen (typically a peptide) that has been processed intracellularly and presented on the cell surface by MHC-I or MHC-II proteins. Antigen processing and presentation during *L. monocytogenes* infection are discussed further below. Signal 2, also referred to as "costimulation," involves the binding of stimulatory protein(s) on the surface of the T cell by ligand(s) typically expressed on professional APCs such as macrophages or dendritic cells. Signal 2 costimulatory molecules are typically upregulated only when professional APCs are activated, such as occurs after exposure to MAMPs. The classic signal 2 pairing involves CD28 on the T cell and B7 (also referred to as CD80/86) on the APC. Early studies showed that the immunodominant $CD8^+$ T cell response was markedly reduced in CD28-deficient BALB/c mice after either i.v. or oral *L. monocytogenes* infection (327). However, at least 15 other pairs of costimulatory molecules have now been described, and there are also inhibitory receptors that can counteract the effects of these signaling cascades (328). The third signal, which can alter the outcome of the T cell response, depends on the local concentration of type I IFN and IL-12 (329). The type and duration of both signal 2 and signal 3 can vary depending on the magnitude of the microbial burden and the local tissue microenvironment, and this can influence both T cell survival and differentiation into various subsets of T cells (Th1, Th2, Th17, etc.).

Antigen Processing and Presentation to T Cells

Classical MHC-I (MHC-Ia)

In all nucleated cells of the body, cytosolic proteins are cleaved into peptide-length fragments (8 to 11 amino acids) by the proteasome and transported into the endoplasmic reticulum, where they bind newly synthesized MHC-Ia proteins and are then translocated to the cell surface. MHC-Ia proteins are normally loaded with fragments of self-proteins; however, during intracellular infection, peptides derived from secreted microbial antigens are also displayed on the cell surface, and this serves as a signal to $CD8^+$ T cells that a foreign agent is contained within. *L. monocytogenes* can readily gain access to the cytosol of most cell types, and therefore, any proteins secreted by *L. monocytogenes* can potentially be processed and presented by the MHC-Ia machinery. BALB/c mice ($H\text{-}2^d$ haplotype) express three MHC-Ia proteins (K^d, D^d, and L^d), but the majority of epitopes recognized by $CD8^+$ T cells appear to be presented by the K^d molecule. A peptide derived from LLO ($LLO_{91\text{-}99}$) is by far the immunodominant epitope (330–332). Other subdominant epitopes that induce proliferation of K^d-restricted T cells during primary *L. monocytogenes* infection of BALB/c mice include $p60_{217\text{-}225}$ (333), $p60_{449\text{-}457}$ (334), $p60_{476\text{-}484}$ (335), and $mpl_{84\text{-}92}$ (336). Validation of immunodominant epitopes for C57BL/6 mice has lagged behind these studies, so recombinant *L. monocytogenes* expressing either viral antigens with defined $H\text{-}2^b$-restricted epitopes or the model antigen ovalbumin (SIINFEKL) are often used to study T cell dynamics in C57BL/6 mice. This approach was recently validated by Wolf and Princiotta, who showed that the efficiency of peptide-MHC complex formation in *L. monocytogenes*-infected cells was similar for both endogenously expressed and recombinant secreted antigens (337). The identification of so many different peptide epitopes makes listeriosis a particularly attractive model system to investigate how the abundance and stability of protein antigens produced during infection and the half-life of peptide-MHC complexes on

the surface of APCs contribute to immunodominance (332, 338–342).

Nonclassical MHC-I (MHC-Ib)

MHC-Ia-deficient mice were fully protected against *L. monocytogenes* infection despite the fact that most of the $CD8^+$ T cells in these animals were depleted in the thymus during T cell development (343). This suggested that a residual population of MHC-Ib-restricted $CD8^+$ T cells was sufficient to mediate full clearance of *L. monocytogenes*. Unlike classical MHC-I, MHC-Ib proteins often have lower cell surface expression and may be found only in some tissues (344, 345). Research in this area is limited, mainly because MHC-Ib genes are not well conserved between humans and mice. The best-characterized MHC-Ib molecule during listeriosis is M3, which binds to short N-formylated peptides derived from mitochondrial proteins in the steady state, or during infection, from the N-terminus of bacterial proteins that initiate with a formylated methionine (346). Three distinct peptides derived from *L. monocytogenes* proteins are known to be presented by M3 during infection: fMIVIL, fMIGWII, and fMIVTLF (340, 347–349). However, MHC-Ia-deficient mice infected with *fmt* mutant *L. monocytogenes* that did not stimulate M3-restricted T cells were still capable of generating protective immunity against secondary *Listeria* challenge (350). Likewise, Cho et al. generated MHC-Ia and M3 doubly deficient mice and showed that their $CD8^+$ T cells were also protective (351). These results argue that there are other MHC-Ib proteins that can activate naive $CD8^+$ T cells during listeriosis. One candidate is Qa-1, which has been shown to bind peptides derived from *L. monocytogenes* (352). Neither M3 nor Qa-1 have human counterparts, but humans have more diversity in subtypes of CD1 molecules than mice do (353). Thus, in both systems, there are multiple types of MHC-Ib restricted T cells that can respond to infection.

MHC-II

MHC-II proteins are expressed only by professional APCs such as macrophages, DCs, and B cells. They bind longer peptides (13 to 25 amino acids) derived from extracellular antigens that are processed in degradative vacuoles, and their cell surface levels typically increase during infection. The first MHC-II-binding epitopes derived from *L. monocytogenes* to be identified were $LLO_{215\text{-}226}$ in mice with an $H\text{-}2^k$ haplotype (354) and $P60_{301\text{-}312}$ in BALB/c ($H\text{-}2^d$) mice (355). A follow-up study specifically targeting these two protein antigens found six additional CD4 epitopes in BALB/c mice and five epitopes recognized by C57BL/6 ($H\text{-}2^b$) mice (335). In both mouse strains, peptides derived from LLO appeared to be immunodominant. It is intriguing that the immunodominant antigen produced by *L. monocytogenes* is a pore-forming toxin capable of causing cytotoxicity in APCs; Carrero et al. examined this relationship and found that LLO mutants with reduced toxicity still retained high antigenicity (356). Although most effort has focused on LLO and P60, a recent study revealed that there is considerably more diversity in the repertoire of CD4 epitopes presented by *L. monocytogenes*-infected cells. Graham et al. immunoprecipitated MHC-II from bone marrow-derived, *in vitro*-cultured $CD11c^+$ cells exposed to *L. monocytogenes* and analyzed the bound peptides by liquid chromatography with tandem mass spectrometry (LC-MS/MS) (357). They found 48 distinct peptides (most not previously described) that were derived from 21 proteins. Surprisingly, most of the *L. monocytogenes* antigens were either secreted proteins or cell wall proteins. This suggests that similar to MHC-Ia antigens, the accessibility of the antigen may be a critical factor in determining the likelihood that peptides will be displayed on the cell surface.

Magnitude and Kinetics of the Primary Response

$CD8^+$ T cells

Within 24 hours after i.v. inoculation, most *L. monocytogenes* bacteria have localized to the T cell zone of the spleen (184, 185, 281), and it is likely that most T cell priming occurs within this time frame. Indeed, if mice are treated with antibiotics at 24 hours postinfection to eliminate replicating *L. monocytogenes*, there is no difference in the kinetics of the $CD8^+$ T cell response (358). Although T cells expressing a variety of different TCRs are almost certainly activated at this stage, only those with a high affinity for their cognate peptide::MHC complex expand significantly (359). *Listeria*-specific $CD8^+$ T cells increase in size as they begin to proliferate, downregulate expression of L-selectin (CD62L), and upregulate expression of CD11a, PD-1, and CD69 (281, 360). Based on upregulation of CD11a on the cell surface, Rai et al. estimated that about 30% of the total $CD8^+$ T cells in the BALB/c spleen 7 days after a high-dose i.v. infection were *Listeria* specific (361). In CD11a-deficient mice, the magnitude of the primary $CD8^+$ T cell response was greatly reduced (362). T cell expansion was also impaired in aged C57BL/6 mice (18 months old) compared to younger animals (363), an observation that is clinically relevant given that the elderly are the patient population most at risk for developing life-threatening systemic listeriosis.

Although *Listeria*-specific $CD8^+$ T cells increase to detectable levels within 3 to 4 days, the peak of the MHC-Ia-restricted $CD8^+$ T cell response typically occurs 7 to 8 days after i.v. infection (360). In contrast, M3-restricted T cells peak much sooner, usually within 5 days of infection (364), probably because T cells that undergo positive selection in the thymus by recognizing M3 mature into naive cells that are partially activated (365). The timing of peak activity for M3-restricted T cells suggests that they have a transitional role that bridges innate and adaptive immunity. In fact, Xu et al. showed that M3-restricted T cells have a nonredundant function that could not be compensated for by classically restricted (MHC-Ia) $CD8^+$ T cells (366). Early cytokine secretion by M3-restricted T cells likely contributes to enhanced maturation of cDCs (367). Much less is known about the priming of $CD8^+$ T cell responses following oral transmission of *L. monocytogenes*. The bacteria presumably interact with APCs in either the Peyer's patches of the small intestine or in lymphoid follicles of the large intestine, and subsets of antigen-laden DCs should also migrate to the draining MLNs, but the timing of such events has not yet been determined. However, it is known that the peak number of antigen-specific CD8 T cells in peripheral blood occurs 8 to 9 days postinfection (368, 369). The extra 1 to 2 days required to see peak T cell expansion may be a consequence of the time required for *L. monocytogenes* to reach the MLNs in significant numbers (2). It should be noted that the kinetics of differentiation and the magnitude of expansion for *Listeria*-specific $CD8^+$ T cells is based primarily on work done in either BALB/c or C57BL/6 mice. Rai et al. showed that these parameters varied considerably in outbred mice, raising the possibility that humans might also show the same variation (361).

Extensive proliferation of $CD8^+$ T cells in response to specific antigens results in a large population of effector cells that can traffic throughout the body to promote clearance of *L. monocytogenes*. As the infection subsides, the majority of

those cells die, and if the inflammatory context is appropriate, the remaining cells develop long-lasting memory. This contraction phase occurs with preprogrammed kinetics, regardless of the duration of the infection (330). Porter et al. used an attenuated Δ*act*A strain, which has a much higher infectious dose than wild-type bacteria, to show that $CD8^+$ T cells begin undergoing apoptosis approximately 5 days after the peak antigen display (370). However, the host probably senses the level of inflammation, rather than the bacterial burden, to trigger initiation of the contraction phase. In the absence of significant IFNγ production, no $CD8^+$ T cell death was observed, and mice doubly deficient for TNFα and perforin had greatly reduced levels of T cell contraction (371). In contrast, B cell-deficient mice displayed greater death of $CD8^+$ T cells during the contraction phase (372). B cells are not involved in the activation of naive $CD8^+$ T cells or the expansion of effector cells but can influence the inflammatory milieu.

$CD4^+$ T cells

Helper T cell expansion and contraction during *L. monocytogenes* infection closely mirrors what has been observed for $CD8^+$ T cells. The peak of $CD4^+$ T cell proliferation in the spleen occurs at about the same time in mice at 6 to 8 days postinfection (360). Proliferation seems to proceed with preprogrammed kinetics regardless of the duration of infection or the amount of antigen displayed. However, the total number of $CD4^+$ effector cells with specific functional properties is influenced by the bacterial burden during the first few days of infection (373). Likewise, dysregulated contraction of $CD4^+$ T cells occurs in the absence of IFNγ production and signaling through the IFNγ receptor (373, 374). Paul Allen's laboratory has been using systemic listeriosis as a model system to study how interactions between TCR and peptide MHC-II complexes affect the $CD4^+$ T cell response using cells from two different transgenic mice that both recognize $LLO_{190\text{-}205}$ bound to $I\text{-}A^b$ (375). They showed that clonal T cells can vary in both their proliferative capacity and their half-life even though they recognize the same antigen (376).

Effector Functions of T Cells

Cytotoxicity

$CD8^+$ T cells (sometimes referred to as cytotoxic T lymphocytes) have cytotoxic potential that must be initiated by recognition of a specific MHC::peptide complex on a target cell (364, 377). One of three distinct pathways can then lead to the destruction of that *L. monocytogenes*-infected cell: Fas-FasL-mediated apoptosis (378), TNFα-dependent apoptosis (175), and granule exocytosis (379, 380). The granules of $CD8^+$ T cells contain the pore-forming toxin perforin as well as granzymes and serine proteases that can induce programmed cell death of the host cell. Perforin-deficient mice infected with *L. monocytogenes* generate more antigen-specific $CD8^+$ T cells than wild-type animals, demonstrating a separate role for perforin in regulating T cell expansion (381). At early time points during listeriosis, most of the responding antigen-specific $CD8^+$ cells have the ability to lyse target cells; however, at the peak of T cell expansion, only about 50% of the cells are cytotoxic (363). This may be a feedback mechanism to limit collateral damage to host tissues. $CD4^+$ T cells also have cytotoxic potential. Mice infected with *L. monocytogenes* induced $CD4^+$ T helper cells with high levels of FasL, and it was shown that some of these cells could directly kill B cells displaying the relevant peptide::MHC-II complex on the cell surface (382). However, cytotoxic $CD4^+$ T cells do not contribute significantly to clearance of *L. monocytogenes*, most likely because the bacteria can invade and replicate in many types of cells that do not express MHC-II (383). Lysis of an infected host cell should result in the release of any remaining live intracellular *L. monocytogenes*, which can then be engulfed by neutrophils or activated macrophages and subsequently killed. Direct intracellular killing of *L. monocytogenes* may also be possible in dying cells that have not yet lysed. The lytic granules of human (but not rodent) $CD8^+$ T cells contain granulysin, a pore-forming protein that preferentially targets microbial membranes (384). A recent report by Walch et al. suggests that granulysin can insert into *L. monocytogenes* membranes and cause death of intracellular bacteria within 90 minutes (385).

Secretion of Th1-type cytokines

A primary function for both $CD4^+$ and $CD8^+$ T cells is the secretion of the proinflammatory cytokines IFNγ and TNFα. Indeed, detection of these cytokines by enzyme-linked immunosorbent spot assay or intracellular cytokine staining is often used as a proxy to identify antigen-specific T cells within a bulk population of cells that have been infected or exposed to peptide epitopes. Effector $CD8^+$ T cells can express IFNγ within just a few hours of exposure to antigen, even when the number of peptide::MHC-I complexes on target cells is limited (386). In contrast, the number of $CD8^+$ T cells secreting TNFα is typically lower, unless the target peptide epitope is present at a high concentration. Both IL-12 and type I IFN are thought to be signal 3 molecules that can drive naive T cells toward a Th1 phenotype. Way et al. showed that neither molecule was required for IFNγ production by $CD8^+$ T cells (387). However, defects in either IL-12 or IFNαβ resulted in fewer IFNγ-producing $CD4^+$ T cells, and the loss of both cytokines resulted in an almost complete lack of IFNγ-producing T helper cells. Eicosanoids may also need to be present for full activation of $CD8^+$ T cells. The Sauer lab recently showed that treatment of mice with COX-2 inhibitors such as indomethacin or celecoxib resulted in decreased IFNγ production by CD8 T cells (388). After oral infection, LLO-specific $CD4^+$ T cells were detected in both lymphoid tissues (spleen and MLN) as well as in the lamina propria of the small intestine. In both compartments, the cells were predominantly Th1-type secreting IFNγ, TNFα, and IL-2 (389).

Antigen-independent bystander killing

Although cytolysis, secretion of IFNγ, and secretion of TNFα αre thought of as the major protective functions of $CD8^+$ T cells, none of these mechanisms are absolutely required for resistance to *L. monocytogenes* infection (175, 178, 381). This may be explained by the fact that both primary effector cells and memory $CD8^+$ T cells can also secrete CCL3 (107, 109). CCL3 is a chemokine that can activate monocytes, macrophages, or dendritic cells to secrete TNFα, which then upregulates reactive oxygen species production in all myeloid-derived cells, including neutrophils (109). Thus, $CD8^+$ T cells can also indirectly promote killing of bystander bacteria that are engulfed by activated phagocytes using an antigen-independent mechanism.

Secretion of Th17-type cytokines

Activated $CD4^+$ T cells that produce the proinflammatory cytokine IL-17A (Th17-type cells) could promote bacterial clearance by inducing neutrophil migration to sites of infection. Th17 cells have well-defined roles in protection

against infection with extracellular bacteria and fungi, but their role during infection with a facultative intracellular pathogen like *L. monocytogenes* is not yet clear. Pepper et al. showed that infection via a mucosal route (intranasal), but not i.v. infection, generated IL-17A-producing cells that comprised about 10% of the *Listeria*-specific $CD4^+$ T cells in the spleen (390). Uchiyama et al. also detected a population of $CD4^+$ T cells that produced both IFNγ and IL-17 (Th1/Th17 cells) in the spleens of i.v.-infected mice (391). A strong IL-1β response was required to see an expansion of this subset of cells. The major source of IL-17A during i.v. infection seems to be TCRγδ T cells in the liver (392, 393). These unconventional T cells may play a role in promoting cross-presentation of antigen by cDCs (393). However, multiple studies have shown that mice lacking γδ T cells have a somewhat prolonged infection, but the animals do clear the bacterial burden (394–396); thus, γδ T cells are not absolutely required for protection. The best evidence to date to suggest that IL-17A-producing T cells can contribute to clearance of *L. monocytogenes* resulted from the infection of p35/EBI3 doubly deficient mice, which lack the ability to produce any of the IL-12 family of cytokines (IL-12, IL-23, IL-27 and IL-35). These mice produced significantly higher levels of IL-17 and IL-22 than did wild-type mice, and antibody treatment to deplete the IL-17 resulted in increased bacterial burdens (150). Furthermore, adoptive transfer of LLO-specific Th17 cells greatly reduced *L. monocytogenes* growth in both the spleen and liver. A subset $CD8^+$ T cells can be driven to produce IL-17 if they are primed in the absence of IL-12 and type I IFN (153). This effect appears to be dependent on the presence of IL-23 and resulted in a loss of cytotoxic potential.

Regulatory T cells

A subpopulation of activated $CD4^+$ T cells that express high levels of Foxp3 regulate immunity by inhibiting T cell function. These regulatory T cells (T_{reg}) are critical for avoiding autoimmunity because they actively suppress immune responses directed against self-antigens, and they are often expanded during chronic infections (397). Ertelt et al. showed that as the percentage of antigen-specific $Foxp3^{neg}$ cells expanded following *L. monocytogenes* infection, the T_{reg} population had a corresponding decrease, because the cells did not proliferate (398). Another group suggested that competition for the growth factor IL-2 could explain why regulatory T cells did not expand and could even undergo a partial loss during listeriosis (399). Treating mice with exogenous IL-2 allowed for T_{reg} proliferation but resulted in a corresponding increase in bacterial burdens. Thus, in most situations, T_{reg} activation is detrimental to the host defense against bacterial infections. A notable exception occurs during pregnancy, when regulatory T cells present at the maternal-fetal interface are critical for maintenance of a suppressive environment so that the maternal immune system does not reject the fetus. Sing Sing Way's group has shown that fetal wastage can occur even if *L. monocytogenes* does not directly invade the placenta if the maternal Th1 response to systemic infection is robust enough to disrupt $Foxp3^+$ T cell-mediated tolerance (400).

Memory T Cell Responses During Secondary Infection

Formation of memory T cells

During the primary response to infection, a subset of effector $CD8^+$ T cells differentiates into memory precursor effector cells that express high levels of CD127 and low levels of KLRG1 (401). Further differentiation of memory precursor effector cells results in the generation of long-lasting memory T cells with epigenetic modifications that underlie their enhanced capacities during recall responses (402). The environmental cues that regulate this process have been explored using many model systems, including *L. monocytogenes* infection. The results of several studies suggest that IL-12 is a critical factor needed for efficient memory cell formation and that IL-23 may be able to partially compensate in some contexts (401, 403, 404). IL-2, a cytokine primarily known as a growth factor to promote T cell proliferation, is also required during differentiation to generate memory cells capable of full expansion during secondary challenge (405). Surprisingly, there may also be a role for IL-10 production in memory formation. Foulds et al. showed that IL-10-deficient mice had fewer memory $CD8^+$ T cells and that adoptive transfer of these T cells provided less protection against *L. monocytogenes* than memory T cells from wild-type mice (193). IL-10 involvement was not related to bacterial burden, because similar results were obtained for memory T cells generated in mice treated with antibiotics 24 hours after infection. Upregulation of the integrin chain CD11a typically occurs during the differentiation of primary effector cells, but this seems to hamper the formation of memory cells. Bose et al. showed that mice lacking CD11a had significantly greater numbers of *Listeria*-specific memory T cells and a more robust recall response than wild-type animals (362). $CD4^+$ T cell help is not needed for the generation of memory $CD8^+$ T cells, but the absence of Th1-type helper cells does affect the stable persistence of the memory pool (406). Very little is known about the formation of memory $CD4^+$ T cells, due to the lack of specific surface markers that can be used to define this cell population.

Recall responses involve faster expansion and higher magnitude

Upon secondary challenge with *L. monocytogenes*, memory T cells recognize their cognate peptide::MHC complex and begin to control the infection within just 6 hours (185). T cell expansion generally occurs more rapidly, with the total number of effector cells being substantially higher than during the primary infection. Since memory T cells develop during the contraction phase of the first infection, the magnitude of the primary T cell response directly affects the potential size of the memory T cell pool. For MHC-Ia restricted memory $CD8^+$ T cells, the peak of proliferation occurs 3 to 5 days postinfection (360, 407). M3-restricted $CD8^+$ T cells do not have a characteristic recall response, so peak expansion also occurs at 3 to 5 days postinfection, just as it did during the primary response (408). Cho et al. showed that the residual population of $CD8^+$ T cells present in MHC-Ia and M3 doubly deficient mice also did not display a classic memory response during secondary challenge (351). Thus, if there are other *Listeria*-specific memory $CD8^+$ T cells restricted by novel MHC-Ib molecules, they would contribute to bacterial clearance with the same kinetics as M3-restricted T cells.

Much less is known about $CD4^+$ T cell recall responses during listeriosis. One study that tracked $LLO_{190\text{-}201}$-specific $CD4^+$ T cells during secondary infection found that the peak expansion was similar to the primary response, and then the antigen-specific T cells continuously declined in number over time (409). The magnitude of the $CD4^+$ T cell recall response is thought to be dependent on the duration of the secondary infection and may be influenced by both the inflammatory context and the availability of peptide antigen

(410, 411). It is possible that substantial recognition of peptide antigens by memory $CD8^+$ T cells (which can occur in any nucleated cell that is infected by *L. monocytogenes*) results in rapid bacterial clearance, limiting the availability of antigens that can be processed by professional APCs that express MHC-II.

Effector functions of memory T cells

The key effector mechanisms used by memory T cells are similar to those used by T cells during the primary infection. For memory $CD8^+$ T cells, IFNγ was shown to be critical for activating infiltrating monocyte-derived phagocytes using either i.v. or oral models of infection (412). In contrast, memory $CD4^+$ T cells needed to secrete TNFα, and IFNγ could enhance protection but was not required for clearance of secondary *L. monocytogenes* infection (413). Olson et al. surprisingly showed that a subset of cells displaying markers of effector $CD8^+$ T cells ($CD27^{lo}KLRG1^{hi}$) persisted in the spleens of mice that had cleared a primary *L. monocytogenes* infection. The cytotoxic potential of these cells significantly contributed to optimal control of a secondary *L. monocytogenes* challenge (414). This result underscores the need to define memory $CD8^+$ T cells by expression of differentiation markers and not just function potential. Oral infection (but not i.v. infection) also stimulated multifunctional memory γδ T cells and a tissue-resident population of $CD8^+$ T cells that provided enhanced bacterial clearance in the gut (369, 415).

Even if the ideal conditions are present to allow for efficient development of memory T cells that stably persist, their recall effector function will still be influenced by the inflammatory environment that is present during secondary infection. The Williams lab has been studying the activation of transgenic lymphocytic choriomeningitis virus-specific $CD4^+$ T cells and has shown that boosting by infecting with recombinant *L. monocytogenes* expressing the same lymphocytic choriomeningitis virus epitope results in the induction of increased numbers of memory $CD4^+$ T cells with greater avidity (416). These alterations in memory cell function appeared to be dependent on the local concentration of IL-12 and type I IFN available during the secondary exposure. They further showed that memory $CD4^+$ T cells induced by heterologous *L. monocytogenes* infection provided partial protection even if IFNγ was depleted but showed no protective capacity when TNFα was neutralized (413). Since heterologous boosting is a common immunization strategy, these results could have a significant impact on vaccine design.

Humoral Immunity

Antibodies may have an underappreciated role in the clearance of *L. monocytogenes*. The idea that humoral immunity could be important for protection against facultative intracellular pathogens was championed by Arturo Casadevall 20 years ago (417), but antibody responses are still understudied in listeriosis. The lack of research in this area is probably due to early work showing that passive transfer of sera from immune mice did not transfer resistance to naive animals (418, 419). Indeed, mice that have been intravenously injected with wild-type *L. monocytogenes* do not have a robust antibody response within 2 to 3 weeks of infection (420–422). However, pretreatment of mice with specific antibodies raised against defined *L. monocytogenes* antigens can alter the course of infection. For example, Edelson et al. showed that administration of anti-LLO monoclonal antibodies that neutralized pore formation *in vitro* could reduce bacterial burdens in the spleen and liver by 1,000-fold (420). More recently, Mohamed et al. found that treatment with monoclonal antibodies specific for ferritin-like proteins (Frl) also protected mice from lethal challenge (423). In contrast, mice preimmunized with purified p60 protein mounted a specific antibody response but showed no reduction in bacterial burdens (424). Thus, the paradigm for the mouse model is that strong antibody responses are not naturally induced during infection and antibodies are not required for clearance; however, if certain antibodies are present, they can play a role in limiting bacterial growth.

It is not yet clear why antibody production is diminished during systemic infection of mice. Extracellular *L. monocytogenes* is readily detected in the intestines, spleen, liver, and gall bladder of infected mice (2, 19, 425), so exposure to bacterial protein antigens and subsequent recognition by B cells should not be an issue. However, it is possible that intracellular growth and cell-to-cell-spread of wild-type *L. monocytogenes* limits the ability of mice to mount a productive antibody response. Infection with attenuated Δ*actA* or Δ*hly* mutants induced higher levels of serum antibody than infection with wild-type bacteria (421, 422). Manohar et al. also showed that oral transmission of Δ*actA L. monocytogenes* generated antigen-specific IgA production that could be readily detected in the Peyer's patches and MLNs starting at 3 weeks postinfection (426). However, this phenotype may be unique to the mouse model since Yu et al. readily found both InlA- and InlC2-specific antibodies in the sera of rabbits, guinea pigs, cattle, and sheep that were experimentally infected with a wild-type serotype 4b strain (427).

Humans with confirmed diagnoses of listeriosis also have circulating *Listeria*-specific antibodies. Gentschev et al. showed by immunoblot analysis that the majority of patient sera samples reacted with several secreted *Listeria* proteins (with p60- and LLO-specific antibodies being the most commonly detected), but sera from otherwise healthy donors did not (424). In a larger study using complement fixation as the readout, Leong et al. found that 12 of 74 healthy blood donors (16%) had antibodies that recognized whole bacteria (422). The results of these studies are consistent with the notion that humans frequently ingest small quantities of *L. monocytogenes*, but only a subset of the population is exposed to a high enough dose to induce circulating IgG antibodies.

USE OF ATTENUATED *LISTERIA* AS A VACCINE VECTOR

Generating an effective immunization strategy that can induce cellular immunity, particularly $CD8^+$ T cell responses, remains one of the final frontiers in vaccine research. A critical challenge is to find a safe and effective means to deliver immunogenic proteins or peptides to the cytosol of APCs. Immunization strategies that use nonreplicating vectors typically require an adjuvant and do not efficiently transport antigen to the MHC-I processing pathway. Engineered viruses are great delivery systems but raise safety concerns for use in humans, especially due to the lack of therapeutics that can effectively disable a viral infection. An intracellular bacterium can overcome these issues by naturally gaining access to the class I MHC processing pathway and by being treatable with antibiotics to ensure that there are no adverse outcomes in immunized patients. Immune responses to *Listeria*, *Salmonella*, and *Mycobacteria* have all been extensively studied in mouse models, but of these intracellular pathogens, only *Listeria* consistently induces robust protective immunity. Thus, it is not surprising that investigators have sought to harness the remarkable immune stimulatory properties of *L. monocytogenes* to develop vaccine vectors.

Attenuated *L. monocytogenes* Is Still Highly Immunogenic

Early work focused on identifying mutations that attenuated the pathogenicity of *L. monocytogenes* without losing immunogenicity, with the goal of developing a vaccine strain that could be safely administered to humans. Virulence factors required to gain access to the host cell cytosol (e.g., LLO) could not be altered, because recombinant antigens expressed by a vaccine strain need to be delivered directly to the class I MHC processing pathway. Instead, investigators targeted other virulence factors that promote cell-to-cell spread and persistence of infection. For example, Δ*actA* *L. monocytogenes* bacteria are significantly less virulent than wild-type bacteria, but they do still replicate and survive in mice for up to a week (428). Since the 50% lethal dose of a ΔActA strain is 1,000 times higher than that of wild-type *L. monocytogenes*, immunizing doses can be very large, and this results in substantially greater antigen display and peak T cell responses that occur at least 1 day sooner (370). Thompson et al. demonstrated that further attenuation of *L. monocytogenes* could be achieved while still inducing protective $CD8^+$ T cell responses (429). Their approach was to generate a triple mutant strain (Δ*dal* Δ*dat* Δ*actA*; referred to as "LmddA") that was capable of invading host cells, escaping to the cytosol, and surviving for a short time. The LmddA strain cannot spread from cell to cell due to the lack of ActA, and the bacteria do not replicate in the host because they lack two genes needed for D-alanine biosynthesis, an amino acid that is present in only trace amounts in vertebrates. Although LmddA bacteria were rapidly cleared from the spleens of mice within 48 hours, the infection was sufficient to generate protective immunity against a subsequent lethal challenge (429). Brockstedt et al. developed a Δ*inlB*Δ*actA* vaccine strain (live attenuated double-deleted [LADD]) that selectively infects only phagocytes, thus promoting antigen presentation to T cells while limiting replication in cells such as hepatocytes (430). Phase I safety trials for these attenuated strains administered either intravenously or orally showed no adverse effects in human patients and no prolonged shedding of *L. monocytogenes* in feces (431–434). Given the widespread prevalence of *L. monocytogenes* in the environment and the likelihood that humans may have prior exposure, one concern was that vaccine strains might be cleared too quickly to generate T cell responses against heterologous antigens. However, preexisting immunity to *L. monocytogenes* did not diminish the effectiveness of vaccine strains in either mice or nonhuman primates (422, 435, 436).

Fusing Antigens to Either LLO or ActA Increases Vaccine Efficacy

L. monocytogenes is genetically tractable and has been engineered to express a variety of heterologous proteins, including antigens derived from other pathogens as well as tumor-associated antigens. In many of these studies, known antigens were fused to secreted *L. monocytogenes* proteins to facilitate expression *in vivo*. Although this strategy undoubtedly enhances the ability of a heterologous antigen to be expressed in *L. monocytogenes*, there may be other reasons that fusion proteins increase the protective effect of immunization (337, 437). For example, LLO has an N-terminal sequence that targets the protein for rapid degradation by the proteasome, and vaccine strains that lack this sequence have diminished T cell responses (438). LLO itself can be recognized by PRRs, which may explain its enhanced adjuvant properties as a fusion partner (438, 439). Chen et al. recently showed that immunization with an E7-LLO fusion protein (E7 is an oncoprotein expressed by human papillomavirus) also had the effect of preferentially expanding $CD4^+Foxp3^-$ cells, resulting in a proportional decrease in T_{regs} (440). Since T_{reg} depletion is known to enhance antitumor immunity, this may be another mechanism to explain the superior ability of LLO fusion proteins to elicit a protective effect in cancer models. Antigens fused to ActA also have enhanced protective capacity, although the mechanisms involved are not as well understood (441, 442).

L. monocytogenes Vaccine Strains Could Be Used To Prevent Infectious Disease

In several animal models, infection with recombinant *L. monocytogenes* expressing heterologous microbial antigens resulted in protection against subsequent challenge with the pathogen of interest (443–447). These preliminary studies utilizing antigens derived from *Francisella tularensis*, *Mycobacterium tuberculosis*, and human immunodeficiency virus suggest that attenuated *Listeria* vectors could be used to develop preventative vaccines for either viral or intracellular bacterial pathogens. However, no successful human trials have yet been performed. Johnson et al. orally immunized 22 human volunteers with either Δ*actA*/Δ*plcB* or Δ*actA*/Δ*inlB* attenuated strains expressing influenza A nucleoprotein (432). Although the vaccine generated anti-*Listeria* responses in all of the volunteers, none had an increase in influenza nucleoprotein-specific T cells. The secreted nucleoprotein antigen in that vaccine was not fused to either LLO or ActA.

Infants are exquisitely susceptible to developing life-threatening systemic infections due to the immaturity of their immune systems. However, several vaccines have been developed that can be safely and effectively administered at birth or shortly thereafter, and the Kollmann lab has argued that *L. monocytogenes* vaccines may be ideal for this purpose (448). Five-day-old mice immunized with Δ*actA* *L. monocytogenes* were protected against secondary lethal challenge 3 months later (449). Interestingly, immunization of neonatal mice achieved a maximal $CD8^+$ T cell response after just a single dose, while effective vaccination of adult mice required a booster dose (450). However, optimal stimulation of $CD4^+$ T cell responses required a booster immunization in both neonates and adults. Given the high rate of mortality for systemic listeriosis in neonates, safety remains a significant hurdle to overcome before anti-infective *Listeria* vaccines reach the clinical development stage. One intriguing possibility for vaccine development could be the use of killed but metabolically active bacteria. *L. monocytogenes* deficient in DNA repair can be rendered incompetent to replicate by UV irradiation, and the bacteria remain able to invade the host cell cytosol and to secrete antigens for several hours (451). If the bacteria have a constitutively active PrfA transcriptional regulator to enhance virulence gene expression during these few hours, then $CD8^+$ T cell responses can readily be activated (452). This could be a promising approach for developing vaccines that could be safely administered to neonates.

Multiple Clinical Trials Using *L. monocytogenes* for Cancer Immunotherapy Are Under Way

The most exciting application of *Listeria* vaccine strains is for therapeutic use in the treatment of several types of cancer. Although surgery, chemotherapy, and radiation remain the primary treatments to eliminate tumor burdens, immunotherapies designed to boost a patient's natural immune

response against tumor antigens are now in widespread clinical use. Tumor cells express altered self-antigens that can be processed by the MHC-I pathway and presented to $CD8^+$ T cells, similar to what occurs during infection with intracellular pathogens. Cancer vaccines that elicit memory $CD8^+$ T cells may benefit patients by promoting enhanced recall responses that can quickly eliminate tumor reoccurrences and possibly prevent metastasis. *L. monocytogenes* is a particularly attractive delivery system for tumor antigens because even the attenuated strains elicit such a robust innate immune response that the infection can overcome central tolerance to tumor-associated antigens that are viewed as "self" by the immune system (453). The earliest preclinical studies in mice focused on viral antigens (E6/E7) derived from human papilloma virus (HPV) and demonstrated that immunization with *Listeria* vaccines led to regression of established HPV-16 transformed tumors (437). Importantly, the E7-expressing *L. monocytogenes* strain was able to induce a protective T cell response even in transgenic mice engineered to express the E6 and E7 oncogenes in the thymus, indicating that the vaccine strategy was able to break tolerance to an endogenously expressed protein (454). In the years since then, *L. monocytogenes* has been engineered to stimulate T cells specific for many other tumor-associated antigens, and vaccination with those strains resulted in regression of tumors in small animal models of melanoma (455), hepatocellular carcinoma (456), and prostate (457), pancreatic (458), and breast (459) cancer.

These encouraging results in mouse models have led to the initiation of more than 30 clinical trials testing multiple *L. monocytogenes* cancer vaccines. About half of the trials involve LmddA variants developed by Advaxis, Inc. (Princeton, NJ), and the rest are testing LADD-based strains developed by Aduro BioTech, Inc. (Berkeley, CA). The vaccine that has progressed the farthest to date is ADXS11-001, an LmddA strain expressing the HPV E7 oncogene fused to truncated LLO. The vaccine is currently being tested in conjunction with chemoradiation in a phase III trial with advanced-stage cervical cancer patients (clinicaltrials.gov identifier NCT02853604). The success of this vaccine has led to additional phase I and II trials to test for efficacy in patients with oropharyngeal and anal cancers (460). Another promising LmddA vaccine (ADX S31-164) was engineered to secrete LLO fused to domains of Her2/neu, an epidermal growth factor receptor family member that is overexpressed in many breast cancers with a poor prognosis. Preclinical trials with this strain shifted the ratio of $CD8^+$ T cells and immune suppressive T_{regs} inside tumors (459) and a phase I study in dogs reported an increase in median survival (461). In 2018, the U.S. Department of Agriculture granted approval for use of this vaccine in the treatment of canine osteosarcoma, making it the only *L. monocytogenes* vaccine currently approved for clinical use. The most widely tested LADD-based vaccine (CRS-207) targets mesothelin, a normal host protein that is overexpressed in multiple tumors, including pancreatic, ovarian, and lung cancer. The vaccine has been tested in phase II trials in conjunction with GVAX, a treatment consisting of irradiated pancreatic tumor cells engineered to secrete granulocyte-macrophage colony-stimulating factor (462), and trials are under way to supplement these treatments with immune checkpoint inhibitors. Another promising development from Aduro BioTech is the recent approval (clinicaltrials.gov identifier NCT03189030) to test LADD-based strains that express personalized neoantigens (mutated self-proteins expressed only in tumor cells). If this vaccine proves to be efficacious, it could lead to increased use of personalized medicine in the treatment of colorectal cancer. For more detail about each of the 10 *L. monocytogenes* cancer vaccines that have progressed to either phase I, phase II, or phase III clinical trials over the past decade, please see the comprehensive reviews recently published by Flickinger et al. (463) and Wood and Paterson (453).

CONCLUDING REMARKS

The large body of work highlighted in this article along with the extensive published studies of pathogenic mechanisms encoded by *L. monocytogenes* reviewed elsewhere combine to give us what is perhaps the most complete understanding of a host-pathogen interaction, yet there is still much to learn. One relatively unexplored frontier in the field is the effect of aging on protective immunity (464). The elderly are the patient population most at risk for developing life-threatening systemic listeriosis, yet few studies to date have examined how innate or adaptive immune responses to *L. monocytogenes* differ in aged mice compared to younger animals. Another area of emphasis for the future will be to define the mucosal immune responses that occur in the gut during natural infections acquired by the oral route. Because of the extensive existing knowledge base regarding innate and adaptive immune responses to *L. monocytogenes*, murine infection will likely continue as the favored model system to study how mucosal immunity deals with microbial pathogens that are orally acquired and then disseminate systemically, a category that includes many bacteria and viruses.

Regulation of *Listeria monocytogenes* Virulence

JÖRGEN JOHANSSON AND NANCY E. FREITAG

52

A VARIETY OF MULTIFUNCTIONAL GENE PRODUCTS CONTRIBUTE TO *LISTERIA MONOCYTOGENES* ENTRY AND SURVIVAL WITHIN MAMMALIAN CELLS

The move from soil to cytosol requires the interplay of *L. monocytogenes* factors that promote survival in the gut, bacterial invasion, phagosomal escape, replication and movement within the cytosol, and spread to adjacent cells (Fig. 1). Bacterial gene products contributing to many key aspects of host infection continue to be identified, and new factors and novel functions often emerge (1, 2). Among the cast of well-known players are surface proteins that promote bacterial attachment to and invasion of nonprofessional phagocytic cells, such as the internalins InlA and InlB as well as Lap and InlP (which appears to be specific for placental invasion) (3–5). Following cell entry, *L. monocytogenes* escapes from host cell vacuoles via the secretion of the pore-forming cytolysin listeriolysin O (LLO) and two phospholipases, a phosphatidylinositol-specific phospholipase C (PI-PLC) encoded by *plcA* and a broad-range phospholipase C (PC-PLC) encoded by *plcB* (6). Entry into the cytosol requires metabolic adaptation as *L. monocytogenes* shifts from glycolysis to the oxidative pentose phosphate pathway and replicates by scavenging phosphorylated sugars, glycerol, lipoic acid, branched-chain amino acids, and peptides from conquered host cells (7). Bacteria spread to neighboring cells by usurping actin polymerization as a motile force, a process dependent upon expression of the bacterial surface protein ActA (8). The breaking and entering of *L. monocytogenes* into adjacent cells is further facilitated by InlC, which relieves cortical tension to allow the extension of membrane protrusions (9). Escape from the double membrane vacuoles formed as a result of *L. monocytogenes* cell-to-cell spread is once again dependent upon the activities of LLO, PC-PLC, and PI-PLC. Protein secretion of a variety of factors thus promotes bacterial survival and life within host cells, and central to the secretion of active protein products is the presence of the secretion chaperone PrsA2, located at the bacterial membrane-cell wall interface, where it contributes to the folding and activity of translocated polypeptide chains (10). *L. monocytogenes* is thereby able to maintain a complex and multifunctional protein arsenal to increase bacterial survival and replication within mammalian host cells.

To better understand bacterial adaptation to the host environment, a number of studies have focused on the identification of bacterial genes expressed within tissue culture cells, within blood, or within infected animals. Microarray analyses of bacterial transcripts induced during *L. monocytogenes* infection of tissue culture cells revealed that approximately 20% of bacterial genes were differentially expressed, including genes with products that have established roles in bacterial virulence (11). Genes with increased expression in cytosolic bacteria included those with roles in general stress responses, cell division, modification of the cell wall, and the use of carbon sources such as glycerol and phosphorylated sugars. Transcriptional profiling of *L. monocytogenes* genes expressed during *in vivo* growth in mouse spleens also indicated that approximately 20% of bacterial genes were differentially expressed (12). Similar to the findings reported for bacteria grown within tissue culture cells, genes induced *in vivo* included those with defined roles in virulence, stress responses, cell wall metabolism, DNA metabolism, RNA/protein synthesis, and cell division. In contrast to tissue culture-based expression studies, transcripts from genes encoding enzymes involved in glycolysis were induced *in vivo*, while those involved in the nonoxidative phase of the pentose phosphate pathway had decreased levels of expression. These contrasting results may reflect differences observed between growth conditions within tissue culture cells versus growth in whole organs and animal tissues.

PrfA, THE MASTER REGULATOR OF *L. MONOCYTOGENES* INTRACELLULAR SURVIVAL

While life is never simple, a transcriptional activator known as PrfA does appear to suffice as the master virulence regulatory protein that enables *L. monocytogenes* to optimize life within a mammalian host while still managing a saprophytic existence in soil. PrfA is a 27-kDa transcriptional activator that is a member of the Crp/Fnr family of transcriptional regulators, and it regulates its target genes via the binding of a 14-bp palindromic DNA binding site, also known as the PrfA box, located in the –40 region of its target promoters (13–17). PrfA regulates the expression of a large number of gene products directly associated with bacterial virulence in mammals, and mutants lacking *prfA* are severely impaired for intracellular growth and are >100,000-fold less virulent in murine infection models (15). In addition to gene products required for host cell invasion, intracellular replication, and cell-to-cell spread, PrfA induces the expression of gene products required for surviving the journey through the

doi:10.1128/microbiolspec.GPP3-0064-2019

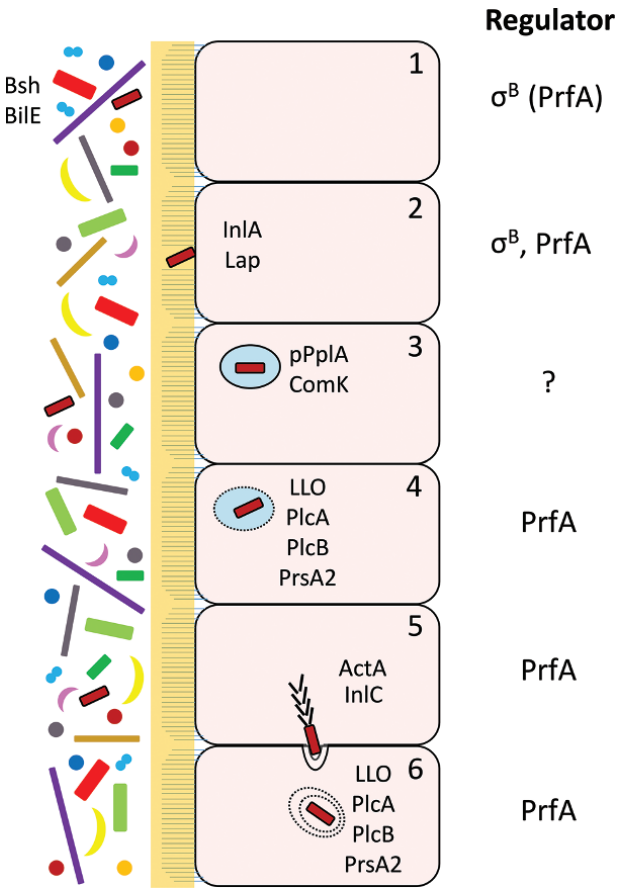

FIGURE 1 Schematic overview of *L. monocytogenes* colonization of the intestine by pathways controlled by σ^B and/or PrfA. The human microbiota is depicted to the left, lying beside the microvilli-containing epithelial cells (1). Survival of *L. monocytogenes* in the gut is mediated by different factors, among them Bsh and BilE (2). The bacterium adheres to cells using different adhesins (e.g., InlA and Lap) (3). Once inside the phagosome, the pPplA and ComK systems become activated, facilitating phagosomal escape (4). Different PrfA-regulated factors mediate lysis of the phagosome (5). Through recruitment of the Arp2/3 complex, ActA allows polymerization of actin at the pole of the bacterium, driving it through the cytoplasm. The entry of *L. monocytogenes* to adjacent cells requires InlC, which relieves cortical tension (6). The escape from the double membrane vacuole requires the action of LLO, PlcA, and PlcB. Regulators (σ^B or PrfA) involved in the different regulatory steps during intestinal passage of *L. monocytogenes* are shown at the right.

gastrointestinal tract, including a bile salt hydrolase (encoded by *bsh*) and a bile exclusion system (encoded by *bilE*) (18, 19). Full PrfA activation occurs following bacterial entry into the cytosol of host cells and results in the expression of gene products that enable intracellular replication and bacterial spread to adjacent cells. A subset of genes directly regulated by PrfA is located on an *L. monocytogenes* pathogenicity island referred to as LIPI-1 (*hly*, *plcA*, *prfA*, *mpl*, *actA*, and *plcB*), while others (*inlA*, *inlB*, *inlC*, *bsh*, *prsA2*, and *hpt*) have distinct chromosomal locations. Comparison of the profiles of wild-type *L. monocytogenes* grown in brain heart infusion broth with those of a strain harboring a constitutively active PrfA protein suggests that the expression of at least 145 genes may be modulated by PrfA (20).

Given that PrfA is critical for enabling *L. monocytogenes* to mediate the balance between life in soil and life inside an infected host, the activity of PrfA is itself carefully regulated by a variety of mechanisms that include transcriptional, posttranscriptional, and posttranslational control. These critical regulatory circuits work together to tightly control *prfA* expression and PrfA activity as outlined below.

Transcriptional Regulation of *prfA* Expression

Transcriptional regulation of *prfA* expression occurs via three promoter elements (Fig. 2). Two promoters, *prfA*P1 and *prfA*P2, are located immediately upstream of the *prfA* translation initiation codon, while the third promoter lies immediately upstream of *plcA* and results in the generation of a *plcA-prfA* bicistronic transcript (14, 21, 22). The *prfA*P1 and *prfA*P2 promoters direct the synthesis of monocistronic transcripts of *prfA* that generate the initial levels of PrfA protein required to activate expression of *hly* and *plcA*, whose gene products are needed for efficient escape of *L. monocytogenes* from host cell phagosomes (22, 23). The *plcA* promoter, which is activated by PrfA, directs the synthesis of the *plcA-prfA* transcripts, resulting in the high levels of PrfA synthesis that are required to induce *actA* expression for efficient bacterial cell-to-cell spread. The *prfA*P1 promoter contains characteristics of a σ^A-dependent promoter, which is the vegetative sigma factor determining RNA polymerase specificity required for transcription in actively growing, unstressed bacterial cells. The *prfA*P2 promoter region contains sequences that resemble a PrfA binding box, a σ^A-dependent promoter, and the general stress response sigma factor σ^B-dependent promoters (23–26). σ^B directs RNA polymerase to the promoter regions of a large number of genes involved in adaptation to general environmental stresses, such as conditions of low pH, high osmolarity, oxidative stress, and carbon starvation (see below). A number of genes coregulated by PrfA and σ^B have been shown to contribute to pathogenesis of *L. monocytogenes* (e.g., *bsh* and *inlAB*), suggesting a cross-talk network between these two regulators and possibly other stress response regulators and alternative sigma factors (18, 27, 28). Interestingly, work by Guldimann et al. (29) suggests that activation of PrfA and σ^B occurs stochastically within individual bacterial cells under defined stress conditions, with evidence that PrfA activation appears population-wide, while σ^B activation is restricted to subpopulations.

In addition to stress-responsive promoter elements, Lobel et al. have recently identified CodY to activate transcription of the *prfA* gene (30). CodY is a regulatory protein that links *prfA* expression with the metabolic status of the bacterium. Intriguingly, CodY binds to a region located 15 bases downstream of the *prfA* start codon (30). CodY responds to the presence of branched chain amino acids and GTP, and *L. monocytogenes* appears to regulate CodY activity by controlling the internal isoleucine pool, a mechanism that has been postulated to have evolved to enable isoleucine to serve as a host signal and virulence effector (31, 32). *L. monocytogenes* thus appears to tie in multiple environmental signals that include both stress and metabolism in its quest to regulate virulence gene expression within host cells.

Posttranscriptional Regulation

It has long been recognized that virulence factors as well as PrfA are mainly expressed at body temperature, 37°C, although the mRNA encoding the PrfA protein is present also at low temperatures (below 30°C) (21, 33). Computer

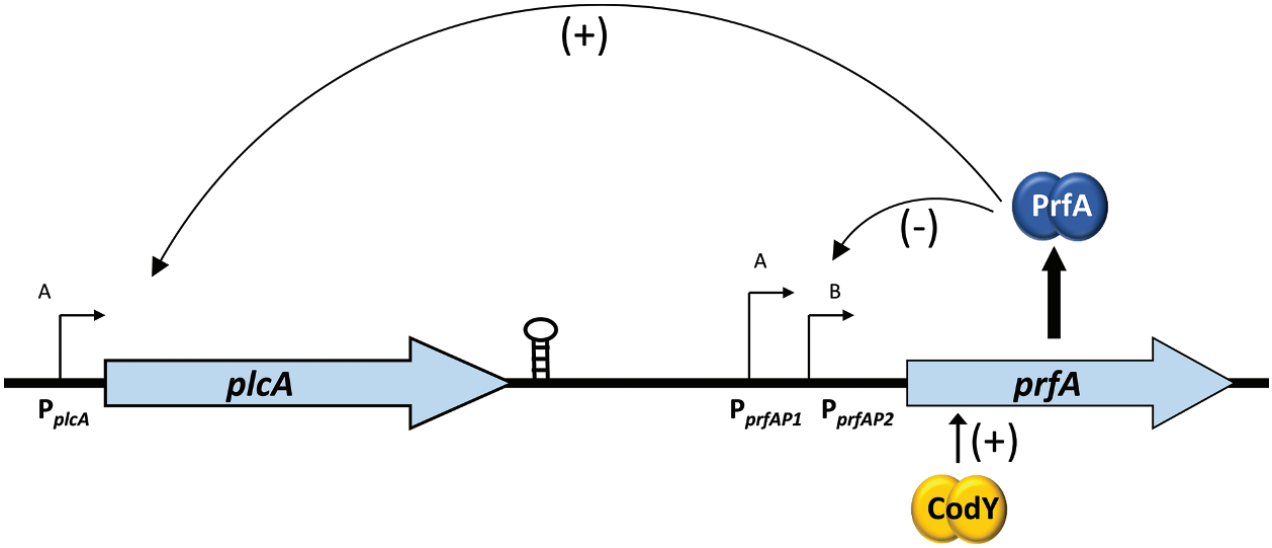

FIGURE 2 Transcriptional regulation of *prfA* expression. The *prfA* transcript is expressed from three different promoters, P1 (σ^A regulated), P2 (σ^A and σ^B regulated), and *plcA* (generating a *plcA-prfA* bicistronic messenger). The *plcA* promoter is positively regulated by active PrfA, creating a positive feedback loop of PrfA expression. CodY positively regulates expression of *prfA* by binding within its coding region. The stem-loop structure shows a putative transcriptional terminator located 3′ of the *plcA* gene.

prediction and chemical probing experiments showed that a 115-nucleotide (nt)-long 5′ untranslated RNA (UTR) present in front of the *prfA* encoding mRNA could form a long hairpin where the Shine-Dalgarno (SD) site was partially masked by an anti-SD site (34) (Fig. 3). *In vitro* translation of the wild-type *prfA* showed a thermoregulated expression, with PrfA mostly expressed at higher temperatures. Mutational analysis suggested that the actual thermosensing occurred in the middle part of the hairpin since mutations that destabilized the *prfA*-UTR structure abolished much of the thermoregulation (34). These data suggested a simple mechanism of thermosensing: at low temperatures, the SD site is closed due to an interaction with an anti-SD site, and binding of the ribosome is prevented. With increasing temperature, the region surrounding the *prfA*-SD site is destabilized, allowing binding of the ribosome and initiation of translation (34–36) (Fig. 3). However, a more complex mechanism of *prfA* translation initiation has been put forward, involving a ribosomal stand-by site inside the *prfA* coding RNA (37).

In addition, *prfA* translation is controlled by at least two prematurely terminated *S*-adenosyl methionine (SAM) responsive riboswitches (38). Riboswitches are RNA elements that are able to control downstream gene expression by directly binding specific metabolites with a high affinity. The metabolite-riboswitch interaction results in RNA restructuring, usually terminating transcription in Gram-positive bacteria (39, 40). When binding SAM, transcription is terminated and short (150 to 250 nt long) transcripts are generated. Two of the prematurely terminated SAM riboswitches in *L. monocytogenes* (SreA and SreB) can base-pair with the 5′ UTR of *prfA* and thus reduce PrfA expression by an unknown mechanism (38) (Fig. 3). Here, the function of the terminated riboswitches resembles the role played by several *trans*-acting small RNAs (41). Interestingly, SreA is unable to inhibit translation at low temperatures, possibly because its interaction site in the *prfA* thermosensor is in a closed conformation, preventing base-pairing with *trans*-acting RNA elements. Expression of PrfA can therefore be affected by SAM riboswitches only at temperatures encountered during infection. The entire SreA is not required for repression; instead, the central core part of the SreA is sufficient for efficient blocking of PrfA translation (S. Krajewski and J. Johansson, unpublished results). Intriguingly, SreA expression is positively controlled by PrfA, creating a negative feedback loop, where high levels of active PrfA turn off its own expression by increasing the level of the repressive element SreA (38). It therefore seems that the 5′ UTR of the *prfA* transcript can act as a sensor, integrating both the environmental temperature and the metabolic state of the bacterium through SAM sensing.

Posttranslational Regulation

The third critical mechanism for regulating PrfA activity occurs via posttranslational modification (Fig. 4). As stated above, PrfA protein is a member of the cyclic AMP receptor protein (Crp)-Fnr family of transcriptional regulators, of which there are approximately 400 members (42). Proteins in this family generally function as dimers and require the binding of small molecule cofactors (for example, cyclic AMP for Crp) or other forms of posttranslational modification (such as the binding of carbon monoxide by the heme moiety of CooA) for full activity. The PrfA cofactor has recently been identified as glutathione, and PrfA-glutathione cocrystals indicate that the cofactor binding site is located at the intraprotein tunnel site, located between the N- and C-terminal domains of the PrfA monomer (43–46). Working models have suggested that once inside the cytoplasm, both uptake of cytosolic glutathione and, most importantly, upregulation of the glutathione synthase, *gshF*, lead to increased glutathione concentrations in *L. monocytogenes* (43, 45). This is required since glutathione only binds PrfA with a modest affinity (0.5 mM), so the increased glutathione concentration thus signals to the bacterium its arrival into the cytosol. Recently, Krypotou et al. (47) proposed that Cys-containing peptides transported into *L. monocytogenes* via the Opp peptide transport systems provide for the generation of glutathione leading to PrfA activation. Interestingly, the authors further suggested that inhibitory peptides transported

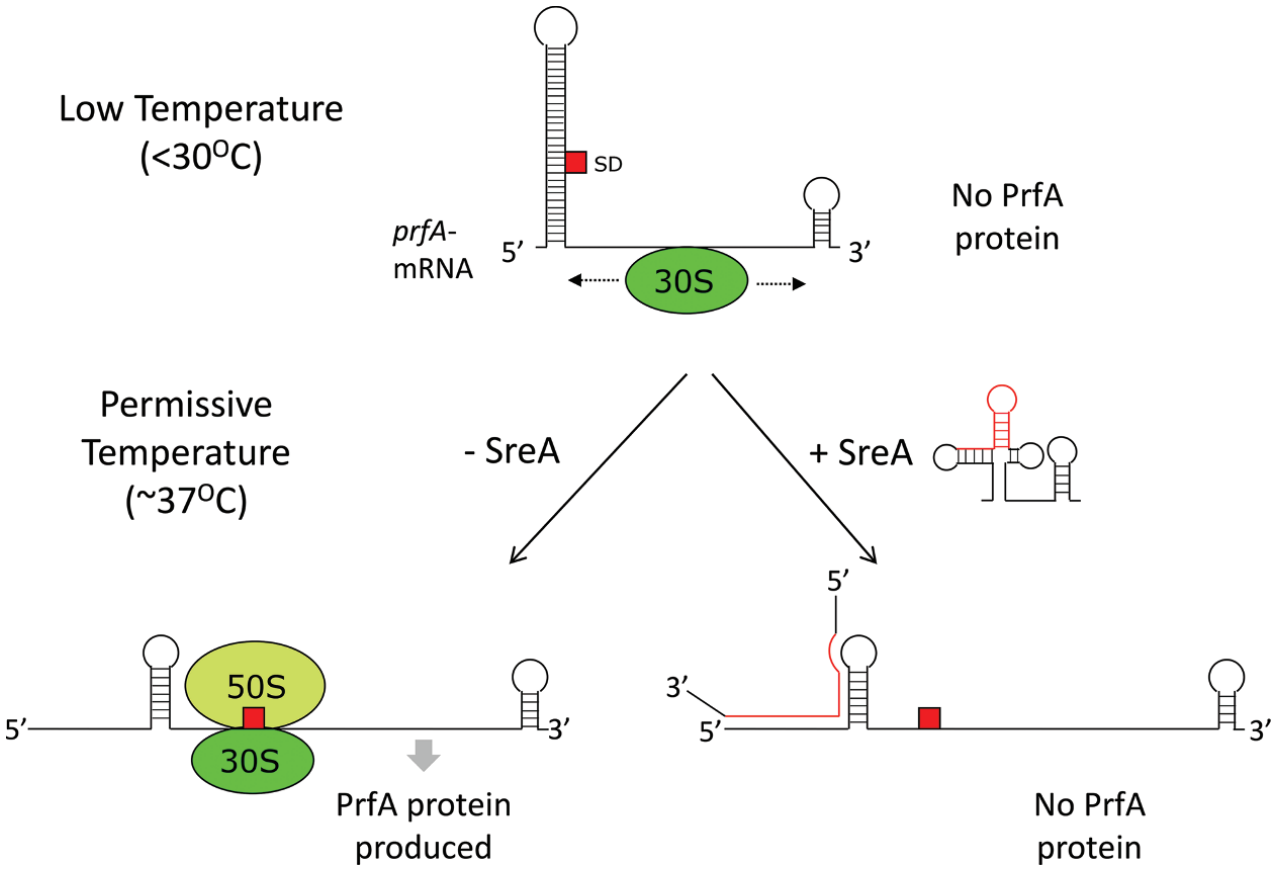

FIGURE 3 Posttranscriptional control of PrfA expression. At low temperatures (<30°C), the Shine-Dalgarno site (SD, red square) is sequestered in an RNA thermosensor, preventing binding of the 30S subunit (green sphere) of the ribosome. Possibly, the binding of the 30S subunit involves a ribosomal standby site, where it primarily binds to the coding region of the *prfA* mRNA, where it scans the transcript. At permissive temperatures (~37°C), the RNA thermosensor dissociates, allowing access of the 30S subunit to the SD, where it can recruit the 50S subunit (light green sphere), and translation can initiate. Under conditions in which a terminated S-adenosylmethionine riboswitch is produced (+SreA), it can bind to the RNA thermosensor and by an unknown mechanism prevent PrfA production.

by this same system bind to PrfA and inhibit PrfA activation by inhibiting the binding of glutathione. The complexity of PrfA activation continues to increase.

Years prior to the identification of glutathione as the PrfA cofactor, Ripio et al. identified an *L. monocytogenes* strain containing a single mutation within *prfA* coding sequences that resulted in the constitutive expression of PrfA-dependent virulence genes in broth culture (48). The substitution of a serine for a glycine at position 145 within PrfA was the first identification of a PrfA* mutation, so named because it appeared analogous to an A144T mutation identified within Crp that resulted in the constitutive expression of Crp-dependent gene products in the absence of cofactor (Crp* mutants) (49). Similar to Crp*, the PrfA G145S mutation was demonstrated by structural analyses to alter PrfA protein confirmation and increase the DNA binding affinity of PrfA for its target promoters via the repositioning of a helix-turn-helix DNA binding motif (50, 51).

There have now been a number of additional mutations identified that confer PrfA activation, albeit at differing levels of activation. Reported *prfA** mutations include G145S, Y63C, S71C, E77K, A94T, L140F, Y154C, L148P, G155S, and P219S substitution mutants (52–61). These mutations in some cases map to very different regions of PrfA in comparison to the original G145S PrfA* mutation, and strains containing these different *prfA** alleles exhibit levels of PrfA-dependent gene expression in broth culture that range from 4-fold to >200-fold greater than the levels of expression observed in wild-type bacteria (62, 63). With the exception of PrfA G145S, for which the structure has been solved using X-ray crystallography (51), the mechanisms by which the other *prfA** mutations confer constitutive activation are not clear.

*prfA** MUTATIONS REVEAL THE DIVERSITY OF GENE PRODUCTS REGULATED BY PrfA ACTIVATION

PrfA* mutants may be considered to phenotypically resemble *L. monocytogenes* under conditions of cytosolic activation (bound to glutathione), and thus the mutant strains have proven useful for the identification of novel virulence factors following transcriptomic and proteomic analyses. Milohanic et al. initially identified substantial overlap between genes whose expression was influenced by PrfA and stress-responsive genes regulated by the stress-responsive alternative sigma factor σ^B (20). However, studies by Ollinger et al. (64) using reverse transcriptase PCR reported that the transcript levels of some of PrfA-associated genes identified by Milohanic et al. (20) were not significantly affected by the presence or absence

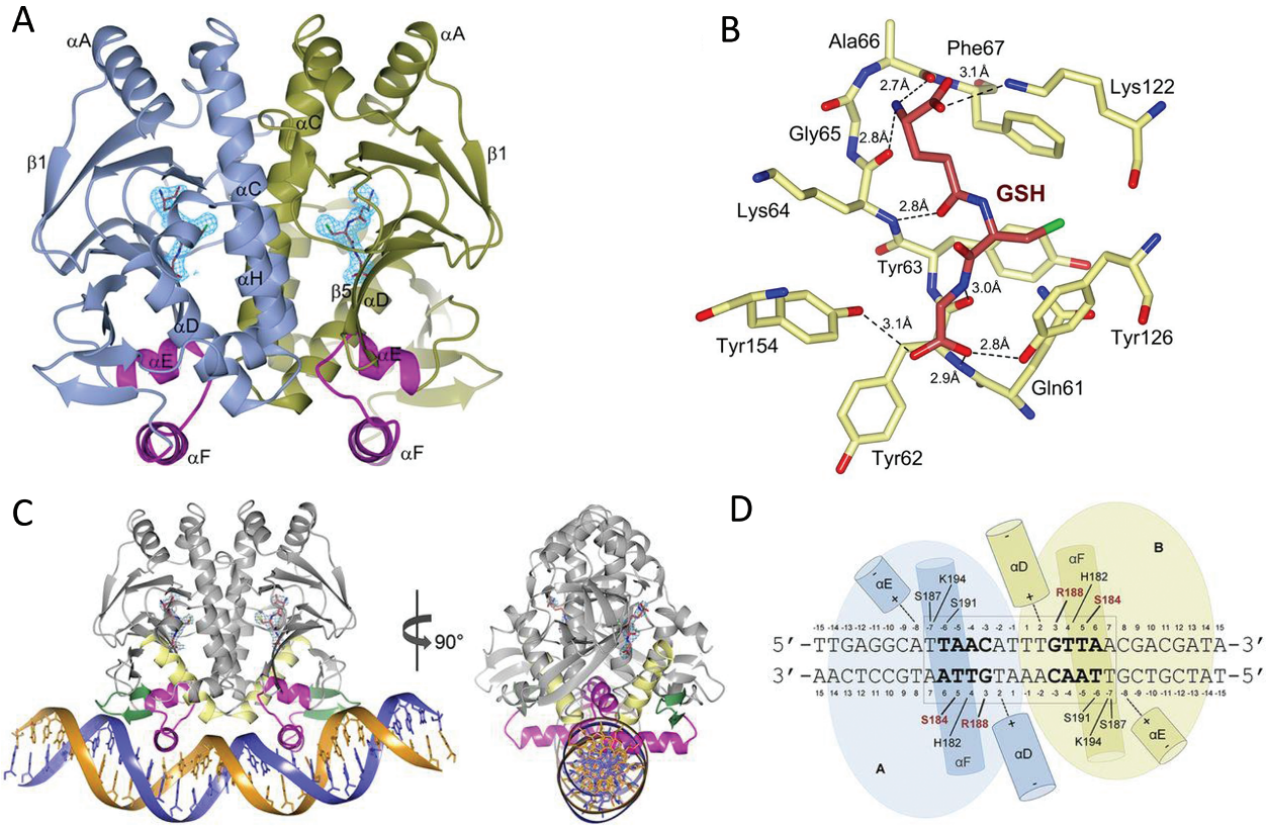

FIGURE 4 Structures of PrfA in complex with glutathione (GSH) and PrfA in complex with GSH and DNA. (A) Ribbon representation of the PrfA homodimer with GSH bound at the tunnel site of each monomer. The monomers A and B are colored blue and green, respectively. The helix-turn-helix motif is highlighted in magenta, and GSH has crimson carbon atoms with light blue electron density. (B) Local amino acid interactions and structural features of GSH-PrfA binding. Direct hydrogen bonds between amino acids and GSH are shown by dashed lines. (C) Ribbon representation of the DNA-bound homodimer in complex with GSH. The monomers A and B are colored gray, the helix-turn-helix motif is magenta, αD is yellow, and the winged β-hairpin is green. GSH is shown as sticks with the carbon atoms in crimson. The 30-bp palindromic operator is shown in dark blue and orange. (D) Schematic drawing of the PrfAWT-DNA interactions. Amino acids S184 and R188 make base-specific contacts and are highlighted in red. Other interactions are nonspecific between protein side chains and the DNA phosphate backbone. Figure adapted with permission from Hall et al. (44).

of PrfA. Discrepancies between these independent studies may reflect disparities between laboratory conditions, variations between strains used for examination (EGDe versus 10403S), or additional undefined complexities associated with PrfA-dependent gene expression.

Secreted proteins are often the first bacterial factors to interact with the host, and a comparison of secreted protein profiles derived from the culture supernatants of wild-type, Δ*prfA*, and *prfA** mutants identified at least 17 proteins that were differentially secreted following PrfA activation (52). The majority of the genes encoding these proteins did not contain recognizable PrfA binding sites in their upstream promoter regions, suggesting that the synthesis and/or secretion of these proteins was indirectly influenced by PrfA activation. Proteins with increased abundance in the supernatants derived from *prfA** cultures included a number of previously identified virulence factors as well as putative ABC transporters, cell wall-modifying enzymes, chitinases, antigenic lipoproteins, and chaperone proteins associated with protein secretion. Many of these PrfA-dependent secreted proteins also depended on the presence of the secretion chaperone PrsA2 for full activity (65). A significant number of secreted gene products that appear indirectly regulated by PrfA have been demonstrated to contribute to *L. monocytogenes* pathogenesis, and these gene products serve as further examples of the expansive influence of PrfA on *L. monocytogenes* life within the host.

THE IMPACT OF CARBON SOURCES ON PrfA ACTIVATION AND THE STIMULATION OF PrfA-DEPENDENT VIRULENCE GENE EXPRESSION

The expression of virulence factors has long been known to respond to the presence of sugars in the medium (66–71). Sugars (e.g., cellobiose and glucose) taken up by the phosphoenolpyruvate):phosphotransferase system (PTS) repress PrfA activity, whereas non-PTS sugars (e.g., glycerol) modestly stimulate PrfA activity. Importantly, the PTS-mediated repression of PrfA activity is not mediated by the catabolite control protein A (CcpA), which controls expression of many genes in different *Firmicutes* in response to PTS sugars (72, 73). Instead, the phosphorylation state of the different PTS permeases appears to dictate the activation level of PrfA (74). In the presence of PTS sugars, the permeases are in an unphosphorylated state as they donate the phosphate group

they received from the phosphoenolpyruvate system to the incoming sugar. In the absence of PTS sugars (and the presence of non-PTS sugars), the permeases are phosphorylated. It has been suggested that unphosphorylated permeases might bind and sequester PrfA directly, thereby blocking PrfA-mediated virulence gene expression (74). Glucose can be transported into *Listeria* by several different permeases. One of the mannose permeases, EIIABMan, was suggested to act as a PrfA-binding partner or, alternatively, to interact with a PrfA-activating molecule (75). In addition, the repressive effect of PTS sugars can be relieved by the addition of charcoal or amberlite to the medium during bacterial growth (76, 77). This suggests that a component released by *L. monocytogenes* could repress PrfA activity, either directly or indirectly. Precisely how the action of PTS-permeases or repressive extracellular molecules such as inhibitory peptides affect the level of glutathione (the PrfA cofactor) or PrfA binding of glutathione remains to be determined.

MAINTAINING THE BALANCE BETWEEN LIFE INSIDE AND OUTSIDE THE HOST: CONSTITUTIVE ACTIVATION OF PrfA IS NOT BENEFICIAL FOR *L. MONOCYTOGENES* SURVIVAL

At first glance, *prfA** strains would appear to exhibit a number of advantages over wild-type bacteria. Strains containing *prfA** are hyperinvasive, mediate more efficient phagosome escape, and initiate bacterial actin-based motility more rapidly. Activation of PrfA also shifts *L. monocytogenes* metabolism toward the preferred use of three carbon sugars and phosphorylated sugars, the principal carbon sources used by *L. monocytogenes* for growth within the cytosol (78). *prfA** mutants are hypervirulent in mouse infection models and exhibit a competitive fitness advantage over wild-type strains during both oral and intravenous mixed infections in mice (78).

The fitness advantage observed for *prfA** strains within the host does not, however, translate into bacterial fitness in the outside environment (78, 79). Constitutively activated *prfA** mutants exhibit impaired flagellum-mediated swimming motility, a defect that would be expected to compromise bacterial fitness in environments where the bacteria must be able to detect and swim toward available nutrient sources and which would additionally impair biofilm formation. *prfA** mutants also exhibit a pronounced fitness defect when grown in the presence of wild-type bacteria in mixed broth culture despite displaying no obvious growth defects in monoculture. Stress conditions such as high osmolarity or low pH exacerbate the competitive defects observed for *prfA** strains in a manner that is independent of the stress-responsive sigma factor σ^B. Lastly, *prfA** mutations appear to negatively impact the ability of *L. monocytogenes* to survive long periods of starvation. Interestingly, a PrfA* strain devoid of most PrfA-regulated genes did not display a fitness cost (80). The multiple mechanisms that thus exist to regulate PrfA activity appear to have evolved to carefully balance gene expression patterns so as to maintain bacterial fitness in the soil as well as in the cytosol.

BEYOND PrfA: OTHER MODES OF *L. MONOCYTOGENES* REGULATION OF GENE EXPRESSION

PrfA is a central factor in the regulation of *L. monocytogenes* virulence gene expression; however, numerous other regulatory factors and mechanisms exist that enable the bacterium to adapt its physiology in response to the diversity of environmental conditions encountered by this ubiquitous organism. A sample of some of these alternative regulatory modalities is presented below.

Posttranscriptional Regulation of Bacterial Gene Expression

Untranslated regions of mRNA (UTRs) have been demonstrated to regulate translation of the associated gene products for multiple genes. The 5′ UTRs located upstream of *inlA*, *actA*, and *hly* have been shown to control expression of their protein products (27, 81, 82). These 5′ UTRs appear, however, to support expression of InlA, ActA, and LLO, respectively, which is in contrast to the previously described *prfA*-UTR, which represses PrfA expression. It has been shown that partial deletions of the 5′ UTRs of *inlA*, *actA*, and *hly* decrease the protein production, but the exact mechanism(s) by which the 5′ UTRs act has not yet been revealed. Interestingly, it was shown that the coding region of *hly* could be important for LLO production (83). Whether this is due to alterations of secondary structures, binding of small regulatory RNAs (sRNAs), or some other factors remains to be investigated.

Regulation by sRNAs

Several hundred sRNAs have been identified in *L. monocytogenes*, ranging in size from less than 100 to more than 500 nt and with different expression patterns (84–88). However, the functions of only a subset of these sRNAs have been revealed, and an even smaller number have been shown to participate in virulence gene expression. Rli27 is an intracellularly induced sRNA able to interact with the 5′ UTR of *lmo0514*, encoding an LPXTG cell wall protein that is also upregulated during intracellular growth (89). Lmo0514 is required for survival of the bacteria in plasma and during infection of mice (90). The 5′ UTR of *lmo0514* contains an inhibitory RNA structure that sequesters the SD region and blocks translation initiation. Binding of Rli27 to the 5′ UTR disrupts the inhibitory structure, thereby allowing intracellular expression of Lmo0514 (89).

Rli38 is a long (514 nt) sRNA that is highly induced when *L. monocytogenes* is exposed to blood (86). A Δ*rli38* mutant strain exhibited reduced bacterial loads in several organs compared to the wild-type strain. The target of Rli38 (RNA or protein) is not yet known, nor is its mechanism of action. Another sRNA induced when *L. monocytogenes* is exposed to blood is RliB (86). In contrast to Rli38, the absence of RliB increased bacterial loads in the liver compared to the wild-type strain. RliB is a substrate for polynucleotide phosphorylase, but it is also a clustered regularly interspaced short palindromic repeat (CRISPR) element, devoid of associated Cas proteins (91). However, presence of *trans*-encoded Cas proteins and polynucleotide phosphorylase allows RliB to exert DNA interference directed against matching protospacers. Why *Listeria* has a degenerated CRISPR system is not clear and deserves further study.

Possibly the most well-known sRNAs in *L. monocytogenes* are the sibling family of LhrC, consisting of seven members, all with varying degrees of conservation (86, 92–95). The LhrCs control expression of at least three virulence factors: *lapB*, encoding an adhesin, *oppA*, encoding an oligopeptide protein, and *tcsA*, encoding a CD4+ T cell-stimulating antigen. The different members of the LhrC family are able to bind to the 5′ UTRs of their targets. For *lapB* and *oppA*, the LhrCs directly interact with their SD region to inhibit translation, whereas the LhrCs destabilizes the *tcsA* transcript

by binding a site distally from the SD region (93, 95, 96). Interestingly, two CU-rich binding sites in LhrC4 were identified to be important for *oppA* binding, giving the possibility of two target mRNAs being sequestered by one sRNA. Another exciting aspect of the LhrC family is that the expression of individual members is controlled by exposure to various environmental cues, such as blood and growth in the intestine and in macrophages through at least one bacterial two-component signaling system (93).

The functions of several sRNAs in bacteria are dependent on RNA chaperones. In Gram-negative bacteria, Hfq plays a vital role, stimulating interaction between short complementary sequences of the sRNA and the target mRNA (97). The role of Hfq appears to be more crucial if the level of complementarity between the RNAs is low. Although the phenotypes of a Δ*hfq* strain are less pronounced in *L. monocytogenes* than a Δ*hfq* strain in Gram-negative bacteria, Hfq has been shown to be associated with sRNAs and to contribute to *L. monocytogenes* virulence (84, 98). However, the interaction between the sRNA LhrA and the target mRNA *lmo0850* is the only example so far described in *L. monocytogenes* when Hfq is needed for a functional regulatory outcome (99). Other RNA chaperones could in some cases replace Hfq.

The SpoVG protein of *L. monocytogenes* is an RNA binding protein that regulates lysozyme resistance, virulence, and swarming motility (100). The sRNA Rli31 was shown to interact with both the 5′ UTR of the *spoVG* transcript and the SpoVG protein (100). Surprisingly, Rli31 did not appear to affect the levels of either the *spoVG* transcript or the SpoVG protein, raising the possibility that Rli31 acts as a "sink" to inactivate SpoVG, in analogy with the CsrA/Rsm systems of posttranscriptional regulators in Gram-negative bacteria. Finally, RNA helicases have been shown to contribute to virulence gene expression in *L. monocytogenes* (101, 102). sRNAs are becoming increasingly recognized for their contributions to diverse aspects of *L. monocytogenes* physiology and virulence.

Regulation Induced in Response to Environmental Stress

During its life as a saprophyte and pathogen, *L. monocytogenes* encounters a diversity of stress-conditions, many of them potentially life-threatening. To survive disparate stresses, the bacterium makes use of a number of strategies. As mentioned previously, the expression of several proteins important for stress survival depends on the stress sigma factor σ^B, which competes with the vegetative sigma factor σ^A for binding to the RNA polymerase (103, 104). Activity of σ^B is controlled by a complex relay of protein interactions and phosphorylation events, ultimately freeing σ^B from the anti-sigma factor RsbW. At the top of this relay hierarchy lies a sensory organelle, the "stressosome," which is a large (~1.8 MDa) multiprotein complex, thus far primarily studied in *Bacillus subtilis* (105). The stressosome is able to detect and integrate environmental cues into a signal transduction pathway that eventually allows the liberation of σ^B and initiation of the expression of σ^B-regulated genes.

In *L. monocytogenes*, it has been suggested that there may be interplay between σ^B and PrfA activity, such that σ^B controls genes important for the initial steps of infection (i.e., during survival in the gut and adhesion to intestinal epithelial cells), whereas PrfA controls the expression of genes involved in subsequent steps (i.e., adhesion and intracellular growth as well as further dissemination in the host) (25, 26, 86, 106, 107). Interestingly, some genes, such as the genes encoding the two important invasins, InlA and InlB, are controlled by both σ^B and PrfA (27, 108). This dual regulation allows the expression of the bicistronic *inlA-inlB* message from two promoters, integrating several external cues and thereby permitting bacterial invasion of several host cell types. Both the σ^B- and PrfA-generated *inlA-inlB* transcripts contain unusually long 5′ UTRs (445 and 396 nt, respectively) possibly acting at the posttranscriptional level to sense environmental factors (27). Whether the stressosome is able to act as a central hub to integrate external signals to control virulence gene expression in concert with other regulators (e.g., PrfA) remains to be determined. Very little is known about the mechanisms underlying stressosome sensory perception and signal integration. It has been shown that a blue-light receptor can sense light and activate σ^B through the stressosome, but the exact mechanism is not known (109–111). A small peptide, Prli42, has been demonstrated to bind the stressosome, and its absence reduces σ^B-dependent gene expression while also affecting expression of virulence factors (112). Prli42 harbors a transmembrane domain and is associated with the membrane, potentially allowing the stressosome to sense stress exerted through membrane disturbance.

Fatty Acids and Regulation of Virulence

Many enterobacteria use fatty acids (FAs) to regulate virulence gene expression. For example, *Vibrio cholerae*, the causative agent of cholera, controls the expression of cholera toxin and toxin coregulated pilus using the transcriptional activator ToxT; unsaturated long-chain FAs were shown to directly bind to and repress activity of ToxT (113). Using the X-ray structure of palmitoleic acid bound to ToxT as a blueprint, highly effective ToxT inhibitors were synthesized that were able to inhibit intestinal colonization in mice (114). FAs have also been shown to affect virulence factor expression in *L. monocytogenes* and have been suggested to interfere with PrfA activity (115, 116). The addition of increasing amounts of non-branched-chain FAs (both saturated and nonsaturated) to bacterial cultures was found to reduce virulence factor expression (116). A similar effect was observed by decreasing the bacterial content of branched-chain FAs (115), possibly because this increases the amount of non-branched-chain FAs. Interestingly, a strain carrying a constitutively active PrfA protein ($PrfA_{G155S}$) also exhibited reduced virulence factor expression in the presence of FA, suggesting that the repressive effect of FAs lies at a level subsequent to PrfA-activation (116). Additional work is required to decipher if FAs interact directly with PrfA or if the effect of the FAs is mediated through another pathway.

Regulation by Two-Component Sensing Systems

To sense and respond to environmental cues, many pathogenic bacteria use two-component systems (TCSs). Typically, the TCS consists of a histidine kinase (HK) that senses an external signal and transfers a phosphor group to activate a response regulator (RR) controlling the expression of genes important for the response of the particular stimulus (117). *L. monocytogenes* harbors 16 TCSs, one of which, DegU, is an orphan RR (118). Several of the *Listeria* TCSs have been implicated in virulence (119–122). One of them is part of the accessory gene regulator (Agr) system of *L. monocytogenes*, consisting of a quorum sensing/TCS system (119). In the Agr system, a small auto-inducing peptide (AIP, derivative of the *agrD* gene product) is processed and transported by AgrB to the outside of the bacterium. The AIP of *L. monocytogenes*

was shown to be a cyclic pentapeptide (CFMFV) (123). Once outside, the AIP is recognized by the HK AgrC, which activates the RR AgrA. Exactly how the Agr system contributes to *L. monocytogenes* virulence is unclear, since the bacterium lacks RNAIII, an sRNA expressed divergently from the *agr* locus and which controls the expression of several virulence factors in *Staphylococcus aureus* (124). Another TCS implicated in *L. monocytogenes* virulence is LisrK (120). Loss of LisK (the HK) reduced bacterial growth in the spleens of mice. Interestingly, LisRK has been shown to be important for expression of the serine-protease HtrA and the sRNA LhrC, both of which contribute to *L. monocytogenes* pathogenesis (93, 125). The flagellin-associated TCSs CheY and CheA are important for listerial adhesion and invasion of cultured Caco-2 cells; however, bacteria lacking this system exhibited normal growth within the spleens of mice (121). The DegU RR appears to be of interest, because it lacks its associated HK, and the absence of DegU impairs *L. monocytogenes* growth in mice (126–128). DegU is also the epistatic regulator of motility by positively activating expression of the antirepressor GmaR, which in turn, inactivates the repressor of motility MogR (129). Having no accompanying kinase, DegU appears to be phosphorylated by intracellular acetyl phosphate (130). The VirRS TCS system was originally identified using a signature tagged mutagenesis screen seeking genes important for mouse infection (122). Surprisingly, VirR can be activated independently of the HK VirS, possibly through variations in bacterial intracellular acetyl phosphate concentrations. VirR controls the expression of several virulence-associated genes upregulated during infection (12). Recently, it was shown that the VirAB ABC transporter controls VirR function in response to the antimicrobial Nisin and/or host factors (131).

Regulation of Virulence via Peptide Pheromones

In addition to the peptide-responsive Agr system discussed above, an additional peptide pheromone system has been recently shown to contribute to *L. monocytogenes* virulence. A PrfA-inducible secreted peptide pheromone-encoding lipoprotein (PplA) was identified that shares significant homology with the *Enterococcus faecalis* Cad lipoprotein encoding the cAD1 peptide pheromone (132, 133). Similar to the cAD1 pheromone of *E. faecalis*, the pPplA peptide is processed from the released PplA lipoprotein N-terminal signal sequence (SS) peptide following secretion of the lipoprotein through the general secretory pathway. In contrast to *E. faecalis*, where the cAD1 pheromone stimulates a mating response between plasmid-containing and plasmid-free cells, the pPplA peptide pheromone has functionally evolved to enhance vacuolar escape of *L. monocytogenes* within nonprofessional phagocytic cells. Studies of mutants lacking both the PplA lipoprotein and its signal sequence-encoded peptide pheromone versus the lipoprotein alone have demonstrated that the pPplA peptide pheromone is a critical virulence factor that contributes to both bacterial aggregation in broth culture and survival in mouse models of infection. The PplA lipoprotein has no apparent role in vacuolar escape; however, its function as an extracellular electron transport protein that contributes to bacterial fitness within the gut has recently been described (134).

L. monocytogenes mutants lacking the pPplA peptide exhibit delays in escape from the vacuoles of nonprofessional phagocytic cells but escape with normal kinetics from the phagosomes of macrophage-like cell lines or in bone marrow-derived macrophages (132). Interestingly, loss of the pPplA pheromone did not impair LLO-dependent perforation of the vacuole, only bacterial escape into the cytosol. These data strongly suggest that complete vacuole escape requires an additional mechanism beyond initial pore formation mediated by the activity of the hemolysin LLO. The pPplA peptide was also found to contribute to maintenance of surface-associated and secreted proteins, and it is possible that some of these gene products may contribute to either the stabilization of LLO-induced membrane pores and/or the physical disruption of the vacuole membrane (Fig. 5).

Interestingly, all bacterial virulence defects associated with the loss of the pPplA peptide could be completely compensated for by the introduction of constitutively active PrfA*, suggesting a possible connection between the pPplA signaling pathway and PrfA activation (132). These studies suggest a model in which *L. monocytogenes* senses the confines of the host vacuoles as a result of the accumulation and import of the pPplA peptide, leading to PrfA activation and enhanced bacterial escape into the cytosol. The *L. monocytogenes* pPplA peptide thus appears to have evolved to enable the bacterium to sense the confined environment of the vacuole so as to induce the expression of gene products required for full membrane disruption and entry of the bacterium into the cytosol.

In addition to the pPplA peptide-signaling pathway, another potential peptide-based signaling system related to competence development has been implicated in enhancing escape of *L. monocytogenes* from host cell vacuoles, specifically, the phagosomes of macrophages (135). Competence is a brief physiological state during which the bacterial cells collectively become primed to transport extracellular DNA across the cell wall and bacterial membrane, at times resulting in integration of the newly acquired DNA into the bacterial genome (136). Several gene products, including those encoded by *com* genes, are required for peptide pheromone signaling and DNA uptake. Although it has not been demonstrated to exhibit natural competence, *L. monocytogenes* possesses a number of *com* genes that share homology with those involved in competence development in other bacteria; however, not all the genes required for competence are present (118). Most but not all of the regulatory components and late genes involved in assembly of the Com apparatus required for DNA transport are present in the *Listeria* genome. Because of these missing components, it is unclear if the competence system is functional in *L. monocytogenes*, and natural competence has not been demonstrated under laboratory conditions.

One competence regulator that is encoded by *L. monocytogenes* is ComK, a master transcriptional regulator that induces the expression of late *com* genes involved in assembly of the Com apparatus for DNA uptake, and it is this system which has been reported to be important for *L. monocytogenes* in vacuole escape of professional phagocytic cells (135). Interestingly, the *comK* gene in some strains of *L. monocytogenes* is inactivated by the presence of an A118-like prophage that integrates at a specific attachment site within the *comK* gene. However, Rabinovich et al. have found that the late competence genes regulated by ComK are highly expressed during intracellular growth as a result of prophage excision (135). In addition, mutants missing the specific components of the pseudopilus or the DNA translocation channel were impaired for vacuole escape in macrophages and were attenuated for bacterial virulence in mice, whereas the DNA binding components were dispensable for these processes. A strain cured of the prophage and containing an intact *comK* gene grew similarly to wild-type *L. monocytogenes* in macrophages, and many naturally occurring strains of *L. monocytogenes* lack this prophage and are capable of growth

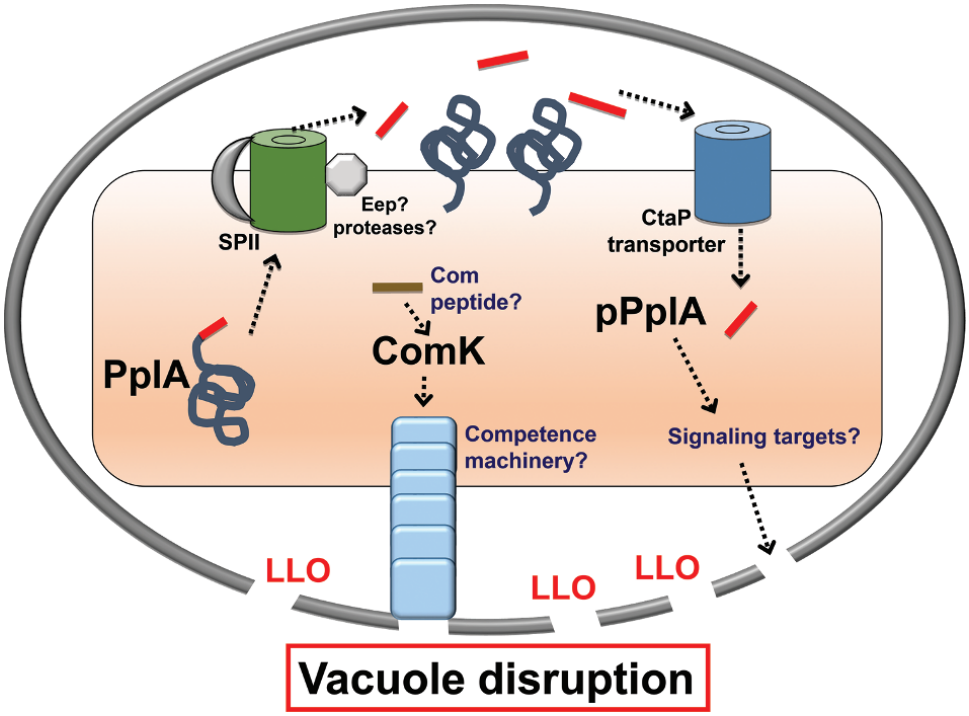

FIGURE 5 *L. monocytogenes* peptide signaling and expression of competence gene products via phage excision within the host vacuole. *pplA* encodes a lipoprotein (PplA) with a peptide pheromone (pPplA) located within the N terminal secretion signal peptide (shown in red). The signal sequence of prePplA is processed by signal peptidase II (SPII), and the released signal peptide is further cleaved by the protease Eep, releasing the pPplA pheromone, while the PplA protein becomes lipid modified and associated with the membrane. The confined space of the vacuole leads to import of the secreted pPplA pheromone, presumably stimulating a signaling cascade that results in the production of an unknown factor(s) that contributes to vacuole lysis. As part of a separate pathway, an unknown signal, potentially also involving a peptide pheromone, leads to the expression of ComK and the expression of a competence-associated pilus that may also aid in vacuole membrane disruption. Select *L. monocytogenes comK* genes harbor a lysogenic phage that must excise to enable ComK expression. The ComK pathway is required for *L. monocytogenes* vacuole escape from professional phagocytic cells; the pPplA system is required for bacterial escape from nonprofessional phagocytic cells.

within macrophages. For strains that do contain prophages, data suggest that prophage integration/excision serves to regulate virulence gene expression and that the ComK system is somehow involved in sensing the presence of *L. monocytogenes* within host cell vacuoles in professional phagocytic cells. Thus, while no peptide pheromone has yet been identified to stimulate the induction of the *L. monocytogenes com* genes within the phagosome, it could be hypothesized that the bacterium has adapted components of the *com* peptide pheromone system for spatial sensing, similar to pPplA (Fig. 5).

The requirement of selected *com* gene products and the pPplA peptide for vacuole escape in different cell types makes it tempting to speculate that a competence-like pseudopilus may help stabilize the pores initially formed by LLO or that maybe the pseudopilus exerts physical pressure on the vacuole membrane to aid in membrane disruption and bacterial entry into the cytosol. It is possible that the pPplA and ComK systems are interconnected in some way and that fundamental differences in the vacuole membranes of professional phagocytic cells versus nonprofessional phagocytic cells necessitate the requirement for differentially regulated components. Additional characterization of the gene products regulated by pPplA and *com* gene products may clarify how these components function to enhance bacterial entry into the cytosol.

MAKING NEW FRIENDS: REGULATION AND THE EXAMINATION OF *L. MONOCYTOGENES* STRAINS BEYOND THE COMMONLY USED ISOLATES

Most studies of *L. monocytogenes* have been performed using EGDe, EGD, or 10403S strains, all belonging to lineage II. However, the most severe outbreaks of listeriosis are caused by *L. monocytogenes* strains belonging to a subset of lineage I (137, 138). These lineage I strains contain an additional pathogenicity island, LIP-III, which appears crucial for the higher virulence potential of lineage I strains. LIP-III encodes eight proteins involved in the synthesis, modification, and transport of listeriolysin S (LLS) (137). LLS was identified as a hemolysin and cytotoxin contributing to *L. monocytogenes* pathogenicity. This finding was challenged by a study suggesting that LLS was not important for infection or killing of eukaryotic cells (139). Instead, LLS was shown to act as a bacteriocin, potentiating survival of *L. monocytogenes* in the microbiota (140, 141). Bacteriocins are peptides capable of killing bacteria closely related to the bacteriocin-producing strain. It should, however, be noted that bacteriocins produced by another bacterium, *Staphylococcus pseudintermedius*, can act both as a bacteriocin and as a cytotoxin (142). An *L. monocytogenes* lineage I strain overexpressing LLS was

shown to kill *Lactococcus lactis* and *S. aureus* as well as *L. monocytogenes* strains of lineage II *in vitro* (140). It was demonstrated that orally administered lineage I strains carrying LLS affected the microbiota in mice, whereas the microbiota remained undisturbed if infected with strains lacking LLS (140). Two of the bacterial genera that were significantly decreased in the gut in the presence of lineage I were *Alloprevotella* and *Allobaculum*. Interestingly, these two genera produced butyric acid, a fatty acid that has been shown to decrease *L. monocytogenes* virulence gene expression, possibly by interfering with PrfA activity (as mentioned earlier in this article). In contrast to LIP-I and LIP-II, expression of genes from LIP-III is not governed by PrfA, thereby allowing expression of LIP-III under conditions that repress PrfA activity (143). It can thus be speculated that LLS-producing *L. monocytogenes* kill bacteria that otherwise would impair PrfA-directed expression of factors needed for passage through the intestinal barrier. The production of LLS in lineage I strains may at least partially explain why this lineage is more often associated with outbreaks than linage II. The induced expression of LIP-III in lineage II strains might answer if other factors in lineage I strains also contribute to infection.

TARGETING REGULATION: THE SEARCH FOR NOVEL ANTIMICROBIALS EFFECTIVE AGAINST *L. MONOCYTOGENES*

Although resistance to traditional antibiotics is fortunately still limited, the increased occurrence of horizontal gene transfer makes the development of new antibacterial compounds targeting *L. monocytogenes* relevant. Stress survival mechanisms are clearly critical for *L. monocytogenes* existence, and a number of attempts have been undertaken to identify novel antibacterial and/or antivirulence chemical compounds targeting facets of *L. monocytogenes* stress resistance and/or virulence. Through a high-throughput screen, a substance (FPSS) was identified that could block the σ^B regulon and thereby also several genes encoding virulence factors (144). The exact mechanism of action of FPSS remains elusive (for example, direct interaction with σ^B or with another upstream component); however, the prospect of being able to inhibit the general stress response and virulence gene expression is exciting.

A different approach using analogs to metabolites that bind and control purine riboswitches led to the identification of 6-aminohydroxyl purine (6-N-HAP) as being able to exhibit both antibacterial and antivirulence properties (145). The target of 6-N-HAP has not yet been revealed, but addition of 6-N-HAP increased the bacterial mutation rate by almost 10,000-fold. Another screening approach identified a natural flavonoid (fisetin) as an efficient inhibitor of LLO activity (146, 147). Molecular modeling and interaction studies suggested that fisetin directly interacts with loops 2 and 3 of LLO, thereby preventing cholesterol binding and LLO oligomerization. Interestingly, fisetin prolonged the survival of mice infected with *L. monocytogenes*. Yet another screening-based approach was used to identify heterocyclic 2-pyridones as efficient inhibitors of *L. monocytogenes* infection and virulence factor expression; the target of the 2-pyridones was shown to be PrfA (148, 149). A 2-pyridone: PrfA cocrystal revealed that the compound bound in an

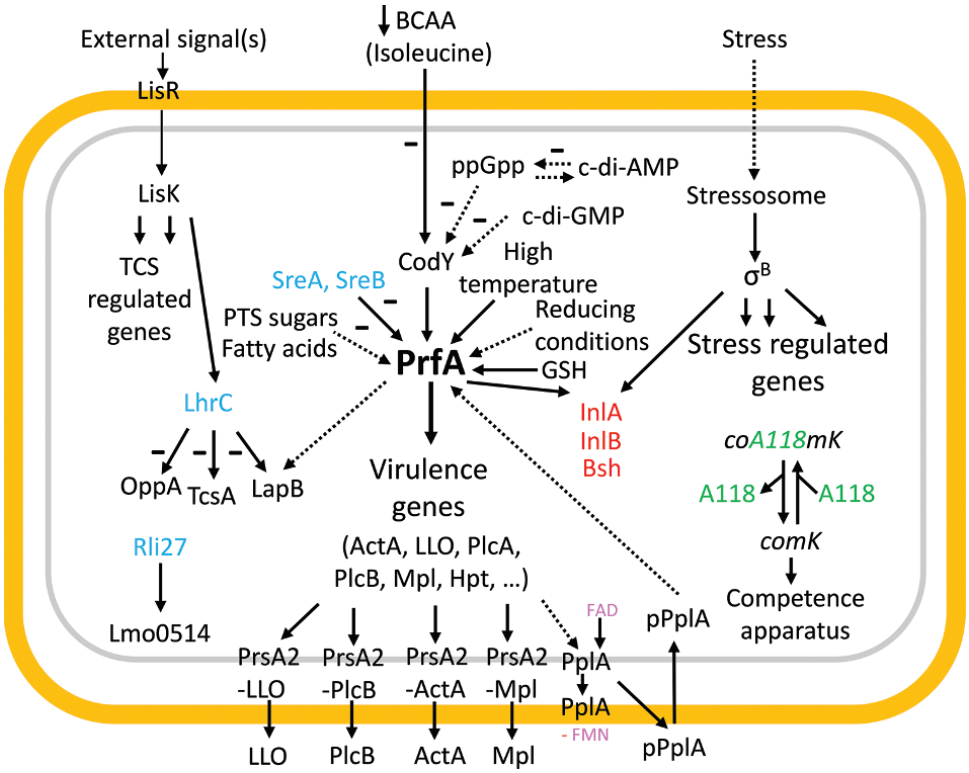

FIGURE 6 A summary of regulatory events underlying stress regulation and virulence factor expression in *L. monocytogenes*, especially highlighting the role of the PrfA system, but also TCS (here represented by LisRK), sRNAs (blue), and σ^B. Gene products regulated by both PrfA and σ^B are shown in red. Consult the text for further details.

intraprotein "tunnel" site, pulling the DNA-binding helix-turn-helix motif in an unfavorable position. The possibility of using tailor-made substances (such as fisetin and 2-pyridones) to inactivate specific targets (LLO and PrfA, respectively) is very appealing since it should only impair *L. monocytogenes* while leaving the remainder of the host microbiota untouched.

CONCLUDING REMARKS AND FUTURE OUTLOOK

L. monocytogenes is notable for its ability to survive and thrive both as an extraordinary pathogen of diverse animal hosts and as a saprophyte in the soil; to accomplish this bacterial gymnastic feat, *L. monocytogenes* utilizes an integrated myriad of regulatory systems (Fig. 6). The most centrally important virulence regulator identified to date is the transcriptional activator PrfA, which controls the expression of the majority of virulence factors in response to environmental cues such as redox status, temperature, energy levels, and potentially in combination with diffusion sensing of the limited space of the vacuole. PrfA is itself regulated by an impressive number of mechanisms that include transcriptional and posttranscriptional regulation as well as translational and posttranslational regulation, each combining to integrate environmental signals into an appropriate regulatory output of bacterial gene expression. It will be intriguing to study single bacterial cells to better understand how the PrfA regulatory network integrates into other sensory systems and how these systems collectively contribute to virulence. Despite being the subject of extensive study for the past 30 years, *L. monocytogenes* still appears to hold regulatory secrets that await discovery.

Listeria monocytogenes: cell biology of invasion and intracellular growth

JAVIER PIZARRO-CERDÁ AND PASCALE COSSART

53

Listeria monocytogenes is a facultative intracellular pathogen that has the capacity to actively invade and multiply within mammalian cells. Intracellular replication of *L. monocytogenes* within mononuclear cells was noted in the 1926 publication by Murray and colleagues reporting on this bacterial pathogen for the first time (1). In the 1960s, the seminal work of Mackaness that identified the main actors of cellular immunity against bacterial intracellular pathogens took advantage of the *L. monocytogenes* intracellular lifestyle as a model (2). In the late 1980s and early 1990s, major *L. monocytogenes* virulence factors involved in bacterial adaptation to intracellular life were molecularly characterized (3–7) and the precise stages of the *L. monocytogenes* intracellular life-cycle were morphologically identified (8, 9). Since then, cellular effectors involved in the infection process have been also identified and characterized (10–12). In this article, we review the molecular mechanisms driving *L. monocytogenes* adaptation to the mammalian host cell intracellular environment.

ADAPTATION TO INTRACELLULAR LIFE: GENERALITIES

L. monocytogenes is able to invade and proliferate within macrophages and epithelial nonphagocytic cells. For entry into the latter, bacterial surface molecules (InlA, InlB) interact with cellular ligands, activating signaling cascades that lead to internalization of the pathogen within a membrane-bound compartment (Fig. 1). Residency in the internalization vacuole is prevented by secretion of a pore-forming toxin (listeriolysin O [LLO]) and two phospholipases (PlcA, PlcB) that disrupt the vacuolar membrane, promoting *L. monocytogenes* translocation to the host cell cytoplasm. In this intracellular location, *L. monocytogenes* activates several bacterial metabolic pathways that favor the uptake of cellular resources sustaining bacterial proliferation. The pathogen also displays several strategies to escape cytoplasmic innate immune responses, which include the polymerization of actin by a bacterial surface protein (ActA), allowing *L. monocytogenes* to spread to neighboring cells. In secondary infected cells, *L. monocytogenes* is located in a double-membrane compartment that is disrupted by the same set of secreted enzymes that favor lysis of the primary internalization vacuole. *L. monocytogenes* translocation to the cytoplasm of secondary infected cells leads to a new bacterial replication cycle and further spread to other cells in infected tissues. The intracellular lifestyle is therefore critical for *L. monocytogenes* virulence: it allows escape from extracellular host defense mechanisms, including the complement or antibodies, and hinders detection by patrolling cell populations, e.g., neutrophils; in macrophages, cytoplasmic translocation allows escape from degradative components of the phagocytic cascade, while it provides access to a "Trojan horse" host cell population that can safely transport bacteria to distant locations within the infected organism.

THE CELLULAR INVASION PROCESS

Upon *L. monocytogenes* contact with host target tissues, cellular invasion is morphologically characterized by a localized extension of the plasma membrane around invading bacteria, triggering bacterial internalization within a tight vacuolar compartment. Mechanistically, bacterial surface proteins interact with host cell receptors that are posttranslationally modified (phosphorylation, ubiquitylation), favoring the recruitment of protein adaptors and enzymes that contribute to actin polymerization, the key molecular event required for plasma membrane reorganization. Depending on the invaded cell type, bacterial modulation of the phosphoinositide (PI) metabolism is also critical to trigger cortical actin polymerization.

InlA is the archetypal member of a family of *L. monocytogenes* surface proteins named internalins, which are characterized by the presence of N-terminal leucine-rich repeats (LRR) which mediate interaction with host cell ligands (6, 13). The internalins InlA and InlB, encoded within a single locus in the *L. monocytogenes* genome, are the two major surface molecules driving bacterial entry into host cells. More than 20 other internalins have been identified, but they do not necessarily participate in the cell invasion process, contributing instead to diverse functions including cell-to-cell spread and escape from innate immune responses (i.e., InlC [14, 15]) and escape from autophagy (i.e., InlK [16]). The pore-forming toxin LLO, the actin polymerizing factor ActA, and other bacterial surface proteins have been described as supporting bacterial entry independently of the InlA and InlB invasion pathways (see below).

doi:10.1128/microbiolspec.GPP3-0013-2018

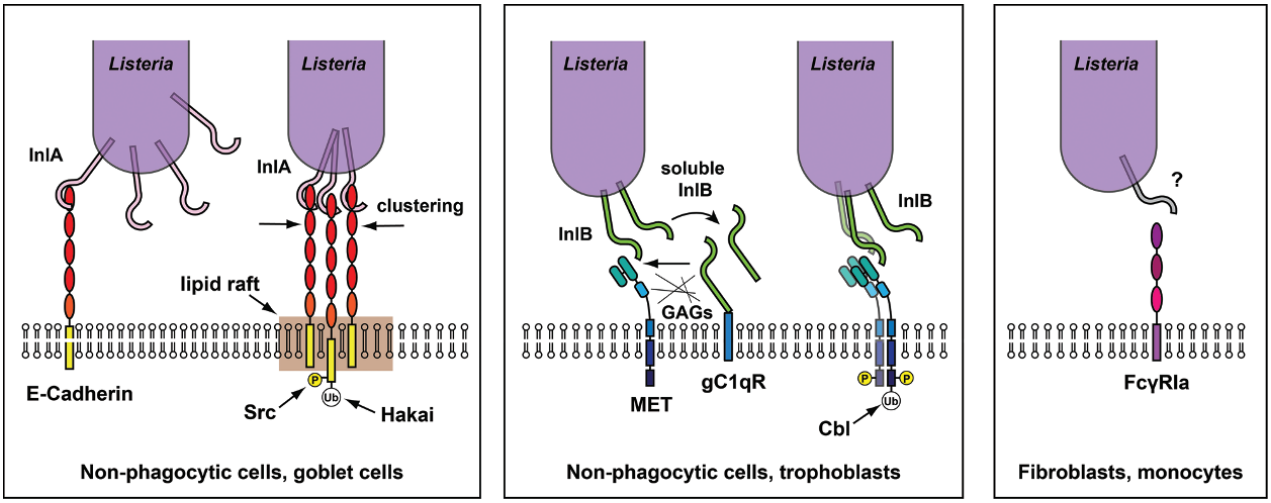

FIGURE 1 Cellular receptors for *L. monocytogenes* in host cells. The receptor for InlA in nonphagocytic polarized cells (including goblet cells) is the transmembrane molecule E-cadherin. Interaction takes place between the InlA leucine-rich repeats (LRRs) and the first extracellular domain of E-cadherin, leading to phosphorylation and ubiquitylation of the cytoplasmic domain of E-cadherin by the kinase Src and the ubiquitin ligase Hakai, respectively. Clustering of E-cadherin requires the presence of lipid rafts (left panel). Via its C-terminal glycine-tryptophan (GW) repeats, InlB interacts with the receptor for the globular part of the C1q complement component (gC1qR) and glycosaminoglycans, which enable interaction of the N-terminal LRRs of InlB with the tyrosine receptor kinase Met in nonphagocytic cells (including trophoblasts). Met dimerization upon interaction with InlB leads to autophosphorylation and recruitment of the ubiquitin ligase Cbl, which ubiquitylates the cytoplasmic tail of Met (center panel). In fibroblasts and monocytes, a function for the FcγRIA receptor has been described for *L. monocytogenes* internalization, via interaction with a still unidentified *L. monocytogenes* surface molecule (right panel). Modified from reference 12.

InlA/E-Cadherin-Mediated Entry

InlA displays a C-terminal LPXTG domain that favors covalent binding to the *L. monocytogenes* cell wall (6). The LRR domain of InlA interacts with the cellular receptor E-cadherin (17, 18), a transmembrane glycoprotein present in the adherens junctions of polarized tissues (e.g., the intestine and the placenta). E-cadherin normally plays a key role in the maintenance of tissue stability, and while the ectodomain participates in most cases in homotypic interactions (E-cadherin/E-cadherin intercellular binding), the cytoplasmic domain interacts with the actin cytoskeleton machinery. By subverting the E-cadherin physiological function, *L. monocytogenes* promotes cortical actin polymerization and plasma membrane rearrangements, favoring cellular invasion and traversal of the intestinal and the feto-maternal barriers (19, 20). InlA access to intestinal E-cadherin mostly occurs at the level of goblet cells, which expose this cellular receptor to bacteria during mucus secretion (21). Exposure of E-cadherin to *L. monocytogenes* during apoptotic cell extrusion at the tip of intestinal villi has also been documented (22). The interaction between InlA and E-cadherin is species-specific (23). A proline at position 16 allows interaction between InlA and human E-cadherin, while a glutamic acid at the same position, as observed in the mouse E-cadherin, does not allow InlA binding. A transgenic mouse model specifically expressing the human E-cadherin in the murine intestine allows a more efficient animal infection through the oral route, demonstrating the pivotal role of InlA in the crossing of the intestinal barrier (19).

In *in vitro* polarized cellular systems, lipid rafts are critical for InlA-dependent E-cadherin clustering (24). InlA binding promotes two successive posttranslational modifications in the cytoplasmic tail of E-cadherin: phosphorylation by the host kinase Src, followed by ubiquitylation by the ubiquitin ligase Hakai (25). These events are critical for the recruitment of a clathrin coat via the adaptor Dab2; the coat is stabilized by tyrosine phosphorylation of the clathrin heavy chain, followed by sequential recruitment of the protein adaptor Hip1R, which in turn coordinates recruitment of actin; myosin VI and unconventional myosin VIIa provide the pulling force that finally leads to bacterial internalization (26, 27). Interestingly, the nonmuscle myosin heavy chain IIA is specifically phosphorylated by Src upon *L. monocytogenes* infection and restricts bacterial entry (28). Several other molecules modulate actin association to the E-cadherin cytoplasmic site during *L. monocytogenes* InlA-dependent invasion: β- and α-catenins provide a physical link between E-cadherin and actin filaments during bacterial entry (29, 30), while cortactin and Src participate in the activation of the Arp2/3 complex, a major actin nucleator (31), highlighting the exploitation of adheren junctions and classical E-cadherin endocytosis components by *L. monocytogenes* during invasion of polarized tissues (32, 33). In the intestinal barrier, the constitutive PI 3-kinase activity is required for promoting actin polymerization during *L. monocytogenes* cell entry; in the placenta, PI 3-kinase activity is not constitutive, and InlB is required for PI 3-kinase activation and InlA-mediated cell invasion (34, 35).

InlB/Met-Mediated Entry

InlB was identified as a second *L. monocytogenes* invasion protein (6, 36). InlB allows *L. monocytogenes* entry into nonpolarized epithelial cells *in vitro* (37), and it cooperates with InlA during placental invasion *in vivo* (34, 35). In nonpregnant animals, InlB expression is associated with an increase of necrotic foci in the liver and spleen (38). The C-terminal region of InlB is characterized by the presence of glycine-tryptophan (GW) repeats that favor loose binding to bacterial membrane-tethered lipoteichoic acids (39, 40) and

pedptidoglycan-bound wall teichoic acids (41). At the surface of host cells, the GW repeats mediate binding to the receptor of the globular part of the complement component C1q (42) and to glycosaminoglycans (43). The N-terminal region displays LRRs that are critical for cell invasion (44, 45) and bind the hepatocyte growth factor receptor Met (46) in a species-specific manner (47). Met expression is modulated by epithelial keratins, which promote InlB-mediated *L. monocytogenes* infection of epithelial cells (48). Met is a tyrosine kinase receptor, and its interaction with InlB leads to Met autophosphorylation and recruitment of the protein adaptors Gab1, Shc, Cbl, and CrkII (49–51), which play key roles in the activation of PI 3-kinase (52–54). Production of $PI(3,4,5)P_3$ and its accumulation in lipid rafts leads to Rac1 activation (24, 55) and recruitment of Ena/VASP, WAVE, and N-WASP, which activate the Arp2/3 complex promoting actin polymerization in a tightly regulated manner (56, 57). The serine/threonine kinases mTOR and protein kinase C-α also control actin polymerization downstream of the InlB/Met interaction (58). The host 5′-phosphatase OCRL restricts *L. monocytogenes* entry by reducing $PI(3,4,5)P_3$ levels and actin polymerization at bacterial entry foci (59). Production of PI 4P by type II PI 4-kinases, downstream of the tetraspanin CD81, is also critical for *L. monocytogenes* entry into host cells (60, 61). The PI 3-kinase adaptor Cbl also displays ubiquitin ligase activity and promotes ubiquitylation of Met upon InlB binding, leading to modulation of actin polymerization via clathrin recruitment (62–64). InlB also modulates exocytosis and favors the delivery of the endocytic GTPase dynamin 2 to bacterial entry sites (65). Finally, the septin cytoskeleton is recruited during cell invasion by *L. monocytogenes* in an InlB-dependent manner (66), and it controls the anchorage of Met to the cortical actin cytoskeleton (67–69).

Additional Adhesion/Entry Effectors

L. monocytogenes displays other surface and secreted molecules that can modulate adhesion and entry into host cells by indirectly affecting the surface exposure of InlA or InlB, by behaving as adhesins, by directly binding putative cellular receptors, and/or by activating cellular pathways that lead to actin rearrangements and bacterial engulfment. For example, the internalins InlE, InlG, and InlH support the InlA-dependent-invasion pathway in Caco-2 cells and might modulate the bacterial cell wall organization, consequently affecting InlA exposure (70). On the other hand, InlJ favors bacterial adhesion but not invasion in a specific subset of polarized epithelial cells (71, 72). A role for InlF in cell adhesion and invasion has been detected only upon inhibition of the RhoA/Rho kinase pathway (73, 74).

Several *L. monocytogenes* autolysins modulate cell adhesion and/or entry processes: Ami is involved in cell adhesion (75, 76), and Auto has been implicated in entry (77), while IspC is required for adhesion and/or invasion in a cell line-dependent manner (78). The lipoteichoic acid modifiers GtcA and DltA (79, 80), the lipoprotein LpeA (81), the prolipoprotein transferase Lgt (82), and the lysylphosphatidylglycerol modifier MprF (83) play roles in host cell adhesion or invasion probably by modulating the bacterial surface charge and/or by altering the organization of bacterial surface proteins. The surface protein ActA, involved in cytoplasmic actin-based motility (see below), has been proposed to favor host cell invasion through interaction with heparan sulfate (84, 85). Additional *L. monocytogenes* surface adhesins or invasins include Vip (86, 87), Lap (88), LapB (89), and FbpA (90).

LLO, a secreted cholesterol-dependent pore-forming toxin that is required for *L. monocytogenes* vacuolar escape (see below), is also secreted by extracellular bacteria and induces a transient influx of extracellular calcium within host cells that correlates with increased cell invasion (91). Mitochondrial fragmentation also correlates with the LLO-dependent calcium influx, and it has been proposed that *L. monocytogenes* modulates the bioenergetic state of resting cells to trigger cell invasion (92). LLO has been recently proposed to mediate *L. monocytogenes* entry into epithelial cells in a $Ca2^+/K^+$-, cholesterol-, dynamin-, tyrosine kinase- and actin-dependent but InlA/InlB- and clathrin-independent manner (93, 94). A broad-range phospholipase C of *L. monocytogenes*, PlcB (see below), has been reported to induce a calcium influx required for efficient bacterial internalization in macrophages (95).

THE VACUOLAR STAGE

The modulation of the actin cytoskeleton and the rearrangements of the plasma membrane upon *L. monocytogenes* interaction with its host cell receptors lead to bacterial engulfment and internalization in a membrane-bound vacuole (Fig. 2). In the intestinal epithelium, and particularly in the goblet cells, *L. monocytogenes* does not escape from this compartment and is directly transcytosed to the lamina propria, where the bacteria disseminate systemically (21). In other cell types, *L. monocytogenes* is able to disrupt its containing compartment and translocates to the host cell cytoplasm. The cholesterol-dependent pore-forming toxin LLO, together with two bacterial phospholipases, are the major bacterial effectors controlling *L. monocytogenes* vacuolar escape. *L. monocytogenes* residency and persistence in vacuolar compartments have also been described (96, 97) (see below).

LLO and Vacuolar Disruption

LLO is able to induce hemolysis *in vitro*, and early on, this activity was correlated with *L. monocytogenes* virulence (98). This toxin is encoded by the *hly* gene, located within a pathogenicity island that also encodes other important virulence factors, including two phospholipases, a metalloprotease, the actin polymerizing factor ActA, and the transcriptional activator PrfA (99). Inactivation of the *hly* gene coupled with electron microscopic observations subsequently demonstrated that LLO is required for bacterial escape from internalization vacuoles (100). LLO belongs to the family of cholesterol-dependent cytolysins which also includes perfringolysin O from *Clostridium perfringens* and streptolysin O from *Streptococcus pyogenes* (101). Perfringolysin O studies indicate that a conserved undecapeptide provides a structural conformation for a threonine-leucine pair at the C-terminal region of cholesterol-dependent cytolysins responsible for cholesterol binding (102, 103). Theoretically predicted to form large pores (20 to 80 monomers), based on initial perfringolysin O studies (104), electron microscopy and atomic force microscopy analyses indicate that LLO oligomers actually form arc-like structures that assemble into lineactants, and these heterogenous structures are responsible for membrane disruption and vacuolar rupture (105, 106). Membrane perforation by LLO not only facilitates *L. monocytogenes* translocation to the cytoplasm, but it also controls the vacuolar pH and calcium concentration, delaying the maturation of the bacteria-containing compartment and inhibiting lysosomal fusion (107, 108).

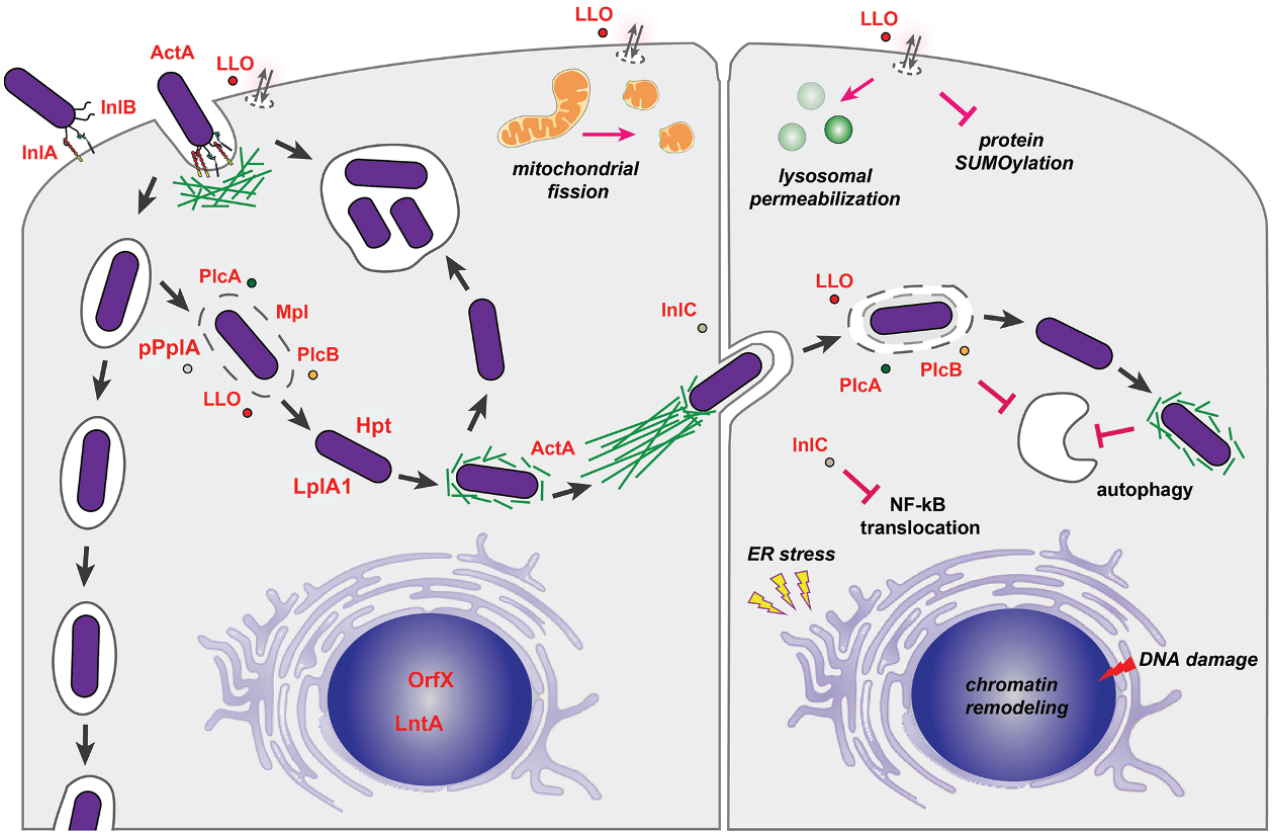

FIGURE 2 *L. monocytogenes* intracellular stages. *L. monocytogenes* is able to induce its entry into nonphagocytic cells mainly via the interaction of InlA and InlB with host cells receptors that promote actin recruitment, remodeling of the plasma membrane, and bacterial engulfment. The surface molecule ActA and the secreted pore-forming toxin LLO have also been implicated in the early *L. monocytogenes* entry steps (left cell, upper left). In goblet cells, upon internalization, *L. monocytogenes* is localized in a vacuole, and through transcytosis the bacterium is translocated to the lamina propria (left cell, left). In other cells, the combined activity of diverse virulence factors, including the pore-forming LLO, the metalloprotease Mpl, the phospholipases PlcA and PlcB, and the pheromone pPplA, favor disruption of the vacuole and *L. monocytogenes* release in the cytosol, where the bacteria takes advantage of host metabolites via the phosphate transporter Hpt and the lipoate protein ligase LplA. The surface protein ActA promotes actin-based motility, and the secreted protein InlC favors reduction of plasma membrane cortical tension, allowing *L. monocytogenes* to form protrusions and to invade neighboring cells. LLO and the phospholipases PlcA and PlcB contribute to the disruption of the double-membrane vacuole (right cell). *L. monocytogenes* has been observed in large spacious compartments that may arise rapidly after internalization of bacteria or upon decrease of ActA expression in already cytoplasmic bacteria (left cell, upper center). Extracellular LLO is able to modulate different cellular functions, including mitochondrial fission, lysosomal permeabilization, protein SUMOylation, ER stress, DNA damage, and chromatin remodeling. The phospholipases PlcA and PlcB, together with actin polymerization by ActA, have been implicated in the resistance to autophagy (195). The secreted molecule InlC prevents NF-κB translocation to the nucleus. Modified from reference 12.

Several physical parameters and host molecules modulate the activity of LLO. Removal of LLO pores from the host cell plasma membrane is mediated by an LLO PEST-like sequence recognized by the clathrin adaptor Ap2a2, favoring pore endocytosis and protection of plasma membrane integrity (109). At 37°C and neutral pH, LLO undergoes denaturation, but it is in a stable conformation at acidic conditions (105). Consequently, within mammalian hosts, the LLO pore-forming activity is compartmentalized to slightly acidified bacteria-containing compartments (110, 111). Cytoplasmic LLO activity, which is cytotoxic to host cells and detrimental to intracellular *L. monocytogenes* (112), is limited by translational regulation of LLO synthesis (113) and by cytoplasmic LLO degradation by the ubiquitin system (114). LLO is activated by reducing agents (115), and within the vacuole of macrophages, the γ-interferon-inducible lysosomal thiol reductase is responsible for reducing and activating LLO (116). The increase in vacuolar chloride concentration mediated by the cystic fibrosis transmembrane conductance regulator has been proposed to enhance LLO oligomerization and *L. monocytogenes* cytoplasmic escape (117). LLO-disrupted vacuoles trigger the recruitment of the protein kinase C (PKC) ε, suggesting that this enzyme is involved in the recognition of damaged membrane organelles (118).

Phospholipases PlcA/PlcB and Vacuolar Disruption

L. monocytogenes secretes two phospholipases, a phosphatidylinositol-specific phospholipase C named PlcA (119) and a broad-range phospholipase C/sphingomyelinase named PlcB (120, 121), which is activated by the metalloprotease Mpl (122–124). Both enzymes have been shown to contribute to *L. monocytogenes* escape from primary vacuoles and

from secondary vacuoles during bacterial cell-to-cell spread (4, 125–128).

PlcA from *L. monocytogenes* is the only bacterialphosphatidylinositol-specific phospholipase C that lacks a Vb β-strand that increases activity toward glycosylphosphatidylinositol-anchored proteins (129); interestingly, expression of this β-strand in PlcA impairs bacterial escape from vacuoles and cell-to-cell spread (130), suggesting that an *L. monocytogenes* adaptation to the intracellular environment requires reduced activity against glycosylphosphatidylinositol-anchored proteins. It has been proposed that PlcA translocating via LLO pores reaches the host cell cytoplasm, and in this compartment PlcA cleaves intracellular phosphatidylinositol into inositol phosphate and diacylglycerol (131); production of diacylglycerol, which might also take place through activation of host phospholipases C and D in an LLO-dependent signaling pathway (132), leads to activation of PKC βI and βII, which are required for vacuolar disruption (133). Because both PKC βI and βII are recruited to the *L. monocytogenes* internalization vacuole (134), it is speculated that the phosphorylation of PKC βI and βII targets at the surface of the bacteria-containing compartment is critical for a still unidentified signaling cascade leading to vacuolar rupture (133).

PlcB maturation and activation by the metalloprotease Mpl requires acidification of the vacuole (135, 136), and as has been observed for LLO, compartmentalization of this phospholipase C activity is critical for intracellular survival of *L. monocytogenes* (137). Both PlcA and PlcB have been found to activate NADPH oxidase during *L. monocytogenes* infection, which might be harmful to internalized bacteria via the production of reactive oxygen species; however, modulation of vacuolar maturation by LLO restricts NADPH oxidase localization to the *L. monocytogenes*-containing compartments (138).

Additional Mechanisms Regulating Vacuolar Disruption

Several other bacteria- and host-related mechanisms have been proposed to modulate the *L. monocytogenes* vacuolar stage. A recent study indicates that *L. monocytogenes* secretes a pheromone, pPplA, that triggers the production of an unknown factor that cooperates with LLO in facilitating vacuolar disruption (139): pPplA is processed from the N-terminal secretion signal sequence of the lipoprotein PplA; pPplA is secreted, accumulates in the space of the *L. monocytogenes* vacuole, and is then exported by the CtaP peptide transporter; cytoplasmic pPplA induces the production of a factor that accelerates vacuolar disruption mediated by LLO in a still unidentified manner (139).

Modulation of bacterial gene expression by "reversible lysogeny" has also been proposed to modulate *L. monocytogenes* vacuolar escape (140). The prophage A118 is inserted within the coding region of the gene *comK*, a master regulator of competence genes that are normally not expressed by *L. monocytogenes*; interestingly, during the bacterial vacuolar stage, A118 is excised, and this event allows reactivation of *comK* and expression of the competence machinery by *L. monocytogenes*; by a still unknown mechanism, the competence system promotes efficient bacterial translocation to the host cell cytoplasm. In this environment, the phage reinserts into *comK* (140).

Additional host factors have been reported to control *L. monocytogenes* vacuolar residency. Rab5a was shown to control the accelerated maturation of *L. monocytogenes*-containing vacuoles (141, 142); the product of the gene *Lmo*2459 was subsequently shown to induce the specific ADP ribosylation of Rab5a, inhibiting its activation and reverting its bactericidal functions (143). The activity of the cytosolic cysteine protease calpain has been shown to be required for efficient *L. monocytogenes* vacuolar escape, but the targets of this protease remain to be identified (144).

THE CYTOPLASMIC STAGE

By translocating from the vacuolar stage toward the cytoplasm, *L. monocytogenes* escapes cellular degradative mechanisms associated with phagosomal pathways. On the other hand, *L. monocytogenes* must adapt its metabolism to nutrients and metabolites found in this novel intracellular compartment and must also escape from additional innate immunity defenses including autophagy. The hexose phosphate transporter Hpt and the actin-polymerizing surface protein ActA play key roles in the survival of *L. monocytogenes* in the host cell cytoplasm.

Utilization of Host Metabolites

Glucose-1-phosphate is the primary degradation product of glycogen and is broadly available within mammalian cells. The observation that *L. monocytogenes* uses glucose-1-phosphate as a carbon source in a PrfA-dependent manner suggested that related hexose phosphates could be important growth substrates for intracellular bacteria (145). *In silico* analysis of the *L. monocytogenes* genome identified the gene *hpt* as encoding a hexose phosphate transporter responsible for the uptake of glucose-6-phosphate in the cytoplasm of host cells, playing a key role in *L. monocytogenes in vivo* virulence (146). A subsequent screen for identification of additional genes required for bacterial intracellular replication recognized lplA1 as a lipoate protein ligase that could potentially use host-derived lipoic acid to modify bacterial substrates (147). LplA1 was later confirmed to be essential for intracellular growth of *L. monocytogenes* under limiting concentrations of available small mammalian lipoylated peptides (148). A genetic screen led to the discovery that the menaquinone synthesis intermediate 1,4-dihydroxy-2-naphtoate is required for *L. monocytogenes* cytosolic survival, but full-length menaquinone is not (149).

Cytoplasmic Innate Immune Responses

Autophagy is a cellular mechanism responsible for protein turnover and removal of abnormal or superfluous subcellular components. The pioneering work of Rich et al. (150) demonstrated that cytoplasmic and metabolically arrested *L. monocytogenes* can be targeted for destruction by the autophagic machinery. Different mechanisms have been proposed to participate in the active escape of cytoplasmic *L. monocytogenes* from autophagy: polymerization of actin by the surface protein ActA favors cytoplasmic motility and avoidance of autophagosomes (151); polymerized actin or Arp2/3 sequestering by ActA may also act as a protective physical barrier preventing the accumulation of signaling molecules (i.e., ubiquitin) that are required for autophagy activation (152, 153). PlcA and PlcB have also been implicated in autophagosomal avoidance (151, 154, 155), and recent studies suggest that these PLCs decrease cytoplasmic levels of PI 3P, causing stalling of preautophagosomal structures and preventing efficient targeting of cytosolic bacteria (156). The surface internalin InlK has also been proposed to recruit the major vault protein and to protect cytoplasmic *L. monocytogenes* from autophagic recognition (16), but these

results have been recently challenged using a different *L. monocytogenes* strain (157).

Cytoplasmic *L. monocytogenes* secretes small molecules leading to activation of an IRF3-dependent cytosolic pathway, resulting in type I interferon activation (158). One of these small molecules, cyclic-di-AMP, is sufficient to activate production of interferon β in macrophages (159). Sensing of tri-phosphorylated RNA via RIG-I and a MAVS-dependent pathway triggers type I interferon production in epithelial cells (160, 161). *L. monocytogenes* cytoplasmic DNA is recognized through STING, TBK1, IRF3, and IRF7, leading to the upregulation of the di-ubiquitin-like protein ISG15 and ISGylation of endoplasmic reticulum (ER) and Golgi proteins, which correlate with increased secretion of cytokines that counteract infection (162). *L. monocytogenes* also activates the type III interferon pathway (163).

Persistence

It is increasingly recognized that bacterial pathogens may persist within host tissues in a dormant state that allows resistance to antibiotics and subsequent reinfection. In macrophages of severe combined immunodeficient (SCID) mice, *L. monocytogenes* can persist in large compartments termed spacious *Listeria*-containing phagosomes (SLAPS), which are formed in an LLO-dependent manner (96). LC3-associated phagocytosis has been proposed to precede the formation of SLAPS (164). A recent study indicates that in epithelial cells, cytoplasmic *L. monocytogenes* bacteria in which ActA production is halted are trapped in acidic vacuoles that are not associated with classical autophagosomal markers and in which bacteria enter a viable but nonculturable state (97). These studies indicate that *L. monocytogenes* may persist in different host cellular populations, favoring the asymptomatic carriage of this pathogen.

CELL-TO-CELL SPREAD

Actin-based motility allows *L. monocytogenes* not only to escape autophagy but also to reach neighboring cells within infected tissues, favoring cell-to-cell spread and bacterial dissemination in organs, avoiding exposure to humoral immunity. Motile *L. monocytogenes* first induces the formation of a membrane protrusion in the primary infected cell that is accompanied by membrane internalization in the neighboring bystander cell, leading to bacterial entrapment in a double-membrane vacuole that is then disrupted (9). Several bacterial virulence factors, including ActA, the internalin InlC, the pore-forming toxin LLO, and the phospholipases PlcA and PlcB, participate at different stages of *L. monocytogenes* cell-to-cell spread.

Cytoplasmic Actin-Based Motility

The surface protein ActA is sufficient to trigger actin polymerization at the surface of *L. monocytogenes* (7). The central region of ActA contains four short proline-rich repeats that bind members of the enabled/vasodilator-stimulated phosphoprotein (Ena/VASP) family; these molecules contribute to the persistence of speed/directionality of bacterial movement by recruiting profilin, which provides polymerization-competent actin monomers (165). The N-terminal region of ActA recruits the Arp2/3 complex which drives actin nucleation (166, 167). The Arp2/3 complex is formed of seven subunits, and it has been traditionally considered a single molecular entity (168). A genome-wide small interfering RNA screen demonstrated that different Arp2/3 complexes are required to control *L. monocytogenes* cell invasion and actin-based motility: the Arp2, Arp3, ARPC2, and ARPC3 subunits are conserved, but the ARPC1B subunit is only involved in cell invasion, while the ARPC1A subunit is required for actin-based motility, and the ARPC4 subunit is dispensable for cell invasion, while the ARPC5 subunit is dispensable both for cell invasion and actin-based motility (169). Multiple actin cross-linking proteins, actin filament-capping or -severing proteins, and protein scaffolds are recruited to the *L. monocytogenes* actin tail (170). Cryo-electron tomography of actin tails has demonstrated that actin bundling is critical for ensuing actin-based motility (171).

Cortical Actin Rearrangements and Protrusion Formation

In mammalian tissues, cortical membrane tension represents a physical barrier for motile *L. monocytogenes*, inhibiting the deformation of the plasma membrane into protrusions. InlC, a secreted member of the internalin family devoid of a cell wall anchoring motif (13), perturbs apical cell junctions by interacting with the protein adaptor Tuba, inhibiting the recruitment of the actin regulatory protein N-WASP and COPII proteins and therefore relieving cortical membrane tension favoring *L. monocytogenes* protrusion formation (14, 172, 173). The downregulation by *L. monocytogenes* of the small GTPase Cdc42, another Tuba interactor, is also required for efficient protrusion formation (174). Within the protrusion, the membrane-cytoskeletal linker ezrin has been proposed to support the formation and stabilization of protrusions (175). Arp2/3 drives actin polymerization at the proximal *L. monocytogenes* rear-end within protrusions, but at distal locations the recruitment of Rho GTPases activate diaphanous-related formins which promote the formation of unbranched actin filaments (176). Inhibition of actin polymerization by components of the AIP1-dependent actin disassembly machinery (177) and ActA processing by the metalloprotease Mpl (178) are proposed mechanisms for the resolution of membrane protrusions into double membrane vacuoles. Efficient cell-to-cell spread can be facilitated by the exofacial exposure of phosphatidylserine at the tip of protrusions promoted by the pore-forming activity of LLO, which leads to phosphatidylserine binding by the TIM-4 receptor in macrophages and protrusion internalization (179).

Lysis of Secondary Vacuoles

Internalization of *L. monocytogenes*-induced protrusions into neighboring bystander cells leads to bacterial localization within a double-membrane compartment (9). Initial studies suggested that phospholipases PlcA and PlcB, together with LLO, contributed to cell-to-cell spread (4, 125, 127), and a more specific contribution of PlcB to double-membrane vacuolar rupture was suggested (128). A current model proposes that PlcA and PlcB contribute to the disruption of the inner membrane of the spreading vacuole, while LLO participates more precisely in the disruption of the outer membrane of this vacuole (180). Bacterial translocation to the cytoplasmic space of neighboring cells allows *L. monocytogenes* to start a new infection process.

MODULATION OF CELLULAR, ORGANELLAR, AND NUCLEAR FUNCTIONS

L. monocytogenes is able to modulate a broad range of cellular functions, even before being internalized within host cells. The pore-forming toxin LLO, which plays a major role in

vacuolar escape (see above) is able to modulate from the extracellular space the function of mitochondria, the ER, lysosomes, protein posttranslational modifications, and DNA stability. Several bacterial nucleomodulins have been identified which directly affect the transcription of host genes involved in the control of immune responses.

LLO Influence on Mitochondria

Mitochondria are critical organelles involved in the generation of chemical energy in eukaryotic cells. As mentioned above, extracellular LLO triggers the influx of calcium, which leads to transient fission of mitochondria, triggering a bioenergetic change of host cells that is beneficial for *L. monocytogenes* host cell invasion (92). Interestingly, atypical mitochondrial fission through a Drp1-independent fragmentation process has been associated with *L. monocytogenes* cellular infection (181).

LLO Influence on the ER

The unfolded protein response is a signaling cascade that maintains the function of the ER under stress conditions. *L. monocytogenes* activates the unfolded protein response in an LLO-dependent manner prior to bacterial entry into host cells (182). The induction of ER stress by drugs such as thapsigargin or tunicamycin leads to a decrease in bacterial intracellular numbers, suggesting that the unfolded protein response represents an innate immune response to bacterial infection (182).

LLO Influence on Lysosomes

The integrity of lysosomes has been shown to be compromised by extracellular LLO, which induces permeabilization and release of lysosome content, including cathepsins, which remain transiently active in the cytoplasm (183). The functional significance of this finding for *L. monocytogenes* infection and survival remains to be identified.

LLO Influence on Protein Posttranslational Modifications

Posttranslational modifications allow the rapid modification of the activity of cellular proteins. Sumoylation is an essential posttranslational modification that is impaired by *L. monocytogenes* through the proteasome-independent degradation of the E2 enzyme Ubc9 following calcium influx mediated by extracellular LLO (184). The downregulation of cellular protein sumoylation, together with the proteasome-dependent degradation of some sumoylated proteins, favors bacterial infection *in vitro* and *in vivo* (184). Histone modifications are also associated with the *L. monocytogenes* infection process (185) (see below).

LLO Influence on DNA Stability

L. monocytogenes modulates general DNA stability in host cells in different manners. *L. monocytogenes* induces DNA strand breaks and simultaneously blocks the DNA damage response through degradation of the sensor Mre11 in an extracellular LLO-dependent manner (186), promoting a cell cycle delay that favors bacterial intracellular replication (187). Interestingly, it has been also reported that LLO-induced calcium influx leads to the proteasomal degradation of the human telomerase reverse transcriptase, an event that is detrimental to bacterial replication (188).

Bacterial Influence on Gene Expression

LntA is the first nucleomodulin discovered in *L. monocytogenes* (189): it targets the chromatin repressor BAHD1 and fine-tunes transcription of interferon-stimulated genes, which is required for efficient *in vivo* infection (190, 191). More recently, the nucleomodulin OrfX has been shown to interact and decrease the levels of the regulatory protein RybP, dampening the oxidative response in macrophages probably through modulation of host transcriptional responses (192). The secreted internalin InlC interferes with innate immune responses by targeting the IκB kinase subunit IKKα, inhibiting NF-κB translocation to the nucleus (15). LLO modulates gene transcription with opposite effects for infection: LLO induces a dramatic dephosphorylation of histone H3 and deacetylation of histone H4 that leads to reduced transcriptional activity of key immunity host genes (185); LLO has also been shown to modulate the functionality of the promyelocytic leukemia protein nuclear bodies, activating a signaling response that decreases *L. monocytogenes* infection (193). Finally, an InlB/PI 3-kinase pathway is required for the SIRT2-dependent deacetylation of histone H3 on lysine 18, which is involved in efficient bacterial infection *in vitro* and *in vivo* (194).

CONCLUSIONS

The study of the interactions of *L. monocytogenes* with eukaryotic host cells during bacterial invasion, intracellular growth, and cell-to-cell spread has proven to be fundamental to better understanding the exquisite adaptation of this bacterial pathogen to mammalian hosts. Indeed, *L. monocytogenes* is able to hijack multiple cellular functions including receptor signaling, membrane trafficking, cytoskeletal rearrangements, organellar dynamics, DNA stability, and gene transcription. The work reviewed in this article also highlights that *L. monocytogenes* is an extraordinary tool to manipulate and to unravel host cell signaling cascades, in particular, innate immune responses that allow us to expand our understanding of the control of bacterial intracellular infections.

We thank members of the Cossart lab for helpful discussions. We apologize to those people who have contributed to advancements in the field of listeriosis but whose work was not cited in our article due to space limitations.

J.P.C. received support from the Institut Pasteur Transversal Research Program PTR521 and from National Research Agency (ANR) grant ANR-15-CE15-0017, StopBugEntry. Work in P.C.'s laboratory received financial support from Institut Pasteur, INSERM, INRA, ANR-13-IFEC-0004-02 ERANET Infect-ERA PROANTILIS, the French government's Investissement d'Avenir program, the Laboratoire d'Excellence Integrative Biology of Emerging Infectious Diseases (ANR-10-LABX-62-IBEID), the European Research Council (ERC) (advanced grant H2020-ERC-2014-ADG 670823-BacCellEpi), the Human Frontier Science Program Organization (RGP011/2013), the Fondation le Roch les Mousquetaires, and the Fondation Balzan. P.C. is a senior international research scholar at the Howard Hughes Medical Institute.

Metabolism of the Gram-Positive Bacterial Pathogen *Listeria monocytogenes*

JOHN-DEMIAN SAUER, ANAT A. HERSKOVITS AND MARY X.D. O'RIORDAN

54

METABOLIC POTENTIAL

The bacterial pathogen *Listeria monocytogenes* is well adapted to life in the soil and on vegetation as a saprophyte (i.e., extracellular environments) and to life in the cytosol of mammalian cells as a pathogen (i.e., intracellular environment). These environments differ greatly in their metabolite repertoires (e.g., carbon, sulfur, and nitrogen sources) and abundance (e.g., amino acid availability). Therefore, *L. monocytogenes* requires niche-specific adaptations to support growth and uses metabolic cues to trigger virulence mechanisms, such as the master virulence regulator, PrfA (1). The complete metabolic potential of *L. monocytogenes* has been inferred bioinformatically from genomic (2–5) and transcriptomic studies (1, 6–8), as well as experimentally using both defined media as a test for auxotrophy (9–12) and more recently by isotopologue metabolomics (13, 14). While these studies have certainly taught us much about *L. monocytogenes*' metabolic potential, it is important to note that, given the wide array of environments *L. monocytogenes* is capable of inhabiting, our understanding of its metabolic potential and how strain to strain variation might affect this potential, is incomplete.

The first comparative genomic study of *L. monocytogenes* (EGD-e) and *Listeria innocua* (CLIP 11262) demonstrated that complete glycolysis, pentose phosphate, respiratory chain, and multiple fermentation pathways were present in both pathogenic and nonpathogenic *Listeria* isolates (2). In contrast, an incomplete tricarboxylic acid (TCA) cycle was documented due to the lack of α-ketoglutarate dehydrogenase in both organisms, while biosynthetic pathways for vitamins including riboflavin, biotin, thiamine, and lipoate were absent or incomplete, consistent with observed auxotrophies (9). Finally, biosynthetic pathways for all amino acids were present, despite a variety of reported amino acid auxotrophies in various growth conditions, suggesting not surprisingly, that regulation of these metabolic pathways under different growth conditions leads to conditional auxotrophies. Since this original comparative genomics study, more than 100 additional *L. monocytogenes* genomes have been sequenced in addition to many other non-*monocytogenes Listeria* species (4, 15). The core genome of *L. monocytogenes* comprises 1,791 genes, with estimates of up to 6,500 genes in the pan genome of all *Listeria* species, 54% of which are predicted to be dedicated to metabolism in one way or another, highlighting the potential diversity of metabolic adaptations of different *Listeria* species and even potentially different *L. monocytogenes* strains to different environments (3, 4). Defining how all of these accessory metabolic pathways contribute to the colonization of niches, either environmental or host, will be of critical importance over the coming years.

Multiple efforts at developing a minimal medium to define *L. monocytogenes* metabolic requirements have been attempted over the years, dating back to initial efforts by Welshimer in the early 1960s (9). Different strains and different media have yielded some consistent findings and some that are confounding. As noted above, and consistent with genetic analysis, *Listeria* is auxotrophic for a variety of essential vitamins, including thiamine, lipoate, biotin, and riboflavin, which *L. monocytogenes* cannot produce *de novo* (9–11). In addition, multiple growth experiments in minimal defined media have demonstrated that *L. monocytogenes* requires the supplement of methionine and cysteine for growth (i.e., auxotrophic to Met and Cys). Moreover, addition of branched chain amino acids (BCAAs; lle, Leu, and Val), arginine, histidine, phenylalanine, and tryptophan substantially enhance *L. monocytogenes* growth in minimal media, while glutamine can serve as a nitrogen source (which can be replaced with ammonium or ethanolamine) (10–12, 16, 17). The requirement for Met and Cys is explained by the fact that most *L. monocytogenes* genomes are missing the gene(s) for reducing sulfate to sulfide, which is further condensed with *O*-acetylserine to form cysteine (2, 12). Supplementing *L. monocytogenes* bacteria with thiosulfate, which can be alternatively condensed with *O*-acetylserine to form cysteine, does not support *L. monocytogenes* growth, nor does the addition of methionine, indicating the lack of the transsulfuration pathway (converting methionine to cysteine) (12). Notably, strain-specific requirements for Cys and Met are observed. For example, the EGD-e strain requires only cysteine, without the addition of methionine, while the 10403s strain requires both, suggesting a disruption in one or more of the *met* genes, whose gene products convert cysteine to methionine (*metI*, *metC*, and *metD*). The requirement for BCAA, arginine, histidine, phenylalanine, and tryptophan in defined media is more difficult to explain, because *L. monocytogenes* genomes encode for all the biosynthesis genes of these amino acids (more details below). The

doi:10.1128/microbiolspec.GPP3-0066-2019

addition of BCAA and arginine appears to be essential for efficient growth, whereas histidine, tryptophan, and phenylalanine are not essential but can improve the growth of distinct *L. monocytogenes* strains in chemically defined media (10–12, 16).

With respect to carbon metabolism, as a facultative aerobe *L. monocytogenes* can both ferment glucose and respire when oxygen is present. *L. monocytogenes* catabolizes glucose through the classical glycolytic (Embden-Meyerhof-Parnas) pathway to pyruvate and generates ATP through substrate-level phosphorylation. Pyruvate can be shunted to acetate, acetoin, and lactate (18) or converted to acetyl-CoA by pyruvate dehydrogenase complex or pyruvate formate lyase. Under anaerobic conditions, fermentation favors the formation of ethanol and formate, and acetyl-CoA can be broken down to produce acetate and ethanol (18). Acetyl-CoA can be funneled into the oxidative branch of the TCA pathway to generate amino acid precursors (19). It is predicted that two putative type II NADH dehydrogenases (*lmo2389* and *lmo2638*), glycerol-3-phosphate (*glpD*), and formate dehydrogenases (*lmo2586*) may shuttle electrons to either cytochrome *bd* oxidase or cytochrome aa_3 oxidase via menaquinone (MK) (20). Electron transfer through the electron transport chain generates a membrane potential and drives oxidative phosphorylation of ATP by F_0F_1-ATPase. In the absence of oxygen or disruption of the electron transport chain, *L. monocytogenes* displays decreased growth, likely due to less ATP generation (20, 21). Interestingly *L. monocytogenes* is missing several key TCA enzymes—α-ketoglutarate dehydrogenase, succinyl-CoA synthase, and malate dehydrogenase (2)—and therefore exhibits a branched variant of the TCA cycle. *L. monocytogenes* is also unable to bypass these steps using the glyoxylate shunt, though it has been proposed that succinate could be generated by the γ-aminobutyric acid shunt (22). The only way to replenish oxaloacetate is through anapleurosis, using pyruvate carboxylase to convert pyruvate and CO_2 to oxaloacetate (23, 24).

LIFE AS A SAPROPHYTE

While *L. monocytogenes* has been extensively studied as a both a human and a livestock pathogen for decades, significantly less is known about its life in the environment as a saprophyte. Seminal early studies by Welshimer demonstrated that *L. monocytogenes* was capable of surviving on soil (25), while a series of studies in the intervening decades demonstrated the ubiquity of *L. monocytogenes*. *L. monocytogenes* has been isolated from environmental samples ranging from uncultivated fields and meadows, where the incidence ranges from 5 to 50% (26, 27), to cultured fields and dairy farms, where the incidence is consistently lower, ranging from 3 to 24% (27–29). Its prevalence varies not only by geography and soil type but also temporally, seasonally, and with meteorological conditions. Importantly, in all of these studies while the frequency of positive soil samples was relatively high, the abundance of *L. monocytogenes* in these samples was very low and required specific enrichment techniques to facilitate identification (30). Not surprisingly, given the diversity of locations from which *L. monocytogenes* can be cultured, a variety of soil types have been demonstrated to support the maintenance of *L. monocytogenes*. In one study, 100 soil samples were tested, and all were capable of maintaining *L. monocytogenes* survival for at least 14 days, while 71% were able to support growth for longer than 80 days (31). A variety of physiochemical characteristics, ranging from water content and pH were identified as contributing to *L. monocytogenes* survival in soil. Finally, the abundance of competing microorganisms is a major determinant in the success of soil colonization by *L. monocytogenes*, as evidenced by the increased growth of *L. monocytogenes* in a variety of autoclaved soils relative to nonautoclaved controls (25, 27, 32). Given the diversity of soil types and geographic locales in which *L. monocytogenes* can be cultured from soil, it is not surprising that there is little information regarding metabolic adaptations required for life in the soil. Much of what we do know about metabolism under saprophytic conditions comes from genomic and transcriptomic studies. For example, the *L. monocytogenes* EGD-e genome encodes over 330 putative transporters, which is 2 and 3 times more transport genes than either *Escherichia coli* or *Bacillus subtilis*, respectively (2). Of these transporters, 84 assemble into 29 complete phosphoenolpyruvate-dependent phosphotransferase systems (PTSs) (33). Despite this abundance of PTSs, they are downregulated during infection and are dispensable for intracellular replication in macrophages, suggesting that they likely have a role facilitating the use of varied carbon sources in the nutrient poor environment (33, 34). Both transport and metabolic genes are overrepresented in both the core genome and accessory genomes (3, 35, 36). In addition to genomic studies suggesting that extreme diversity in transport and metabolic systems likely facilitates survival in diverse environments, a limited number of transcriptomic studies have begun to elucidate gene expression changes that facilitate growth and survival in the soil. In one study, although many genes were differentially regulated at any given time point following introduction of *L. monocytogenes* into the soil, only 94 genes were specifically upregulated at all time points assessed (15 min, 30 min, and 18 hours). Of these 94, 37 genes were involved in various PTS transport systems, while an additional 26 were involved in other metabolic processes, including chitinases and β-glucosidases (37). Similarly, consistent with the limited availability of amino acids, 15 genes of the regulon of CodY, a repressor of BCAA biosynthesis, were upregulated at all time points following instillation of *L. monocytogenes* into soil (37). In a follow-up study with different soil, upregulation of PTS systems was also observed, including those for cellobiose, mannitol, and maltose, among others (38). Finally, both of these studies observed repression of genes regulated by the master virulence regulator, PrfA, consistent with the longstanding observation that in the presence of PTS substrates, PrfA expression is repressed (39).

PrfA also reciprocally regulates the PTS system as Hpr levels are lowered *in vivo* (40), and constitutive PrfA expression results in impaired growth on glucose (14) and impaired fitness in the soil (41). Thus, while *L. monocytogenes* is ubiquitous in the environment, and its core genome accommodates an expanded repertoire of metabolic and transport capabilities to facilitate growth in these diverse environments, our understanding of the metabolic adaptation to any specific nonhost environment remains rather limited.

LIFE INSIDE THE HOST

As a foodborne opportunistic pathogen, *L. monocytogenes* primarily enters host organisms by passage through the gastrointestinal tract (42). For most immunocompetent individuals, commensal microbes may provide a first-line of defense against *L. monocytogenes* colonization and infection, at least in part by competing for available nutrients (43).

L. monocytogenes is competent for growth in anaerobic environments such as the intestinal tract, and a forward genetic screen identified genes encoding components of the F_0F_1-ATPase as essential for anaerobiosis (20). An additional aspect of energy metabolism relevant in the intestinal tract is the recently discovered flavin-based extracellular electron transfer (EET) locus (44). EET supports growth on nonfermentable carbon sources by mediating electron transfer to extracellular acceptors; an EET mutant exhibited a competitive defect within the mouse gastrointestinal tract (44). From within the gut, *L. monocytogenes* is able to traverse the intestinal epithelium to establish an intracellular infection (45), where its intracellular metabolism has been extensively studied.

L. monocytogenes doubles in the host cytosol approximately every 40 min, demonstrating its exquisite metabolic adaptation to the cytosolic niche. Given that cytosolic replication is essential for virulence, metabolism during intracellular growth has been extensively studied. Traditional genetic and biochemical studies of *L. monocytogenes* virulence, coupled with newer transcriptomic and metabolomics approaches, have been used to understand both host and bacterial metabolism during infection. Surprisingly, a comprehensive analysis of the nutritional availability of the cytosol has not been performed and may differ in different cell types. However, based on the observation that only cytosol-adapted pathogens can fully exploit the cytosol as a replication niche, it has been hypothesized that the cytosol is a nutrient-limiting environment (46, 47). The cytosol is a highly reducing (48), neutral pH environment (49) that is low in free amino acids (50) and free metal ions such as magnesium, sodium, calcium, and iron (51). Despite this nutrient-limiting environment, *L. monocytogenes* must acquire nutrients from its host to facilitate replication and must do so in a way that both promotes survival of the host cell and minimizes detection of the pathogen by the innate immune system (52, 53). In addition, *L. monocytogenes* has evolved a metabolic network that not only utilizes nutrients for replication but also integrates signals regarding nutrient availability to regulate virulence gene expression once inside the cell (39, 54–56).

Intracellular Carbon Metabolism

Carbon utilization is one of the most well-described aspects of *L. monocytogenes* cytosolic metabolism where hexose-phosphates and glycerol are the primary carbon sources scavenged from the host. Hexose-phosphates are acquired through the use of a dedicated permease Hpt (gene *uhpT*), which is both required for virulence (55) and directly regulated by the master virulence regulator, PrfA, upon entry into the host cytosol (57). Based on isotopologue metabolomic studies in infected cells, host-derived glucose-6-phosphate is primarily shunted into the pentose phosphate pathway, where it is used to build nucleotides and aromatic compounds but likely contributes little from an energy perspective (24). In contrast, glycerol, the second major intracellular carbon source for *L. monocytogenes*, is the primary energy source during intracellular replication (13). Glycerol does not significantly contribute to gluconeogenesis but, instead, feeds into lower glycolysis and the TCA cycle, and as such it is also used in *de novo* synthesis of some amino acids (13). As expected given its critical role in energy generation and anabolism, glycerol utilization mutants (*glp* and *dha* genes) are also attenuated and defective for intracellular replication (54, 58). Despite the key role of both glycerol and hexose phosphates in *L. monocytogenes* cytosolic metabolism, a combinatorial mutant that can use neither glucose-6-phosphate nor glycerol (Δ*C3*Δ*uhpT*) was still partially able to replicate in macrophages (13), albeit at significantly decreased levels, suggesting that alternative carbon sources are likely available during intracellular replication. Some evidence indicates that lactate, but not pyruvate, could be used as an additional carbon source during cytosolic replication, while amino acids are unlikely to be a major source of carbon and energy generation (13). *L. monocytogenes* lacks genes required for beta-oxidation of fatty acids, likely ruling fatty acids out as another potential carbon source for *L. monocytogenes* in the cytosol (2). However, the breakdown of phosphatidylethanolamine in mammalian membranes could liberate not only glycerol, but also ethanolamine (59, 60), which can be converted into acetaldehyde and ammonia by adenosylcobalamin-dependent ethanolamine lyase (encoded by *eut*) (17). Consistent with phospholipids contributing to carbon metabolism during cytosolic replication, *L. monocytogenes eut* mutants are defective for intracellular replication in epithelial cells (58). Thus, *L. monocytogenes* has diversified the carbon sources that it scavenges from the host cell, likely to promote host cell survival and prevent activation of innate immune defense mechanisms.

Despite the presence of *de novo* synthesis pathways for most amino acids, *L. monocytogenes* relies on both *de novo* synthesis and uptake of amino acids from the host for the promotion of full virulence. Specifically, during intracellular growth in macrophages, *L. monocytogenes* synthesizes *de novo* BCAA, histidine, and arginine, likely reflecting the shortage of these amino acids in the macrophage cytosol. Consistent with this observation, mutants deleted in genes central to these amino acid biosynthetic pathways exhibit intracellular growth defects (56, 58). Additionally, ^{13}C-isotopologue profiling of intracellular *L. monocytogenes* using ^{13}C-glucose demonstrated that *L. monocytogenes de novo* synthesizes many of the other amino acids during intracellular growth (e.g., Ala, Glu, Asp, Ser, Gly, Pro, Thr, and Lys) (13, 14, 24). Nevertheless, despite the importance of *de novo* synthesis, additional ^{13}C-isotopologue profiling with labeled amino acids clearly demonstrated that cytosolic *L. monocytogenes* also imports these amino acids from the host cell, along with most other essential and nonessential amino acids, and that these scavenged amino acids are directly incorporated into newly synthesized proteins with little to no catabolism (13). The one exception is aspartate, which is exclusively synthesized *de novo* (13), consistent with a previous observation that *L. monocytogenes* lacks the ability to take up exogenous aspartate (61). Further demonstrating the importance of amino acid scavenging for intracellular growth, mutants in cysteine, arginine, and glutamine transport systems are each impaired for intracellular replication and attenuated for virulence (61–63), while many other amino acid transporters have yet to be identified and/or characterized. For some scavenged amino acids the amounts required to support the growth of *L. monocytogenes* are consistent with their availability within the host cell cytosol (e.g., glutamine), while for others the requirement exceeds the actual availability (e.g., arginine, cysteine, and methionine) (64). It was therefore speculated that perhaps peptides are acquired from the host cell, where they are then degraded by aminopeptidases for utilization in protein synthesis (65, 66). Indeed, the ability of *L. monocytogenes* to acquire peptides was demonstrated *in vitro* (64, 67, 68), and several peptide transporters contribute to *L. monocytogenes* intracellular growth in macrophage cells or to infection of mice. Among these are the oligopeptide transporter

Lmo0135-0137 (CtaP), which is also associated with cysteine acquisition (3, 61, 69), the oligopeptide transporter OppABCDF (58, 61, 70, 71), and the di-tripeptide transporter, DtpT (72). In addition, the putative peptide transporter Lmo0152 is transcriptionally induced during intracellular growth and therefore may contribute to *L. monocytogenes* pathogenesis (6). Altogether, these studies establish that *L. monocytogenes* relies on both *de novo* synthesis and uptake of amino acids to support intracellular growth (13, 14, 24, 56, 73).

Intracellular Vitamin Metabolism

As previously noted, *L. monocytogenes* is auxotrophic for a variety of essential cofactors, including thiamine, lipoate, biotin, and riboflavin (10, 11), and must acquire them from the host. Biotin and riboflavin scavenging are likely mediated by the putative biotin (BioMNY) and riboflavin transporters (RibU and the ECF complex), respectively (74–76). Interestingly, although *L. monocytogenes* is unable to synthesize thiamine *de novo*, due to the absence of the 4-amino-hydroxymethyl-2-methylpyrimidine phosphate (HMP-P) synthase ThiC, provision of HMP-P/HMP *in vitro* facilitates growth of *L. monocytogenes* in the minimal media lacking thiamine. Furthermore, although the HMP transporter has not been definitively identified, both the thiamine transporter (ThiT) and enzymes for later *de novo* thiamine biosynthesis (ThiD) are required for intracellular replication (77), suggesting that, as is the case with many amino acids, *L. monocytogenes* must concurrently scavenge host-derived thiamine and synthesize additional thiamine from HMP to support robust growth. Finally, *L. monocytogenes* is also auxotrophic for lipoic acid and must acquire it from the host. Two nonredundant lipoate ligase enzymes are required for lipoylation of dehydrogenase complexes, including the pyruvate dehydrogenase complex, branched-chain α-keto acid dehydrogenase (BKD), and glycine cleavage pathway (78). LplA1 is likely the major lipoate host-scavenging enzyme active in the cytosol due to its higher affinity for lipoate (79) and its essentiality for virulence (78, 80). Ultimately, both the pyruvate dehydrogenase complex and BKD are required for virulence, likely explaining the essentiality of LplA1 *in vivo* (21, 81).

Intracellular Fatty Acid Metabolism

Fatty acid synthesis (FAS) is engaged during infection by many Gram-positive bacterial pathogens, due to its role in the biogenesis of phospholipid membranes, lipoproteins, and lipoteichoic acids (82, 83). The FASII pathway used by bacteria, plants, and parasites is structured such that each enzyme of the pathway is encoded by a separate gene that encodes for one protein responsible for the catalysis of a single enzymatic step (84). The initial condensation reaction of the FASII pathway involves short-chain fatty acid thioesters, typically acetyl-CoA and malonyl-ACP (85). This reaction is catalyzed by FabH, with subsequent rounds of condensation and acyl chain elongation catalyzed by FabF. The condensation reactions catalyzed by FabH and FabF result in the formation of β-ketoacyl-ACP products. These products are reduced by FabG to form β-hydroxyacyl-ACP and then dehydrated and reduced to acyl-ACP by FabZ and FabI to complete the cycle (85).

Several key aspects of fatty acid synthesis are relevant to the infectivity and pathogenesis of *L. monocytogenes*. The *L. monocytogenes* FabH enzyme exhibits selectivity toward ante-iso branched chain fatty acid (aiBCFA) precursors (86), resulting in a membrane that is highly enriched in aiBCFA. High aiBCFA content promotes increased membrane fluidity, conferring upon *L. monocytogenes* the unusual property of being able to replicate at refrigeration temperatures (87). Moreover, aiBCFAs contribute to *L. monocytogenes* stress resistance against antimicrobial host mechanisms, including lysozyme and cationic peptides (81). Methicillin-resistant *Staphylococcus aureus*, another Gram-positive pathogen, also displays similar membrane composition, enriched in aiBCFA (88). The high demand for aiBCFA precursors to populate the *L. monocytogenes* membrane results in a reliance on exogenously supplied BCAA, most notably isoleucine, which is the precursor for the predominant membrane BCFA species, despite the capacity for *de novo* synthesis of these amino acids. In defined medium and in the host cytosol, BCAA scavenging is critical for robust replication of *L. monocytogenes* (89). The lipoylated BKD complex is central to conversion of BCAA into the short branched chain thioesters that are the precursors for FASII and is required for virulence (90), likely due at least in part to decreased membrane stress resistance. Thus, *L. monocytogenes* intracellular metabolism is highly dependent on BCAA, particularly isoleucine, not only to provide building blocks for protein synthesis, but also for fatty acid synthesis, which confers resistance to membrane stress.

The Intersection between Metabolism and Virulence

In addition to fulfilling essential metabolic needs for optimal growth, the availability of metabolites such as amino acids and intracellular carbon sources also plays a key role in regulating virulence. As discussed above in the context of environmental PrfA repression, regulation of this essential master virulence regulator is mediated in large part by the presence or absence of carbon sources found in the cytosol of host cells. Both hexose-phosphates and glycerol promote full activity of PrfA, consistent with their function as the primary cytosolic carbon sources (54, 57). In contrast, metabolism of glucose and other PTS substrates not utilized for cytosolic replication actively inhibits PrfA activity, consistent with these PTS systems being dispensable for cytosolic replication (33, 39, 91). Inhibition of PrfA is not mediated by native sugars themselves; instead, one model suggests that uptake and metabolism of PTS sugars induces serine phosphorylation of the phosphocarrier protein Hpr (92) and that Ser-P Hpr directly inhibits PrfA activity (93). Other studies have not observed this effect and instead have proposed that PrfA is regulated by other components of the PTS system (54, 94). PrfA is also responsive to redox conditions in the host cytosol (95, 96), highlighting the importance of this virulence regulator as a key hub for integrating environmental cues with bacterial metabolism.

In addition to carbon source availability, *L. monocytogenes* regulates virulence in response to low BCAA availability and high availability of glutamine as occurs in the host cytosol (56, 62, 97). The response to BCAA is dependent on CodY, a global regulator and a sensor of isoleucine. Whereas under high BCAA conditions, isoleucine-bound CodY acts as a repressor of BCAA biosynthesis pathways, under BCAA-limiting conditions in the cytosol CodY-mediated repression of BCAA biosynthesis is alleviated and isoleucine-unbound CodY instead acts as a transcriptional activator of *prfA*, intimately coupling BCAA sensing to the regulation of virulence gene expression (97). Sensing of BCAA levels is not limited to host BCAA, because a recent study suggests that

BCAA *de novo* synthesis is restricted to sustain virulence gene expression (98). A riboregulator (Rli60), functioning as a ribosome-mediated attenuator, was identified upstream of the BCAA biosynthesis genes that persistently restricts BCAA biosynthesis, even under low BCAA conditions, essentially keeping *L. monocytogenes* starved for BCAA and thus ensuring PrfA expression in the low BCAA environment of the cytosol. In fact, Rli60 was found to be the reason for *L. monocytogenes* partial auxotrophy for BCAA, a phenotype that likely evolved to enable isoleucine to serve as a host signal and effector of virulence (98). In contrast, the mechanism by which L-glutamine regulates virulence gene expression is less clear, because its direct sensor in *L. monocytogenes* is not known, though GlnR is likely a good candidate (62). L-glutamine uptake by *L. monocytogenes* via GlnPQ triggers virulence gene expression only when the internal concentration of L-glutamine in *L. monocytogenes* crosses a certain threshold. Inactivation of GlnPQ arrested L-glutamine uptake and virulence gene expression and led to attenuation of virulence in mice (62). Finally, though not directly tied to PrfA regulation, arginine sensing mediated by the highly conserved ArgR arginine-responsive transcription regulator (99) represses the arginine biosynthesis genes (*arg*C*JBDF* and *arg*G*H*), as well as the arginine deiminase (ADI) pathway (i.e., the ADI genes *arc*A, *arc*B, and *arc*C), the latter of which is required for *L. monocytogenes* acid tolerance and intracellular survival (100, 101). Because both arginine biosynthesis and catabolism genes are regulated during intracellular growth, arginine sensing by ArgR likely plays a key role during *L. monocytogenes* infection (56, 58, 100, 101).

In addition to the classical central metabolic processes required for virulence, many secondary metabolic pathways and their metabolites contribute to virulence both through direct regulation of PrfA and through other, often unknown mechanisms. For example, *S*-adenosylmethionine (SAM) is a methionine precursor that regulates gene expression by binding to SAM-responsive riboswitches (102). The *L. monocytogenes* genome contains seven such riboswitches upstream of Cys-Met biosynthesis genes, which in all cases terminate gene transcription upon SAM binding. Consistent with the theme of tying metabolism to virulence regulation, the prematurely terminated transcripts (i.e., the SAM-bound RNAs) act *in-trans* on *prfA* 5′UTR (via base-pairing), downregulating its transcription specifically under nutrient-rich conditions (102). In contrast, glutathione, an abundant tri-peptide either synthesized by *L. monocytogenes* from cysteine, glutamate, and glycine or acquired directly from the host cytosol, where it is necessary for maintaining redox balance (103), is an allosteric regulator that can increase PrfA activity as much as 150-fold (104, 105). Additionally, glutathione posttranslationally regulates listeriolysin O via *S*-glutathionylation of its conserved cysteine residue, thus rendering it nonactive and minimizing listeriolysin O toxicity in the cytosol and promoting virulence (106). Shikimate biosynthesis, which generates precursors for the biosynthesis of aromatic amino acids (i.e., tyrosine, tryptophan, and phenylalanine), is essential for *L. monocytogenes* intracellular growth (56, 107). However, shikimate biosynthesis is also needed for the generation of both menaquinone (MK) and its biosynthetic precursor 1,4-dihydroxy-2-naphthoate (DHNA), which are also both independently necessary for virulence (21). *L. monocytogenes* genes for the electron transport chain, including genes for MK biosynthesis (*men*) and *L. monocytogenes* cytochrome *bd* and aa_3 oxidases, are induced in cell culture and *in vivo* (6, 70), consistent with a role for the electron transport chain and generation of a membrane potential during infection (21, 66, 107). As discussed previously, utilization of glycerol as a primary energy source requires ATP synthesis through oxidative phosphorylation, at least partially explaining the requirement for MK for virulence. However, the electron transport chain has also been implicated in redox balance (108), oxidative/nitrosative stress responses (109), subcellular localization of cell division machinery (110), nucleotide biosynthesis (111), and solute transport of betaine/carnitine (112) in other bacteria. As such, the requirement for shikimate biosynthesis for virulence is complicated and likely multifactorial, because even the role of MK in infection is not straightforward. To add complexity to ascribing virulence functions to metabolic pathways, it was recently reported that the MK biosynthetic intermediate 1,4-dihydroxynaphthoate (DHNA), is required for virulence and survival in the cytosol independent of full-length MK (21), further emphasizing that the complex portfolio of intermediate products generated through metabolism may be a rich source for signaling and virulence regulation during infection.

Bacterial Metabolism and the Host Immune Response

The metabolic potential of bacterial pathogens such as *L. monocytogenes* is robustly adapted to promote survival and replication within the host, but the highly conserved nature of many products of bacterial metabolism presents an Achilles heel that can be recognized by the host immune system. The capability of the innate immune system to sense microbial ligands has been extensively reviewed elsewhere (113), with the most well-studied paradigm being recognition of bacterial products such as lipopeptides by the Toll-like receptors. However, studies over the past two decades have revealed a surprisingly diverse repertoire of sensing mechanisms within the mammalian host cytosol that are responsive to bacterial virulence factors and metabolites. A striking example is host recognition of the bacterial metabolite, cyclic di-AMP, a cyclic dinucleotide that controls growth, cell wall homeostasis, and virulence (114). *L. monocytogenes* secretion of cyclic di-AMP through multidrug transporters into the host cytosol enables recognition of this bacterial metabolite by a host protein, STING, and then triggering of upregulation of type I interferon and the interferon response (115–117). A recent study suggests that there is a richer diversity of cyclic nucleotides produced by bacteria than previously suspected (118). While only a few *L. monocytogenes* metabolites have been established as ligands for cytosolic pattern recognition, the evolutionary conservation of many metabolic functions implicates these molecules as likely targets for the innate immune system. Evidence points to host recognition of chemically distinct metabolites from other bacterial species, including citrate, heptose-1-7-bisphosphate, and ADP-heptose (53, 119, 120). Thus, bacterial pathogens must evolve to navigate a fine balance between fully exploiting the host niche for nutrients and their visibility to the host immune system through the by-products of their own metabolism.

SECTION 5

Spore-Forming Pathogens

Section Editor: **Julian I. Rood**

Pathogenic bacteria that belong to the *Clostridium* and *Bacillus* genera cause classical diseases, many of which were recognized well before the advent of the science of microbiology and what we now regard as modern medicine. These syndromes were known before the germ theory of disease had been verified and before the concept of spontaneous generation had been disproved. Their analysis has provided some of the paradigm formative studies in microbiology, such as the demonstration by Koch in 1877 that *Bacillus anthracis* was the causative agent of anthrax and the identification of tetanus toxin in 1889 by Kitasato.

In recent years research on these bacterial pathogens has advanced dramatically as a result of multidisciplinary studies involving microbial genetics, bacterial pathogenesis, structural biology and microbial genomics. The crystal structures of key toxins have been elucidated as well as the genetic organization of genes encoding numerous virulence factors and the determination of their functional role in disease pathogenesis. These are exciting times for research on these classical bacterial diseases and other diseases that have been recognized more recently. Wherever possible, the chapters in this edition have been expanded and

reorganized to include recent research that has significantly increased our understanding of fundamental biological processes and disease pathogenesis.

The chapters in this section are organized on the basis of the mechanism of pathogenesis rather than the bacterial species. These diseases all involve the elucidation of powerful protein toxins. Irrespective of which bacterium produces these toxins, they primarily affect either the nervous system or the gastrointestinal tract or cause diseases that involve extensive tissue damage and necrosis. Therefore, it was considered that a more coherent understanding of the pathogenesis of these diseases would result from having separate system-based chapters that discussed the various types of infections. The increasing importance of *Clostridioides* (formerly *Clostridium*) *difficile*-mediated infections, and the depth of research in this field, has been recognized by splitting the previous enterotoxemic infections chapter into two, one dealing exclusively with *C. difficile* infections. The importance of genetic tools for the development of our understanding of clostridial diseases and of plasmids and spores in the dissemination of clostridial toxin genes has warranted separate chapters on these topics, along with a separate chapter on clostridial genomics. By contrast, a different approach has been taken for the discussion of *Bacillus*-mediated infections, with these aspects discussed in a single integrated chapter.

The *Bacillus cereus* Group: *Bacillus* Species with Pathogenic Potential

MONIKA EHLING-SCHULZ, DIDIER LERECLUS AND THERESA M. KOEHLER

55

TAXONOMY: HISTORICAL AND SOCIOECONOMIC ASPECTS

The microorganisms constituting the *Bacillus cereus* group are Gram-positive low-GC-content bacteria belonging to the phylum *Firmicutes*. The group of spore-forming, aerobic, facultative anaerobic, rod-shaped bacteria comprises at least eight closely related species: *B. anthracis*, *B. cereus*, *B. thuringiensis*, *B. mycoides*, *B. pseudomycoides*, *B. weihenstephanensis*, *B. cytotoxicus*, and *B. toyonensis* (1). With the exception of *B. cytotoxicus*, which is the most divergent of the group, with a chromosome of 4.085 Mb (2), the genomes of the *B. cereus* group species are highly conserved, with sizes of 5.2- to 5.9-Mb and very similar 16S rRNA gene sequences.

The definition of these species and the distribution of the strains within them were based on phenotypes and their clinical and economic significance and mainly associated with plasmid content (3, 4). *B. anthracis* harbors two plasmids, pXO1 (182 kb) and pXO2 (95 kb), carrying the structural genes for the toxin proteins and the biosynthetic genes for capsule formation, respectively (5). The emetic *B. cereus* strains harbor plasmid pCER270, encoding enzymatic components required for the nonribosomal biosynthesis of the toxin cereulide (6, 7). *B. thuringiensis* harbors several plasmids encoding a large variety of the insecticidal toxins Cry and Cyt, which form the parasporal crystal characteristic of the species (8–10). The other five species are discriminated by morphological or physiological traits. *B. mycoides* and *B. pseudomycoides* have typical rhizoid growth (11, 12). *B. weihenstephanensis* strains are psychrotolerant. Like the mostly mesophilic members of the *B. cereus* group, the optimal growth temperature for *B. weihenstephanensis* is between 25 and 35°C, but the species is distinguished by its ability to grow at temperatures as low as 4°C (13). On the other hand, *B. cytotoxicus* strains are thermotolerant and can grow in up to 50°C (14). Finally, *B. toyonensis* was characterized for probiotic properties and is used as such in animal feed (15).

Speciation based on plasmid content and on morphologic or certain physiological features is confusing and can result in subjective conclusions. A recent genomic analysis of 224 strains shows that the *B. cereus* group can be divided into 5 major clades which do not match the 8 species described above (see Fig. 1). This lack of congruence between genomic-based phylogenetic analysis and specific phenotypes leads to the conclusion that plasmids carrying toxin genes such as the pXO plasmids of *B. anthracis* and the *cry* plasmids of *B. thuringiensis* cannot serve as signatures for species identification (1). As proposed by Helgason and colleagues (16) and by Rasko and coworkers (4), it is more useful to consider the *B. cereus* group a unique species comprising extremely diverse strains whose properties differ due to plasmid content or gene expression associated with key regulatory genes. For example, the global transcription regulator PlcR is active in *B. cereus* and *B. thuringiensis* but inactive in *B. anthracis*, abolishing the expression of a major regulon in that species (17, 18).

While it is arguably appropriate to refer to members of this highly related group of bacteria as *B. cereus* subsp. *cereus*, *B. cereus* subsps. *anthracis*, *B. cereus* subsp. *thuringiensis*, etc., in keeping with current practice, we will refer to the individual subspecies by their traditional names. We focus here on *B. anthracis*, *B. cereus*, and *B. thuringiensis* because of the abundance of research related to their clinical and socioeconomic importance. We first present some unique and overlapping traits of these bacteria.

B. anthracis

B. anthracis, a major scourge of humanity, was first characterized by Koch and Pasteur as the etiologic agent of anthrax. Their investigations of this bacterium in the late 19th century represented early breakthroughs in microbiology and vaccination. Koch's postulates, criteria designed to establish specific causal relationships between microbes and diseases, were based on studies of *B. anthracis*. In addition, an attenuated strain of *B. anthracis* served as the first live bacterial vaccine (19, 20).

Historically, strains harboring pXO1 and/or pXO2 were designated *B. anthracis*. However, recent reports of closely related species harboring similar plasmids indicate that speciation can be complex. *B. cereus* strains that harbor pXO1- and pXO2-like plasmids, named *B. cereus* bv. anthracis, have been isolated as the causative agents of anthrax-like infections in primates in Cameroon and Côte d'Ivoire (21, 22). Similar *B. cereus* strains that produce the anthrax toxins were identified as the etiological agents of an anthrax-like cutaneous infection and anthrax-like respiratory infections in metalworkers (23–27). The well-studied *B. cereus* strain G9241, isolated from a welder with a severe anthrax-like

doi:10.1128/microbiolspec.GPP3-0032-2018

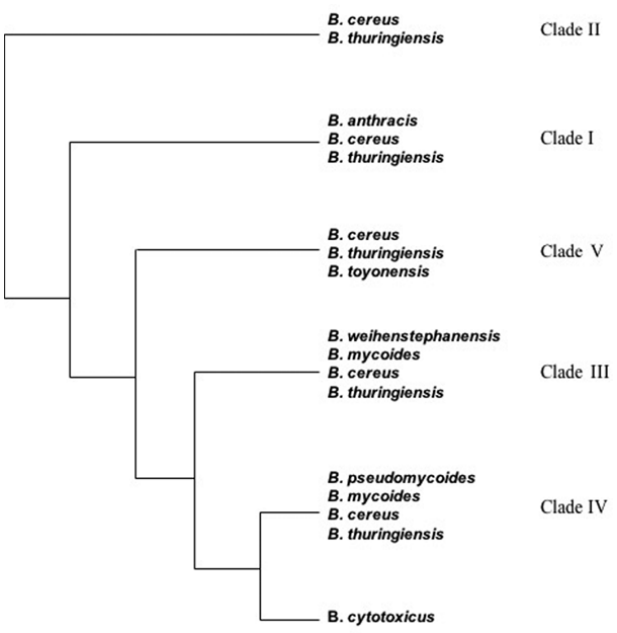

FIGURE 1 The five major phylogenetic clades of the *B. cereus* group. Clade I is known as the *B. anthracis* clade but also includes emetic *B. cereus* and several clinical *B. thuringiensis* isolates. Clade II is known as the *B. cereus*/*B. thuringiensis* clade and includes most of the commercially used *B thurigiensis* as well as the *B. cereus* and *B. thuringiensis* type strains. Clade III is known as the *B. weihenstephanensis* clade and comprises most of the psychrotolerant isolates of the *B. cereus* group. Clade IV includes strains belonging to various *B. cereus* group species. These clades are based on multilocus sequence typing, amplified fragment length polymorphism, and whole-genome sequence data (429–431). The thermotolerant strains belonging to the species *B. cytotoxicus* cluster together in a separate group.

respiratory illness, contains two virulence plasmids, pBCXO1 and pBC210 (also known as pBC218), as well as pBClin29, a linear plasmid that harbors cryptic prophage genes. The plasmid pBCXO1 has high similarity to pXO1 and contains the toxin genes *pag*A, *lef*, and *cya*, encoding toxin proteins with amino acid sequences of 96% or greater identity to their counterparts in *B. anthracis* (24). Plasmid pBC210 encodes a toxin protein paralogue, PA2, and the novel ADP-ribosyltransferase certhrax (24, 28–30). Each plasmid contains genes required for synthesis of a unique polysaccharide capsule; the enzymes needed for hyaluronic acid capsule production are encoded by the *has*ACB operon on pBCXO1, and the proteins required for elaboration of a putative tetrasaccharide capsule are encoded by the *bps* locus on pBC210 (24, 31). Interestingly, although *B. cereus* G9241 and *B. anthracis* Ames both produce capsule(s) and the anthrax toxin proteins, the virulence of G9241 in rabbits is more similar to that of *B. anthracis* Sterne strain 34F2 (pXO2$^-$), which produces the toxins but not capsule (32).

B. cereus

B. cereus was first isolated from air in a cow shed and was characterized as a highly motile bacterium, generally appearing as single cells but occasionally forming longer threads and causing rapid liquefaction of gelatin (33). In the second half of the 20th century, *B. cereus* was recognized as a common food contaminant responsible for two types of poisonings. More recently, *B. cereus* has been increasingly recognized as an etiological agent of localized wound and eye infections as well as systemic infections (34, 35).

In the 1950s, Hauge showed that consumption of *B. cereus*-contaminated vanilla sauce could cause diarrhea (36). Since Hauges' remarkable discovery, two protein toxin complexes (Nhe and Hbl) and a single-protein toxin (CytK) have been described, which are generally thought to contribute to the diarrheal type of food poisoning (37). More recently, several exoproteins with enzymatic activities, such as proteases or phospholipases, have been discussed as putative virulence factors contributing to the diarrheal syndrome (38, 39). Notably, these diarrhea-associated known and putative virulence factors are encoded by chromosome genes. In contrast, genes encoding the biosynthetic machinery for production of the depsipeptide toxin cereulide, which is the causative agent of the emetic type of *B. cereus*-mediated food poisoning, are on the 270-kb megaplasmid pCER270 (35). In contrast to the enterotoxin genes, which are broadly distributed among the members of the *B. cereus* group and show a high degree of molecular diversity (40), the cereulide synthetase gene is restricted to genetically closely related strains and shows rather low molecular diversity (41, 42). The ecological and evolutionary mechanisms driving the diversification processes of *B. cereus* virulence were hitherto poorly understood.

B. thuringiensis

B. thuringiensis was first isolated in 1901 in Japan from infected silkworm larvae (*Bombyx mori*). The bacterium was identified as the causal agent of the sotto disease (sudden-collapse disease), a lethal infection of this economically important insect (43). Subsequently, Berliner isolated the bacterium from the cadavers of flour moth larvae (*Ephestia kuehniella*) collected in a mill in Thuringia (44) and named it *Bacillus thuringiensis*, after the German province.

Based on its entomopathogenic properties, *B. thuringiensis* was rapidly commercialized and used as a biopesticide for pest control. The insecticidal activity spectrum of the bacterium was initially thought to be restricted to a few lepidopteran species. However, in 1977 discovery of the israelensis strain of *B. thuringiensis*, which is active against mosquitoes (45), accelerated a search for additional strains active against several species of insects and other invertebrates.

Today, a large number of strains have been shown to have activity against coleopteran insects or nematodes (46, 47). *B. thuringiensis*-based biopesticides account for approximately 75% of the global bioinsecticide market, representing about 4% of global insecticides (48). Several thousand *B. thuringiensis* strains have been shown to form crystalline Cry protein inclusions during sporulation, which in many cases are key to the insecticidal or nematicidal activity of the bacteria. However, not all *B. thuringiensis* isolates that produce Cry proteins have been found to be toxic. It is possible that some Cry proteins are inactive or have unidentified target hosts.

All the insecticidal toxin genes (*cry*, *cyt*, and *vip*) of *B. thuringiensis* are located on large plasmids (9, 49, 50). Generally, these plasmids are conjugative (51), and the *cry* genes are frequently found in the vicinity of various mobile genetic elements, such as the transposon Tn*4430* and the insertion sequences IS*231* and IS*232* (8, 52, 53). The localization of the insecticidal toxin genes on elements associated with horizontal gene transfer is likely responsible

for the great diversity of these genes and their multiplicity within the *B. thuringiensis* strains.

ECOLOGY: ENVIRONMENTS AND PATHOGENICITY

The *B. cereus* group species are endemic soil bacteria that occupy diverse ecological habitats as depicted in Fig. 2 (41, 54). Due to the formation of heat-, UV-, acid-, and desiccation-resistant endospores, the bacteria can persist in a dormant state, making it difficult to elucidate their primary ecological niches. In addition to soil, the species have been isolated from fresh and stored foods, invertebrates, and plants (55–60). Some reports suggest that the *B. cereus* group species do not germinate and grow in nonsterile soils unless a nutrient source, such as decomposing plants, insects, or animals is present (61–64). Reports of the isolation of *B. cereus* associated with plants may even point toward an endophytic lifestyle as an alternative niche for *B. cereus* (65, 66). Due to their ubiquitous presence, these organisms are hard to control and can enter food production and processing at various points (Fig. 2). Certain *B. cereus* strains have been reported to promote plant growth and to suppress plant diseases (67, 68). Recently, it was reported that the *B. cereus* AR156 strain induces systemic resistance to *Pseudomonas syringae* pv. tomato in *Arabidopsis thaliana* (69), suggesting that plant rhizospheres represent a natural niche for *B. cereus*.

Genome and physiology studies revealed that unlike true soil microorganisms, bacteria of the *B. cereus* group have few genes involved in the degradation of carbohydrate polymers. Conversely, these species contain a wide arsenal of genes encoding extracellular factors such as degradative enzymes (phospholipases, proteases, and chitinases), cytotoxic proteins (hemolysins, enterotoxins, and cytotoxins), and cell surface proteins (70, 71). These factors are potentially involved in the virulence and propagation of the bacteria in an animal host, thus conferring an obvious pathogenic lifestyle to the species (72). Outside of their hosts, the *B. cereus* group species are generally considered to reside as spores. Nevertheless, it is likely that the bacteria undergo some cycling of saprophytic growth, sporulation and germination in the soil. Epidemiological studies of clinical and nonclinical isolates suggest loss and horizontal movement of plasmids (22, 73–75).

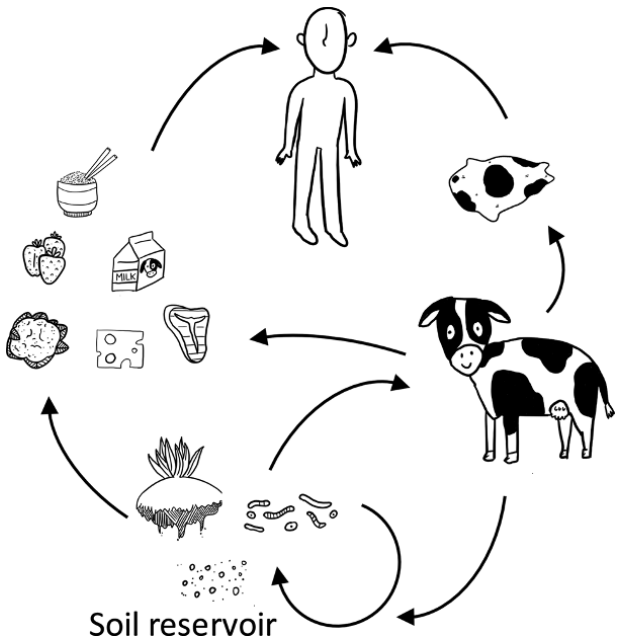

FIGURE 2 Transmission of the *B. cereus* group species from the soil reservoir to humans via food and textile production. Soil and soil-associated organisms including plants, insects, nematodes, and amoebae, serve as the major reservoirs for acquisition of spores. The bacteria are transferred to humans through agricultural products including food and animal-associated textiles, entering humans and other mammals through ingestion, inhalation, and breaks in the skin. Illustration credit: Olive E. Morrison.

The ecology of *B. thuringiensis* remains unclear despite multiple investigations (54, 76), and *B. cereus* ecology is even less explored (66). Studies of *B. anthracis* ecology have been fueled by the severity and worldwide occurrence of anthrax disease. *B. anthracis* can infect all mammals, some birds, and possibly even reptiles. The most severely affected parts of the world are central Asia and western areas of Africa. An "anthrax belt" exists from Turkey to Pakistan. In North America, anthrax is endemic in northern Alberta and the Northwest Territories. In the United States, sporadic outbreaks of anthrax occur in northwest Mississippi/southeast Arkansas and western Texas. The disease is also endemic throughout Mexico, Central America, and many South American countries. "Anthrax seasons" are characterized by hot dry weather which stresses animals and reduces their innate resistance to infection. Data from studies of central Asia support seasonal outbreaks, with the largest number of cases occurring in late summer (77, 78).

The prevalence of *B. anthracis* spores in the soil is affected by mean annual temperature, annual precipitation, elevation, amount of vegetation, soil moisture content, and soil pH (77, 78). Multiplication of *B. anthracis* outside of the host has been controversial. Concentrations of spores following disease outbreaks are thought to result from rains that pool spores in low-lying areas, as opposed to bacterial proliferation. Decomposition of infected animals at anthrax carcass sites leads to increased numbers of vegetative cells, but ultimately the numbers decrease as cells sporulate or die (79). Some studies suggest that *B. anthracis* competes poorly against indigenous bacteria; however, germination and amplification of anthrax spores by soil-dwelling amoebas and in the context of the plant rhizosphere have been reported (63, 80).

Humans and scavenging animals acquire gastrointestinal (GI) anthrax by ingesting spores in meat from infected animals, while wild and domestic herbivores ingest or inhale *B. anthracis* spores from the soil while grazing (81). Acquisition of spores from water appears to be less common (82). The infectious dose and severity of disease vary widely in different hosts. Domestic livestock, including sheep and cattle, and wild herbivores, such as bison, elephants, hippopotami, and kudu, are particularly susceptible to infection (83).

Inhalation anthrax in humans, also known as woolsorter's disease, was once common among textile workers who inhaled spores in dust generated from contaminated wool and animal hides. Today, most naturally acquired human cases of anthrax are cutaneous infections resulting from contact with dead infected animals or their products. Intentional dissemination of *B. anthracis* spores occurred in the United States in 2001. Eleven inhalation and eleven cutaneous cases of anthrax in humans were traced to four envelopes containing *B. anthracis* spores in powder form. The envelopes were sent to different locations via the U.S. Postal

Service, and most of the patients were either mail-handlers or were exposed at worksites where contaminated letters were processed or received. Others are thought to have been exposed to cross-contaminated mail (84). This tragic event demonstrated the apparent ease with which the organism can be dispersed and solidified the placement of *B. anthracis* on the list of biothreat agents.

B. anthracis: the Anthrax Pathogen

Systemic anthrax, generally resulting from inhalation or ingestion of *B. anthracis* spores, has a high fatality rate. When *B. anthracis* spores are inhaled, alveolar macrophages and dendritic cells transport the organism to the proximal lymph nodes. Following spore germination, vegetative cells produce the antiphagocytic capsule and the anthrax toxin proteins, virulence factors which are critical for initiation of systemic disease (85, 86). In humans, bacteremia begins after an asymptomatic incubation period of 1 to 6 days. Following the onset of bacteremia, patients can experience flu-like symptoms for 1 to 5 days prior to an acute disease stage that lasts 1 to 2 days. Ultimately, death results from respiratory failure, sepsis, and shock (84, 87).

B. anthracis virulence is attributed primarily to production of anthrax toxin and capsule. The toxin structural genes and capsule biosynthesis genes are encoded by plasmids pXO1 and pXO2, respectively, and both plasmids are required for full virulence in immunocompetent hosts. The tripartite anthrax toxin, which comprises three secreted proteins—protective antigen (PA), edema factor (EF), and lethal factor (LF)—has been the focus of investigations of anthrax disease. PA facilitates entry of EF and LF into host cells. EF is a calmodulin-dependent adenyl cyclase, and LF is a zinc protease. Together, the toxins disable the host's innate and adaptive immune systems to induce lethal disease (88, 89).

The poly-γ-D-glutamic acid (PGA) capsule of *B. anthracis*, provides protection of the bacterium from phagocytosis, as is true for many bacterial capsules which are more commonly made of polysaccharide. High concentrations of capsule released from *B. anthracis* cells during infection are important also for host-pathogen interactions (90–93). The PGA capsule has been shown to augment lethal toxin-mediated cytotoxicity and induce production of inflammatory cytokines and nitric oxide, which likely contribute to systemic inflammation and sepsis at the terminal stage of infection (94–97).

In addition to toxin and capsule, other secreted and nonsecreted factors have been reported to affect host-pathogen interactions and affect host pathology (98, 99). Among these are extracellular proteases that interfere with the immune response by cleaving antimicrobial peptides (100). The proteases NprB/Npr599 (also designated NprA in *B. thuringiensis* and *B. cereus*) and InhA1 can degrade host tissues, resulting in increasing barrier permeability (101–103). Crossing of the brain barrier is considered to be key to the extensive brain pathology that has been reported for human disease (104).

B. cereus and Gastrointestinal Disease

B. cereus pathogenicity is based on a panoply of virulence factors, which are far from understood, contributing to a range of human disease. *B. cereus* can cause two types of food poisoning, which are primarily characterized by diarrhea and emesis (37, 105, 106). The diarrheal syndrome has been linked to different enterotoxins thought to be produced after outgrowth of spores, taken up with contaminated foods, and active in the small intestine. The emetic syndrome is the result of an intoxication caused by the single depsipeptide toxin cereulide, which is preformed in food. The genes encoding the cereulide synthetase toxin genes are primarily found in a distinct subgroup of *B. cereus*, while the enterotoxin genes are broadly distributed among the members of the *B. cereus* group (41, 107). Usually, these GI-related diseases are self-limiting, but more severe forms require hospitalization, and occasionally fatalities have been reported (58, 108, 109). Intoxication related to cereulide has been linked to severe clinical manifestation, such as acute liver failures and acute encephalopathy (110). Due to the high biological activity of the cereulide toxin, occasionally liver transplantation is necessary as a life saving measure (111, 112). Generally, the pathogenic potential of *B. cereus* strains is highly variable and ranges from strains that show no cytotoxic activity in cell culture assays to strains that are highly cytotoxic (113, 114). In addition to intrinsic strain-associated differences in pathogenic potential, virulence is affected by environmental factors (58, 115, 116).

Apart from its food poisoning potential, *B. cereus* is increasingly recognized as an opportunistic pathogen that can cause local as well as systemic infections. Immunocompromised people and neonates are at special risk for hospital-acquired *B. cereus* infections, such as infections of the central nervous system, endocarditis, respiratory and urinary tract infections, wound infections, and septicemia (34). Outside of hospital-acquired infections, *B. cereus* has been linked to eye infections, such as endophthalmitis and keratitis (117). Furthermore, *B. cereus* can cause severe mammary gland infections in ruminants (118, 119). The virulence factors contributing to infections in ruminants and to most non-GI-related human infections are unknown.

B. thuringiensis Infection of Invertebrates

In addition to virulence genes common to the *B. cereus* group and to specific insecticidal toxin genes, the *B. thuringiensis* genome contains several genes encoding chitinases, suggesting a close relationship between this bacterium and the insects. Many well-studied *B. thuringiensis* strains were isolated from insects (44–46), and large screens of natural environments have shown that insects were more fruitful sources of the bacterium than soil samples (120). About 40% of the invertebrates tested were found to harbor *B. thuringiensis* spores. While insects appear to be the preferred target of *B. thuringiensis*, the bacterium can propagate in other invertebrates (121, 122). Nematode-*B. thuringiensis* association is highly probable in soil and other natural environments, and several *B. thuringiensis* strains harbor *cry* genes that are specifically active against nematodes (123). When nutrients are available, *B. thuringiensis* might be a multihost pathogen (124) with two pathogenic lifestyles: one resulting from its specific toxins (Cry or Vip) encoded by plasmid genes and targeting insects, nematodes, and other invertebrates (49, 125) and one nonspecific, depending on various chromosomal factors providing opportunistic properties. These nonspecific factors may allow the bacteria to propagate and eventually to kill various organisms if they are weakened by any cause, for example, by Cry toxins in the case of insects (126). This second pathogenic lifestyle may be shared with *B. cereus*, which possesses the same chromosome-encoded virulence factors (70). In this point of view, the Cry toxins of *B. thuringiensis* are "public goods" which can act cooperatively and thus profit cheater bacteria such as *B. cereus* (127).

The genome of *B. thuringiensis* contains a 41-gene regulon devoted to its saprophytic or necrotrophic lifestyle (128).

This regulon, which includes genes encoding various degradative enzymes, is activated by the quorum sensing regulator NprR and allows *B. thuringiensis* to survive in the insect cadaver. The NprR regulon is also transcribed in all other *B. cereus* group species, suggesting that the bacteria of this group have similar saprophytic properties (129). Altogether, these pathogenic and saprophytic functions are highly efficient adaptive traits that allow the species to grow and survive in various natural conditions and niches.

CELL STRUCTURE AND DEVELOPMENT

Vegetative cell and spore structures do not vary greatly among the *B. cereus* group species. Generally, vegetative cells appear in chains, with the square ends of the cells fitting closely together. Variations in chain length occur as a normal aspect of growth in different media and environments (34, 130). Interestingly, *B. anthracis* vegetative cell chains in infected tissues are generally shorter than those formed during growth *in vitro*. Chaining of *B. anthracis* cells impedes invasion of host cells and is associated with escape from phagocytic clearance (131). Spores of the three species also have similar morphology. Spore size and morphology can vary between strains of the same species, but most strains produce spores with diameters of approximately 1 μm that are surrounded by a loose-fitting outer layer termed the exosporium (Fig. 3). Fine features of spores can be altered in different growth and sporulation conditions.

Vegetative Cell Envelope

The surface of *B. anthracis*, including secondary cell wall polysaccharides (SCWPs), the surface layer (S-layer), and capsule, has been the most well studied of the *B. cereus* group species. The *B. anthracis* SCWP comprises trisaccharide repeats [→4(-β-ManNAc-(1→4)-β-GlcNAc-(1→6)-α-GlcNAc-)1→] with α-Gal and β-Gal substitutions tethered to the peptidoglycan by acid-labile phosphodiester bonds. SCWP is essential for cell growth, shape, and division.

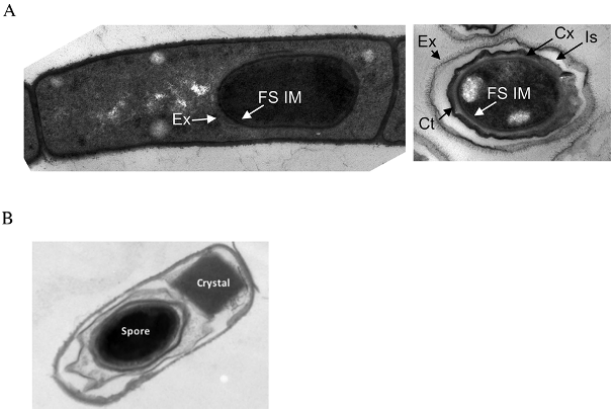

FIGURE 3 (A) Thin-section transmission electron micrograph of *B. anthracis* cell after 5 hours of sporulation (left image) and a mature spore (right image). The forespore inner membrane (FS IM) and nascent exosporium (Ex) (left image), and forespore inner membrane (FS IM), mature exosporium (Ex), coat (Ct), interspace, (Is), and cortex (Cx) (right image) are labeled. (B) *B. thuringiensis* sporulating cell with parasporal crystal. Cells were sporulated, prepared, and imaged as described in reference 432. Image credit: (A) Tyler Boone and Adam Driks. (B) Fuping Song.

Although the enzymes for SCWP synthesis have not been fully characterized, two proteins, WpaA and WpaB, have been proposed as glycosyltransferases that act to assemble the SCWP polymers prior to attachment to the peptidoglycan. The *B. anthracis* SCWP is critical for maintenance of cell shape and for full virulence. Depletion of the glycosyltransferases results in irregularly shaped, nonviable cells (132). In addition, a mutant lacking a UDP-glucose 4-epimerase required for SCWP galactosylation exhibited reduced encapsulation and decreased virulence in a murine model of anthrax (133). Recent investigations of *B. cereus* isolates causing anthrax-like disease indicate SCWP with a structure similar to that of *B. anthracis* but with an additional α-Gal substitution at O3 of *N*-acetylmannosamine (134).

In *B. anthracis* and some pathogenic *B. cereus* strains, S-layer proteins have been shown to attach to the cell wall via noncovalent interactions with SCWPs (135). The S-layers are paracrystalline arrays of protein that serve as protective barriers and as scaffolds for housekeeping enzymes and virulence factors (136). Major S-layer proteins of *B. anthracis* are Sap (for surface associated protein) and EA1 (for extractable antigen 1). Fully assembled and acetylated SCWP is important for assembly of some S-layer proteins. Mutants deleted for putative acetyltransferases are unable to deposit the S-layer-associated murein hydrolase BslO at cell division septa and have altered chain lengths (137).

Finally, a key distinguishing feature of *B. anthracis* is its capsule. The *B. anthracis* capsule comprises PGA. As is true for typical polysaccharide capsules, the *B. anthracis* capsule protects cells from phagocytosis during infection. In addition, the *B. anthracis* capsule renders the bacterium somewhat resistant to mammalian proteases and is a poor immunogen (138, 139). An immunoassay for PGA using monoclonal antibodies has revealed that PGA is shed into the blood during infection of mice and nonhuman primates (91, 140, 141), likely due to the activity of a capsule depolymerizing enzyme, CapD, that is coexpressed with the capsule biosynthesis operon. The capsule degradation products are thought to inhibit the innate immune response through targeting of cytokine pathways (142).

The PGA capsule is also produced by some but not all *B. cereus* isolates that cause anthrax-like disease. These strains harbor plasmids that allow strain-specific differences in synthesis of the PGA capsule, a hyaluronic acid capsule, and a tetrasaccharide capsule. The results of virulence studies to assess the role(s) of the *B. cereus* capsules are somewhat contradictory and incomplete (22, 24, 31, 75). Further investigations are needed to determine the specific functions of these capsules.

Spore Architecture

The architecture of the *B. cereus* group species spore is comparable to the spores of other *Bacillus* species. The innermost compartment of the spore contains the DNA. The DNA is housed with cations and pyridine-2,6-dicarboxylic acid in a 1:1 chelate with divalent calcium ions, which serve to maintain the spore's dormant state and resistance to DNA-damaging agents. Germinant receptors in the inner membrane initiate the signal transduction pathway that leads to outgrowth of the spore and the vegetative cell state (143). Germinants of the *B. cereus* group species can be a subset of sugars, amino acids, and ribonucleosides, as well as other small molecules, depending on the species and strain (144). A shell of peptidoglycan containing two sublayers, the cortex and the germ cell wall, surrounds the inner membrane. The cortex constricts the core's volume to retain the relatively dry

state of the core. At outgrowth of the spore, the germ cell wall becomes the nascent cell wall of the vegetative cell. Surrounding the cortex is the spore coat, which contains approximately 70 proteins arranged in layers to form a somewhat flexible structure (143).

The exosporium, an additional layer surrounding the spore coat of some *Bacillus* species that has been most well studied in *B. cereus* and *B. anthracis* (145), can respond to changes in spore hydration. The exosporium comprises a crystalline basal layer overlaid by a "hairy nap." The composition and assembly process of the exosporium are poorly understood. BclA and related proteins form the hairy nap. Among the approximately 20 proteins of the basal layer is ExsY, which can self-assemble into structures resembling the intact basal layer and thus appears to be a key player in exosporium formation (146). The exosporium excludes large molecules. It also provides resistance to specific chemicals *in vitro* and to nitric oxide in the context of the macrophage (147–149). Removal of the exosporium from *B. anthracis* spores does not impede virulence in several animal models (150–152). However, the exosporium protein BclA binds macrophage receptors to mediate interactions with epithelial cells and extracellular matrix proteins (153, 154), suggesting a role for the exosporium in pathogenesis (145).

Germination Dynamics and Signals

The overall process of germination, in which spores transition to metabolically active vegetative cells, is highly conserved in the *Bacillus* genus, but the specific signals and associated receptors vary among species. *B. anthracis* germinates in response to alanine or purine ribonucleotides, with one or more additional amino acids acting as cogerminants (155–157). Many germinant receptors have been described in the inner membrane of *Bacillus* species. Notably, a unique set of germination genes, the *gerX* operon, is located on pXO1 of *B. anthracis*. Mutants missing the operon are altered for germination *in vivo* (158, 159). Once *Bacillus* spores germinate, spore cortex lytic enzymes degrade the cortex peptidoglycan, allowing core rehydration and cell outgrowth (160). *B. anthracis* differs from other species examined in that it contains an additional spore coat lytic enzyme which appears to work synergistically with the common enzymes (161).

Germination in the Host

Multiple routes of infection with *B. anthracis* spores lead to disease, suggesting that germination can be triggered by signals in different host niches. Studies of *B. anthracis* germination *in vivo* have yielded intriguing results. Inhalation anthrax models have shown that phagocytes and dendritic cells phagocytose spores and transport the bacteria to the lymph nodes (162, 163). Spores and vegetative cells appear in phagocytic cells, but it is unclear whether spores germinate before or after phagocytosis. Moreover, some strains germinate quickly in the lung, while others remain ungerminated for days (164, 165), suggesting that germinants plus additional unknown factors influence development *in vivo*. Finally, germination occurs in cell-free macrophage-conditioned media, indicating that phagocytes are not required for *B. anthracis* spore germination (157).

Studies of *B. thuringiensis* germination include experiments simulating conditions encountered in the insect midgut. The pH of the lepidopteran midgut is 10, and pretreatment of *B. thuringiensis* spores with larval midgut fluid or with an alkaline buffer stimulates germination (166, 167). This alkaline activation of spores requires plasmid-encoded germination genes (168). Cry proteins associated with the spore surface allow *B. thuringiensis* spores to bind brush border membrane vesicles prepared from lepidopteran insects, and the binding has been proposed to be responsible for stimulation of alkali-activated germination (169). It should be noted however, that the spore surface-Cry protein association may simply result from concomitant synthesis rather than from a specific interaction. Finally, germination of *B. thuringiensis* spores in the intestines of nematodes has also been reported (122).

Sporulation

The sporulation signal cascade has been well studied in *Bacillus subtilis*, and the pathways and regulators of sporulation in the *B. cereus* group species appear to be similar to those of *B. subtilis*. Nevertheless, variations among species have evolved with specific niches. *B. anthracis* does not sporulate during infection. In the wild, spores (which are the infectious form of the bacterium) only form when the blood of an infected carcass is exposed to the environment (78). The lack of sporulation in the mammalian host appears to result from a specific configuration of the phosphorylation cascade in this species (170–172). In contrast, it has been shown that part of the *B. thuringiensis* population sporulates during infection in insect larvae, and this process is under the control of the bifunctional regulator NprR (173, 174). The Rap phosphatases negatively control sporulation by stimulating a component of the phosphorelay involved in the phosphorylation of Spo0A, the master regulator of sporulation initiation (175). Rap activity is controlled by the Phr signaling peptides through a quorum sensing system. In *B. anthracis* and *B. thuringiensis*, plasmids harbor *rap-phr* genes involved in sporulation (176). These plasmid-borne Rap-Phr systems may provide advantages for adaptation of these pathogenic bacteria to their respective ecological niches.

TOXINS

Toxins, the first bacterial virulence factors to be described (177), represent the major drivers of pathogenicity within the *B. cereus* group. A variety of chromosome- and plasmid-encoded toxins, some shared among the species and some species specific, have been described. Table 1 shows an overview on the most important *B. cereus* group exotoxins. The species-specific toxins, namely, the *B. anthracis* tripartite anthrax toxin complex and the *B. thuringiensis* insecticidal Cry toxins, as well as the depsipeptide toxin cereulide of the emetic type of *B. cereus*, are encoded on plasmids, while many other *B. cereus* group toxins are encoded by the chromosome. Some *B. anthracis* and *B. cereus* isolates harbor duplicated and/or closely related toxin genes (35, 178), and *B. thuringiensis* strains can harbor several *cry* genes.

B. anthracis Toxins

Anthrax toxin has been a major focus of anthrax research since the initial discovery of the toxigenic potential of *B. anthracis* culture supernates. *B. anthracis* secretes three proteins, PA, LF, and EF, known collectively as anthrax toxin. Purified toxin proteins in binary combinations have distinct effects when injected into experimental animals. Lethal toxin (LeTx), a mixture of LF and PA, causes death, while edema toxin (EdTx), a mixture of EF and PA, produces edema. PA (83 kD) mediates binding and translocation of the enzymatic proteins LF (90 kD) and EF (89 kD) into host cells.

PA is a nonenzymatic but critical component of LeTx and EdTX because it mediates toxin binding to host cells and

TABLE 1 Exotoxins, the major virulence factors of the *B. cereus* group

Toxin	Toxin type	*B. anthracis*	*B. cereus*	*B. thuringiensis*
Anthrax toxin (PA, LF, EF)	AB toxin	+	+[a]	–
Emetic toxin (cereulide)	Heat-stable depsipeptide toxin	–	+	–
Enterotoxins (Nhe, Hbl, CytK)	Pore-forming toxins	–[b]	+	+
Insecticidal toxins (Cry, Cyt, Vip, Sip)	Pore-forming toxins	–	–	+

[a]Some rare strains.
[b]*nhe* genes are present but inactive.

facilitates translocation of LF and EF into cells. PA binds to one of two related proteins, capillary morphogenesis protein 2 (CMG2 or ANTRX2) and tumor endothelial marker 8 (TEM8 or ANTRX1), which are found on cells of many different tissues. CMG-2 is the most important for pathogenesis, while TEM-8 has a minor role (179, 180). In the model of anthrax toxin entry, furin and possibly additional host-associated proteases cleave PA into two fragments, PA63 (63 kDa) and PA20 (20 kDa) (89). The receptor-bound carboxyterminal 63-kDa fragment (PA63) oligomerizes to form a ring-shaped structure comprising seven or eight PA63 molecules. One to three molecules of LF and/or EF bind to the PA ring, and the complex is endocytosed by clathrin-coated vesicles. Endosome acidification induces a conformational change in the ring such that it converts from a "prepore" to a pore (channel) in the membrane, facilitating translocation of EF and LF across the membrane (181).

LF, a zinc-dependent metalloproteinase, is the central effector of shock and death from systemic anthrax. Initial investigations of LF activity revealed that the protein cleaves mitogen-activated protein kinase kinases, resulting in disruption of multiple signaling pathways and causing broad downstream effects on cell physiology (182). More recent reports show that low levels of LeTx inhibit the glucocorticoid receptor, an important component of host defense against inflammation. LF targets the inflammasome sensor NLRP1, causing activation of the caspase-1-dependent cell death signaling pathway (183). Finally, murine susceptibility to lethal toxin has been associated with genetic polymorphisms in the *Ltx* gene on mouse chromosome 11. The *Ltx* gene encodes a kinesin-like motor protein, Kif1C, but the relationship between lethal toxin and Kif1C is not clear (184).

EF is a calmodulin-dependent, Ca^{+2}-dependent adenylyl cyclase (185). As is true for other bacterial toxins that elevate cAMP levels, disruption of normal second-messenger signaling has many effects on host cell physiology. EdTx weakens antibacterial responses of phagocytes, impairing apoptosis, motility, and release of inflammatory cytokines. Human neutrophils treated with the toxin have reduced phagocytic and oxidative burst abilities (186).

A comprehensive model of the molecular basis of anthrax toxin effects on mammalian hosts is still evolving, but a wealth of current information reveals that together, the toxin components severely impinge on the immune functions of susceptible hosts, which are key to the outcome of *B. anthracis* infection (89, 187, 188).

Anthrolysin O is a cholesterol-dependent cytolysin with properties similar to the pore-forming toxins of other Gram-positive pathogens (189). Initially discovered as a hemolysin (190), ALO has lytic activity against phagocytes (191), decreases the barrier function of human polarized epithelial cells (192), and appears to play a role in gut epithelial disruption during *B. anthracis* infection (193). Expression of the *alo* gene is highly responsive to *in vitro* growth conditions (190). During infection, *alo* transcripts are present in newly germinated bacteria after phagocytosis of the spores by mouse macrophages (194, 195). Concurrent deletion of *alo* and phospholipase genes attenuates virulence and reduces growth and survival in phagocytes, suggesting a role for the toxin in destabilization of the phagocytic membrane (196).

B. cereus Toxins

Various *B. cereus* exotoxins have been associated with pathogenicity, but the actual contribution and importance of these toxins for GI and non-GI related diseases is largely unknown. So far, four *B. cereus* exotoxins have been clearly linked to food poisoning. Three pore-forming enterotoxins (Nhe, a three-component nonhemolytic enterototoxin, Hbl, a three-component hemolytic enterotoxin, and the single protein cytotoxin CytK) are thought to provoke diarrhea after toxicoinfections with *B. cereus* spore-contaminated food (37). Hbl enterotoxic activity has been demonstrated *in vivo* on rabbit intestine (197), but direct *in vivo* proof for Nhe and CytK activity is lacking. Nhe was identified from a strain isolated from a foodborne outbreak in Norway (198), and CytK was originally isolated from a *B. cereus* strain that was responsible for a severe foodborne outbreak in which several people developed bloody diarrhea and three elderly people died (199). Enterotoxins may act synergistically with each other and with other virulence factors, making it difficult to predict the overall enterotoxic potential of a given strain (39, 106, 200–204). Nhe, Hbl, and CytK show cytotoxic activity on Vero and Caco2 cells as well as on other human cells. Different cell lines show distinct susceptibilities to the different toxins (205), suggesting different modes of toxin action.

Typically, symptoms occur after 6 to 12 hours and are self-limiting. However, in rare cases the severity of symptoms requires hospitalization, and fatalities among neonates and immunocompromised patients have been reported (108, 109, 199).

The fourth toxin, the so-called cereulide, is linked to the emetic type of *B. cereus* food poisoning (206). Cereulide is a depsipeptide toxin, composed of alternating α-amino and α-hydroxy acids (D-O-Leu–D-Ala–L-O-Val–L-Val)$_3$ (Fig. 4), that is structurally related to the potassium ionophore valinomycin (206). It is produced by the cereulide peptide synthetase Ces (6, 42, 207, 208), which represents a novel type of nonribosomal peptide synthetase (6, 207–209). Cereulide is usually preformed in food, and the onset of symptoms occurs between 15 minutes and 6 hours after uptake of contaminated food (105). In the past, quantification of cereulide has been hampered by the lack of appropriate methods (58). The recently developed ISO method (EN ISO 18465), based on a stable isotope mass spectrometry-based dilution assay (210), will allow accurate cereulide quantitation in the future. Recently, 18 cereulide isoforms were described, with cytotoxic potential ranging from nontoxic to

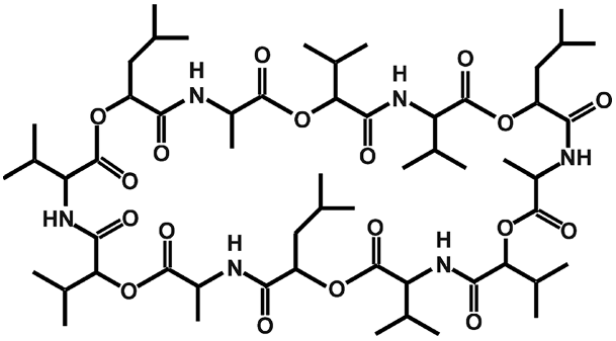

FIGURE 4 Cereulide, the emetic toxin of *B. cereus*.

10-fold more toxic than the classic cereulide (211). Cereulide is not inactivated during stomach passage in the host because it is resistant to cleavage by pepsin and trypsin (105, 212). Due to its hepatotoxic activity, cereulide can cause rhabdomyolysis, liver damage, and severe multiorgan failure (110, 112). Recently, cereulide was linked to the induction of diabetes by causing beta cell dysfunctions (213).

B. thuringiensis Toxins

Except for the cereulide toxin, *B. thuringiensis* strains generally produce the same toxins as *B. cereus* (214). The phenotype distinguishing *B. thuringiensis* from the other species of the *B. cereus* group is the production of a crystal inclusion during sporulation (Fig. 3). This crystal generally appears beside the spore in the mother cell compartment of the bacteria (215), but other situations have been reported in a few strains, including a crystal between the exosporium and the spore coat (216), and production of spores and crystals in two distinct subpopulations of bacterial cells (217). The crystal inclusion can account for up to 25% of the dry weight of *B. thuringiensis* cells, which means that a massive production of proteins should occur during sporulation or stationary phase. This massive protein production results from several mechanisms, including efficient transcription regulation, an exceptionally high stability of *cry* gene mRNA, and the crystallization of the proteins (218). In most of the *B. thuringiensis* strains the expression of the *cry* genes depends on sporulation-specific sigma factors, Sigma E and Sigma K, which are functional in the mother cell compartment during a long period of the sporulation process. Some exceptions have been observed. For example, the *cry3* genes encoding coleopteran-active toxins are expressed during stationary phase independently of the sporulation sigma factors (218).

The crystal inclusions are composed mainly of two types of proteins, the Cry and the Cyt proteins, also called δ-endotoxins (49, 219). Various combinations of toxins can be found on the crystal, depending on the *B. thuringiensis* strain. The commercial strain *kurstaki* HD1 Dipel® contains five *cry* genes (*cry1Aa*, *cry1Ab*, *cry1Ac*, *cry2Aa*, and *cry2Ab*), all encoding proteins active against lepidopteran larvae (220). The strain israelensis contains four *cry* genes (*cry4Aa*, *cry4Ba*, *cry10Aa*, *cry11Aa*) and two *cyt* genes (*cyt1Aa* and *cyt2Ba*), all encoding proteins toxic for the mosquito larvae (9). The Cry proteins are distributed into 75 distinct classes, with less than 45% identity between them (http://www.lifesci.sussex.ac.uk/home/Neil_Crickmore/Bt/). They are pore-forming proteins whose activity requires the binding to specific receptors on the surface of midgut cells (194). The Cyt toxins are cytotoxins specifically active against dipteran larvae (199); they also have a synergistic action by serving as receptors for dipteran-active Cry proteins (221).

In addition to the Cry proteins forming parasporal inclusions, some *B. thuringiensis* strains secrete insecticidal proteins: the Sip (secreted insecticidal protein) and Vip (vegetative insecticidal protein) proteins. Sip1A is active against coleopteran insects and was isolated from a *B. thuringiensis* strain harboring a coleopteran-specific *cry3* gene (207). The toxin Vip3A is specifically toxic against lepidopteran insects and is generally produced by strains that also produce Cry1A lepidopteran-active toxins (209). The insecticidal activity of the exported proteins Vip and Sip and their association with Cry proteins showing related activity spectra suggest that the larvicidal activity of the Cry proteins is reinforced by the secretion of Sip and Vip proteins, thus increasing the entomopathogenicity of the *B. thuringiensis* cells multiplying in the infected insect larvae.

Common Secreted Enzymes of the *B. cereus* Group Species

Phospholipases, sphingomyelinases, hemolysins, proteinases, and peptidases likely represent additional virulence factors of the *B. cereus* group species (39, 106, 202–204). In a murine model of anthrax, protease inhibitors enhance the positive effect of antibiotics, suggesting that one or more proteases contribute to anthrax disease (222).

Immune inhibitor A (InhA1) is a particularly well-studied protease that has homologues in all three species. *B. anthracis*, *B. cereus*, and *B. thuringiensis* each carry multiple apparent *inhA* genes, with transcription of each gene being subject to different regulation (223, 224). Autolytically processed active InhA1 of *B. anthracis* cleaves multiple host proteins and other proteins in the *B. anthracis* secretome (225, 226). A *B. anthracis inhA1*-null mutant is attenuated in a murine model of anthrax (227). The reduced virulence of the mutant likely results from its broad activity on multiple targets, ultimately facilitating bacterial dissemination. InhA1 disturbs the host coagulation machinery by cleaving von Willebrand factor and its regulator ADAMTS13 (102). The enzyme also cleaves zonula occluden-1, resulting in disruption of the blood-brain barrier (103). Degradation of hemoglobin by InhA in the bloodstream has been proposed to allow *B. anthracis* access to essential amino acids required for proliferation in the blood (227). In *B. cereus* and *B. thuringiensis*, deletion of the three *inhA* genes strongly affects virulence (202). InhA1 is required for efficient escape from macrophages (228).

MODELLING HOST INTERACTIONS

Animal Models of Anthrax

Multiple animal models differing in host species, bacterial strain, and delivery route are used to investigate *B. anthracis*-host interactions. The significant variability among laboratory animals in susceptibility to *B. anthracis* infection makes modeling human anthrax particularly challenging. Nonhuman primates are considered superior models for studies of potential therapeutics and vaccines, but the high cost and ethical considerations limit their use. Rabbits serve as good models because the disease pathology is similar to that observed in nonhuman primate and clinical human cases of anthrax. Mice and guinea pig models are used frequently because of experimental ease and moderate cost. For most

animal studies, the spore form of the bacterium is used as the infectious agent, modeling natural infection. Methods for pulmonary delivery of spores include intranasal inoculation, aerosol exposure, and tracheal injection. Spores can also be introduced subcutaneously. To model late-stage disease, vegetative cells are inoculated directly into the bloodstream, bypassing the requirement for *in vivo* germination of spores (229).

Mice are the most common experimental animal for investigations of *B. anthracis*. Inbred mice infected via the parenteral and pulmonary routes develop acute disease, with vegetative cells in multiple tissues. Immunodeficient ($C5^-$) mouse strains such as A/J and DBA/2J are susceptible to relatively low doses (10^3 to 10^4 CFU) of capsule-deficient ($pXO1^+pXO2^-$) Sterne-type strains and are used often for studies of the roles of anthrax toxin *in vivo* and for testing the efficacy of toxin-based therapeutics and vaccines. Exposure of $C5^-$ mice to aerosolized Sterne spores results in pathology similar to that observed in rabbit and nonhuman primate models, with lethal toxin required for dissemination and development of protective immunity (230).

Studies of pathogenesis and host responses related to nontoxin factors have been commonly assessed in infections of immunocompetent mice with nontoxigenic ($pXO1^-$ $pXO2^+$) strains. Interestingly, guinea pigs, rabbits, and nonhuman primates are not susceptible to infection by $pXO1^-$ $pXO2^+$ strains (231). It is also notable that mice are not protected from fully virulent ($pXO1^+$ $pXO2^+$) strains by the PA-based vaccine AVA, whereas AVA is fully protective for rabbits and nonhuman primates but only partially protective for guinea pigs (232, 233).

Mouse models have revealed interesting aspects of germination and dissemination of *B. anthracis* during infection (229). Carr and coworkers (234) demonstrated functional redundancy among the five known germinant receptors, and McKevitt and coworkers (159) showed that the germination inhibitor D-alanine reduced the infectious dose of spores, suggesting that timing of germination is important for disease. Experiments conducted by Glomski and colleagues (235, 236) using luminescent recombinant strains showed that germination and dissemination from pulmonary, skin, and GI entry points does not require transport to lymph nodes, but spore dose and method of delivery can affect the timing and location of germination. Their data also revealed a role for capsule in dissemination.

Inbred mice have also been used extensively to explore the host response to *B. anthracis* infections. Investigations of host systems important for recognition of bacterial factors and activation of immunity have revealed a model in which *B. anthracis* activates Toll-like receptors and the nucleotide-binding oligomerization domain-like receptor (NLR) inflammasome, resulting in tumor necrosis factor alpha production by a mitogen-activated protein kinase signaling pathway. LeTx suppresses this response by cleaving mitogen-activated protein kinase kinases. EdTx-mediated increases in cAMP also disrupt cell signaling pathways. In the battle between host and pathogen, the immunosuppressive effects of LeTx are countered by Nlrp1b, the product of a "lethal toxin sensitivity" locus on chromosome 11. In response to lethal toxin, the lethal toxin-sensitive Nlrp1b allele activates caspase-1, inducing proinflammatory cytokines that recruit neutrophils and mononuclear cells. Thus, in mice, LeTx-mediated Nlrp1b-dependent activation of caspase-1 is a major factor in the control of *B. anthracis* infection (229).

Guinea pigs are keenly susceptible to *B. anthracis* spore infection but not very sensitive to the anthrax toxins. While other animal models show some inconsistencies in terminal loads of bacteria, intramuscular challenge of guinea pigs with a fully virulent ($pXO1^+$ $pXO2^+$) strain leads to specially and temporally consistent infections. Aerosol infection of guinea pigs results in edema and hemorrhage in the spleen, lungs, and lymph nodes, facilitating studies of pathology. Guinea pigs have been used in competitive infection studies employing different strains and mutants. These experiments have revealed roles for biosynthetic genes and surface proteins in disease (229).

Rabbits have been useful to determine virulence differences in *B. anthracis* strains and mutants and to examine pathology, which is similar to that observed in humans and nonhuman primates. Multiple investigations of vaccines and therapeutics have employed rabbit models. Rabbits exhibit a strong immune response to PA and have played a key role in the development of correlates of immunity. A quantitative anti-PA IgG enzyme-linked immunosorbent assay and a toxin neutralization assay developed using sera from vaccinated rabbits are used to evaluate the human immune response to PA-based vaccines (237–240).

Nonhuman primates provide a valuable model for anthrax disease because infection with aerosolized spores results in a disease course that most closely matches human infection. Nonhuman primates, including rhesus macaques, cynomolgus macaques, African green monkeys, and marmosets, represent the only animal models of inhalational anthrax in which anthrax meningitis is consistently observed. Infected nonhuman primates, like humans, also develop bacteremia, lymphadenitis, splenitis, mediastinitis, pneumonia, pleural effusions, hepatitis, adenitis, and vasculitis. Tissues of diseased animals and humans also show hemorrhage, necrosis, and edema. Sera from infected nonhuman primates have been used to develop biomarkers for early diagnosis of infection. Capsule and toxin, detected using enzyme-linked immunosorbent assay, chemiluminescence, and mass spectrometry, serve as reliable markers.

Because nonhuman primate responses to infection most closely resemble human physiological and immune responses, these animals are best suited for immunogenicity, toxicity, and safety testing of vaccines and therapeutics for anthrax. Nonhuman primates have been used extensively for studies of antibiotic efficiency. Investigations of the dose, pharmacokinetics, and time course of antibiotic treatment have shown that antibiotics are only effective against germinating spores and vegetative cells. The long-term persistence of spores and extended time periods to germination mean that complete protection from high doses of aerosolized spores requires prolonged antibiotic treatments over more than 30 days.

Rats are somewhat resistant to challenge with *B. anthracis* spores, but they are exquisitely sensitive to injection of LeTx. Thus, the Fisher 344 strain has been used as a model system for toxin activity. The rat toxin model was key to determining the role of the NLR sensor Nlrp1 in animal susceptibility to LeTx (241, 242). The model also provides a sensitive means to test the efficacy of small-molecule toxin inhibitors, monoclonal antibodies, dominant-negative toxin components, and other potential antitoxin countermeasures (229).

Animal Models of *B. thuringiensis* and *B. cereus* Infection

The opportunistic properties of *B. thuringiensis* and *B. cereus* have been investigated using nasal instillation in mice (243,

244) and intraocular infection in mice and rabbits (245). In all cases, the results highlight the importance of the PlcR regulon in the pathogenic properties of these bacteria. However, established mammalian models of GI infections caused by *B. cereus* are lacking. It has been hypothesized that rodents are not suitable models of GI-related *B. cereus* infection because their gut physiology does not support germination of spores and subsequent enterotoxin production (246). In a more recent study, Rolny et al. (247) used intragastric gavage to test the effect of vegetative *B. cereus* cells on the host immune system. They found some modifications in immune cells in the spleen, Peyer's patches, and mesenteric lymph nodes but did not report any enterotoxin production. Thus, an appropriate mammal model for enterotoxigenic *B. cereus* awaits development.

The emetic activity of the *B. cereus* toxin cereulide was first shown in a rhesus monkey model (248, 249). Results from a study in *Suncus murinus* suggest that cereulide causes emesis through the 5-HT receptor (206). However, it is still unclear if the *S. murinus* model reflects the physiology of the human gut. Thus, further studies will be needed using model organisms, such as pig, more closely resembling the human gut physiology.

Insect Models of *B. cereus* and *B. thuringiensis* Infection

In insects susceptible to *B. thuringiensis* infection, the first stage of the disease results from gut paralysis due to the crystal inclusion (250, 251). Cry toxins are responsible for this initial step. The toxins damage the peritrophic membrane and cause lysis of the intestinal cells by producing osmotic shock (252–254). Depending on the amount of Cry toxins and the susceptibility of the insect larvae to a given Cry toxin, the toxemia resulting from toxin ingestion may result in insect death. This toxemia and the paralysis of the gut allow spore germination. Several studies have shown that the presence of *B. thuringiensis* cells synergizes the toxic effect of the crystals (243, 255–259).

As natural targets of *B. thuringiensis*, insect larvae are a valuable model for studying the virulence of these bacteria. The utility of this infection model is increased by using insects that are poorly susceptible to the ingestion of crystals alone. A commonly used insect is the lepidopteran species *Galleria mellonella* (the greater wax moth) because the larvae are killed by the ingestion of *B. thuringiensis* spore-crystal mixtures but are only weakly affected by the ingestion of crystals alone (243, 258, 259). This model host has also been used to assess the virulence of *B. cereus*. Many other human pathogens are unable to kill *G. mellonella* in this infection model, reflecting the entomopathogenic specificity of these two species (260).

The *G. mellonella* host can be used in two infection methods. In association with Cry toxins to impair the insect defenses, the pathogenicity of *B. thuringiensis* and *B. cereus* can be assayed via the oral route. At the last instar, *G. mellonella* larvae are large enough (2 cm long and 250 mg) to be force-fed, thus allowing the ingestion of defined doses of bacteria (243). Larvae can be raised at various temperatures to mimic different natural conditions, including the mammal environment. This infection model allows determination of a 50% lethal concentration, measurement of bacterial survival, and assessment of the infectious process. The behavior of the bacteria in the intestinal environment, including bacterial factors interacting with the intestinal barrier, can be investigated (261). *G. mellonella* was used to demonstrate the major role of the PlcR regulon in the virulence of *B. thuringiensis* and *B. cereus* (243). The regulon consists of 45 genes encoding a large number of extracellular virulence factors such as degradative enzymes, hemolysins, and cytotoxins (17, 70). The PlcR-regulated metalloproteases InhA2, Bel, and ColB were demonstrated to be involved in *B. thuringiensis* virulence (38, 262, 263). In addition to *G. mellonella*, a nematode oral infection model in association with Cry proteins has also revealed virulence factors of *B. thuringiensis* (264). The ColB protease and another metalloprotease (Bmp1) were found to be involved in the pathogenicity of *B. thuringiensis* against *Caenorhabditis elegans* (262, 265).

A second mode of insect infection is direct injection of the bacteria into the hemocoelic cavity of the larva. This model bypasses the intestinal barrier and therefore does not require the crystal proteins. In addition to *G. mellonella*, the silk worm, *B. mori*, and several other insect species can be used. Bacteria are injected through the intersegmental membrane between the fourth and fifth abdominal legs of fourth-instar larvae (38). Most insect larvae are highly susceptible to the direct injection of vegetative cells or spores of *B. thuringiensis* and *B. cereus* into the hemocoel. This mode of infection led to the identification of multiple virulence factors, including genes associated with (i) iron metabolism and acquisition (266–268), (ii) resistance to the host defenses, including antimicrobial peptides, phagocytic cells, or nitric stress (202, 269–271), (iii) motility (272), and (iv) key transcription factors for *B. cereus* pathogenicity (273). The major role of the sphingomyelinase in the pathogenicity of *B. cereus* was also revealed by this method (39), thus confirming the observation that clinical strains of *B. cereus* overproducing sphingomyelinase were more virulent than environmental strains (203).

Data from these experimental infections clearly demonstrate that *B. thuringiensis* is a true entomopathogenic bacterium (Fig. 5), producing specific toxins that weaken or kill invertebrates and other virulence factors, shared with other *B. cereus* group isolates, that allow bacteria to provoke septicemia and death of the host (72). Moreover, it has been shown that these bacteria harbor a regulon conferring the ability to survive in the insect cadaver through a pathway independent of the sporulation and corresponding to a necrotrophic lifestyle (128, 174). This regulon is activated during the stationary phase of the bacteria by the NprR-NprX quorum sensing system and consists of 41 genes encoding several degradative enzymes, including proteases and chitinases. Although the role of each component is not determined, altogether they should contribute to maximizing the consumption of the nutriments found in the host cadaver. Furthermore, the insect model was successfully employed to demonstrate antibiotic-induced small colony variants, a novel persister phenotype of *B. cereus* (274).

Cell Culture

Immortalized cell lines are employed for testing the cytotoxic potential of *B. cereus* strains. Hep2 cells are used to check strains for the emetic toxin cereulide, while Vero cells are commonly used to check strains for their enterotoxic potential (35). However, more recently, it has been reported that different human cell lines show distinct susceptibility for specific enterotoxins, which must be taken into consideration when functional studies on enterotoxins are carried out (205). These results are in line with a previous study from Doll et al. (39) showing that in polarized colon epithelial cells *B. cereus* sphingomyelinase is a strong inducer of epithelial cell death, by synergistically interacting with Nhe,

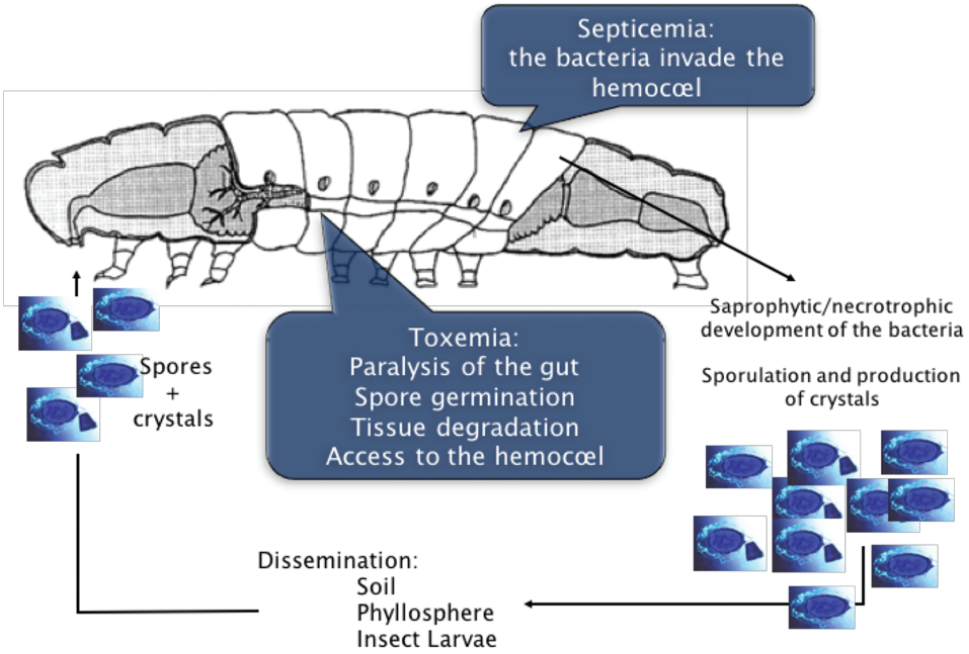

FIGURE 5 The infectious cycle of *B. thuringiensis* in a susceptible insect larva. Ingestion of spores and crystals is followed by the dissolution of the crystal in the alkaline environment of the midgut. Insect proteases activate Cry proteins. Spores germinate in the paralyzed insect gut. Cry toxins degrade the peritrophic membrane. Bacteria multiply and express PlcR-regulated genes. The intestinal barrier is disrupted and bacteria gain access to the hemocoel. The bacteria resist host defenses and cause a fatal septicemia. The NprR regulon is activated, and the bacteria survive in the host cadaver. Finally, spores and vegetative cells are disseminated outside of the host.

while most of the cytotoxic effect on primary endothelial cells can be explained by the cytotoxic activity of Nhe (205). Studies carried out on pancreatic beta cells revealed a detrimental effect of cereulide toxin on these cells, even in low concentrations, rendering it possible that long-term uptake of cereulide could have some implications in diabetes (213). Since beta cell dysfunction and cell death play key roles in the pathophysiology of diabetes, it will be important to study the long-term effects of subemetic doses of cereulide in more detail in appropriate eukaryotic cell models.

Furthermore, boar sperm has been used to show the mitochondrial activity of the *B. cereus* emetic toxin cereulide (275), and the enterotoxic activity of Hbl has been demonstrated in a rabbit ligated ileal loop test (197).

In vitro Simulation of GI Transit

Several systems that mimic gastric passage of *B. cereus* have been described (276–278). *B. cereus* spores, and to a certain extent vegetative cells, survive in these models, but enterotoxin production has not been detected, making these models suboptimal for studies of *B. cereus* enteropathogenicity. Such systems mimicking the physicochemical conditions from mouth to ileum have been successfully used to study probiotic bacteria (279) but lack the influence of host factors, which have been shown to be important for enterotoxin production in *B. cereus* (116).

VIRULENCE GENE EXPRESSION

Virulence gene expression within the *B. cereus* group is controlled by complex regulatory circuits. In addition to global transcription regulators, such as CodY and AbrB, that play key roles in the integration of virulence and bacterial metabolism (273, 280, 281), *B. cereus* group-specific regulators exert control of virulence gene expression on the transcriptional and posttranscriptional levels. The global transcriptional regulator AtxA, encoded by pXO1 of *B. anthracis*, plays a key role in the pathogenicity of *B. anthracis*, while the chromosome-encoded pleiotropic transcriptional regulator PlcR is the key regulator in *B. cereus* virulence (70, 282). Most of the virulence factors in *B. cereus* described so far are at least partially under the control of PlcR, except cereulide toxin synthesis, which belongs to the Spo0A-AbrB regulon (283). In addition, some reports highlight the importance of post-transcriptional regulation of virulence factor expression, which is largely unexplored (114, 284, 285).

Global Transcription Regulators

CodY, a global transcriptional regulator integrating virulence and metabolism, plays an essential role in regulation and timing of virulence gene expression in the *B. cereus* group. CodY, which is highly conserved in low-G+C-content Gram-positive bacteria, senses the nutritional and energetic status of a cell by binding to branched chain amino acids and GTP (286, 287). It often exerts control of virulence factors indirectly by acting on downstream regulators (288, 289). Although the majority of CodY-regulated genes are repressed during rapid growth, CodY is a positive regulator of some virulence genes (286, 290). In *B. cereus*, CodY governs the expression of virulence factors by impacting key regulatory circuits (66). CodY directly represses cereulide toxin synthesis in emetic *B. cereus* during early growth stages but acts indirectly on virulence genes belonging to the PlcR regulon by controlling import of the signaling peptide PapR, which is

required for PlcR activity (273, 281, 433). CodY was also reported to be essential for full virulence of *B. anthracis*. Data suggest that CodY exerts indirect positive control on post-translational regulation of AtxA accumulation (284). By acting, either directly or indirectly, on other virulence regulators, CodY adds an additional level of complexity to the regulatory circuits governing metabolic activities and virulence within the *B. cereus* group.

AbrB is a global transition state regulator that links virulence and cell development. It has been extensively characterized in *B. subtilis* but also highly conserved in other Gram-positive bacteria (291, 292). As is true for *B. subtilis*, AbrB is negatively regulated in the *B. cereus* group by the response regulator Spo0A at the onset of the transition phase. AbrB has been shown to control the expression of the anthrax toxin genes *pag*A, *lef*, and *cya* in *B. anthracis* as well as the cereulide (*ces*) synthetase genes in emetic *B. cereus*. In *B. thuringiensis*, *abrB* represses expression of *inhA1* during vegetative growth (293). During early exponential growth phase, *abrB*-null mutants synthesize elevated levels of anthrax toxin in *B. anthracis* and cereulide levels in emetic *B. cereus* (283, 294). Thus, it can be assumed that AbrB plays a pivotal role in the correct timing of toxin expression in *B. anthracis* as well as in emetic *B. cereus*.

Alternative sigma factors have also been implicated in transcription of virulence factors of the *B. cereus* group. The sporulation gene regulator SigH represents a target of the AbrB repressor in *B. subtilis* (295), and it has been postulated that AbrB acts on anthrax toxin gene expression via control of *sigH* (296). However, the *B. subtilis* consensus sequence for recognition by SigH has not been found upstream of the anthrax toxin genes nor upstream of the *ces* genes in emetic *B. cereus*, and no direct SigH-dependent toxin promotor activity could be shown (283, 297). Therefore, it is tempting to speculate that SigH is not directly linked to toxin gene regulation in *B. anthracis* or emetic *B. cereus*. SigB, another alternative sigma factor, may be a minor regulator of virulence in *B. anthracis*. Although there is no evidence that SigB affects toxin or capsule gene expression, a *sigB* mutant exhibits reduced virulence in a mouse model of anthrax (298).

RNPP Quorum Sensors

A major trait of the *B. cereus* group is the unique presence of two transcriptional regulators, PlcR and NprR, forming two distinct quorum sensing systems in association with their cognate signaling peptides, PapR and NprX, respectively (129, 299). In addition to these specific regulators, the bacteria of the *B. cereus* group produce proteins homologous to the Rap phosphatases of *B. subtilis* (175, 300). These quorum sensors define the RNPP family according to the name of the prototypical members Rap, NprR, PlcR, and PrgX (301). Quorum sensing systems connect gene expression to cell density, thus coordinating the behavior of the whole bacterial community able to respond to the same signaling peptide. In insects, it was shown that the sequential activity of RNPP regulators (PlcR, NprR, and Rap) controls the physiological stages of *B. thuringiensis* throughout the infectious cycle, from virulence to sporulation (302).

PlcR positively regulates 45 genes, most of which encode exported virulence factors such as the enterotoxins Hbl and Nhe, the cytotoxin CytK, the cholesterol-dependent hemolysins, and several degradative enzymes (70). As discussed above, PlcR plays a key role in the virulence of *B. thuringiensis* and *B. cereus* in their invertebrate or mammal hosts (70, 72, 245). The *plcR* gene is present in all *B. cereus* group species but does not always produce a functional protein (303). Notably, in *B. anthracis* a nonsense mutation inactivates the PlcR function (17, 18). PlcR is a 34-kDa helix-turn-helix-type transcription factor activated upon binding of PapR. This binding induces a drastic conformational change of the dimeric form of PlcR, allowing an appropriate positioning of the helix-turn-helix domains and their binding to the PlcR-boxes located upstream from the −10 region of the PlcR-regulated promoters (299, 301, 304). Binding of PapR to PlcR is highly specific, and polymorphisms exist within the *B. cereus* group. Four specificity groups, or pherotypes, can be distinguished (305, 306).

NprR is also found in all *B. cereus* group species and acts as a transcriptional regulator at the onset of sporulation (128). As indicated above, NprR is an RNPP regulator whose transcriptional activity depends on a signaling peptide (NprX) that switches NprR from a dimeric apo form to a tetrameric form (307). Similar to PlcR-PapR, the NprR-NprX system is strain specific, and seven pherotypes were defined within the *B. cereus* group (129). NprR-NprX activates the transcription of a regulon including genes encoding degradative enzymes (proteases, lipases, and chitinases) and a lipopeptide (kurstakin) involved in biofilm formation (128, 308). Using insect larvae as an infection model, it was shown that the NprR regulon allows bacteria to enter in a necrotrophic lifestyle essential for the survival of the bacilli in the cadavers of infected insects. In the absence of its cognate peptide, the apo form of NprR functions as a phosphatase inhibiting the sporulation process (309). It has been shown that sporulation occurs only in bacteria expressing the NprR regulon and following a necrotrophic lifestyle in the insect cadaver (174). These results are in agreement with the dual function of NprR and indicate that its phosphatase activity should be turned off by NprX to allow the sporulation of the bacteria.

AtxA, the Key Regulator in *B. anthracis* Virulence

AtxA, named for its control of toxin gene expression (310) and encoded by a pXO1 gene, is the master virulence regulator of *B. anthracis*. AtxA positively controls transcript levels of the structural genes for anthrax toxin, *pag*A, *lef*, and *cya*, located on pXO1; the capsule biosynthetic operon *cap*BCADE located on pXO2; and multiple other genes on the plasmids and chromosome (5, 282, 311–318). An *atx*A-null *B. anthracis* strain is highly attenuated in a murine model of anthrax disease (318, 319). The *atx*A gene has also been associated with control of *B. anthracis* development. AtxA activates expression of a pXO2-encoded sporulation kinase inhibitor to repress sporulation in conditions in which AtxA is highly expressed and active (320). This activity may be related to the lack of *B. anthracis* sporulation during infection.

Paralogous regulators, AcpA and AcpB encoded by pXO2 genes, were first identified as regulators of *cap*BCADE (321, 322). AcpA and AcpB do not appear to affect toxin gene expression but may affect expression of noncapsule genes (282, 323). Data from experiments employing null mutants reveal that expression of the *atx*A, *acp*A, and *acp*B genes is interdependent and suggest that AcpA and AcpB have similar functions. The primary means for AtxA control of *cap*BCADE is via positive regulation of *acp*A transcription. The *acp*A gene is located upstream of the *cap* locus and in the opposite orientation. Two apparent transcriptional start sites, one expressed at a low constitutive level and one controlled positively by AtxA, drive expression of *acp*A. AcpA can positively affect transcription of *cap*BCADE in the absence of AtxA and AcpB. The *acp*B gene, located downstream of *cap*BCADE and in the same orientation, is expressed as a

monocistronic transcript initiated from a weak constitutive promoter. AcpB, like AcpA, can positively affect *capBCADE* expression in the absence of the other regulators. A weak transcription terminator located between *capE* and *acpB* results in cotranscription of *acpB*, with *capBCADE* in roughly 10% of transcripts, thus forming a positive feedback loop (324).

AtxA expression is also subject to complex regulation. Transcription of *atxA* is affected by temperature, carbohydrate availability, redox potential, metabolic state, and growth phase (325–328). In addition, CodY controls AtxA protein levels posttranscriptionally by an unknown mechanism (284), and AbrB represses *atxA* expression by binding to the *atxA* promoter region upstream of the P1 transcriptional start site (294, 329). Finally, an unknown additional repressor binds to the *atxA* promoter to negatively regulate expression (319).

AtxA, AcpA, and AcpB belong to an emerging class of regulators termed PCVRs (phosphoenolpyruvate-dependent phosphotransferase system regulation domain [PRD]-containing virulence regulators) (330, 331). Generally, PCVRs contain nucleic acid-binding domains and PRDs subject to phosphorylation by the phosphotransferase system (332). AtxA crystalizes as a dimer, and distinct associated folds predicted that DNA-binding domains and PRDs are apparent in each chain. The model for PRD control of AtxA function is that phosphorylation events at two specific histidines, one in each PRD, have opposing effects on AtxA function.

Specific DNA-binding activity of AtxA has not been reported, but phosphorylation of H199 of PRD1 is predicted to affect the interaction of AtxA with DNA, while phosphorylation of H379 in PRD2 disrupts AtxA dimerization and abolishes activity (333). Phosphorylation of AcpA and AcpB has not been demonstrated. Although comparisons of the AcpA and AcpB amino acid sequences and structure predictions are highly suggestive of the presence of PRDs, the placement of histidines within the PRDs differ between the three regulators, suggesting large differences in the potential phosphorylation sites (330). If indeed the AcpA and AcpB PRDs control PCVR function, the relationships between phosphorylation and protein structure may differ between the PCVRs, affecting their target specificity and relative activity.

GENETIC TOOLS

Natural Genetic Exchange: Intra- and Interspecies

Historically, facile identification of the *B. cereus* group species has relied on their plasmid content: plasmids carrying the crystal insecticidal genes of *B. thuringiensis*, the anthrax toxin and capsule genes of *B. anthracis* and more recently *B. cereus* bv. *anthracis*, and the biosynthetic gene cluster for cereulide synthesis of *B. cereus* (6, 16, 49, 334). However, genetic experiments have revealed that plasmids can move among the strains of the *B. cereus* group by conjugation and transduction (335–338), thus complicating the speciation of strains belonging to this bacterial group. Horizontal genetic transfer of plasmid and chromosome DNA has likely contributed to the remarkable diversity of the strains composing the *B. cereus* group.

Transducing phage have been characterized for all three *B. cereus* species. The bacteriophage CP-51, isolated from *B. cereus*, was the first generalized transducing phage discovered for the group and has been the most utilized for genetic manipulation (339). CP-51 and CP-54, a phage with a broader host range than CP-51, also mediate generalized transduction in *B. thuringiensis* (340, 341). They can transduce various plasmids between the *B. cereus* group species and are also useful for intraspecies transduction of chromosomal markers (338, 342). CP-51-mediated transduction of pXO2 from *B. anthracis* to *B. cereus* was instrumental in demonstrating that the plasmid was associated with capsule synthesis (343), while the first genome maps of *B. thuringiensis* were established using this phage (340, 341, 344).

Plasmid conjugation in bacteria of the *B. cereus* group was first demonstrated by showing the transfer of plasmid-borne *cry* genes from *B. thuringiensis* strains to *B. cereus* (51). These observations were then extended to other plasmids and species, including *B. anthracis* (343, 345). Conjugative plasmids native to *B. thuringiensis* have been shown to transfer to *B. anthracis* and *B. cereus* and in some cases to mobilize other non-self-transmissible plasmids. Among these are *B. thuringiensis* plasmids harboring insecticidal toxin genes, such as pXO12 (348) and pHT73 (347). The conjugation experiments performed between *B. anthracis* and *B. thuringiensis* revealed transfer of plasmids by a conduction process involving the formation of cointegrate structures between a conjugative plasmid (i.e., pXO12) and the nonconjugative plasmid pXO1. These experiments showed that the transposon Tn*4430*, located in various conjugative plasmids of *B. thuringiensis* (8, 346), mediates the transfer of nonconjugative plasmids by a conduction process (348). These findings indicate that transposable elements associated with conjugative plasmids may have important adaptive functions by mediating the horizontal transfer of genetic material, including toxin genes, within the *B. cereus* group.

Plasmid transfer among the *B. cereus* group has been reported to occur in various niches, including the insect gut (349–351), gnotobiotic rats (352), the plant rhizosphere (63), soil (61), water (353), and dairy products (354, 355), and a growing database of DNA sequences from clinical and environmental isolates reveals evidence for extensive genetic exchange among the *B. cereus* group. Multiple isolates from soil carry pXO1- and pXO2-like plasmids (24, 355–358). In some cases, clinical isolates from humans and animals have been reported with newly discovered combinations of potential plasmid-borne virulence genes. Interestingly, pAW63, from a *B. thuringiensis kurstaki* strain, shares a common backbone sequence with pXO2 of *B. anthracis* and with pBT9727 from the pathogenic *B. thuringiensis* subspecies *konkukian* (359, 360). *B. cereus* strain G9241, isolated from a patient with life-threatening pneumonia, carries a specific PA gene (*pagA*) on plasmid pBCXO1 and a gene on plasmid pBC218 that encodes a polysaccharide capsule (24).

Some reports have also described genetic exchange between *B. subtilis* and members of the *B. cereus* group. Plasmid pLS20 from *B. subtilis* subspecies *natto* is self-transmissible and facilitates transfer of other plasmids from *B. subtilis* to the *B. cereus* group species (361). Although integrative and conjugative elements (ICEs) have not been reported in the *B. cereus* group, *B. anthracis* has been shown to be an effective recipient of ICE*Bs1* from *B. subtilis* (362). The presence of *cry* genes encoding insecticidal toxins in *Bacillus popilliae* (363) and *Clostridium bifermentans* (364) strongly suggests a horizontal transfer of *B. thuringiensis* plasmids to other spore-forming Gram-positive bacteria.

Generation of Recombinant Strains and Genetic Analysis

B. cereus group members are not naturally transformable, and the commercialization of the BioRad electroporation system in the 1980s was a crucial milestone in the development of

genetic approaches for these bacteria. In 1989, several electroporation procedures were published for the transformation of *B. thuringiensis* and *B. cereus* (365–367, 434) and were followed by procedures functional in *B. anthracis* (311) or in the emetic *B. cereus* strains (42, 370).

Interestingly, it was shown that electrotransformation is significantly improved when plasmids are prepared in DNA methyltransferase-deficient (*dam*) *E. coli* strains or from *B. subtilis* 168, a strain that is not known to possess adenine-methylating activities (371, 372). Plasmids can also be transferred from *Escherichia coli* to the bacteria of the *B. cereus* group by heterogramic conjugation (368, 369, 373). A second important milestone for the development of genetic studies in the *B. cereus* group was the construction of cloning and expression vectors. This was notably achieved thanks to the use of the pHT1030 replicon, which allowed the construction of a series of highly stable vectors (374, 435). Due to the relatively low transformation frequency of the *B. cereus* strains, site-directed mutagenesis and direct allelic exchange is not possible using linear DNA and requires the use of shuttle plasmids such as pMAD or pRN5101, whose replication in Gram-positive bacteria is thermosensitive (375, 436). More recent systems draw upon methods first developed for other bacteria. They include group II intron targeting (376) and systems using tyrosine site-specific recombinases that catalyze cutting and joining reactions between short specific DNA sequences. The systems employing tyrosine site-specific recombinases and their cognate target sequences have been derived from *E. coli* bacteriophage P1 Cre-loxP, *Saccharomyces cerevisiae* Flp-FRT, and a newly discovered IntXO-PSL system from *B. anthracis* plasmid pXO1 (377). A method for conducting I-SceI-mediated allelic exchange in which recombinational loss of a chromosomally integrated allelic exchange vector is stimulated by creation of a double-stranded break within the vector by the homing endonuclease I-SceI has also been described (378, 379). This system has been used to make in-frame deletions in genetic elements of *B. anthracis* (152, 161, 380), *B. cereus* (381, 382), and *B. thuringiensis* (383).

For random mutagenesis, Tn*10*- and *mariner*-based mini-transposons have proved useful for the detection of virulence genes or for the study of genetic systems (384–388). Insertion mutant libraries have also been generated using *Enterococcus faecalis* transposons Tn*916* and Tn*917*. However, insertions of these transposons can be unstable and are sometimes accompanied by local deletions and DNA rearrangements (389, 390).

An *in vivo* expression technology was developed for the identification of *B. cereus* genes specifically expressed during infection in an insect host (266). This genetic tool allows identification of transient promoter activation by using site-specific recombination. The activity of a promoter cloned upstream from a recombinase gene results in the loss of a resistance marker and the activation of a new resistance gene. The *in vivo* screening of a *B. cereus* genomic library led to the characterization of genes expressed during infection in the insect *G. mellonella*. One of these genes was found specifically expressed in the hemocoel and was required for iron acquisition (267), while a five-gene cluster, specifically expressed in the larval gut, was essential for glucose-6-phosphate uptake (391).

Measurements of Gene Expression

Whole-transcriptome sequences of *B. anthracis* and *B. cereus* cultured in different growth conditions have been described (392–394). Not surprisingly, the data predict gene functions and reveal multiple transcripts not associated with previous genome annotations. As is true for other bacteria, the advent of RNA whole transcriptome shotgun sequencing (RNASeq) and quantitative reverse transcriptase PCR (qRT-PCR) has lessened the need for recombinant methods to measure gene expression. Nevertheless, for some studies of the bacteria of the *B. cereus* group, expression of specific genes can be readily monitored using transcriptional fusions employing promoterless genes for β-galactosidase and chloramphenicol acetyltransferase (369, 396, 397). Investigations of transcript and protein function are also aided by the use of recombinant constructs harboring promoters inducible by isopropyl-β-Dthiogalactopyranoside or xylose (223, 273, 299, 398) or by use of recombinant constructs harboring promoters inducible by cold (283).

Bioluminescent reporter systems, based on *luxABCDE* promoter fusions, for real-time monitoring of gene transcription have been described for *B. anthracis* and for *B. cereus*. A *sspBp::lux* plasmid was used for *in vivo* spore germination of *B. anthracis* in mice (164), and a *cesP1::lux* plasmid was successfully employed for monitoring cereulide synthetase (*ces*) promoter activity in complex environments, such as foods (58, 370). Various fluorescent reporters were used to record gene expression at the single-cell level and to follow the physiological stages of *B. thuringiensis* in different growth conditions, including biofilm and infection in insect larvae (174, 399). Furthermore, the *E. coli*/*B. cereus* shuttle vector pAD123 with a promoterless red-shifted green fluorescent protein gene (*gfpmut3a*) was shown to be an effective tool for promoter studies in *B. cereus* (370, 400).

THERAPEUTICS AND VACCINES

Antibiotic therapy is the primary treatment for anthrax and for severe infections caused by *B. cereus and B. thuringiensis*. The *B. cereus* group species have similar antibiotic susceptibility profiles and are susceptible to the majority of front-line antibiotics. Historically, penicillin was the antibiotic of choice for the treatment of known or suspected anthrax. However, intrinsic or inducible resistance to β-lactam antibiotics has been reported in clinical isolates (401–403).

Because *B. cereus* and *B. thuringiensis* infections are relatively rare, are generally treatable with antibiotics, and in the case of *B. cereus* food-poisoning, are self-limiting, vaccines have not been developed for these infections. Anthrax vaccines for humans have been available for decades, but the nature of the vaccine, as described below, provides the impetus for continued research in anthrax vaccine development.

Anthrax Prophylaxis and Treatment

The Centers for Disease Control and Prevention recommends fluoroquinolones, such as ciprofloxacin or doxycycline, as first-line drugs for postexposure prophylaxis and treatment of *B. anthracis* infections. The bactericidal activity and exceptional central nervous system penetration make ciprofloxacin recommended over doxycycline. For treatment of severe systemic and life-threatening disease and for cases with fulminant bacteremia, ciprofloxacin with additional antibiotics, especially clindamycin, is recommended. Clindamycin inhibits protein synthesis, potentially reducing toxin production (404, 405). Treatment with additional antibiotics is also recommended because of reports of ciprofloxacin-resistance generated following serial passage in the presence of increasing concentrations of the antibiotic. Ciprofloxacin resistance is associated with a point mutation in the *gyrA* gene encoding gyrase A (406, 407).

Long courses of antibiotics are recommended for anthrax prophylaxis and treatment because *B. anthracis* spores have been reported to remain viable for up to 60 days in nonhuman primates. Recently, the U.S. Food and Drug Administration approved the anthrax vaccine AVA for postexposure prophylaxis in conjunction with antimicrobials. The efficacy of antibiotic therapy for anthrax decreases as the time between exposure and treatment increases (408–411), likely due to increasing toxin levels, indicating a need for antitoxin therapeutics. Toxin inhibitors in development include a variety of peptides and antibodies (412, 413).

Anthrax Vaccines

Current human vaccines for anthrax are the U.S.-licensed AVA (anthrax vaccine adsorbed, BioThrax) and the United Kingdom-licensed AVP (anthrax vaccine precipitated). The anthrax toxin protein PA is the major immunogenic component of both vaccines. PA elicits toxin-neutralizing antibodies that correlate with protection against anthrax disease in humans and many animal models (414–418). AVA is an aluminum hydroxide-adsorbed, PA-containing supernate from a culture of a toxin-producing ($pXO1^+$) but noncapsulated ($pXO2^-$) strain of *B. anthracis*. The standard AVA vaccination protocol requires five doses administered intramuscularly over 18 months, followed by annual booster injections (419), while a more recently approved regimen requires three doses over 6 months. AVP is precipitated with aluminum potassium sulfate (alum) from culture supernates of a different toxinogenic noncapsulated strain. The AVP vaccine is administered as four doses over 32 weeks with annual boosters. Unlike AVA, AVP contains low levels of LF and EF, and some reports indicate that humoral responses to LF and EF generated by AVP may contribute to toxin neutralization (420, 421).

The prolonged immunization regimen with reports of reactogenicity, cold-storage requirement, and 4-year half-life make the anthrax vaccines nonoptimal for pre-exposure prophylaxis and postexposure therapy. Thus, various expression systems, immunogens, adjuvants, and delivery vehicles are in development to achieve a higher-performing and more user-friendly vaccine.

Efforts include investigations of purified recombinant PA preparations, *Lactobacillus*- and *Salmonella*-producing PA for oral delivery, DNA vaccines, and non-PA-based vaccines with alternative targets such as the *B. anthracis* capsule, cell wall S-layer proteins, spore components, and the toxin proteins EF and LF (422–427). The veterinary anthrax vaccine is a live spore vaccine developed in 1937 by Max Sterne (428). The strain, 34F2 or "Sterne," was first isolated as a stable noncapsulated isolate and was later shown to carry $pXO1^+$ but not $pXO2^-$. Animals injected with the Sterne vaccine develop humoral immunity within 4 weeks, but the immunity is not long-lived, and annual revaccination is recommended. Although the vaccine can be effective in livestock populations, in many parts of the world, underreporting, logistics, and limited resources make implementing vaccination campaigns difficult.

FUTURE DIRECTIONS

Substantial effort has gone into determining biomarkers and distinguishing features of the closely related members of the *B. cereus* group. However, distinctions between the species and between virulent and nonvirulent strains of the species are not always clear. A key issue for *B. cereus* (and for *B. thuringiensis*) is the detection of pathogenic strains responsible for food poisoning resulting in diarrheal syndromes. These syndromes are suspected to be caused by the various cytotoxins and degradative enzymes produced by bacteria under the control of the virulence regulator PlcR. However, most strains produce these factors and are not generally pathogenic, as is likely the case with *B. thuringiensis* strains that are used as biopesticides.

B. thuringiensis is defined by the ability to produce a parasporal inclusion made of Cry proteins. Numerous Cry proteins are insecticidal or nematicidal toxins, but some have no known targets. The search for the presumed targets, whether in arthropods or other organisms, is of scientific and economical interest and will facilitate increased understanding of the expanded ecology of these bacteria. Efforts to identify biomarkers specific for *B. anthracis* are a significant part of biodefense research. While such studies have affirmed some novel features of the species, the recent reports of *B. cereus* isolates causing anthrax-like disease suggest that strains of other species may also present a bioweapon threat. Moreover, increased environmental surveillance and expanded genome sequencing are revealing newly recognized *B. cereus* group isolates with unique physiology, genetics, and virulence capabilities.

The emergence of clinical isolates with novel combinations of plasmids and recombinant forms of well-characterized plasmids suggests an evolving virulence repertoire. It will be interesting to explore the mechanisms by which these changes occur and the frequencies of apparent horizontal gene transfer in nonhost environments. What relationships, if any, exist between plasmid content and specific chromosomes? What happens to the signaling networks controlling gene expression in these atypical isolates? For some *B. cereus* isolates, plasmids can represent up to 20% of the total DNA. With the exception of genes involved in pathogenicity, the adaptive functions of these plasmids are still largely unknown.

Much has been learned about host-pathogen interactions associated with virulent strains of the *B. cereus* group species. What are the core genomic factors of the *B. cereus* group species that are required to cause distinct diseases? Can such factors actually be defined? Do the "virulence" plasmids play roles in the nonhost environments of the *B. cereus* group species? To answer these questions, more advances must be made in the study of the ecology of these organisms, their lifestyles outside of their hosts, and their interactions with each other.

Sporulation and Germination in Clostridial Pathogens

AIMEE SHEN, ADRIANNE N. EDWARDS,
MAHFUZUR R. SARKER AND DANIEL PAREDES-SABJA

56

Notably, different mechanisms exist between these organisms for forming and germinating spores. Some of these differences reflect phylogenetic differences between the *Clostridiaceae* (represented by *C. perfringens* and *C. botulinum*) and the *Peptostreptococcaceae* (represented by *C. difficile*) (1). Other differences reflect genetic diversity within each species (2–4). *C. botulinum* is the most divergent, being divided into four metabolic groups (groups 1 to IV) that effectively represent different species despite their shared production of botulinum toxin (5).

IMPORTANCE OF SPORES TO CLOSTRIDIAL PATHOGENESIS

Disease transmission by clostridial pathogens depends on their ability to form aerotolerant, metabolically dormant spores before exiting their hosts (6). Since spores are highly resistant to extreme temperature and pressure changes, radiation, enzymatic digestion, and oxidizing agents (7), they can persist for long periods of time and serve as environmental reservoirs for these organisms (8). Spores from *C. perfringens*, *C. botulinum*, and *C. difficile* can be isolated from diverse environments, including animal gastrointestinal tracts and carcasses, wastewater, lawns, hospital rooms, and soil (8). Infections by these pathogens typically are initiated upon ingestion of spores, although *C. perfringens* can also enter the body via contaminating wounds. Upon sensing small-molecule germinants, spores from these pathogens germinate and outgrow into toxin-secreting vegetative cells.

C. perfringens

C. perfringens causes two major human diseases: food poisoning and gas gangrene (also known as clostridial myonecrosis [9]). Clostridial myonecrosis occurs when spores from the soil enter muscle tissue, typically through a wound, while food poisoning arises when spores or vegetative cells in contaminated food are ingested. Unlike most clostridial pathogens, *C. perfringens*' vegetative form can initiate infection when present at sufficiently high levels to survive passage through the stomach. *C. perfringens* causes disease by secreting a number of toxins; *C. perfringens* strains are subdivided into toxigenic types A to E based on the combination of the alpha-, beta-, epsilon-, and iota-toxins they produce.

C. perfringens spores can be remarkably heat resistant, with some type A strains surviving boiling for >1 h (10, 11). Spores from food-poisoning isolates exhibit greater resistance to heat (~60-fold), cold, and oxidizing agents (12, 13) than nonfoodborne isolates, suggesting that their resistance properties facilitate their survival in undercooked or improperly held food (10).

C. botulinum

C. botulinum causes a flaccid paralysis known as botulism through the production of the potent neurotoxin, botulinum toxin (BoNT). *C. botulinum* strains are subdivided based on their production of one or more of seven BoNT types (A to G) (14, 15). Botulism typically results from the ingestion of preformed BoNT in contaminated foods, but ingestion of *C. botulinum* spores in contaminated foods such as unpasteurized honey can cause infant paralysis, particularly in those <1 year old (16). Even in cases of botulism intoxication, the spore form is critical for contaminating food, where incomplete sterilization or processing, such as during home canning, can create anaerobic environments that allow *C. botulinum* spores to germinate and form toxin-producing vegetative cells that subsequently intoxicate the food (17).

C. difficile

C. difficile is a leading cause of antibiotic-associated diarrhea and pseudomembranous colitis worldwide (18, 19). *C. difficile*-associated disease occurs when spores, ingested by susceptible hosts, germinate in response to specific bile acids sensed in the mammalian gut; the resulting vegetative cells produced secrete glucosylating toxins that are the primary cause of disease symptoms (20). Notably, antibiotic exposure sensitizes individuals to antibiotic-resistant *C. difficile* by removing the colonization resistance conferred by our gut microflora (21). Spores are critical to this infection process not only because they are essential for transmitting *C. difficile* infections (6) but also because they are inert to antibiotics and resist many commonly used disinfectants in health care settings (22, 23). Accordingly, spores are easily detected in health care-associated environments (24) in addition to numerous other sites (8).

OVERVIEW OF SPORE FORMATION

The first morphological stage of sporulation is the formation of a polar septum, which generates two morphologically distinct,

doi:10.1128/microbiolspec.GPP3-0017-2018

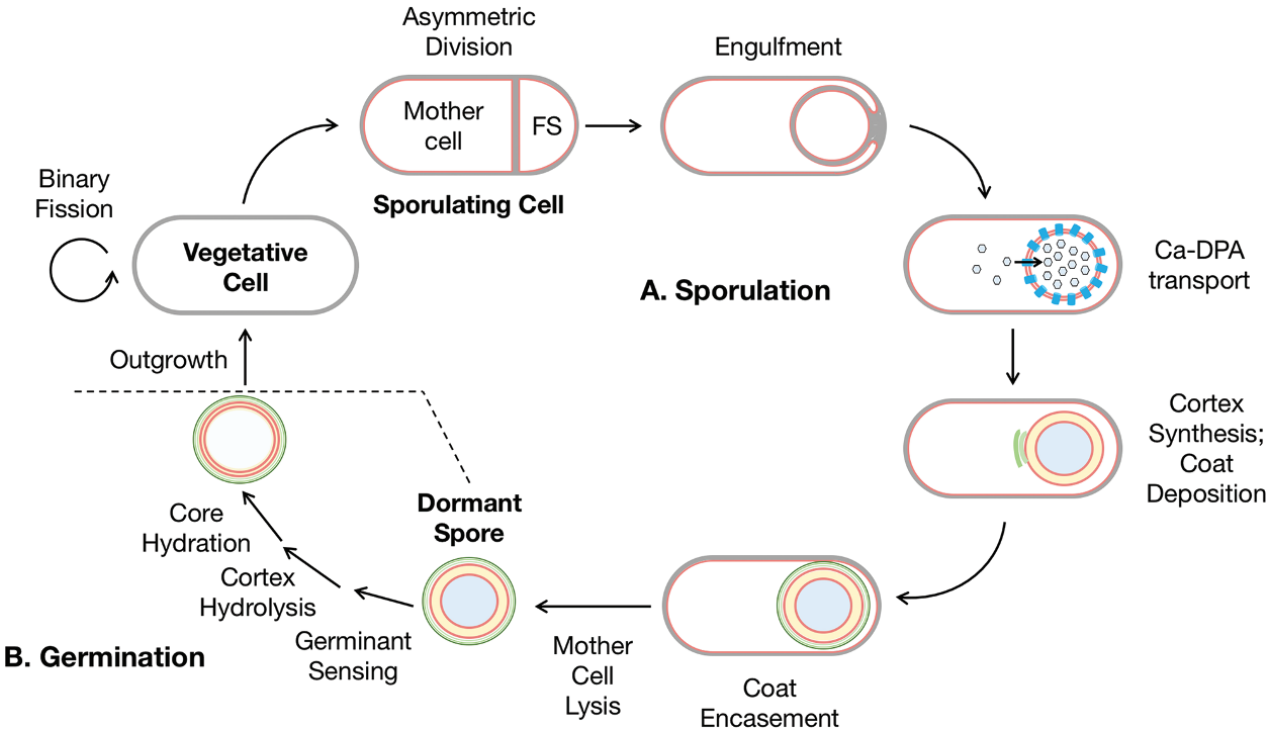

FIGURE 1 Lifecycle of endospore formers. (A) Sporulation. Upon sensing certain environmental conditions, endospore formers activate Spo0A and initiate sporulation. The first morphological event is the formation of a polar septum, which creates a larger mother cell and smaller forespore. The mother cell engulfs the forespore, and the two cells work together to assemble the dormant spore. Calcium dipicolinic acid (Ca-DPA) is synthesized in the mother cell and transported into the forespore in exchange for water. The cortex is formed between the two membranes, and coat proteins polymerize on the surface of the mother cell-derived membrane. Once the spore is mature, the mother cell lyses and releases the dormant spore into the environment. (B) Germination. Upon sensing the appropriate small molecule germinants, the spore initiates a signaling cascade that leads to activation of cortex hydrolases and core hydration, which is necessary for metabolism to resume in the germinating spore.

but genetically identical, cells (Fig. 1) (25). The larger mother cell engulfs the smaller forespore cell, leaving the forespore within the mother cell cytosol surrounded by two membranes. A thick layer of modified peptidoglycan known as the cortex forms between the two membranes, conferring spores with heat and ethanol resistance (26, 27). A series of proteinaceous layers known as the coat assembles around the outer forespore membrane and protects the spore against enzymatic and oxidative insults. In *C. difficile*, an additional layer known as the exosporium assembles on the coat, but this layer is not present in all spore-forming organisms.

The mother cell and forespore also coordinately prepare the forespore for dormancy. The mother cell produces large amounts of dipicolinic acid (pyridine-2,6-dicarboxylic acid) complexed with calcium (Ca-DPA), which it pumps into the developing forespore in exchange for water (28). The resulting partially dehydrated forespore cytosol prevents metabolism. The forespore produces large amounts of small acid-soluble proteins (SASPs), which coat the chromosome, prevent transcription, and protect against DNA damage (26, 28). Once the forespore completes its maturation, the mother cell induces lysis and releases the metabolically dormant spore into the environment.

SPORULATION INITIATION IN CLOSTRIDIAL PATHOGENS

The decision to initiate sporulation requires that vegetative cells recognize specific environmental and nutritional signals and assimilate these cues into a robust response. All sporulating *Firmicutes* use the conserved transcriptional regulator, Spo0A, as a key checkpoint for integrating these signals. The response regulator Spo0A initiates spore formation by activating or repressing the expression of genes encoding early sporulation regulators (6, 29–34), and its DNA-binding activity is directly controlled by phosphorylation. In the model organism *B. subtilis*, Spo0A phosphorylation is orchestrated by a complex regulatory network, known as a phosphorelay, which consists of several orphan sensor histidine kinases (KinA-E; orphan refers to histidine kinases that are not encoded beside a response regulator) and two phosphotransfer proteins (Spo0F and Spo0B) (35). The KinA to KinE kinases directly phosphorylate Spo0F, which subsequently transfers the phosphate to Spo0B and finally to Spo0A (Fig. 2) (36). Antikinases and two classes of phosphatases inhibit Spo0A phosphorylation levels by either blocking kinase activity or stripping Spo0A or Spo0F of its phosphate (37). The complexity of this regulatory pathway functions as a noise generator, creating heterogeneous levels of Spo0A phosphorylation within a population such that only a portion of its population commits to sporulation (38–40).

Notably, the *B. subtilis* phosphorelay is absent in clostridial pathogens, since clostridia lack orthologs of the Spo0F and Spo0B phosphotransfer proteins (41, 42). Thus, Spo0A appears to be directly phosphorylated by histidine kinases in clostridial organisms (32, 33, 43–46), although the kinases, regulatory pathway, and environmental signals used to

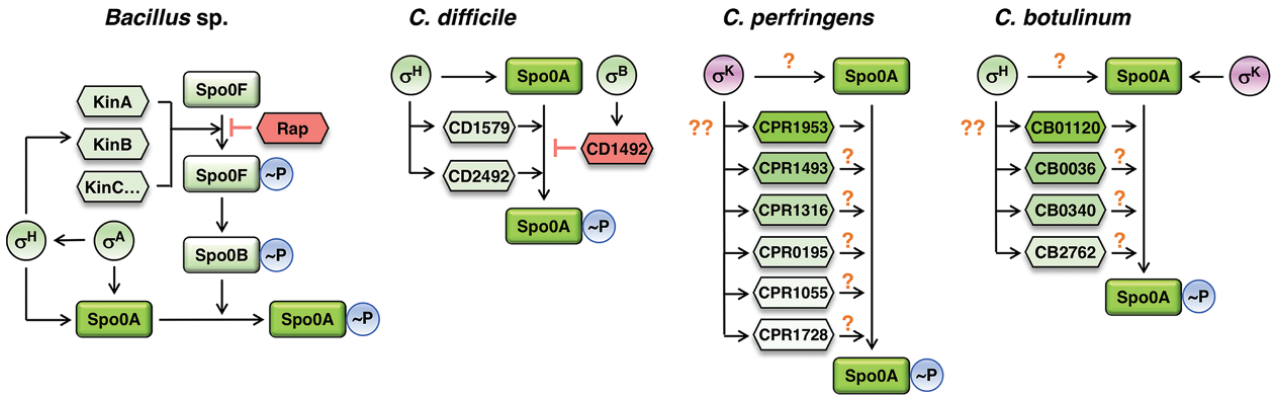

FIGURE 2 Sporulation initiation via Spo0A phosphorylation. Sigma factors are shown as circles, histidine kinases and phosphatases as hexagons (adapted from Al-Hinai et al. [85]). Positive regulators are shown in green (with the exception of σ^K, which is shown in purple), and negative regulators are shown in red. In *B. subtilis*, the KinA-E orphan histidine kinases phosphorylate the phosphotransfer protein Spo0F, the first component in the phosphorelay (25). The Rap phosphatases remove phosphates from phosphorylated Spo0F. The phosphate is transferred from Spo0F to Spo0B to Spo0A. In *C. difficile*, the orphan histidine kinases CD1579 and CD2492 appear to phosphorylate Spo0A (32), while CD1492 likely dephosphorylates Spo0A (47). A more detailed description of *C. difficile* Spo0A regulation is shown in Fig. 3. Although all the putative orphan histidine kinases with the potential to phosphorylate Spo0A in *C. perfringens* and *C. botulinum* are shown, whether they act as positive or negative regulators remains unstudied. The stationary factor σ^H activates expression of *spo0A* in *B. subtilis* and *C. difficile* (101), while σ^K activates *spo0A* transcription in *C. botulinum* (74) and possibly *C. perfringens*, the latter of which induces sporulation during log-phase growth (65).

control clostridial Spo0A phosphorylation remain largely uncharacterized.

C. difficile

Sporulation initiation has been most extensively studied in *C. difficile*, where key Spo0A regulatory proteins have been identified (Fig. 3). An initial study identified three orphan histidine kinases with significant homology to the *B. subtilis* family of sporulation-associated phosphotransfer histidine kinases (32). Loss of one of these putative histidine kinases, CD2492, decreased spore formation ~3-fold in rich liquid media, while another kinase, CD1579, directly phosphorylated Spo0A *in vitro* (32). These results suggest that both CD2492 and CD1579 promote Spo0A activation. Loss of the third putative histidine kinase, CD1492, increases sporulation ~4-fold on solid sporulation media in a manner dependent on its conserved histidine residue (47), suggesting that CD1492 functions as a phosphatase rather than as a kinase.

Interestingly, CD2492 does not necessarily always promote sporulation, since a *CD2492* mutant exhibits increased sporulation on solid sporulation media independent of its conserved histidine residue (A. Edwards and S. McBride, unpublished data). The discrepancy in *CD2492* mutant sporulation phenotypes could be due to differences in growth conditions and/or methods for measuring spore formation. The signals that control kinase versus phosphatase activity of sporulation-associated histidine kinases are largely unknown, even in *B. subtilis*; thus, the activity observed may depend on the presence or absence of unidentified signals. Indeed, one *B. subtilis* kinase mutant exhibits varying sporulation phenotypes depending on the growth conditions used (48, 49). This contradiction highlights the importance of assessing sporulation using multiple conditions and verifying spore frequencies with at least two different methods (50).

Notably, sporulation-associated histidine kinases directly control Spo0A phosphorylation through competing kinase and phosphatase activities in *C. acetobutylicum* and *C. thermocellum*, where at least one sporulation-associated histidine kinase in each species inhibits sporulation *in vivo* (44, 45), and a *C. acetobutylicum* histidine kinase has been shown to dephosphorylate Spo0A *in vitro* (45). Altogether, clostridial sporulation-associated histidine kinases appear to reversibly regulate Spo0A phosphorylation and thus the onset of sporulation.

Spo0A activity in *C. difficile* is further modulated by an RRNPP family ortholog, RstA (regulator of sporulation and toxins) (51), which shares homology with the Rap phosphatases that directly dephosphorylate Spo0F in *B. subtilis*. RRNPP family members have multiple C-terminal tetratricopeptide repeat domains that bind quorum-sensing peptides and regulate the cognate N-terminal helix-turn-helix DNA-binding domain and/or Spo0A/Spo0F-binding domain (52, 53). RstA contains these three conserved regulatory domains, and an *rstA* mutant produces ~20-fold fewer spores than the wild type, indicating that RstA promotes early sporulation events in *C. difficile* (29). Although the helix-turn-helix domain appears to be dispensable for RstA to modulate sporulation (29), the putative Spo0A/Spo0F-binding domain may directly bind and control Spo0A phosphorylation and/or dephosphorylation (A. Edwards and S. McBride, unpublished data). Interestingly, in addition to regulating sporulation, RstA represses motility and toxin production (see below) (51). Homologs of RstA are observed in both pathogenic and nonpathogenic clostridial organisms, including *C. sordellii*, *C. perfringens*, *C. botulinum*, and *C. acetobutylicum* (51).

RRNPP systems in other spore formers use quorum-sensing peptides to control activity of the regulator and, thus, sporulation initiation. For example, *B. subtilis* Rap phosphatase activity is inhibited by quorum-sensing peptides imported by the conserved oligopeptide permeases Opp and App, promoting sporulation (32, 34–36). Further, *C. acetobutylicum* sporulation is affected by the deletion or overexpression of genes encoding RRNPP-type regulators, which are located adjacent to putative quorum-sensing peptide genes (54). However, it is unclear whether *C. difficile* RstA activity is regulated by quorum-sensing peptides. Regardless, peptide transport coordinates the onset of sporulation in *C. difficile*, since the loss of Opp and App increases *C. difficile*

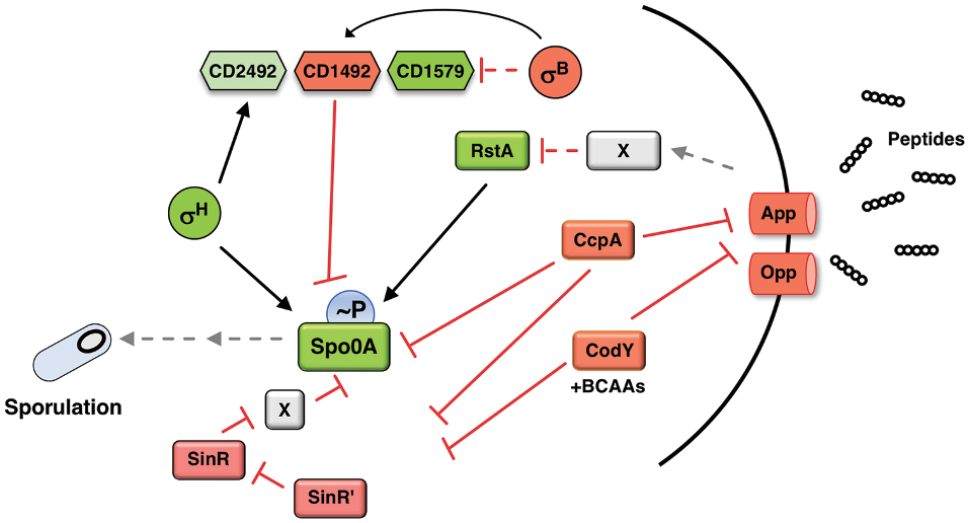

FIGURE 3 Regulatory pathway controlling Spo0A activation in *C. difficile*. Early sporulation factors experimentally determined to function as positive regulators of Spo0A are highlighted in green, and those that inhibit Spo0A are highlighted in red (32, 47, 51, 55, 56, 59, 61, 62, 101). Hexagons indicate histidine kinase/phosphatases, rounded rectangles demarcate transcription factors, and circles highlight sigma factors. Red lines indicate negative regulation, and black lines indicate positive regulation. SinR and SinR′, *C. difficile* orthologs for regulatory proteins characterized in *B. subtilis* (gray), were recently shown to promote sporulation (60). Solid lines indicate defined regulatory interactions, and dashed lines suggest proposed, and potentially indirect, regulatory effects. Branched-chain amino acids are a CodY cofactor (59), and their precursors are likely imported primarily through the Opp and App oligopeptide transporters (55, 61). CcpA-independent carbon-specific regulation is not shown (56). The reciprocal transcriptional regulation of early sporulation factors by Spo0A has also been omitted for simplicity (100).

sporulation ~20-fold (55). These results suggest that the peptides imported by *C. difficile* Opp and App serve as nutrients rather than quorum-sensing molecules such that *C. difficile opp* and *app* mutants may initiate sporulation earlier due to decreased nutrient acquisition.

Metabolic cues regulate the initiation of *C. difficile* sporulation because the global regulators CcpA and CodY directly control the expression of genes encoding early sporulation regulators. CcpA senses carbon availability (56, 57), and CodY senses GTP and branched-chain amino acid levels (58, 59). CcpA directly represses the expression of *spo0A* and the *opp* and *sigF* operons (*sigF* encodes the first sporulation-specific sigma factor to be activated). CcpA also indirectly downregulates transcription of *sinR* (56), which encodes an early sporulation regulator that enhances sporulation (60). Not surprisingly, sporulation is increased ~10-fold in a *ccpA* mutant (56), providing further evidence that *C. difficile* initiates sporulation in response to nutrient deprivation. Similarly, CodY downregulates transcription of *sinR* and the *opp* operon, and a *codY* mutant exhibits increased sporulation (61). However, CodY's effect on sporulation is strain specific, given that an R20291 *codY* mutant produces ~100-fold more spores than the parent strain, but the equivalent mutant in 630Δ*erm* produces only ~2-fold more spores (61). Interestingly, the addition of glucose reduces sporulation frequency in a CcpA-independent manner (56), revealing that additional regulatory pathways impact the timing of sporulation in response to nutritional cues.

C. difficile also uses alternative sigma factors to control sporulation initiation. SigH, which controls the transition to stationary phase, is essential for sporulation and directly drives the expression of *spo0A*, similar to *B. subtilis* (35), and *CD2492*, which modulates Spo0A phosphorylation. In contrast, SigB, the general stress response sigma factor, inhibits predivisional sporulation-specific gene expression and decreases spore formation (62). SigB likely decreases Spo0A phosphorylation by reducing transcription of *CD1579*, which encodes a Spo0A kinase (12), and increasing transcription of *CD1492*, which encodes a putative Spo0A phosphatase (47).

The *C. difficile* genome encodes orthologs of additional *B. subtilis* early sporulation factors, such as SinRI, Spo0J-Soj, Spo0E, and KipI/KipA (see reference 63 for more detail). However, if the trend from recent research holds true, these uncharacterized *C. difficile* orthologs likely function differently from those in *B. subtilis*. Indeed, recent analyses indicate that the *C. difficile sinR* locus encodes two *sinR* homologs, *sinR* and *sinR′*, with SinR′ antagonizing SinR function, analogous to *B. subilis* SinI's negative effect on SinR activity. In *C. difficile*, SinR functions as a DNA-binding transcriptional regulator and enhances sporulation, although the mechanism is unclear. There is some evidence that SinR regulates early sporulation events, because Spo0A-dependent gene expression is significantly decreased in a *sinRR′* mutant and is not rescued by *spo0A* overexpression (60). Furthermore, additional novel *C. difficile* regulators of sporulation initiation are likely to be discovered given that *C. difficile* encounters a diverse array of environmental conditions during growth in the gut, which strongly induces sporulation gene expression relative to broth culture growth to promote survival outside of the host (64).

C. perfringens

In contrast to most spore-forming organisms, *C. perfringens* induces sporulation during the exponential phase (65).

Sporulation induction depends in part on sensing cell density through the Agr-like quorum-sensing system because an *agrB* mutant, which no longer makes a mature quorum-sensing peptide, has reduced Spo0A protein levels and produces ~1,000-fold fewer spores than the wild type (66). Like *C. difficile*, *C. perfringens* CcpA and CodY modulate sporulation (67, 68), although unlike *C. difficile*, *C. perfringens* CcpA activates rather than represses sporulation (68), with a *C. perfringens ccpA* mutant making ~60-fold fewer spores than the wild type. Nevertheless, similar to *C. difficile*, glucose strongly reduces *C. perfringens* sporulation frequency (~2,000-fold) in a CcpA-independent manner.

CodY regulates *C. perfringens* sporulation in a strain-specific manner, again analogous to *C. difficile*. Loss of CodY in the type D strain CN3178 increases spore formation ~10-fold (67, 68), whereas loss of CodY in the food-poisoning strain SM101 reduces sporulation ~1,000-fold relative to the wild type (69). CodY likely regulates sporulation by altering expression of *abrB*, which encodes a negative regulator of sporulation that functions in a strain-specific manner (67). *C. perfringens* also employs a regulatory RNA, *virX*, to repress sporulation by decreasing the expression of genes encoding sporulation-specific factors (70).

While the kinases that phosphorylate *C. perfringens* Spo0A remain unknown, six putative orphan histidine kinases have been identified in BLAST searches (71). Given that the bile acid deoxycholate induces *C. perfringens* Spo0A phosphorylation and thus sporulation (72), these kinases may specifically respond to this bile acid. Similarly, inorganic phosphate induces *C. perfringens* sporulation (73) and could stimulate kinase activity.

C. botulinum

Unlike *C. perfringens*, *C. botulinum* sporulates during the transition from exponential to stationary phase (74). Like *C. perfringens*, the Agr-like quorum-sensing system is important for sporulation initiation, with *agrB* and *agrD* *C. botulinum* mutants producing ~1,000-fold fewer spores (75). While the impact of CcpA and CodY on *C. botulinum* sporulation remains to be studied, five putative orphan kinases have been identified as possible regulators of Spo0A (33). The CB01120 histidine kinase appears to phosphorylate Spo0A based on the observation that production of CB01120 with wild-type Spo0A, but not with a nonphosphorylatable form of Spo0A, causes lethality when heterologously produced in *B. subtilis* (33).

THE LINK BETWEEN SPORULATION AND TOXIN GENE EXPRESSION IN *C. DIFFICILE*

Although most *Clostridium* species initiate sporulation to survive unfavorable conditions, *C. perfringens* and *C. botulinum* directly couple toxin production (10, 30) to sporulation, while *C. difficile* coordinates these processes in a strain-specific manner (76).

C. perfringens Enterotoxin (CPE)

C. perfringens type A causes food-poisoning and nonfoodborne gastrointestinal disease (3). These diseases are caused by the CPE toxin (13), which is encoded either (*cpe*) chromosomally or on a large plasmid: most food-poisoning isolates carry chromosomal *cpe*, while most nonfoodborne isolates carry a plasmid-borne *cpe* (13, 77, 78). Food poisoning typically occurs when chromosomal *cpe* isolates are ingested with food, while nonfoodborne disease is primarily acquired by ingesting spores. Regardless, growth of *C. perfringens* in the small intestine leads to CPE production and thus disease (3).

Numerous studies have demonstrated a strong correlation between spore formation and CPE production (79–82). The first genetic evidence linking *C. perfringens* sporulation with CPE synthesis came from studies showing that mutants blocked at asymmetric division during sporulation failed to produce CPE, while mutants blocked at later stages of sporulation produced CPE (81). For example, a *C. perfringens* strain SM101 *spo0A* mutant cannot produce CPE (29), while inorganic phosphate (Pi) induces both sporulation and CPE production in the wild type (73).

Expression of the *cpe* gene is induced during sporulation, with the *cpe* transcript being detected only in sporulating, but not vegetative, *C. perfringens* cultures (80, 83). *cpe* is transcribed from three promoters, named P1, P2, and P3, that are either σ^E- or σ^K-dependent (83). These promoters induce high levels of CPE production during sporulation, with CPE constituting up to 20% of the total protein present (84). σ^E and σ^K are likely mother cell-specific (85), so CPE production appears to be restricted to the mother cell cytoplasm, where it reaches sufficiently high concentrations to induce paracrystalline inclusion body formation (84). However, rather than being secreted from sporulating cells, CPE is released upon mother cell lysis in the late stage of sporulation (84). Accordingly, *sigK* and *sigE* mutants of the food-poisoning strain SM101 fail to express *cpe* (65), while a *sigF*, but not a *sig*G, mutant exhibit defects in *cpe* expression and CPE production based on reverse transcription PCR (RT-PCR) and Western blot analyses (86). Thus, only σ^F, σ^E, and σ^K are necessary for *cpe* transcription and CPE production (65), even though all four sporulation-specific sigma factors are required for *C. perfringens* sporulation (10, 65).

Since CPE production is strictly sporulation dependent, factors that regulate early events of *C. perfringens* sporulation also regulate CPE production. Accordingly, the Agr-like quorum-sensing system in the nonfoodborne strain F5603 and CodY in the food-poisoning strain SM101 both activate CPE production by activating Spo0A and inducing σ^F production (66, 67). *virX*, a regulatory RNA that represses sporulation, accordingly reduces *cpe* expression and CPE production (70). Notably, while sporulation is crucial for CPE production, CPE is not required for sporulation, because *cpe* mutants sporulate at wild-type levels (13, 87).

C. perfringens TpeL Toxin

Many *C. perfringens* isolates encode a novel toxin named TpeL, which belongs to the family of large clostridial toxins (88) and is encoded both chromosomally and on plasmids (89–91). While the contribution of TpeL to *C. perfringens* pathogenesis is unknown, *tpeL* expression is specifically induced during sporulation based on transcriptional reporter studies (92). The *tpeL* promoter region contains σ^E- and σ^K-dependent sequences, and loss of σ^E strongly reduces *tpeL* expression (~100-fold) (92), indicating that *tpeL* expression also depends on σ^E, similar to *cpe*. More recent analyses indicate that *tpeL* expression is induced by TpeR, a transcriptional regulator encoded in the same pathogenicity locus (PaLoc) as *tpeL*; in these analyses, TpeL production was observed under conditions that promote vegetative cell growth (93).

C. botulinum Type Neurotoxin (BoNT)

Toxin production and sporulation coincide during the transition from exponential to stationary phase, suggesting that

these processes may be coregulated. The Agr-like quorum-sensing system may coordinate these processes as in *C. perfringens*, since toxin and spore formation are reduced in *agrB* and *agrD* mutants (75). In aquatic *C. botulinum* type E strains (94, 95), sporulation and BoNT production are directly linked, because loss of Spo0A prevents spore formation and reduces BoNT production >10-fold relative to the wild type (30). Spo0A likely directly regulates toxin production, because Spo0A directly binds the *botE* promoter *in vitro*, which contains a Spo0A box (30). Interestingly, Spo0A is the first neurotoxin regulator identified in *C. botulinum* type E, which does not encode the alternative sigma factor, BotR, which activates botulinum gene expression in other strains (96).

C. difficile Glucosylating Toxins

C. difficile produces two large exotoxins, toxin A (TcdA) and toxin B (TcdB), which are critical for virulence (97–99). The regulatory links between *C. difficile* toxin production and sporulation are complex and appear to be strain dependent. Spo0A represses toxin expression in epidemic 027 ribotypes (6, 76), does not impact toxin expression in the emerging 078 ribotype (76), and variably impacts toxin expression in the historic 012 ribotype (6, 31, 32, 76, 100). In the 630 background (012 ribotype), the stationary phase sigma factor, SigH, downregulates toxin gene expression (101), and the phosphotransfer protein, CD1492, positively affects toxin production (47), presumably through indirect means. However, as with sporulation, nutrient availability strongly influences toxin gene expression since amino acids and glucose repress toxin gene expression through the global regulators CodY and CcpA, respectively (57, 59, 102).

The most direct link between toxin gene expression and sporulation is RstA, the RRNPP family member discussed above, which inversely regulates toxin production and sporulation (51). RstA inhibits transcription of *tcdA* and *tcdB* by directly binding to the promoters and inhibiting the transcription of *tcdR* and *sigD* (29; A. Edwards and S. McBride, unpublished data). *tcdR* encodes the sigma factor that directly activates toxin gene expression (103), while *sigD* encodes the flagellar-specific sigma factor that also directs *tcdR* transcription (104, 105). This multitiered regulation suggests that RstA tightly controls toxin production. While RstA-dependent repression of toxin gene expression requires its DNA-binding domain, its regulation of sporulation does not. Thus, RstA regulates sporulation and toxin gene expression through independent mechanisms (51). However, it remains unclear if this bifunctional protein links sporulation and toxin regulation in the same cell: single-cell analyses would reveal whether toxin-producing cells also sporulate or whether these important processes are asynchronous. Interestingly, the regulatory pathways between sporulation and toxin gene expression may be reciprocal in some *C. difficile* strains, because TcdR enhances spore formation in R20291 (027 ribotype) but not 630 (106).

Overall, several *C. difficile* regulators control both sporulation and toxin gene expression, suggesting that the coordinate regulation of both of these processes is important for *C. difficile* survival.

THE SPORULATION TRANSCRIPTIONAL PROGRAM

Once Spo0A is phosphorylated, it induces asymmetric division, which eventually leads to the activation of four sporulation-specific sigma factors: σ^F, σ^E, σ^G, and σ^K. These sigma factors are essential for sporulation (25, 85, 107) because they coordinate the activation of distinct transcriptional programs within the mother cell and forespore, respectively, that culminate in the formation of a metabolically dormant spore. While the regulation of sporulation-specific sigma factors has been extensively analyzed in *B. subtilis*, the conserved sporulation sigma factors exhibit notable differences in their regulation and function in clostridial organisms relative to *B. subtilis* as well as between clostridial organisms. We first describe the activation and functions of sporulation-specific sigma factors in *B. subtilis* and then compare these properties with those in *C. difficile*, *C. perfringens*, and *C. botulinum*.

B. subtilis sporulation-specific sigma factors are posttranslationally activated in a compartment-specific and sequential manner. σ^F is activated in the forespore, followed by σ^E in the mother cell; σ^E then activates σ^G in the forespore, which subsequently activates σ^K in the mother cell (Fig. 4) (25). Intercompartmental signaling regulates sporulation sigma factor activation and couples it to specific morphological changes (108). Spo0A induces the transcription of *sigF* and *sigE* in the predivisional cell such that σ^F and σ^E are present in both the mother cell and forespore, although both sigma factors remain inactive until asymmetric division is complete. σ^F is first activated in the forespore when the preferential activation of the SpoIIE phosphatase in the forespore leads to dephosphorylation of the anti-anti-sigma factor, SpoIIAA (109–111), which antagonizes the anti-sigma factor, SpoIIAB. Inhibition of SpoIIAB frees σ^F to bind its target promoters, which include *sigG* and *spoIIR*. The resulting production of SpoIIR leads to σ^E activation because SpoIIR activates SpoIIGA, the protease that removes σ^E's inhibitory propeptide in the mother cell (112–114).

Activated σ^E directs the transcription of genes (115) required for the mother cell to (i) engulf the forespore in a phagocytic-like process (*spoIID*, *spoIIP*, and *spoIIM* [116–118]), (ii) localize coat proteins to the forespore (119), (iii) activate σ^G in the forespore (*spoIIIA* operon [120]), and (iv) produce and activate σ^K in the mother cell (*sigK*, *spoIIID*, *spoIVFA-B*, *ctpB*, and *spoIVCA* [121–125]). The SpoIIIA proteins form a complex with GerM and the forespore-specific SpoIIQ to form a channel connecting the mother cell and forespore (126–129). This channel, also known as the "feeding tube," is required to maintain transcriptional potential in the forespore (126) and, thus, σ^G activity. SpoIIQ also contributes to σ^G activation by controlling the localization of SpoIIE, which likely antagonizes the σ^G-specific anti-sigma factor, CsfB (130). Thus, discrete anti-sigma factors control the activation of σ^F and σ^G, respectively, in *B. subtilis*.

Engulfment increases σ^G activity, which couples its transcriptional program to morphological changes (131). Activated σ^G directs the transcription of genes in the forespore (132) required to (i) modify the cortex (133), (ii) prepare the forespore for dormancy (7), and (iii) activate σ^K via regulated proteolysis by the mother cell-localized protease SpoIVFB (125). Thus, proteolytic signaling cascades induced by the forespore activate σ^E and σ^K in *B. subtilis*.

σ^K production depends on σ^E because σ^E activates transcription of *spoIIID*, which encodes the transcriptional regulator that induces *sigK* expression (134). σ^E also controls the expression of *spoIVCA*, which encodes the site-specific recombinase necessary to mediate excision of the *skin* element, a 42-kB prophage-like region that disrupts the *sigK* gene (122). Thus, multiple levels of σ^K regulation control the precise timing of its activation in *B. subtilis* to ensure proper spore assembly, since activated σ^K induces cortex and coat assembly genes (135).

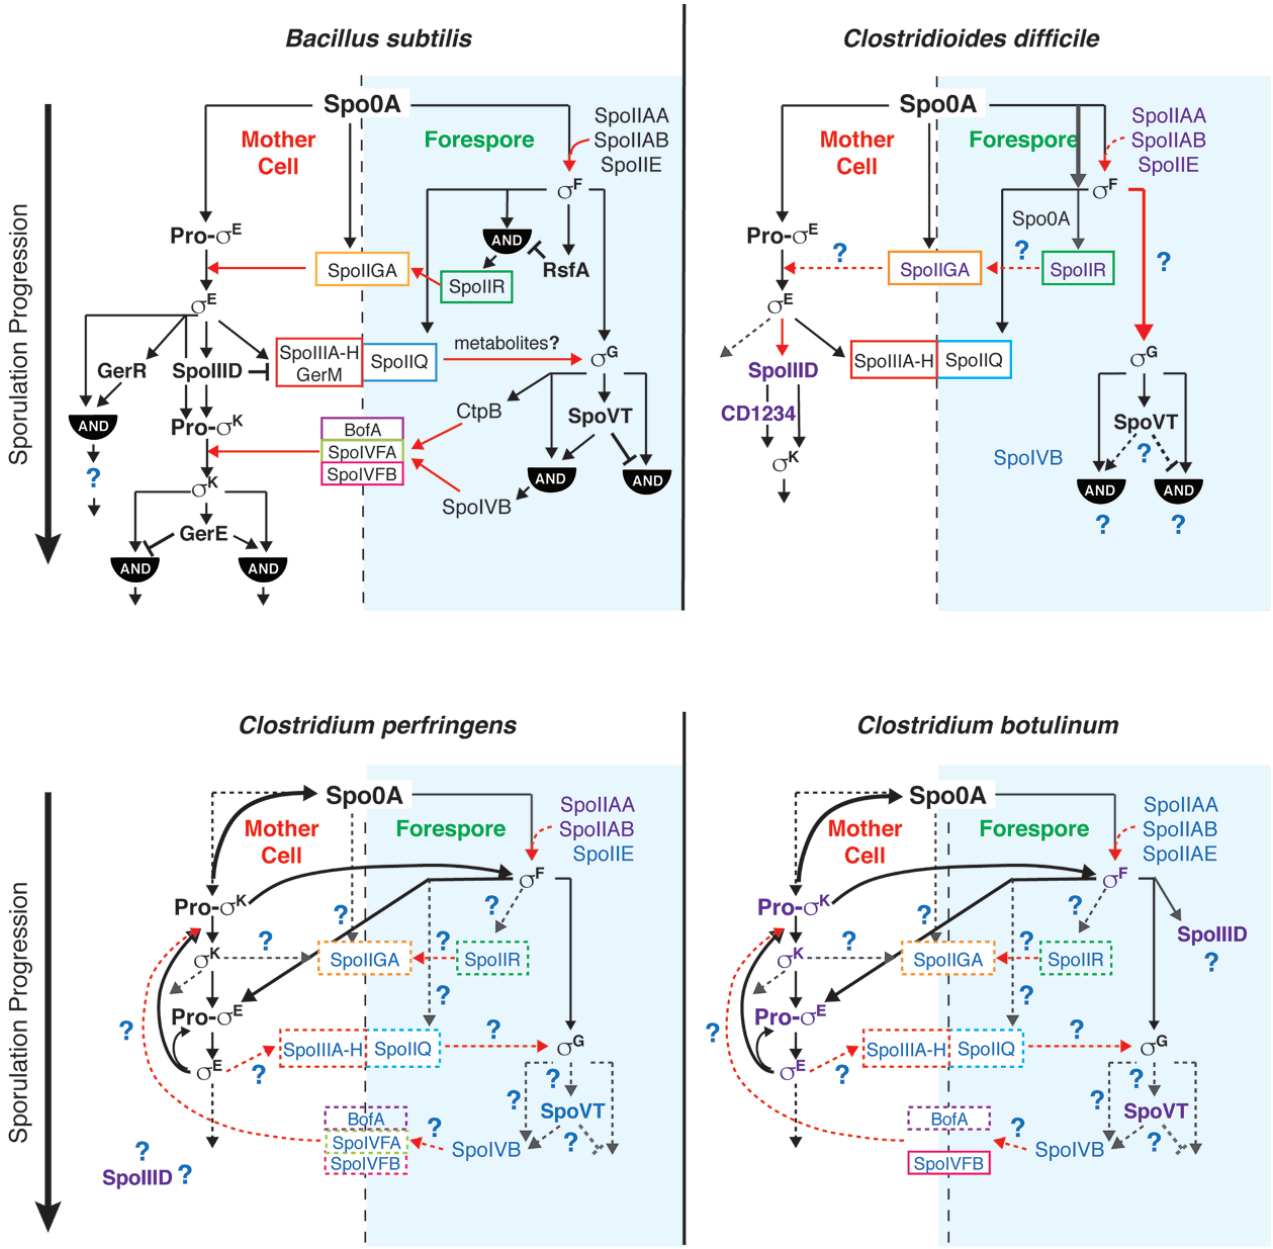

FIGURE 4 Diversity in the regulation of the transcriptional programs controlling sporulation in the *Firmicutes*. The temporal progression of sporulation is shown from top to bottom. Transcription factors and sigma factors are shown in bold, and proteins enclosed in boxes directly participate in signaling between the mother cell and forespore (dashed boxes indicate that trans-septum signaling has not been tested yet). Text color denotes whether the factor has been detected at both the transcript and protein level (black), at either the transcript or protein level (purple), or has not been tested yet at the transcript or protein level (blue). Black arrows delineate transcriptional control of gene expression, red arrows indicate signaling pathways, dashed lines indicate that the regulatory relationship remains unknown, and thick arrows demarcate notable points of divergence from the pathway defined in *B. subtilis*. AND gates are indicated. The figure is adapted from Fimlaid et al. (137) under Creative Commons BY 4.0.

Taken together, *B. subtilis* sporulation gene expression is tightly controlled both spatially and temporally, with events in the forespore being coupled to events in the mother cell. Sporulation sigma factor activation and function are further controlled by additional feedback and feedforward loops to ensure that the timing of sporulation gene expression is tightly coordinated with morphological changes (136).

Notably, while most of the gene products that control sporulation sigma factor activation in *B. subtilis* are conserved in the clostridia, the functions of some of these gene products and the timing of their action are not always conserved. Many of the regulatory loops that fine-tune the timing of sporulation sigma factor activation and function in *B. subtilis* are not conserved in clostridial organisms (42, 71) (Fig. 4), suggesting that (i) sporulation sigma factor activity may not be as tightly regulated in clostridial pathogens relative to *B. subtilis* and/or (ii) additional regulatory pathways exist. While this review focuses on sporulation sigma factor

regulation in pathogenic clostridia, this process has also been examined in detail in *C. acetobutylicum*, which revealed notable differences in the regulation of these sigma factors relative to *B. subtilis* (reviewed by Al-Hinai et al. [85]).

C. difficile

Sporulation sigma factor activation has been best studied in *C. difficile*, where genome-wide transcriptional analyses of sigma factor mutants have defined the regulons of sporulation-specific sigma factors (137, 138). These factors were shown to function in a compartment-specific manner similar to that in *B. subtilis* (Fig. 4) through the development of SNAP tag-based transcriptional reporter constructs by the Henriques group (139). Specifically, *C. difficile* σ^F and σ^G activity is restricted to the forespore, while σ^E and σ^K activity is restricted to the mother cell (139). This regulation resembles *B. subtilis* (25), with the exception that *sig*G expression does not require σ^F and is likely activated by Spo0A (137).

The mechanisms underlying both *C. difficile* σ^F and σ^E activation likely occur through a mechanism similar to that in *B. subtilis* based on gene conservation. Consistent with this notion, the σ^F-activating phosphatase, SpoIIE, and the σ^E-activating protein, SpoIIR, are essential for sporulation based on a transposon screen (140). Similar to *B. subtilis*, *C. difficile* SpoIIR is required for pro-σ^E processing (138). However, unlike *B. subtilis*, *C. difficile* σ^F is not essential for this proteolytic activation event because *spoIIR* is expressed from both Spo0A-dependent and σ^F-dependent promoters (138). Thus, *C. difficile* σ^E is partially active in a *sigF* mutant (137, 138).

C. difficile σ^G and σ^K activation differs markedly from that in *B. subtilis*. Whereas σ^G activation depends on the SpoIIQ-SpoIIIA channel complex in *B. subtilis*, *C. difficile* σ^G is active in the absence of this channel and its associated engulfment defects (141, 142). Notably, σ^G is present but inactive in the absence of σ^F (137), indicating that *C. difficile* σ^G activity is posttranslationally activated in the forespore through an unknown mechanism.

Unlike most spore-forming organisms, *C. difficile* σ^K lacks the N-terminal inhibitory propeptide (143) that tethers *B. subtilis* pro-σ^K to the membrane (123). As a result, *C. difficile* σ^K is active upon translation, since expression of *sigK* from a tet-inducible promoter in vegetative *C. difficile* allows σ^K-dependent genes to be transcribed in contrast to *B. subtilis* (144). However, similar to *B. subtilis*, *C. difficile sigK* transcription depends on the excision of a large *skin* element that disrupts the *sigK* gene (143) and is activated by σ^E and SpoIIID (138, 144). In contrast to *B. subtilis*, the gene encoding the excision recombinase, *CD1231*, is constitutively expressed rather than activated by σ^E (145). Instead, CD1231 activity is posttranslationally activated by the CD1234 recombination directionality factor, whose production depends on both σ^E and SpoIIID. Thus, CD1231 and CD1234 control the timing of SigK production and enhance the fidelity of spore assembly (145), similar to *B. subtilis* (146).

C. difficile sporulation sigma factors generally control morphological processes similar to those in *B. subtilis*, with σ^F and σ^E being required for initiating engulfment, and σ^E and σ^K being required for coat assembly (139). Unlike *B. subtilis*, *C. difficile* σ^G, but not σ^K, is required for cortex production, and *C. difficile* σ^G is required for engulfment completion at least during sporulation on solid media (137).

Taken together, *C. difficile* sporulation sigma factor mutants exhibit less intercompartmental signaling, with the forespore line of gene expression requiring σ^F and σ^G, but not σ^E, and the mother cell line of gene expression requiring σ^E and σ^K, but not σ^G (107, 137–139) (Fig. 4). Furthermore, the timing of sporulation sigma factor activation does not to appear to be as closely coupled to morphological events as in *B. subtilis* (25, 107).

C. perfringens and *C. botulinum*

The regulation of sporulation sigma factors in *C. perfringens* and *C. botulinum* has not been characterized extensively, although gene conservation analyses indicate that the minimal machinery required for activating these sigma factors is conserved (Fig. 4) (136). *C. perfringens* σ^E and σ^K both undergo proteolytic processing during sporulation, similar to *B. subtilis* and *C. difficile* (65). However, in contrast to these organisms, the *sigK* genes in both *C. perfringens* and *C. botulinum* do not contain intervening *skin* elements. Notably, σ^K appears to function at two stages during sporulation in both these organisms, with the first stage regulating sporulation initiation. Indeed, *sigK* mutants in both organisms do not appear to initiate asymmetric engulfment (65, 74), unlike in *B. subtilis* and *C. difficile*. Thus, the function of σ^K as an early and late regulator of sporulation in *C. perfringens* and *C. botulinum* exhibits similarities to *C. acetobutylicum*, which uses σ^K to initiate sporulation through its activation of *spo0A* and during late stage sporulation (147).

In *C. perfringens*, *sigK* is expressed from two promoters at different stages of sporulation: the upstream *CPR_1739* promoter activates transcription during early log phase, in contrast to *B. subtilis* and *C. difficile*, while a σ^E-dependent promoter controls late-stage sporulation gene expression (65), similar to *B. subtilis* and *C. difficile*. *C. botulinum sigK* transcription is similarly biphasic, occurring during late log phase and late-stage sporulation (74). This latter phase of gene expression occurs from σ^F- and σ^E-dependent promoters (148). Consistent with σ^K being required early during sporulation in both these organisms, *C. perfringens* σ^K activates *sigF* and *sigE* expression (65), and *C. botulinum* σ^K activates *spo0A* and *sigF* expression (74). Furthermore, *sigK* mutants in both organisms fail to complete asymmetric engulfment (65, 74), whereas *sigE* mutants are stalled at this stage (65, 148). While transcriptional analyses indicate that σ^K acts upstream of σ^F, Western blot analyses have revealed that σ^K is not detectable in the absence of σ^F (86), suggesting that the production (or stability) of these two factors is interdependent.

Another major difference in sporulation gene regulation relative to *B. subtilis* and *C. difficile* is that σ^E does not activate *spoIIID* expression in *C. perfringens* and *C. botulinum*. Instead, *C. botulinum spoIIID* transcription is σ^F-dependent (149). Whether σ^F regulates *spoIIID* expression in *C. perfringens* is unclear, but immunoblotting indicates that SpoIIID production does not require σ^E or σ^K (65).

These observations raise the possibility that the sporulation sigma factors exhibit differences in their compartment-specific activation in *C. perfringens* and *C. botulinum* relative to *B. subtilis* and *C. difficile*. Indeed, *sigK* is transcribed early during sporulation in *C. perfringens* (65), suggesting that σ^K may also activate sporulation in predivisional *C. botulinum* cells. These observations raise the question of whether σ^K must be proteolytically activated at this early stage. Furthermore, since *sigK* expression is regulated by both σ^F and σ^E in *C. botulinum* (148), is σ^F activity (and by extension SpoIIID activity) restricted to the forespore?

Summary of Sporulation Regulation

Clearly, major differences exist in the functions and regulation of conserved sporulation sigma factors in *C. difficile*,

C. perfringens, and *C. botulinum* relative to the pathways defined in *B. subtilis*. *C. difficile*'s regulatory architecture exhibits greater similarity to *B. subtilis* than to *C. perfringens* and *C. botulinum*, which appear relatively similar to each other. Further study of *C. perfringens* and *C. botulinum* is needed to define the order of sporulation sigma factor activation, their specific regulons, and the location of their activity. Such studies could provide insight into the evolution of diverse sporulation networks.

SPORE ASSEMBLY

The mechanisms by which spores are physically assembled in clostridial organisms also remain poorly defined, although some progress has been made in *C. difficile*. This section focuses on factors required for engulfment, coat, and exosporium assembly in *C. difficile* and the functions of specific coat and exosporium proteins. We also outline the role of the spore-specific small molecule, calcium dipicolonic acid (Ca-DPA), during *C. perfringens* and *C. difficile* spore formation.

Engulfment

The second major morphological event after asymmetric division is engulfment, whereby the smaller forespore is encircled by the mother cell, leaving the forespore free-floating in the mother cell cytosol surrounded by two membranes (Fig. 1). In *B. subtilis*, engulfment is mediated by peptidoglycan synthesis machinery in the inner forespore membrane working in concert with peptidoglycan degradation machinery localized in the mother cell-derived outer forespore membrane (150, 151). The degradation complex consists of the SpoIIP and SpoIID peptidoglycan hydrolases (152, 153) in complex with the transmembrane scaffolding protein, SpoIIM (154). Loss of any of these *B. subtilis* components prevents engulfment completion and thus heat-resistant spore formation (116–118). Interestingly, *C. difficile* SpoIIM is largely dispensable for engulfment and heat-resistant spore formation, in contrast to *B. subtilis*, while *C. difficile* SpoIIP and SpoIID are critical for these processes, similar to *B. subtilis* (155, 156) . While it is unclear why SpoIIM is dispensable for *C. difficile* engulfment, *spoIID* and *spoIIP* are expressed in different cellular compartments in *C. difficile* relative to *B. subtilis* (156), which may obviate the need for SpoIIM to bring SpoIID and SpoIIP together. *C. difficile* SpoIIP and SpoIID nevertheless have conserved enzymatic activities relative to *B. subtilis* (152, 155, 157), although SpoIIP undergoes site-specific cleavage in *C. difficile* (156), in contrast to *B. subtilis* (158).

The conserved SpoIIQ-SpoIIIA channel is also required for *C. difficile* engulfment, unlike in *B. subtilis*. In *B. subtilis*, the channel (also known as the "feeding tube") connects the mother cell and forespore (120, 126, 128) and serves as a back-up mechanism for engulfment (159). However, in both organisms the channel is essential for maintaining forespore health because the forespore becomes deformed on itself in channel mutants (127, 141).

Coat Assembly in *C. difficile*

The coat consists of ~80 proteins in *B. subtilis* (119) that localize to the forespore and form a series of concentric proteinaceous shells around the forespore. However, given that only 25% of these proteins have homologs in *C. difficile* (160), different pathways likely control coat assembly in these two organisms. Furthermore, *C. difficile* encodes only two of the nine coat morphogenetic proteins that function to recruit coat proteins to the *B. subtilis* forespore.

The two coat morphogenetic proteins shared between *B. subtilis* and *C. difficile* are SpoVM and SpoIVA. SpoVM functions as a landmark protein in *B. subtilis* by recognizing the positive curvature of the forespore membrane and embedding itself within this membrane (161, 162). SpoVM recruits SpoIVA to the forespore and is required for SpoIVA to use its ATPase activity (163) to polymerize around the forespore (161). SpoIVA preferentially localizes SpoVM to the outer forespore membrane (164) and recruits the coat morphogenetic protein, SpoVID, to the forespore by binding SpoVID's C-terminal region A (164). These three proteins form the basement layer of the *B. subtilis* coat (165). SpoVID in turn recruits the inner coat morphogenetic protein, SafA (166), and outer coat morphogenetic protein, CotE (167). *B. subtilis spoIVA* and *spoVM* mutants mislocalize the coat and fail to make cortex, so they cannot produce heat- or chloroform-resistant spores (168–170). Furthermore, *spoIVA* and *spoVM* mutants are actively lysed by a bacilli-specific (171) quality control mechanism mediated by CmpA (172).

C. difficile spoIVA mutants resemble a *B. subtilis* IVA mutant in mislocalizing the coat and failing to produce heat-resistant spores (173, 174). However, in contrast to *B. subtilis*, *C. difficile spoIVA* mutants produce cortex (170, 174), consistent with the absence of CmpA in the clostridia (175). Nevertheless, it is unclear why *C. difficile spoIVA* mutants are heat sensitive, given that they produce visible cortex.

Unlike SpoIVA, *C. difficile* SpoVM is largely dispensable for spore formation. *C. difficile spoVM* mutants exhibit an ~3-fold defect in heat- and chloroform-resistant spore formation, make cortex, and properly localize SpoIVA around the forespore in most cells, in contrast to the 6-log defect in heat and chloroform resistance observed in a *B. subtilis spoVM* mutant (169, 173). While it is unclear whether SpoVM encases the *C. difficile* forespore as it does in *B. subtilis* (161), *C. difficile* SpoVM directly binds SpoIVA in recombinant coaffinity purification analyses (173), so *C. difficile* may use a redundant factor to substitute for loss of SpoVM.

While SpoVM is largely dispensable for *C. difficile* spore formation, the clostridia-specific CD3567 was identified as a coat morphogenetic protein because it is essential for proper coat localization and heat-resistant spore formation but not cortex formation (174). CD3567 was identified based on spore proteomic analyses (176) and targeted mutagenesis (174) and directly binds to SpoIVA through CD3567's C-terminal LysM domain, so it was renamed SipL (SpoIVA interacting protein L) (174). Fluorescent protein fusion analyses indicate that SipL is necessary for SpoIVA to encase the forespore, while SpoIVA is necessary for SipL to localize to the forespore (M. Touchette and A. Shen, unpublished data). Thus, even though clostridia-specific SipL (174) lacks sequence homology with bacilli-specific SpoVID (41), aside from their C-terminal LysM domains, the two proteins are functional homologs because they directly bind SpoIVA, encase the forespore, and recruit coat proteins to the forespore (164, 174).

C. difficile SpoIVA and SipL likely comprise the coat basement layer (Fig. 5), but the specific coat proteins they recruit to the forespore are unknown. Analyses of SpoIVA and SipL localization in engulfment mutants indicate that SpoIVA and SipL can localize to the forespore membrane in the absence of engulfment (156), while the outer coat protein CotE (CD1433) localizes to the cytosolic polymerized coat visible by phase-contrast microscopy (141). These

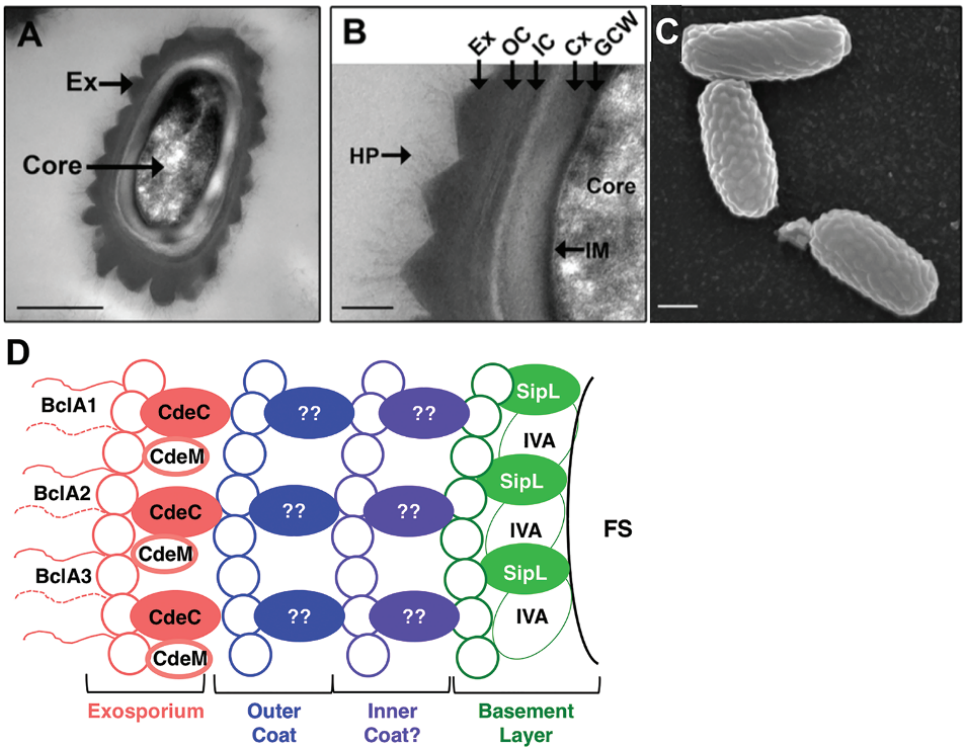

FIGURE 5 Spore coat and exosporium structure in *C. difficile*. (A, B) Transmission electron microscopy sections of *C. difficile* spores highlighting (from outside to inside) the bumpy, outermost exosporium (Ex) layer with its hair-like projections (HPs), outer coat (OC), inner coat (IC), cortex layer (Cx), germ cell wall (GCW), inner forespore membrane (IM), and spore core (cytosol). (C) Scanning electron microscopy of *C. difficile* spores reveals the bumpy surface created by the exosporium. Images used without modification from Rabi et al. (280) under Creative Commons BY 4.0. (D) Schematic of spore coat layers highlighting morphogenetic factors identified as being important for the assembly of specific layers. Assembly of the outermost exosporium depends on the BclA collagen-like proteins, which likely create hair-like projections on the spore surface (186, 187), CdeC (185), and CdeM (D. Paredes-Saja, unpublished data). The proteins that make up the outer and inner coat layers are unknown, but CotA and the mucinase, CotE, have been shown to be surface accessible (180, 182). SpoIVA (IVA) and SipL are interacting coat morphogenetic proteins that are essential for recruiting coat proteins to the forespore and forming heat-resistant spores (173, 174). The specific proteins recruited by SpoIVA, SipL, CdeC, and CdeM remain unknown.

results indicate that SpoIVA and SipL can adhere to the forespore independent of engulfment but that outer layer coat proteins require engulfment completion to stay associated with the forespore (156).

Additional coat proteins have been identified in spore proteomic analyses, some of which have been shown to be surface-localized (176–179). While coat proteins are enriched in these analyses, cytosolic contaminants inevitably become encased as the outer layers are assembled in the mother cell cytosol (176–179). The functions of many of these coat proteins have not been determined. CotA has been implicated in spore assembly and heat and ethanol resistance (180). Nevertheless, enzymatic activities have also been determined for several coat proteins (180, 181). For example, alanine racemase interconverts L- and D-alanine (as well as L- and D-serine) and alters the sensitivity of *C. difficile* spores to the D-alanine cogerminant (181).

C. difficile CotE, which is unrelated to the *B. subtilis* outer coat morphogenetic protein, CotE (119), degrades mucin and promotes spore binding to intestinal epithelial cells (182). Loss of CotE or its C-terminal mucinase domain reduces virulence in a hamster model of infection, indicating that the spore surface actively regulates *C. difficile* colonization and disease (182). Given that *C. difficile cotE* mutant spores do not have obvious ultrastructural or resistance property defects *in vitro* (180), these analyses highlight the importance of analyzing spore function in the context of infection.

Exosporium Assembly in *C. difficile*

The *C. difficile* exosporium layer directly contacts the coat, unlike the exosporium of *Bacillus cereus* group spores, which have an interspace gap between the exosporium and the coat (160, 183, 184). Since the *C. difficile* exosporium is closely associated with the spore coat (Fig. 5), it has been challenging to identify specific components. However, by sonicating spores, the Paredes-Sabja lab enriched for exosporium proteins (178) such as the (i) cysteine-rich proteins, CdeC (CD1067) (185), CdeM (CD1581) (64), and CdeA (CD2375) and (ii) the collagen-like proteins, BclA1, BclA2, and BclA3 (186, 187). Traces of coat proteins such as CotA, CotB, CotD, and CotE were also observed, which may indicate that they are part of the coat/exosporium interface (178).

While it is unclear how the C. *difficile* exosporium is assembled, genetic analyses have identified exosporium morphogenetic proteins. The cysteine-rich proteins, CdeC and CdeM, have been implicated in exosporium morphogenesis (D. Paredes-Sabja, unpublished data). Spores deficient in CdeC have a defective coat that is permeable to lysozyme, have a higher core water content, and are more susceptible to ethanol and heat than wild-type spores (185). Interestingly, cysteine-rich proteins are essential for the morphogenesis of the outer crust of *B. subtilis* and the exosporium of the *B. cereus* group (188–190). These *Bacillus* spp. cysteine-rich proteins self-assemble into two-dimensional crystalline layers (189, 191) that correlate with the two-dimensional crystalline basal layer underneath the hairy nap (extensions) on *B. anthracis* spores. Both CdeC and CdeM form dimers, trimers, and higher molecular weight complexes (178, 185, 192), suggesting that a similar self-assembly mechanism might govern the assembly of the outer layers of C. *difficile* spores.

The C. *difficile* BclA proteins have also been implicated in exosporium assembly: spores lacking either BclA1, BclA2, or BclA3 produce defective exosporiums (186) and exhibit heat-resistance defects (186, 193). The BclA proteins likely compose the hair-like extensions of C. *difficile* spores (187), since these proteins produce hair like-projections on *B. anthracis* spores (160). Furthermore, like *B. anthracis* BclA (194), C. *difficile* BclA3 is glycosylated (193). C. *difficile* BclA orthologues also appear to have a topology similar to that of *B. anthracis* BclA, because both proteins use their N-terminal domains to localize to the spore surface (187).

Exosporium Function in *C. difficile*

As the outermost layer of C. *difficile* spores, the exosporium may contact host component(s) that contribute to the persistence of C. *difficile* spores in the host (195, 196). In transmission electron microscopy analyses of clinically relevant C. *difficile* strains, the exosporium layer appears as electron-dense "bumps" on the spore surface with hair-like extension (185, 196). Notably, two exosporium morphotypes are observed in clonal populations: thin and thick electron-dense layers, although both have hair-like extensions (197, 198). This observation raises the possibility that the different morphotypes may have different roles during C. *difficile* infection, such as spore persistence and immune evasion. Consistent with this hypothesis, loss of the exosporium protein, CdeM (CD1581), decreases C. *difficile* fitness in gnotobiotic mice (64), and loss of individual BclA proteins, particularly BclA1, results in decreased colonization in mice (186).

CLOSTRIDIAL SPORE GERMINATION

Overview of Spore Germination and Outgrowth

During spore germination, metabolically dormant spores lose their resistance properties and transform into metabolically active cells. The low water content of the spore cytosol, known as the core, (~25 to 40%) is critical to this resistance because it prevents metabolism (7). Ca-DPA transport is essential for dehydrating the core, while the modified peptidoglycan cortex layer is essential for maintaining this partially dehydrated state. Thus, spore germination requires the removal of this cortex layer to allow core hydration and metabolism to resume (28).

Spore germination begins when spores sense small molecules termed germinants, which trigger a signaling cascade that leads to cortex degradation, release of Ca-DPA, core hydration, and degradation of SASPs bound to the chromosome. Although many germination-related proteins are conserved in the clostridial pathogens, notable differences in their function and mechanisms of action have been identified in C. *difficile*, C. *perfringens*, and C. *botulinum*. As discussed below, the order in which cortex hydrolysis and core hydration occurs differs between these species and is even strain-specific in the case of C. *botulinum*. Furthermore, C. *difficile* spore germination has several unique features to its signaling pathway that are specific to C. *difficile* and/or *Peptostreptococcaceae* family members.

Germinant Sensing and Signaling

Environmental signals

In most spore-forming bacteria, germinants are nutrient signals such as amino acids, monosacharides, nucleosides, salts, and organic acids (28). In contrast, C. *difficile* responds to cholate-derived bile acids, which are produced exclusively in the mammalian gut (199, 200). Taurocholate is the most potent of the cholate-derived germinants, while chenodeoxycholate is an efficient competitive inhibitor of taurocholate-mediated germination (201). Bile salt-induced spore germination may not be unique to C. *difficile*, since taurocholate can enrich for clostridial species from fecal samples (202), and spores from *Paeniclostridium sordellii*, a *Peptostreptococcaceae* family member, germinate in response to some bile acids (203). Notably, amino acid and calcium ion cogerminants enhance taurocholate-induced C. *difficile* spore germination, with glycine and calcium ions being the most potent of these small molecules (199, 204, 205).

In C. *perfringens* and C. *botulinum*, germinant specificity is species and strain-specific. Universal germinants for C. *perfringens* food-poisoning and nonfoodborne isolate spores include L-cysteine, L-serine, L-threonine, and a mixture of L-asparagine and KCl, while unique germinants for food-poisoning isolate spores are L-asparagine, L-glutamine, KCl, and the cogerminants Na^+ and Pi (206–208). Bicarbonate is a unique cogerminant for nonfoodborne spores (209). L-alanine, L-cysteine, L-methionine, L-serine, L-phenylalanine, and glycine can induce spore germination of group I proteolytic C. *botulinum*, although L-lactate and bicarbonate ions can act as cogerminants (210, 211). Spores of group II non-proteolytic C. *botulinum* germinate in response to L-alanine, L-cysteine, L-serine, L-threonine, and glycine, with L-lactate serving as a cogerminant (211, 212).

Germinant selectivity is likely influenced by adaptation to specific environmental niches. For example, the responsiveness of C. *perfringens* food-poisoning isolate, but not nonfoodborne isolate, spores to KCl or NaPi implies that food-poisoning isolates have adapted to food niches (i.e., processed meat products) where KCl and NaPi are highly abundant (10). Also, the finding that bicarbonate is a unique cogerminant for nonfoodborne spores, which germinate better than food-poisoning isolate spores in the presence of cultured intestinal epithelial cells (196, 210), suggests that nonfoodborne isolate spores are better adapted to germinate in the host's intestinal epithelium environment, where bicarbonate is more prevalent (213). Similarly, the responsiveness of C. *difficile* spores to taurocholate may allow C. *difficile* to sense favorable conditions in the gut, since taurocholate levels are increased in the dysbiotic gut during antibiotic treatment (21).

While classical germinants are directly sensed through germinant receptors, nonnutrient germinants can artificially trigger germination of many bacterial species independent of

germinant receptors. These include the cationic surfactant dodecylamine (28, 214), lysozyme (196), and Ca-DPA (215). While Ca-DPA activates *Clostridium sporogenes* (a proxy for C. *botulinum* group I [5]) spore germination, it does not activate C. *difficile* spore germination (205, 216, 217) and is a relatively weak activator of C. *perfringens* spore germination (218). Interestingly, although high hydrostatic pressure can induce *Bacillus* spp. spore germination independent of germination receptors, high pressure alone is not sufficient to induce spore germination of C. *sporogenes* (219), C. *perfringens* (220), and C. *difficile* (220). For C. *perfringens* and C. *difficile*, the ineffectiveness of high pressure to induce germination is likely due to differences in their germination mechanism relative to *Bacillus* spp. as discussed below.

Transmembrane germinant receptors in *C. perfringens* and *C. botulinum*

Almost all bacterial spores sense environmental signals through germinant receptors localized in the spore's inner membrane; the exception to this rule is C. *difficile* as described below. Germinant receptors usually consist of three protein subunits (A, B, and C) encoded in a tricistronic operon (*gerABC*). GerA and GerB are transmembrane proteins, and GerC is a lipoprotein. Loss of any one of these components generally eliminates germinant receptor function (28, 196).

Many spore-forming bacteria encode multiple tricistronic operons, which are thought to determine the germinant specificity of given strains. While *B. subtilis* encodes three major germinant receptors, there are diverse arrangements for *ger* genes and operons in the *Bacillales* and *Clostridiales* (see 28, 196). For example, C. *perfringens* has a monocistronic *gerAA* that is distant from the *gerK* locus, which encodes a bicistronic *gerKA-KC* operon upstream of the oppositely oriented monocistronic *gerKB* gene (196, 206). While many *Clostridium* species encode monocistronic germinant receptor genes, studies of C. *perfringens* provided the first evidence that functional germinant receptors can consist of a single subunit. Indeed, the lipoprotein GerKC is the sole and essential germinant receptor for all known nutrient- and nonnutrient-induced germination of SM101 and F4969 spores (221, 222), in contrast to *B. subtilis*, in which all three subunits are essential for functional germinant receptor formation. Nevertheless, although GerAA and GerKB can play auxiliary roles in food-poisoning strain SM101 spore germination (206, 222, 223), GerAA is required for nonfoodborne strain F4969 spore germination.

Canonical GerA family germinant receptors localize to the spore's inner membrane in several species, including *B. subtilis* (224) and C. *botulinum* (225). The GerKC subunit is present in the inner membrane of C. *perfringens* spores at ~250 molecules/spore (221); the abundance and relative stoichiometry of the GerKA, GerKB, and GerAA subunits is unclear.

gerA family operons can also contain an additional *gerAD* gene, which encodes a novel protein of 50 to 80 residues with two highly conserved transmembrane sequences in some *Bacillales* and *Clostridiales* species (196). Although GerAD is required for functional germinant receptor formation in *Bacillus* spp. (226, 227), their role in *Clostridiales* spore germination remains unclear.

Genomic analyses of C. *botulinum* strains have identified four *gerABC* subtypes (*gerX* type1 to 4) (211). *gerX* indicates that the germinant recognized by the receptor encoded in the locus is unknown. Notably, although group II C. *botulinum* (gIICb) encodes only one predicted canonical germinant receptor despite being able to respond to many amino acids, deletion of *gerBAC* from gIICb strain NCTC 11219 does not affect germination in response to nutrient or nonnutrient germinants (228). Thus, unidentified germinant receptors appear to mediate spore germination in gIICb in the absence of *gerABC*.

Germinant receptor-mediated spore germination is heat-activatable through a mechanism that is thought to involve conformational changes in the inner membrane germinant receptors and that potentiate their activation (28). Accordingly, both C. *perfringens* and C. *botulinum* spore germination can be enhanced by a transient heat shock (229, 230). In contrast, C. *difficile* spore germination is not heat-activatable, consistent with the absence of germinant receptor genes in its genome (217, 231).

A pseudoprotease, CspC, is the bile salt germinant receptor in *C. difficile*

Since C. *difficile* lacks germinant receptors, it was unclear how it senses bile salt germinants, which are structurally distinct from the nutritional germinants sensed by germinant receptor-encoding spore-formers. Joseph Sorg's group identified the elusive C. *difficile* germinant receptor using a genetic selection for germination-defective mutants (232). This screen identified seven point mutations in *cspC*, which encodes a pseudoprotease from the subtilisin-like serine protease family, and two nonsense mutations in *cspBA*, which encodes a fusion protein consisting of CspB and CspA subtilisin-like serine proteases (Fig. 6). While the CspB protease is catalytically active, both C. *difficile* CspA and CspC are pseudoproteases because they harbor two point mutations in their catalytic triads (233). Subsequent work revealed that CspBA is required for CspC incorporation into spores such that the *cspBA* nonsense mutations identified in the screen effectively lead to loss of CspC (234, 235).

CspC was further implicated as the direct receptor for bile salts using a second genetic screen for altered spore germinant specificity. By selecting for spores that germinate in response to the germination inhibitor, chenodeoxycholate (201), the Sorg group determined that a single point mutation in CspC (G457R) could change the ability of C. *difficile* spores to sense cholate versus deoxycholate derivatives (232). Although direct binding of bile acids to CspC has yet to be demonstrated biochemically, germinant binding to germinant receptors has not been established in any organism.

ACTIVATION OF CORTEX HYDROLYSIS IN CLOSTRIDIAL PATHOGENS

Just as clostridial pathogens use two mechanisms for sensing germinants, these organisms use two mechanisms to degrade their cortex: (i) proteolytic activation of the cortex hydrolase, SleC, and (ii) DPA-mediated activation of the cortex hydrolases CwlJ and/or SleB (Fig. 7) (28). C. *perfringens* and C. *difficile* use the SleC pathway, while C. *botulinum* uses either mechanism in a strain-specific manner, with groups I and III using CwlJ/SleB (211, 230, 236) and groups II and IV presumably using the SleC pathway. While cortex hydrolases are thought to specifically recognize the muramic-δ-lactam modification that characterizes cortex peptidoglycan (237), the CspB-SleC cortex hydrolysis pathway is only found in the clostridia, whereas the CwlJ/SleB system is present in the bacilli and some members of the clostridia (196).

Proteolytic Activation of the SleC Cortex Hydrolase in *C. perfringens* and *C. difficile*

SleC was first identified as a cortex hydrolase in biochemical fractionations of germinating C. *perfringens* exudates (238,

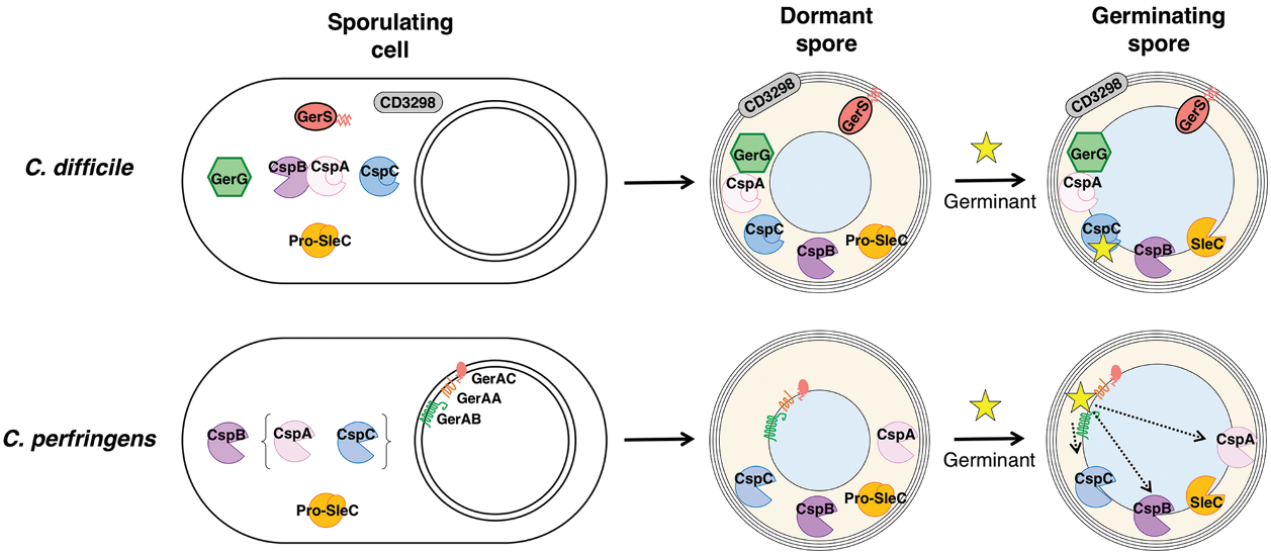

FIGURE 6 Putative locations of germination regulators in C. *difficile* and C. *perfringens*. Germinant signaling proteins, CspC (pseudoprotease and germinant receptor) and its downstream effectors, the CspB protease, and cortex hydrolase, SleC, are all produced in the mother cell under the control of either σ^E or σ^K (137–139). CspB is produced as a fusion to the pseudoprotease, CspA, which is critical for CspC incorporation into mature spores (233–235); all three Csp proteins are incorporated into mature spores. GerG is required for optimal incorporation of CspC, CspB, and CspA into mature spores (253). The GerS lipoprotein (248) is produced in the mother cell and does not directly participate in spore germination (O. Diaz and A. Shen, unpublished data), even though it is required for spore germination to proceed. The ATP/GTP binding protein CD3298 presumably localizes to the cytosolic face of the outer forespore membrane and regulates calcium release and possibly internalization (205). Germinant sensing induces the proteolytic activation of SleC by CspB in both organisms, but CspA and/or CspC can cleave SleC in C. *perfringens* (marked in brackets) (218, 242, 245), since they are active proteases unlike their cognate partners in C. *difficile* (233). C. *perfringens* also produces inner membrane-bound germinant receptors, similar to most spore-forming organisms, in the forespore, in contrast to the soluble CspC protein used by C. *difficile* to sense germinant. The locations of all proteins in mature spores is putative, with the exception of SleC, which has been shown to localize to the C. *perfringens* cortex region by immuno-electron microscopy (251).

239) and was subsequently shown to have lytic transglycosylase and amidase activities (240). SleC's long N-terminal predomain acts as an intramolecular chaperone to ensure proper folding of its hydrolase domain (241). The predomain is removed by proteolysis in a YabG-dependent manner (at least in C. *difficile* [235]) to generate the pro-SleC zymogen. This immature form remains in mature spores until germinant signaling induces the proteolytic removal SleC's inhibitory propeptide to generate active SleC (242).

The proteases responsible for activating SleC were identified as CspA, CspB, and CspC in biochemical fractionations of C. *perfringens* strain S40 germinating exudates (242, 243). These three proteases are members of the subtilisin-like serine protease family (243) and are encoded by a tricistronic operon immediately upstream of the *sle*C gene in C. *perfringens* strain S40 (244). While nonfoodborne C. *perfringens* strains encode this tricistronic operon, C. *perfringens* food-poisoning strain SM101 encodes *cspB* alone upstream of *sle*C (4, 245, 246). Genetic analyses in SM101 revealed that C. *perfringens* CspB is sufficient to proteolytically activate SleC, since *cspB* mutant spores exhibit 10^4-fold germination and cortex hydrolysis defects relative to the wild type (245) and fail to process pro-SleC into active SleC in response to germinants (245).

SleC is the major cortex hydrolase in C. *perfringens*, since *sle*C mutant spores have a 10^3 germination defect relative to the wild type (218). The SleM cortex hydrolase (247) functions as an accessory cortex hydrolase, since a *sle*M mutant exhibits wild-type germination, but a *sle*C *sle*M double mutant has a 100-fold more severe germination defect than the *sle*C single mutant (218).

The CspB protease and SleC cortex hydrolase have similar functions in C. *difficile*, since loss of CspB leads to an $\sim 10^3$ to 10^5 germination defect (233, 234), and complementation with the wild-type *cspB*, but not a catalytic mutant, restores germination and pro-SleC cleavage (233). Loss of *sle*C also results in a similar $\sim 10^3$-fold germination defect relative to the wild type (234) and an inability to hydrolyze cortex (216, 248). However, in contrast with the tricistronic *cspA-cspB-cspC* operon in some C. *perfringens* strains, C. *difficile* strains (and other *Peptostreptococcaceae* family members) universally encode *cspB* fused to *cspA*, with *csp*C encoded downstream of the *csp*BA fusion gene (*cspBA-csp*C) (235).

SleC and Csp proteins are produced in the mother cell of both C. *perfringens* and C. *difficile* (137–139, 249). Western blot analyses of spore fractions in C. *perfringens* and C. *difficile* indicate that CspB and SleC localize to a coat-extractable fraction (248, 250). However, C. *perfringens* SleC can be visualized in the cortex region of mature spores using immune-electron microscopy (251), indicating that fractions previously assumed to comprise coat proteins alone extract proteins from the cortex region. Interestingly, neither C. *perfringens* nor C. *difficile* SleC harbor signal sequences, raising the question of how they are targeted to the intermembrane space (assuming Csp proteins are targeted to this region).

The crystal structure of C. *perfringens* CspB revealed that Csp proteins consist of three main domains: a long N-terminal prodomain, a subtilisin fold, and an internal jelly roll domain (233, 243). Like other subtilisin-like proteases, C. *perfringens* and C. *difficile* CspB have a catalytic triad

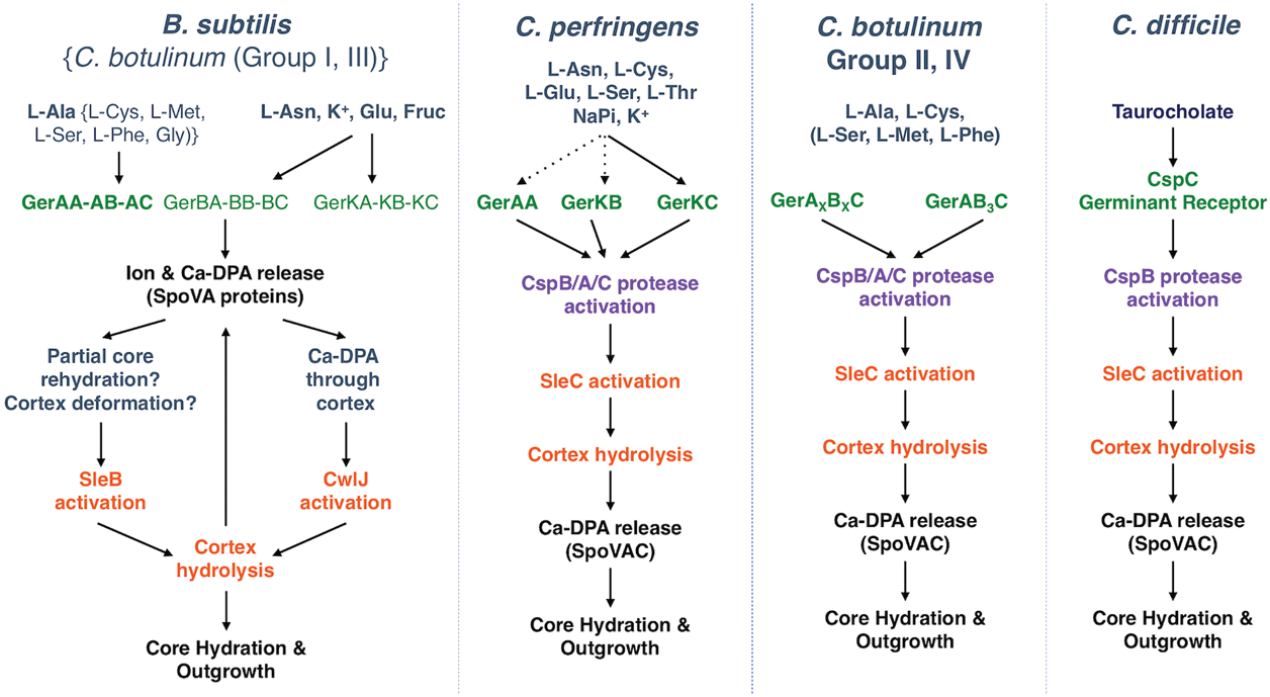

FIGURE 7 Schematic of spore germination signaling pathways. Germinants that are sensed by *B. subtilis*, *C. botulinum*, *C. perfringens*, and *C. difficile* are shown in dark blue; *C. botulinum* group I and III germinants are shown in the brackets (and include L-Ala). Amino acid and calcium ion cogerminants are not pictured for *C. difficile* (199, 204, 205). Germinant receptors are shown in green. The signaling pathway between *B. subtilis* and *C. botulinum* groups 1 and III (far left) differs from the other clostridial organisms mainly with respect to cortex hydrolase (shown in orange) activation mechanisms, with SleC being activated by proteolytic cleavage by Csp proteases, and the CwlJ and SleB cortex hydrolases being activated directly or indirectly by DPA release. Accordingly, the order of cortex hydrolysis and DPA release via SpoVAC differs between these two types of mechanisms. *C. botulinum* groups II and IV encode germinant receptors with variable numbers of A and B components. Adapted from reference 183.

consisting of Asp, His, and Ser, and the prodomain undergoes autoprocessing (233, 243). However, unlike almost all previously studied subtilisin-like serine proteases, both *C. perfringens* and *C. difficile* CspB remain bound to their prodomain following autoprocessing *in vitro* (233, 243). The prodomain sterically inhibits recombinant CspB activity (233), but it is unclear whether it stays bound to CspB in mature spores. Regardless, the prodomain presumably must be removed during spore germination to allow CspB to bind its presumed substrate, SleC. The central jelly roll domain within the subtilase domain is another unique feature of CspB; this domain markedly increases the conformational rigidity of CspB *in vitro* and is necessary for stable CspB production in *C. difficile* (233).

CspB activity has been proposed to require calcium based on the observation that calcium is a critical cogerminant during taurocholate-induced *C. difficile* spore germination (205). Depletion of calcium *in vitro* and in intestinal extracts reduces wild-type *C. difficile* spore germination and abrogates spore germination in a strain lacking CD3298, an ATP/GTP binding protein required for releasing calcium during germination (205). While these data indicate that calcium is a key adjuvant during *C. difficile* spore germination, the precise stage regulated by calcium is unclear, since it could affect CspB activity, CspC activation, germinant permeability, or as-yet-unidentified events. Whether calcium is required for *C. perfringens* spore germination remains to be tested.

Collectively, germinant signaling triggers CspB-dependent processing of inactive pro-SleC into active SleC, which subsequently degrades the cortex in both *C. perfringens* and *C. difficile*. It is unclear how germinant signaling leads to CspB activation, especially since these two organisms use different germinant receptors. The topology of these receptors also differs between these organisms, with Ger receptors being embedded in the *C. perfringens* forespore-derived membrane, and soluble *C. difficile* CspC being made in the mother cell (Fig. 6) (28, 200). *C. difficile* CspC has been hypothesized to be transported across the mother cell-derived membrane into the intermembrane space so that it can activate CspB through protein-protein interactions (200, 234, 252, 253). CspB in *C. perfringens* and *C. difficile* is presumably also transported into the intermembrane space so that it can activate its substrate SleC, which has been localized to this region in *C. perfringens* by immuno-electron microscopy (251). Clearly, many questions regarding the molecular details of this process remain to be addressed.

DPA-Mediated Activation of Cortex Hydrolases in Group I *C. botulinum*

Gene conservation predicts that *C. botulinum* groups II and IV activate cortex hydrolysis via CspB-mediated proteolytic activation of pro-SleC (211), but group I (and likely group III based on homology) use the partially redundant cortex hydrolases, CwlJ and SleB, to remove their cortex layer (211, 230, 236). Both hydrolases are produced in their mature form, but their activation appears to be tied to Ca-DPA release as observed in *B. subtilis* (28, 254). *C. sporogenes* (a proxy for group I *C. botulinum*) *cwlJ* mutant spores do not germinate in response to Ca-DPA, unlike *sleB* mutant spores

(230, 255) and similar to analogous mutants in *B. subtilis* (256). In *B. subtilis*, SleB activity is directly inhibited by YpeB (254), but the mechanism by which SleB is activated during germination is unknown. *C. botulinum* group I *sleB* and *ypeB* mutants exhibit 2- to 3-log defects in spore germination based on colony forming units, whereas *cwlJ* mutant spores produce wild-type levels of colonies on rich media (236). In contrast, *cwlJ* and *sleB* mutant spores in *C. sporogenes* have similar germination defects in single-spore germination analyses (230). Regardless, CwlJ and SleB likely have partially overlapping functions during group I *C. botulinum* spore germination, so a double mutant lacking both enzymes would presumably exhibit a severe germination defect similar to that in *B. subtilis* (257). Interestingly, both group I and group III *C. botulinum* spp. can encode multiple SleB homologs (211), suggesting that there may be additional redundancy in regulating cortex hydrolysis.

Ca-DPA and Spore Formation versus Germination

Ca-DPA is a spore-specific molecule that makes up 5 to 15% of spore dry weight (256). It is synthesized in the mother cell from lysine biosynthesis intermediates (258) and transported across the outer and inner forespore membranes by SpoVV (259) and SpoVAC (260, 261), respectively, in exchange for water. While the partial dehydration of the core by Ca-DPA transport into the forespore confers heat resistance to mature spores (256, 261, 262), Ca-DPA is differentially required for spore formation. In *B. subtilis*, mutants defective in synthesizing or transporting Ca-DPA cannot stably form spores due to premature germination and cortex hydrolase activation (256, 259, 260). Similar to *B. subtilis*, *C. sporogenes spoVA* mutants also produce unstable spores, presumably due to premature SleB activation (211). In contrast, *C. difficile* mutants defective in synthesizing or transporting Ca-DPA can stably form spores, although they are less dense than wild-type spores (261). Interestingly, Ca-DPA synthesis is necessary for *C. perfringens* spore formation (263), but Ca-DPA transport is not (262). Since Ca-DPA does not strongly induce *C. perfringens* germination (262), presumably because it uses the CspB-SleC pathway to activate cortex hydrolysis, it is unclear why DPA is required for spore formation in *C. perfringens* but not in *C. difficile*. This difference may reflect the different mechanisms used by these organisms to synthesize Ca-DPA. While *C. difficile* uses dihydro-dipicolinate synthase (DpaAB or SpoVFAB) to produce Ca-DPA, *C. perfringens* uses an electron transfer flavoprotein, EftA, to make this molecule. Since *C. botulinum* lacks SpoVFAB homologs and likely uses EftA, DPA-less *C. botulinum* spores likely will not be stably produced.

Cortex Hydrolysis Precedes Ca-DPA Release in *C. difficile*

While Ca-DPA release activates cortex hydrolysis in group I *C. botulinum* and other CwlJ/SleB-controlled systems, cortex hydrolysis is necessary for Ca-DPA release in *C. difficile* (261). Cortex hydrolysis activates the mechanosensitive SpoVAC channel (264) to release Ca-DPA from the core, since *C. difficile* spores germinated in high osmolyte solutions degrade their cortex normally but release Ca-DPA more slowly (265). Furthermore, *C. difficile sleC* mutant spores do not release Ca-DPA (216, 217). A similar mechanosensing phenomenon may occur in *C. perfringens*, since a *sleC-sleM* double mutant and a *cspB* mutant exhibit major defects in Ca-DPA release (218, 245). Thus, the CspB-SleC cortex degradation pathway likely induces Ca-DPA release, while the order of these events is reversed in spores that use CwlJ and SleB to degrade their cortex (28).

Events after Cortex Hydrolysis and Ca-DPA Release

While recent studies have provided critical insight into the early stages of germination in clostridial pathogens, namely germinant sensing, cortex hydrolysis, and Ca-DPA release, little is known about subsequent events. Ca-DPA release in *C. difficile* leads to core hydration based on the observation that the optical density of germinating *dpaAB*$^-$ and *spoVAC*$^-$ spores decreases by ~50% relative to the wild type, whereas the optical density of *sleC*$^-$ spores remains unchanged (261). Core hydration allows metabolism to resume, and transcript levels increase within 15 min of germination (231).

In *B. subtilis*, Ca-DPA release activates the Gpr germination protease (266), which degrades SASPs coating the nucleoid. The amino acids liberated by SASP degradation provide substrates for both catabolism and metabolism (267). It is currently unclear whether Ca-DPA activates Gpr homologs in clostridial pathogens.

Loss of Resistance Properties During Germination

The hydration of the core during spore germination allows metabolism to resume while concomitantly leading to loss of resistance. This is because the resistance properties of spores can largely be attributed to (i) the low water content of metabolically dormant spores and (ii) the coating of the genetic material by SASPs, which collectively prevent metabolic activity in the spore core. Indeed, *B. subtilis* mutant spores with higher water content or lacking SASP proteins are more sensitive to heat (256, 268) and in the latter case are more sensitive to UV irradiation (269, 270). Although *B. subtilis* produces three major types of SASP proteins (α, β, and γ), which are encoded by multiple genes (269), SspA and SspB (α and β, respectively) are the major SASPs coating the chromosome and the primary contributors to *B. subtilis* spores' resistance to UV and solar radiation (270).

Similar to *B. subtilis*, *C. difficile* and *C. perfringens* mutant spores with higher spore water content are more susceptible to heat (261, 262, 271) and UV irradiation, possibly because increased hydration reduces SASP binding to DNA (262, 271). Consistent with this idea, *C. perfringens* food-poisoning isolates with extreme resistance properties (e.g., type A chromosomal *cpe* and type C Darmbrand strains) produce an Ssp4 variant (also known as SASP4) that binds DNA with higher affinity than Ssp4 variants from more heat-sensitive *C. perfringens* isolates (272, 273). Mutational analyses indicate that this Ssp4 variant is a major determinant controlling the extreme heat resistance of certain food-poisoning strains. Interestingly, Ssp4 exhibits only ~20% sequence identity relative to the three other SASP proteins (Ssp1 to Ssp3) produced by *C. perfringens* strains, suggesting that this Ssp4 variant may be a specific adaptation of food-poisoning isolates (e.g., SM101). Indeed, it should be noted that Ssp1 to Ssp3 have been shown to confer UV resistance to *C. perfringens* food-poisoning strain SM101 spores using antisense RNA silencing methods (274).

C. botulinum encodes four SASPs, CBO1789, CBO1790, CBO3048, and CBO3145. This latter protein exhibits the lowest sequence conservation and is dispensable for resistance to nitrous acid (275) and thus may function similarly to *B. subtilis* SASP γ in acting as a food source for the outgrowing spore (276). Mutational analyses indicate that CB01789 and CPB01790 are primarily responsible for conferring resistance to nitrous acid, an oxidizing agent (275).

The role of SASPs in conferring resistance to C. *difficile* spores has not been examined, although RNA-Seq analyses suggest that SspA and SspB are the predominant SASPs produced (137). C. *difficile* spores are less resistant to heat than *B. subtilis* and C. *perfringens* spores, since C. *difficile* spores are readily killed at temperatures above 80°C (261).

CONCLUSIONS AND UNIQUE FEATURES OF *C. DIFFICILE* SPORE GERMINATION

Diverse pathways are clearly used by group I C. *botulinum*, C. *perfringens*, and C. *difficile* to mediate spore germination. The pathway used by group I C. *botulinum* spore germination most resembles *Bacillus* spp. germination, with germinant receptors sensing amino acids and stimulating Ca-DPA release followed by cortex hydrolysis by CwlJ and SleB (28). While C. *perfringens* spore germination also uses germinant receptors to sense nutrient germinants such as amino acids, germinant sensing activates the CspB-SleC cortex hydrolysis pathway, after which most Ca-DPA is released. C. *difficile* spore germination is the most divergent, with its unique germinant receptor, the CspC pseudoprotease, sensing bile acids. Like C. *perfringens*, germinant sensing activates the CspB-SleC cortex hydrolysis pathway, and the change in pressure caused by the resulting cortex hydrolysis induces SpoVAC to release Ca-DPA.

Although CspA, CspB, and CspC are conserved in many clostridial organisms, they are produced as single protease domains in the *Clostridiaceae* and *Lachnospiraceae* families and as a CspB-CspA fusion protein in the *Peptostreptococcaceae* family (235). Furthermore, CspB is the only active serine protease, with CspC and the CspA domain being pseudoproteases. Since CspA is critical for incorporating the germinant receptor and pseudoproteases, CspC, into mature spores (234, 235), the catalytic site mutations within CspA and CspC, which are largely conserved across *Peptostreptococcaceae* family members (235), appear to confer unique functions to these proteins.

Recent studies have identified two unique proteins that modulate C. *difficile* spore germination. GerG (CD0311) is a C. *difficile*-specific gel-forming protein that is necessary for incorporating CspA, CspB, and CspC into mature spores, while GerS (CD3464) is a *Peptostreptococcace* family-specific lipoprotein that is necessary for cortex hydrolysis (248) because it is necessary for generating the muramic-δ-lactam required for SleC to recognize its cortex substrate (Diaz and Shen, unpublished data).

While the Csp pseudoproteases, GerG, and GerS are distinguishing features of the C. *difficile* spore germination pathway, it is likely that additional novel regulators specific to certain clostridial families will be identified as this fascinating developmental process is studied using the genetic tools recently developed for studying clostridial pathogens (140, 277–279).

Clostridial Genetics: Genetic Manipulation of the Pathogenic Clostridia

S. A. KUEHNE, J. I. ROOD AND D. LYRAS

57

INTRODUCTION

The *Clostridiaceae* family (and within it the *Clostridium* genus) consists of an extremely diverse group of primarily Gram-positive bacteria that have traditionally been grouped together based on their anaerobic growth requirements and their ability to produce heat-resistant endospores. Historically, the members of the genus were very dissimilar, such that the genus lacked phylogenetic coherence, with over 200 species, at least 35 of which cause disease in humans and animals (1). Two recent studies have proposed a phylogenetic reorganization of the clostridia and subsequently changed the name of *Clostridium difficile* to *Peptoclostridium difficile* (2) and *Clostridioides difficile* (3, 4). However, the earlier name (*P. difficile*) did not comply with the *Internal Journal of Systematic and Evolutionary Microbiology* Bacterial Code and was rejected (3). Also recently, *Clostridium sordellii* has been reclassified as *Paeniclostridium sordellii* (5). For simplicity, in this article pathogenic members of the genera *Clostridium*, *Clostridioides*, and *Paeniclostridium* will all be referred to as pathogenic clostridia.

The most common feature of the pathogenic clostridia is that the cell and tissue damage that they cause primarily results from the production of potent extracellular toxins (6, 7). Although it is somewhat artificial in that it crosses family boundaries, it is useful to divide the pathogenic clostridia into three major groups based on their resultant disease pathology. These groups consist of the neurotoxic clostridia, which produce toxins that affect the nervous system, the enterotoxic clostridia, which produce toxins that affect the gastrointestinal tract, and the histotoxic clostridia, whose necrotic pathology results from the production of one or more toxins that affect the structural and functional integrity of host cells located at or near the site of infection. This article focuses on the genetic manipulation of the pathogenic clostridia and is divided by approaches and techniques rather than individual species.

The genetics and, in particular, the genetic manipulation of the clostridia have been revolutionized in the past decade. In large part, this has been made possible by advances in sequencing technology. The genomes of representatives of all of the pathogenic clostridia have now been completely sequenced, assembled, and annotated. The first *Clostridium perfringens* genome was published in 2002 (8), followed by *Clostridium tetani* in 2003 (9), *C. difficile* in 2006 (10), and *Clostridium botulinum* in 2007 (11). Multiple genome sequences are now available for these pathogens (12–19). The availability of these genome sequences has been important in the development of genetic manipulation technologies because precise sequences are required to design homology arms for homologous recombination, complementation, and use of newer technologies such as clustered regularly interspaced short palindromic repeats (CRISPR).

Genetic manipulation can be broken down into two main categories: forward and reverse genetics. Forward genetics involves random screens to identify genes that are responsible for a particular phenotype and can be employed without knowing the target gene. These methods encompass technologies such as transposon mutagenesis and transposon-directed insertion site sequencing, which are tools of random mutagenesis. Reverse genetics involves the inactivation of a particular gene to study the resulting phenotype and requires the target gene to be identified first. The technologies involved in this approach include insertional mutagenesis, allelic exchange to construct deletions and point mutations, and the insertion of genes or regions of DNA to disrupt genes.

EARLY ADAPTATIONS OF MUTAGENESIS TECHNOLOGIES

Genetic manipulation methods have now been established for most pathogenic clostridia but are most refined for *C. difficile* and *C. perfringens*. The clostridia are not naturally competent, but transformation via electroporation has been described for several of the pathogenic species. Electroporation into *C. botulinum* was demonstrated by Zhou et al. in 1983 (20), and *C. tetani* was transformed with the *Enterococcus faecalis* shuttle vector pAT19 in 1998 (21). So far, however, there have been no further reports of successful transformation (via electroporation) into either of these two species. Whether DNA transfer via electroporation is successful partly depends on the restriction and modification status of the organism and the transformation frequency that can be obtained. Electroporation is not currently feasible for *C. difficile*, despite numerous attempts in many laboratories. It has been successful for *C. perfringens* strain 13 (22, 23), but many other strains of *C. perfringens* are not amenable to DNA transformation.

doi:10.1128/microbiolspec.GPP3-0040-2018

The first defined mutants in a pathogenic *Clostridium* species were constructed in C. *perfringens* by allelic exchange utilizing double crossover events (22, 24). These studies made use of the fact that derivatives of the gas gangrene strain 13 have an apparent lack of active restriction and modification systems, thereby making them very amenable to genetic analysis (8, 25). There are several well-characterized shuttle plasmids that can reliably and reproducibly be introduced into C. *perfringens* cells by electroporation-mediated transformation (23) or by conjugation from *Escherichia coli* (26). The most widely used C. *perfringens-E. coli* shuttle vectors for complementation and other genetic studies are pJIR750 and pJIR751 (27), which are derivatives of the shuttle vector pJIR418 (28). These plasmids all contain the origin of replication *lacZ′* gene and multiple cloning sites of the *E. coli* plasmid pUC18 and the origin of replication and *rep* gene of the C. *perfringens* bacteriocin plasmid pIP404. Detection of recombinants can be achieved by X-Gal screening in *E. coli* and transformants selected on chloramphenicol or erythromycin in either *E. coli* or C. *perfringens*, respectively. Subsequently, derivatives of pJIR750 and pJIR751 were constructed that carried the *oriT* site from plasmid RP4, designated pJIR1456 and pJIR1457, respectively (29). The construction of these vectors facilitated RP4-mediated conjugative transfer of these plasmids from *E. coli* to C. *perfringens*, allowing strains that were not amenable to DNA transformation to be genetically manipulated.

The first genetic manipulation of C. *difficile* was successfully performed using the *oriT*-containing C. *perfringens* vectors, allowing regulatory genes to be introduced *in trans* into this bacterium (30). The first mutants generated in C. *difficile* were derived by homologous recombination from single crossover events. In 2006 O'Connor et al. (31) constructed a chromosomal mutant in CD3255 (*virR*) using pJIR1456 (26). This replicon is relatively unstable in C. *difficile*, and hence it can act as a pseudo-suicide plasmid in this bacterium. While this development represented an important step forward in the genetic manipulation of C. *difficile*, the mutants were sometimes unstable when selective pressure was removed, which could lead to the generation of revertants (31, 32).

A prerequisite for the mutagenesis of C. *difficile* was the use of an erythromycin resistance marker, and hence an erythromycin-sensitive recipient strain was required. C. *difficile* 630 has become the primary strain for laboratory manipulation, because it is amenable to DNA transfer (via conjugation, as discussed below), and it was the first C. *difficile* strain to have its genome sequenced (10). However, C. *difficile* 630 is erythromycin resistant. After a number of passages two erythromycin-sensitive strains were eventually obtained, namely 630E or JIR8094 (31) and 630Δ*erm* (33). Recently, it was discovered through whole-genome sequencing that both of these erythromycin-sensitive derivatives obtained additional mutations during their passaging, which differed between the two derivatives (34–36). JIR8094 showed a larger number of seemingly important changes compared to the parental strain. In light of these differences, which are described in more detail by Collery *et al.* (34), 630Δ*erm* is now the strain of choice in studies to elucidate pathways of virulence, regulation, and metabolism in C. *difficile*.

THE ROADMAP TO CLOSTRIDIAL GENETICS

Overcoming Restriction and Modification Systems

As mentioned above, complete genome sequences are now available for all of the pathogenic clostridia, which has opened up the field for the development of more sophisticated genetic tools. Technologies such as Illumina sequencing are now quick and affordable; however, obtaining accurate reads in repetitive regions is difficult with these technologies because of the short reads that they produce. This problem can be overcome by the use of long-read technologies such as MinION and, in particular, PacBio. When these latter methods are used in combination with Illumina sequencing, they can provide an accurately assembled genome, which is crucial to locate genes and identify up- and downstream defined genetic elements and, importantly, potential restriction-modification systems (37).

Restriction-modification systems have held back much of the genetic development of the clostridia, because they can protect the recipient bacterial cell from foreign DNA, making the transfer of foreign DNA for genetic manipulation difficult or impossible (38). A common method used to overcome restriction barriers is *in vitro* or *in vivo* methylation of the DNA to be introduced, so that the recipient recognizes it as its own. To this end, it becomes important again to have knowledge of the genome sequence, which can reveal all the methylases and restriction-modification systems present. For many years pAN2, which contains a bacteriophage methyltransferase gene, has been used to methylate DNA before transformation into *Clostridium acetobutylicum* (39). Recently, similar systems have been developed for *Clostridium pasteurianum* (40), *Clostridium saccharobutylicum*, (41, 42), and *Clostridium cellulovorans* (43).

In all fields of bacteriology, researchers work mostly on a few select laboratory strains, which are for one reason or another easy to manipulate. For example, C. *difficile* 630 has no active restriction-modification systems, so it is easier to conjugate with, and its genome was the first to be sequenced, so most molecular studies have been carried out with this strain and its derivatives. Similarly, C. *perfringens* strain 13 is the most widely used strain of that species, with transformation protocols having been successfully developed at an early stage. Finally, ATCC 9714 is the laboratory strain of choice for *P. sordellii* studies. While these strains are great tools to unravel the molecular basis of pathogenicity and metabolism, it has become evident that they often have phenotypic limitations. For this reason, clinical isolates need to be considered and used for research studies, particularly those related to virulence. Different ribotypes of C. *difficile* and different toxinotypes of C. *perfringens*, for example, display very different phenotypes, causing different diseases or disease severity (44, 45). Therefore, it is important to understand and develop ways to overcome the barrier to DNA transfer into these organisms, and the use of the genetics roadmap suggested in reference 37 can help to facilitate such an analysis. In this workflow, the genome sequence of a strain is determined first, which gives insight into its restriction-modification system. This information in turn helps to overcome the barriers to DNA transfer, as well as providing the genetic blueprint of the strain, making genetic manipulations such as gene deletion, substitutions or additions (46), and further investigation possible.

Plasmid Cloning Vectors

Conjugation as a method of DNA transfer has been very successful in the pathogenic clostridia. C. *perfringens* strains that cannot be transformed by electroporation have successfully been genetically manipulated using conjugation from *E. coli*, using plasmids pJIR1456 or pJIR1457, as discussed earlier (22, 29, 30). Conjugative manipulation was first established for C. *botulinum* using pJIR1457 (47) with

the RP4-carrying *E. coli* strain S17-1 as the donor strain. Conjugation is also used to introduce DNA into *P. sordellii* and has been used successfully to generate numerous mutants in this clostridial species (48–52).

In early studies, *C. perfringens*-based vectors were used for the genetic manipulation of *C. difficile* (30). For example, plasmid pJIR1457 was used to study the functional capacity of the toxin regulator TcdR (then called TxeR) in *C. difficile* employing RP4-mediated conjugative transfer of a *tcdR*-carrying recombinant plasmid from an *E. coli* donor (30). Note that the difficulty of introducing DNA into some strains using the RP4-based system from *E. coli* resulted in the construction of a novel plasmid transfer system that exploited the conjugation apparatus encoded by the broad-host range transposon Tn916 together with the cognate *oriT* site encoded by this element (53). This system, which uses a Tn*916*-carrying *C. perfringens* or *Bacillus subtilis* strain as a donor and $oriT_{Tn916}$-carrying shuttle plasmids, facilitated the genetic manipulation of previously recalcitrant *C. difficile*, *C. perfringens*, *P. sordellii*, and *Clostridium septicum* strains (54). More recently, heat shock has also been used to increase conjugation efficiency in *C. difficile*, and the choice of media was also shown to affect conjugation frequency (55).

The construction of specific *C. difficile* shuttle vectors was realized by Purdy et al. in 2002 (56). The plasmids derived in this work can replicate autonomously in *C. difficile* and contain either replicon CD6, which was amplified from a *C. difficile* plasmid isolated during the same study, the replicon from pCB102, or that from pIP404; the latter two plasmids were derived from *Clostridium beijerinckii* (57) and *C. perfringens* (28), respectively. A much higher frequency of transfer was achieved using the native replicon pCD6, and plasmids carrying this replicon were shown to be maintained more stably in *C. difficile*. The plasmid constructed in this study, containing the pCD6 replicon, a Gram-negative replication site, possibly including *oriT* for transfer and an erythromycin gene for antibiotic selection, was originally called pMTL9301 and was later renamed pMTL960 (56). pMTL960 has been used successfully in numerous studies, including those involving an examination of the function of the *C. difficile* cell wall protein V, the lipoprotein CD0873 (an adhesin), and the cysteine proteases Cwp84 and Cwp13 (58–60).

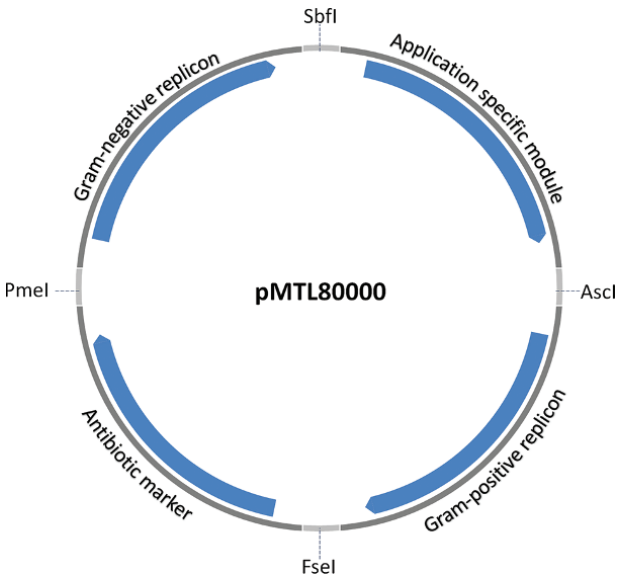

FIGURE 1 Illustration of the pMTL80000 modular vector series. The figure highlights the four modules separated by the unique restriction sites: *Sbf*I, *Asc*I, *Fse*I, and *Pme*I. The modules consist of a Gram-positive replicon module, a selectable marker, a Gram-negative replicon unit with optional transfer (*tra*) genes, and an application-specific module.

TABLE 1 Module choices for pMTL80000 plasmids

Gram+ replicon	Marker	Gram– replicon	Application-specific
0. Spacer*			0. Spacer*
	1. *catP*	1. P15a	1. MCS
2. pBP1	2. *ermB*	2. p15a + *tra*	2. Pthl + MCS
3. pCB102	3. *aad6*		3. Pfdx + MCS
4. pCD6	4. *tetA*	4. ColE1	4. catP reporter
5. pIM13		5. ColE1 + *tra*	

Abbreviations: MCS, multiple cloning site; Pthl, thialase promoter; Pfdx, ferrodoxin promoter

*Spacer: a module may consist of a short spacer in place of a functional component

In 2009, Heap et al. published a modular vector system that has been useful in a number of clostridial species (61). This system includes four main modules: a Gram-negative replicon, a Gram-positive replicon, an antibiotic resistance marker, and an insertion module. All of these modules can easily be swapped and replaced by others, making this system easy to modify depending on the purpose and organism for which it will be used (Fig. 1, Table 1). For example, four different antibiotic resistance markers can be used, and two Gram-negative replicons are included. The use of specific restriction sites that were employed to build the plasmid series allows the straightforward incorporation of new modules incorporating, for example, new Gram-positive replicons. The development of this vector series has helped to standardize the genetic work in many clostridial species. All these vectors can be used as shuttle vectors and can be transferred from *E. coli* via RP4-mediated conjugation, or directly in some species by electroporation, and have successfully been used in many *C. difficile* studies investigating virulence regulation, biofilm formation, colonization, and sporulation (62–64). These plasmids have also been used in other pathogenic clostridial species, including an investigation into the role of two-component systems in neurotoxin regulation of *C. botulinum* (65). If used without the Gram-positive replicon, they act as suicide vectors in the clostridia and have been effectively used in this capacity in studies involving the nonpathogenic species *C. beijerinckii* and *Clostridium autoethanogenum* (66, 67).

Inducible Vector Systems

In many genetic studies it is essential to be able to control or regulate the expression of cloned genes. The usual method is to place the cloned gene behind an inducible or repressible promoter so that expression of the gene of interest is induced by the addition of a low-molecular-weight effector molecule to the culture medium. However, only a limited number of such systems are available for use in the pathogenic clostridia.

In *C. perfringens*, an inducible expression system was made available by the development of the vector pKRAH1 (68). This shuttle plasmid encodes the *C. perfringens* BgaR transcriptional regulator and the inducible promoter, P_{bgaL}, which is activated by BgaR in the presence of lactose.

The addition of lactose to the culture medium therefore leads to the expression of genes cloned downstream of P_{bgaL}. This system initially was validated by cloning the *gusA* reporter gene behind P_{bgaL} and measuring β-glucuronidase (β-GusA) activity in *C. perfringens* SM101 cells with and without lactose induction. Substituting isopropyl β-d-1-thiogalactopyranoside (IPTG) for lactose did not result in increased activity, suggesting that IPTG is either not an inducer or cannot be transported into the cell (68). Subsequently, pKRAH1 was constructed and used to express a *yfp-pilB* construct, which allowed the resultant fusion protein to be localized (68). pKRAH1 has been used in other studies of the biogenesis of type IV fimbriae in *C. perfringens* (69), and the BgaR/P_{bgaL} system was also used to study the role of the endonuclease RNaseY (70) and carbonic anhydrase (71) in *C. perfringens* and for the analysis of acetogenesis in *Clostridium ljungdahlii* (72).

Other workers developed a xylose-inducible gene system for use in *C. perfringens* (73). The vectors, pXCH (confers chloramphenicol resistance) and pXEH (confers erythromycin resistance), encode the XylO transcriptional repressor and the *xylB* promoter from *C. difficile*. Genes are cloned downstream of P_{xylB}, and XylO repression is subsequently relieved by the addition of xylose. The vectors were validated in *C. perfringens* strain 13 by using them to regulate the expression of chloramphenicol acetyltransferase and α-toxin reporter constructs. The xylose-inducible system has been used by other workers in combination with the lactose system (69).

Classic IPTG-inducible systems are not effective in *C. difficile*, but in 2011 Fagan et al. developed an anhydrous tetracycline-inducible system for this bacterium (74). The system is based on pRMC2 from *Staphylococcus aureus* (75), combining the tetracycline-inducible promoter system with a codon-optimized *gusA* gene from pCBR023 on plasmid pRPF185, including the *fdx* terminator from *C. pasteurianum*. The plasmid backbone is taken from the *E. coli-C. difficile* shuttle vector pMTL960. When GusA activity was monitored as a measure for leakiness of the system, no GusA activity was measured in the absence of anhydrous tetracycline (the inducer), providing supporting evidence that the system is tightly regulated (74). This system has been used successfully in other studies involving *C. difficile* to determine the functional role of TcdE (76) and to investigate the spore differentiation pathway, including the creation of an inducible *spo0A* gene most recently (77, 78). Additionally, it has been used to study spore coat proteins of *C. difficile* (79) and has been employed in other clostridial species, such as *P. sordellii*, in which it was used to examine a new conjugation system (51). A second inducible system has also been described and employed in *C. difficile*. Purcell et al. created a nisin-inducible system in which the *cpr* promoter, responsible for the transcription of an ABC transporter, which confers resistance against nisin, is cloned upstream of the target gene. This system was used to study the role of cyclic di-GMP in motility and aggregation of *C. difficile* (80).

Some clostridial genes are toxic when overexpressed in *E. coli* and therefore are difficult to clone, making complementation studies in the original clostridial host problematic. This problem can be overcome by use of the vector pJIR3422 (81, 82). This vector exploits the phenotypic features of the clostridial Tn*4451/3* site-specific recombinase TnpX, specifically, the specificity of binding of this protein to a transposon-derived promoter. TnpX represses expression from its own promoter, P_{attCI}, which is usually located at the joint of the circular form of the Tn*4451/3* elements (83). This promoter is present in pJIR3422, and expression from this promoter is repressed in the presence of a catalytically inactive derivative of TnpX, present in the *E. coli* strain used for cloning, but is not repressed in the clostridial host because of the absence of TnpX. The use of this system facilitated the cloning of the *tcpG* conjugation gene and the *feoB* ferrous uptake gene in *E. coli* and the complementation of mutants of these genes in *C. perfringens*, which could not be achieved without this system (81).

Reporter Assays

Historically, protein reporter systems for the analysis of protein localization have been lacking in most pathogenic clostridia, particularly in *C. difficile*. Widely used reporter proteins such as green fluorescent protein for fluorescence or luciferase for chemiluminescence require oxygen for correct reporter protein folding or full enzymatic activity and hence have been thought to be of limited value in anaerobic bacteria. In the past 5 years, however, a number of assay systems have been established (77, 84, 85), which have made the functional characterization of genes and their encoded products more feasible. Reporters can be split into two main categories: visualizable reporters and enzymatic reporters. The former are utilized to study phenotypic heterogeneity and localizing proteins, whereas the latter serve as read-outs on transcription.

Visualizable reporters

Several of these systems are based on fluorescence. Ransom et al. successfully developed a codon optimized cyan-fluorescent protein and mCherry (mCherryOpt) in *C. difficile* to perform a number of subsequent studies (84, 86). They created two vectors using mCherryOpt, one to study localization, which they used to examine septal location of two cell division proteins, MldA and ZapA, in fixed cells (86). The other vector allows cloning of a promoter upstream of the mCherryOpt gene to study gene expression and has been exemplified by studying the *pdaV* operon, which is required for lysozyme resistance. (84). The variants were successfully expressed in *C. difficile* but required exposure to oxygen for chromophore maturation (84). Recently, work by Ribis et al. used mCherry fusions to establish the importance of SpoIVa and SipL in spore coat assembly and to elucidate the mechanism of engulfment of the forespore by the mother cell in *C. difficile* (87, 88). Other recent examples of the use of mCherry in *C. difficile* include a study of flagellum and toxin phase variation, demonstrating the potential to study single-cell heterogeneity, and work demonstrating that toxin gene expression is bistable in *C. difficile* (89, 90).

Yellow fluorescent protein fusions have recently been used successfully in *C. perfringens* to examine localization and function of PilB, an ATPase responsible for pili assembly (69).

iLOV, a light oxygen voltage domain, has also been optimized for use in *C. difficile*. LOV domains are plant or bacterial blue light receptors and are part of flavin mononucleotide-based fluorescent proteins (FbFPs) (91, 92). These fluorescent reporters can be utilized with and without oxygen, and they are smaller (13 kDa) than green fluorescent protein (25 kDa), which makes them ideal fusion proteins with a reduced probability of disrupting native protein function. iLOV has been used as a fluorescent reporter in *C. difficile* (85), as a translational fusion to study the cell division protein FtsZ. This study also proved that iLOV fusions can be successfully transported out of the cell by constructing a fusion to FliC, the flagella subunit. Functional iLOV fusions

in *P. sordellii* and the nonpathogenic C. *acetobutylicum* were also generated in this study. The brightness of FbFPs is lower than that of green fluorescent protein, and hence a few technical modifications have been suggested to improve their usefulness, such as lowering background noise and improving the quality of the output signal. Flavin-based media, for example, can lead to highly fluorescent backgrounds, which can be reduced by eliminating yeast and beef extract (93). Also, several clostridial species, such as C. *difficile* and C. *acetabutylicum*, have a natural green auto-fluorescence that can increase the background signal (85).

SNAP-tag technology has also been adapted for C. *difficile*. The 20-kDa peptide tags are fused to target genes, and fusions are visualized using a fluorescent microscope by adding the cell-permeable fluorescent substrate TMR-star. This technology has been used to elucidate the role of the sigma factor cascade in the sporulation process in C. *difficile* and, furthermore, a split SNAP-tag has been employed to study protein interactions between the forespore protein SpoIIQ and the mother cell protein SpoIIIAH (77, 94). SNAP-tags have been proven to be versatile and have worked effectively on fixed cells, demonstrating the temporally regulated gene expression of the sigma factors involved in C. *difficile* spore formation and establishing the interactions of C. *difficile* SpoIIQ and SpoIIIA proteins and their control over forespore engulfment and integrity (77, 95).

Enzymatic reporter systems

The widely used β-GusA reporter assay has been used to study the regulation of the large toxins in C. *difficile*. To elucidate the function of the sigma factor TcdR, Mani et al. created *gus*-fusions in C. *perfringens* and then, in a follow-up publication, *gus*-fusions in C. *difficile*, the study of which showed that TcdR positively regulates *tcdA* and *tcdB* expression (30, 96).

An alternative reporter system used in C. *difficile* involves a luciferase gene fusion to the signal sequence of the secreted protein PPEP-1. PPEP-1 is a zinc metalloprotease that has been shown to be one of the most abundant secreted proteins of C. *difficile* (97). Two reporters have been constructed, AmyEopt and sLucopt (98). AmyEopt can be used to measure promoter activity in liquid or plate-based assays due to the production of α-amylase, a codon optimized enzyme from *B. subtilis*, which results in starch degradation. sLucopt is a codon-optimized luciferase based on NanoLuc (99) and has been shown to be detectable in culture supernatants when fused to an inducible promoter (98). Both reporters are assayed under aerobic conditions once the samples have been taken from the anaerobically grown culture (98).

Finally, the *E. faecalis* alkaline phosphatase gene, *phoZ*, has been successfully used in C. *difficile* for the qualitative and quantitative measurement of gene expression using an alkaline phosphatase assay. PhoZ was shown to be active anaerobically and is therefore presumed to fold correctly under these conditions, which makes it a useful reporter gene for anaerobic bacteria (100).

A promoter probe plasmid based on pJIR418 has also been constructed for use in C. *perfringens*. This plasmid, pPSV, was constructed by deletion of the *catP* gene from pJIR418 followed by the addition of a promoterless *catP* gene downstream of the multiple cloning site (101). The *catP* gene has also been used as a reporter system in the promoter probe shuttle vector pTCATT, which contains a promoterless *catP* gene flanked by transcriptional terminators. However, PCR-mediated regeneration of the 5′ terminus of the *catP* gene is required during the construction of promoter fusions in pTCATT, limiting its usefulness (102). Other studies have attempted to develop reporter systems for use in C. *perfringens*. One system involved the construction of a plasmid that contains the *luxAB* genes from *Vibrio fischeri* under the control of the *plc* promoter. Luciferase activity and bioluminescence were obtained from this plasmid in C. *perfringens* (103). In another study, reporter plasmids using the *E. coli gusA* gene cloned into pJIR750 were constructed, and β-GusA production was used successfully to monitor the sporulation-specific regulation of the *cpe* gene in C. *perfringens* (104). More recently, high-level expression of the C. *perfringens* NanI sialidase was achieved by using a ferredoxin promoter-based plasmid, pFF, in C. *perfringens* (105). This system was particularly useful for purification of NanI since the C. *perfringens* expression strain secreted the enzyme, as does the wild type, and seemed to efficiently express the protein, resulting in a 60-fold increased yield in comparison to protein isolation from an *E. coli* host. These results suggest that in C. *perfringens* the pFF plasmid may be very useful for the expression of AT-rich genes from other clostridia and other bacteria (105).

Allelic Exchange and Homologous Recombination

Homologous recombination has been used extensively as a mutagenesis tool for many bacterial species and may involve either single- or double crossover events. Since two crossovers are required for allelic exchange, it is a less efficient process than obtaining mutants by a single crossover event using insertional mutagenesis. However, the disadvantage of single crossover events is that wild-type genes can be regenerated from the mutants by further homologous recombination events. This issue is not a problem with allelic exchange or double crossovers, which result in inherently stable mutants. It is worth noting that the efficiency with which mutants are obtained by allelic exchange depends on the size of the homologous regions that flank the gene of interest, and it is recommended that there be at least 2 kb of flanking DNA present on either side of the gene to be replaced (106). Additionally, a large number of mutants can be generated using homologous recombination, in contrast to a limited number that can be generated with insertional mutagenesis, because of the small number of antibiotic cassettes available, which are required for insertional mutagenesis.

Homologous recombination and allelic exchange methods for the clostridia have also been developed and improved significantly during the past 2 decades. In early studies, allelic exchange was used successfully for genetic analysis in C. *perfringens* (22), and the first defined genetic mutants constructed in the pathogenic clostridia were the *plc* and *pfoA* toxin gene double-crossover mutants that were constructed in C. *perfringens* (22, 24). Since that time many C. *perfringens* mutants have been constructed by allelic exchange, too many to list here, and homologous recombination has become a standard genetic tool for the construction of mutants in this bacterium.

Early homologous recombination studies of C. *difficile* involved the construction of mutants by single crossover events using suicide plasmids that were introduced by conjugation from *E. coli* (31). Subsequently, two improved systems (107, 108) were developed for C. *difficile*, both of which are based on the use of negative selection markers. The first system uses cycloserine deaminase (107) as a counter selection marker and relies on the presence of the *codA* gene on a pseudo-suicide vector (107). Single crossovers are selected on the basis that cells that have the plasmid, which

contains a heterologous *codA* gene from *E. coli*, integrated into their chromosome are able to grow much faster than cells carrying the resistance gene on a plasmid. This is because the plasmid used in this approach is inherently unstable in *C. difficile* and is lost easily from cells. The faster-growing colonies are selected and tested (via PCR) to determine if a single crossover event has occurred. They are then plated on *C. difficile* minimal medium containing 5-fluorocytosine. Only clones in which a second crossover event has occurred, resulting in the loss of the *codA* gene, are able to grow, because the cells still carrying the *codA* gene are killed when 5-fluorocytosine is converted to toxic 5-fluorouracil (97) by CodA. Double crossover events result either in a reversion back to wild type or in the construction of the desired mutant and loss of the plasmid. This system can be used for the construction of DNA deletions or point mutations. Genes can also be complemented by going through another cycle of single and double crossover events, using a different plasmid which contains the intact gene of interest. In this case, genes are reinserted into their original position on the chromosome. It is hence advisable to introduce a watermark or sequence signature into the gene to differentiate it from the wild type (107). This allelic exchange system has successfully been used in a number of studies, including work characterizing two sortase substrates of *C. difficile* and their mechanism, involving cyclic di-GMP, of anchoring proteins to the peptidoglycan layer (109). Another study investigated a dipicolinic acid release mechanism during *C. difficile* spore germination (110).

The second system for allelic exchange in *C. difficile* is based on creating a *pyrE* mutant, carrying a 3′ deletion of the gene, using allele-coupled exchange (111) in the strain of choice and then using a heterologous *pyrE* gene as a negative/counter selection marker. The *pyrE* gene encodes orotate phosphoribosyltransferase, which is involved in pyrimidine biosynthesis. This enzyme is essential for bacterial growth in the absence of exogenous pyrimidines and also acts on 5-fluoro-orotate to generate a toxic derivative of this compound. The *pyrE* mutants are auxotrophs for uracil. A functional *pyrE* gene from *Clostridium sporogenes* is supplied on an allelic exchange plasmid as the counterselection (108). *pyrE*-mutants were generated in *C. difficile* 630Δ*erm* and R20291 (108) and were then used to generate deletion mutants using a process similar to that described for the *codA* methodology. Single crossover clones are selected on the basis of faster-growing colonies once the vector has integrated into the chromosome, since the vector is unstable due to a frameshift mutation in the *oriR*. Double crossover mutants in which the plasmid has been excised from the chromosome are then selected on *C. difficile* minimal medium supplemented with 5-fluoro-orotate and uracil. Once 5-fluoro-orotate-resistant uracil auxotrophs have been isolated and shown to have lost the plasmid, they can easily be restored to prototrophy by conjugative transfer of a plasmid that contains part of the *pyrE* gene that can be utilized to repair the *pyrE* gene in the chromosome using allelic exchange. The resultant transconjugants are streaked on *C. difficile* minimal medium without the addition of uracil, so only bacteria with a repaired *pyrE* gene are able to grow. It is also possible to complement the mutation at the same time as repairing the *pyrE* gene by cloning a copy of the disrupted gene into the plasmid either under the control of its native promoter or through the use of a constitutive promoter for overexpression. Using allele-coupled exchange, the complementation gene is then integrated simultaneously during *pyrE* repair at the *pyrE* locus (108). This technique is very powerful and rapid, allowing for the generation of complementation strains within 5 to 6 days, opposed to obtaining an allelic exchange mutant in 2 to 3 weeks. This approach has been used in several studies; for example, it was used to generate a complete pathogenicity locus deletion in *C. difficile* R20291 to study the role of binary toxin in the absence of the overpowering potency of TcdA and TcdB (112). It was used in a recent study that suggested that the introduction of trehalose into our diets has favored the emergence of so-called hypervirulent *C. difficile* ribotypes, such as RT027 (113). Ribis et al. created the first published quadruple mutant in *C. difficile*, using the *pyrE*-system, in their work studying the roles of putative engulfment regulators, IID (CD0126), IIP (CD2469), and IIM (CD1221), and the known engulfment regulator and putative endopeptidase, IIQ (CD0125) (88).

ClosTron and TargeTron

Two related technologies based on the exploitation of a mobile group II intron were developed for insertional mutagenesis in the clostridia. Mobile group II introns are found in bacterial genomes and are site-specific retroelements. They use a mobility mechanism termed retrohoming to create insertions in DNA, and they do this by inserting an excised intron lariat RNA directly into a DNA target site, which is then reverse transcribed by an intron-encoded enzyme protein (114). The DNA target site is primarily recognized by base pairing of intron RNA, and these bases can be modified to allow intron insertion into any specific DNA target (4). As a result, a mobile group II intron from *Lactococcus lactis, L1.LtrB,* was developed commercially (Sigma-Aldrich) and was used in the development of TargeTron and ClosTron technologies. The use of the TargeTron system in a clostridial species was first described in 2005, when it was used to inactivate the *plc* gene in *C. perfringens* (115). TargeTron was also used as a tool to introduce the simian immunodeficiency virus p27 gene into the *pfoA* gene on the *C. perfringens* chromosome, thereby simultaneously inactivating *pfoA* and introducing the simian immunodeficiency virus p27 gene, which was subsequently shown to be expressed within the mouse gastrointestinal tract (116).

ClosTron technology is an insertional mutagenesis tool similar to TargeTron, but it incorporates the use of a retrotransposition-activated marker (RAM), based on the *ermB* gene, for selective purposes, with successful insertion indicated by the acquisition of resistance to erythromycin (117). The presence of a RAM makes mutant selection much more efficient and less laborious. The retargeted region is designed using an online retargeting algorithm and is then incorporated into the plasmid of choice for subsequent introduction into the clostridial strain (118).

Although the acquisition of a resistance marker in the bacterial genome via ClosTron or similar systems makes mutant selection simpler, it can also be a drawback. In particular, this means that a second mutation using the same marker cannot be obtained. Furthermore, the use of a strong promoter, driving the transcription of the RAM, can lead to unwanted polar effects. While the ClosTron system is very efficient and easy to use, it can, on occasion, be nonspecific, requiring the empirical testing of several insertion sites. To be able to construct double mutants, it is necessary either to use another marker or to remove the initial marker, both of which have been attempted. No other RAM marker other than erythromycin resistance has been described for the clostridia, but markerless ClosTrons or ClosTrons with markers that are not retroposition activated have been used

successfully (115, 119). The alternative and preferred option is marker removal. Flp recombinase has been used successfully in *C. acetobutylicum* to remove the retargeted *ermB* gene from a ClosTron mutant (120). The ability of the Tn*4451/3* site-specific recombinase TnpX to recognize and excise specific DNA fragments has also been exploited for antibiotic resistance marker recycling. Specifically, TnpX was used to remove the *ermB* gene from a marked chromosomal *C. perfringens* mutant, enabling the construction of a double mutant by allowing the removal and subsequent reuse of *ermB* to construct the second mutation (81).

Transposon-Mediated Random Mutagenesis

Transposon mutagenesis has been established in *C. perfringens* for several decades, although the early systems were not optimized and lacked efficiency (22). The most successful early mutagenesis method utilized the conjugative enterococcal tetracycline-resistance transposon Tn*916* (121). In these studies, *C. perfringens* cells were transformed with a suicide plasmid carrying Tn*916*, and transformants were selected on medium containing tetracycline. Hybridization analysis showed that Tn*916* had inserted at different sites on the chromosome but that multiple insertion events were common. However, mutants that had a single Tn*916* insertion and that abrogated the ability to produce perfringolysin O were detected. The insertion site was shown to be located within the *virS* sensor histidine kinase gene, leading to the identification of the VirSR two-component signal transduction system (121). Subsequent studies involved the isolation of Tn*916* insertions in several toxin genes (122), and conjugative transfer or mobilization of Tn*916* from *E. faecalis* and *E. coli*, respectively, has been used to isolate auxotrophic mutants of *C. perfringens*, but again, multiple insertion events were observed (123). Tn*916* mutagenesis also has been used to isolate mutants that have an altered response to oxidative stress (124). In summary, the use of Tn*916* for mutagenesis in *C. perfringens* has been useful, but it is hampered by the presence of multiple insertion and deletion events and subsequently has not been widely adopted.

Other transposon mutagenesis options include transposon mutagenesis of cloned genes in *E. coli* and subsequent transformation and screening in *C. perfringens*. This approach has been used to identify the replication protein of the *C. perfringens* plasmid pCW3 (125). Other workers (126) developed an EZ-Tn*5*-based random mutagenesis system that involved the electroporation of a transposome complex into *C. perfringens* and selection (erythromycin resistance) for the insertion of a modified Tn*5* element. The erythromycin-resistant transformants appeared to contain random single insertions. These experiments led to the mutagenesis and identification of the *agrB* gene, which is involved in the regulation of perfringolysin O production by quorum-sensing (126). Similarly, the bacteriophage Mu-based transposon delivery system has been successfully adapted for *C. perfringens* (127). Electroporation was used to introduce a Mu transpososome complex, and a strain library that contained single transposon inserts was obtained. Finally, the *Himar1* mariner transposon system has been adapted for *C. perfringens* and used to show that the *sagA* gene is required for gliding motility in *C. perfringens* (128). This method utilizes a replicating plasmid that carries an inducible mariner element, but it requires a strain with *galK* and *galT* mutations to ensure that the replicating delivery plasmid can subsequently be selected against in the presence of galactose.

Despite in-depth studies of transposons in *C. difficile* (129), there is only one system for random mutagenesis in this organism. Transposons such as Tn*5397* and Tn*916* (33, 130, 131) have been well characterized, but they either lead to multiple insertion events or show a strong bias to particular target sites. However, the mariner transposon system has been successfully developed for *C. difficile* (132, 133). The transposable element of the mariner system *Himar1* inserts randomly into a TA target site, which lends itself for use in AT-rich organisms such as the clostridia. Furthermore, only the cognate *Himar1* transposase is required for transposition to occur. As mentioned earlier, no transformation system has yet been developed successfully for *C. difficile*, which means that the transposon vectors cannot rely on a plasmid suicide mechanism for their introduction into cells. To overcome this problem, Cartman and Minton (132) developed a pseudo-suicide vector by creating a segregationally unstable plasmid, using the replicon pBP1. This method allowed them to obtain transposition events at a frequency of 4.5×10^{-4} per cell. Drawbacks of this method were the lack of effective control of the time of transposition and lack of plasmid loss, which meant that the size of the library that could be obtained was limited. Library size is important for experiments such as transposon-directed insertion site sequencing, which can be used to determine essential genes under specific conditions. Subsequently, the system was improved by integrating the previously described anhydrous tetracycline system (74) with the transposon vector, generating a plasmid that has tetracycline-dependent conditional replication. The new transposon vector not only has a conditional replication phenotype, but it also has tight control over transposition of the *ermB* transposon. This tetracycline-inducible system consists of two promoters (133); one promoter drives expression of *tetR* (74), and the other promoter drives expression of the codon-optimized Hinmar1 transposase. Upon induction, Dembek et al. showed near complete plasmid loss within 13 generations, whereas 40% of bacteria in the uninduced culture retained the plasmid. (133). The transposon system has been demonstrated in *C. difficile* 630Δ*erm* and in the epidemic strain R20291. Transposon libraries have been created during *in vitro* growth and during sporulation, followed by transposon-directed insertion site sequencing, which resulted in the identification of 404 and 798 essential genes, respectively, for these conditions (133).

Newer Technologies for Genetic Manipulation

New and improved technologies for genetic analysis and manipulation of the pathogenic clostridia are being reported all the time. Most *C. difficile* genomes contain prophages and lysogenic bacteriophages, which have been characterized in some detail (134–136), but to date, no lytic phages have been described. There has been one report of transduction, showing that a novel transposon, Tn*6215*, carrying an erythromycin resistance gene, could be transferred from a donor strain to a recipient strain and integrated into the recipient genome if the bacteriophage ΦC2 was integrated into the recipient genome. The study was unable to show transduction into another three recipient strains, which were all susceptible to the phage, suggesting that conditions for transduction need to be optimized further before it can be used as a reliable genetic tool (137).

Antisense RNA technology has successfully been used to repress gene expression in *C. difficile* and to show that the S-layer proteins and cell wall protein V are translocated across the cell membrane through an accessory Sec-system

(SecA2). Most recently, CRISPR-gene editing technologies were successfully used in the clostridia. Initially developed in nonpathogenic clostridia, such as *C. pasteurianum* (138), *C. beijerinckii* (139), and *C. cellulolyticum* (140), this emerging technology was used in 2017 to generate deletion mutants in *C. difficile* (141). The authors developed a CRISPR-Cas9 system with a reported mutation frequency of 20 to 50%, exemplifying it by deleting *selD*, a selenophosphate synthetase that is essential for the specific incorporation of selenium into selenoproteins. They showed that deletion of *selD* leads to growth reduction and a lack of selenium incorporation, suggesting that the Stickland reaction could be a target for future antimicrobial therapy development. Since then, two more papers were published (142, 143), further developing and refining the technology for use in *C. difficile*. Wang et al. used a plasmid-based CRISPR-Cas9 system for mutagenesis, reporting 100% mutation efficiency and knocking out the sporulation master regulator Spo0A (142). The latest study by Hong et al. developed a CRISPR-Cpf1 system capable not only of targeted deletion from the *C. difficile* genome, including the largest deletion to date of 49.2 kb, but also of simultaneous deletion of at least two targets located on different parts of the genome. This new toolkit could greatly improve the genetic analysis of *C. difficile* and advance the development of new therapeutics and diagnostics by identifying new targets for these strategies (143).

CONCLUSIONS

The pathogenic clostridia are a diverse group of anaerobic, Gram-positive spore formers, all of which can cause human disease. Pathogenesis is toxin mediated, but many auxiliary virulence factors have been described and are still being discovered. Historically, it has been extremely difficult to study the clostridia at a molecular level owing to their anaerobic nature, but also because of a number of other difficulties such as the presence of multiple restriction modification systems, which preclude the uptake of foreign DNA into the bacterial cell. With the advent of next-generation sequencing and, consequently, the availability and analysis of whole-genome sequences, the development of clostridial molecular tools has taken an unprecedented leap. The technologies presented and reviewed in this article open up unique opportunities to study the pathogenic clostridia and their disease mechanisms in detail, with the objectives of improved diagnostics and the development of novel disease therapies.

There is, however, more work to be done. Recent years have seen a surge in interest in the nonpathogenic clostridia, particularly because of their utility in producing a range of biochemicals. Technologies have been developed that could be adapted for use in the pathogenic clostridia, such as a range of allelic exchange systems. Examples include the I-SceI system used in *C. acetobutylicum* and *C. beijerinckii* (144) and the MazF toxin-antitoxin system, which has been used in *C. acetobutylicum* and *C. cellulolyticum* (145, 146).

Additionally, there is an ever-growing interest in the healthy microbiota and in particular clostridial species within that microbiota (147, 148). To date, no mechanistic studies have been conducted, despite studies showing compelling data that suggest benefits to the host or microflora from certain of these species (147). The main reason for this information shortfall is the lack of available genetic tools. With the newest approaches, described in this article, we are likely to see this area of research develop rapidly in the very near future (38, 142).

In conclusion, the past 10 years have seen a rapid increase in mechanistic studies of the pathogenic clostridia owing to the development of novel, sophisticated tools, the outcomes of which are being translated into the clinic through improved diagnostics, prevention strategies, and novel treatments. The next decade will undoubtedly see even more significant advances in clostridial genetics and their subsequent application to provide a more detailed understanding of this important genus of bacteria.

Genomics of the Pathogenic Clostridia

ROBERT J. MOORE AND JAKE A. LACEY

58

INTRODUCTION

The earliest DNA-based studies of the clostridia investigated the guanine + cytosine (G+C) content of DNA and measured hybridization as an indication of the relatedness of strains (1–3). Since those early "genome" studies, a range of other DNA-based typing methods, such as pulsed field gel electrophoresis, amplified fragment-length polymorphism analysis, 16S rRNA gene sequence comparisons, multilocus variable-number tandem-repeat analysis, and multilocus sequence typing (MLST), have been used to classify, group, and differentiate clostridial isolates (4). However, these methods have now been largely superseded. With the rapid advances in DNA sequencing technologies and the subsequent drop in the price and effort required to acquire whole-genome sequence (WGS) data, the comparative analysis of strains is now commonly based on core genome single-nucleotide polymorphisms (SNPs), gene content analysis, MLST on a large group of genes, or average nucleotide identity (ANI) across whole genomes. Whole-genome analysis is the tool of choice for comparing isolates and informs our understanding of the pathogenic mechanisms that are deployed by the clostridia, the epidemiology of disease outbreaks, and the evolutionary histories of the organisms. Analysis of WGS allows the identification of metabolic pathways or the lack thereof (e.g., amino acid metabolism and substrate degradation pathways) and thus indicates how clostridia are adapted to their lifestyles within the ecological niches that they occupy. The quality of WGS information available in sequence databases is variable, so some caution is needed in how it is interpreted when investigating genome structure and absolute gene content. Complete closed genomes are particularly valuable and can be used as scaffolds around which the more usual draft assemblies can be made. Like WGS data from all species, the clostridial WGS annotations need to undergo continual refinement as gene functions are experimentally confirmed and extended. Commonly, a quarter to a third of the open reading frames identified in genomes encode putative proteins of unknown function. Whole-genome analysis provides a much better tool for taxonomic classification than the traditional biochemical, phenotypic, and limited molecular characterization methods (e.g., 16S rRNA gene sequencing) that were previously applied.

The pathogenic clostridial species with the greatest impacts on human and animal health are *C. difficile*, *C. perfringens*, *C. tetani*, *C. botulinum*, and other species that produce botulinum toxins. Among the clostridial species, *C. difficile* has attracted the most active and broad research effort because of its clinical impact and the need for improved treatment options for infections. Therefore, the most intensive genomic research effort has been applied to *C. difficile*, and this is reflected in the number of WGSs that have been submitted to public databases (Table 1) and the depth of information that has been generated regarding strain diversity, transmission, and evolution. The clostridial species that produce botulinum toxins are also well studied, but there is only limited genomic information available for other clostridia, such as the clostridial species for which clinical cases are only rarely seen and the predominantly animal pathogens that, in most cases, are well controlled by vaccines.

Many of the clostridia are ubiquitously found in soil and in the gastrointestinal tract of healthy animals, including humans. Disease generally occurs when there is some tissue damage to the skin or gastrointestinal tract or environmental disruption within the gastrointestinal tract resulting in clostridial proliferation. This bimodal lifestyle, divided between a free-living, often saprophytic existence in the environment and host colonization and pathogenesis, is reflected in the genomes of the clostridia. The spore-forming machinery encoded by all the clostridia may increase resilience and survival in the environment, and the wide array of toxins and degradative enzymes that are encoded assist in nutrient scavenging. Many of the toxins produced by clostridia are encoded on large plasmids, at least some of which have been shown to be conjugative. The main chromosomes of clostridia range in size from 2.4 to 7.2 Mb (Table 1), and hence their genetic potential is quite variable. In general, across all bacteria, smaller genomes tend to be found in bacteria that occupy limited specialist environmental niches, whereas those with larger genomes, such as many of the clostridia, are generalists that can survive in a range of ecological niches and use a wider variety of substrates for growth (5).

CLOSTRIDIAL TAXONOMY IS INFORMED BY GENOMICS

The bacteria that have historically been given the genus name *Clostridium* represent a genetically disparate collection of organisms. The original classifications were based on the phenotypic characterization of isolates as Gram-positive, endospore-forming, obligate anaerobes. However, genomic information, first from 16S rRNA gene sequences and more

C. sphenoides	GenBank BioProject no. PRJEB16486, PRJDB859, and PRJEB6403	43.7–43.8	3	5.2–5.3
C. sporogenes	116	28	30	2.7–4.2
C. taeniosporum	117	26.6	1	3.3
C. tertium	98	27.8	2	3.9–4.0

recently from WGS, has clearly shown that many of the species categorized within the genus *Clostridium* are only distantly related and by all currently accepted taxonomic principles should not be considered as belonging to the same genus (6, 7). Among the major pathogenic clostridial species, *C. difficile* and the taxonomically related species *Clostridium sordellii*, fall outside the main cluster of true clostridial species (Fig. 1). These two species have been grouped within clostridial cluster XI, whereas most of the other important clostridial pathogens (e.g., *C. botulinum*, *C. perfringens*, and *C. tetani*) fall within the "true" clostridia classified within cluster I (Fig. 2) with the type species of the clostridia, *C. butyricum* (8). In recognizing this taxonomic issue, Ezaki reclassified the cluster XI species, including *C. difficile*, *C. sordellii*, *C. sticklandii*, *C. bartlettii*, *C. bifermentans*, and *C. glycolicum*, to the family *Peptostreptococcaceae* (9). The cluster XI clostridia have been assigned to a number of genera within this family, including *Intestinibacter* (e.g., *I. bartlettii*), *Paeniclostridium* (e.g., *P. sordellii*), and *Paraclostridium* (e.g., *P. bifermentans*) (7, 10, 11). Lawson et al. suggested changing the name of *Clostridium difficile* to *Clostridioides difficile* (12), and this new name is now officially recognized (13) and will be used in this review.

The dichotomy between these different groups of clostridia can also be clearly seen in the relative degree of genomic plasticity observed within cluster I species compared with that noted in *C. difficile*. Cluster I species exhibit low genome plasticity compared to many other bacterial genera, whereas *C. difficile* has an extremely plastic genome (see discussion below). Within cluster I the most significant intraspecies genomic variation tends to be in plasmid carriage, prophage sequences, and divergent flagellar genes, whereas the cluster XI intraspecies differences are, in addition, driven by a wider array of mobile elements and high

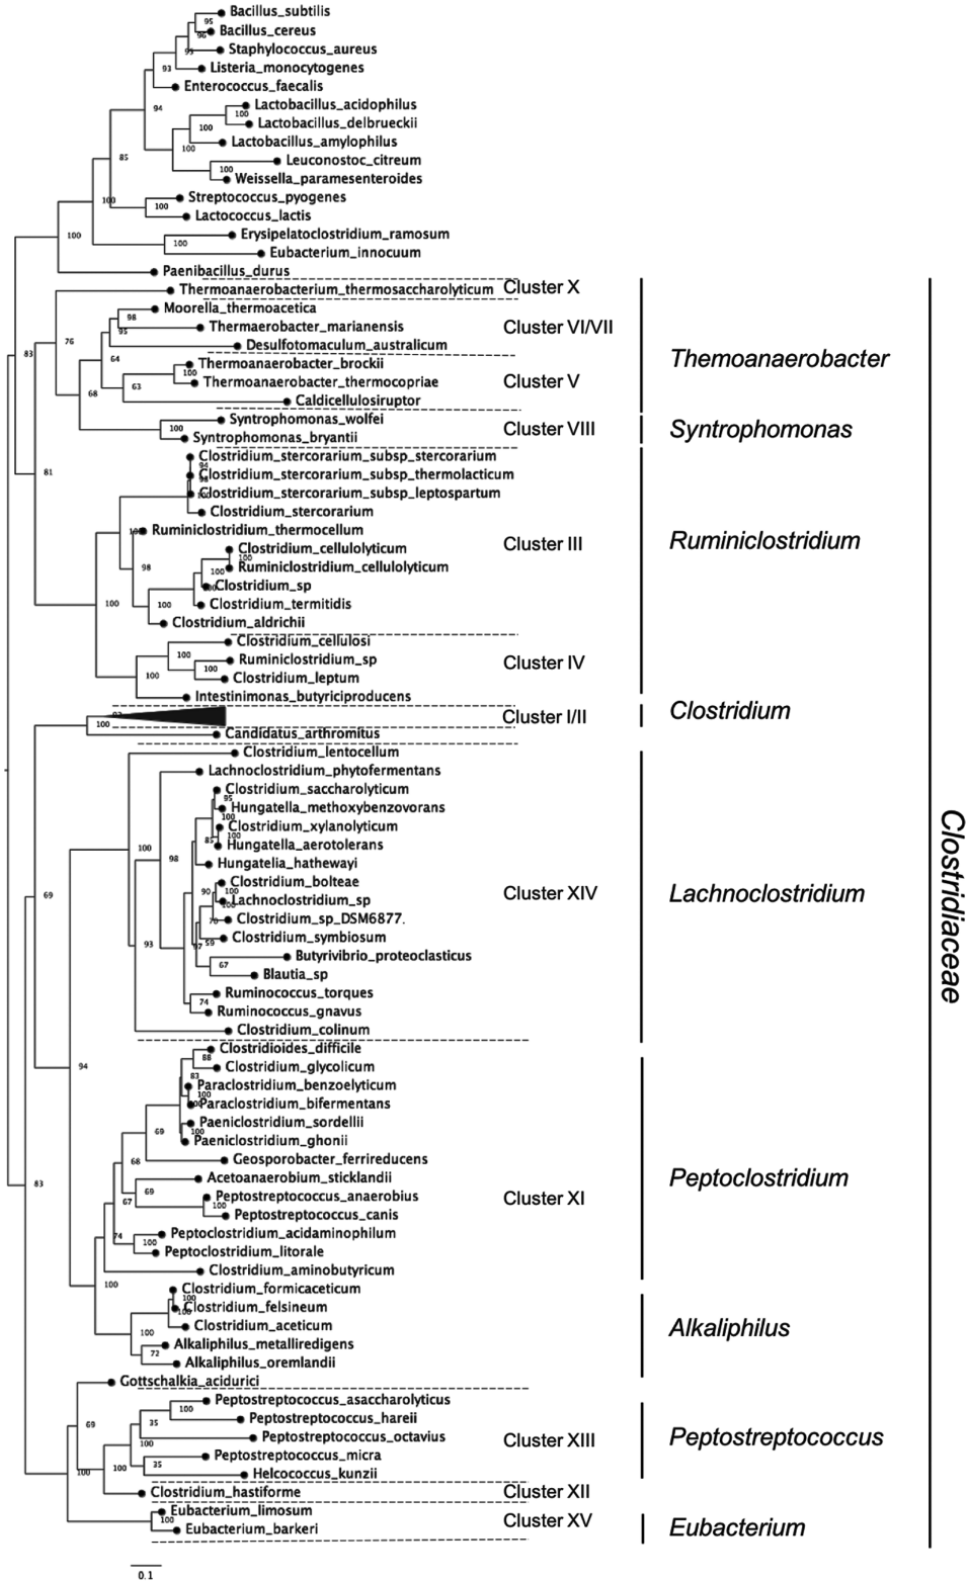

FIGURE 1 Relationships within the *Clostridiaceae*. Maximum likelihood tree of 16S rRNA genes of members of the *Clostridiaceae* family. 16S small subunit rRNA gene sequences were retrieved from RDP (release 11) and NCBI:GenBank (http://www.ncbi.nlm.nih.gov/). Sequences were aligned using Clustal Omega. The multiple sequence alignment was used to build a maximum likelihood tree using IQ-TREE with the general time reversible model (GTR+F+G6) and rapid bootstrapping (-bb 2000) nonparametric bootstraps (-v) (101–103). Clusters are labeled corresponding to the groups proposed in Collins et al. and genus groups as proposed by Parks et al. (7, 8). Clusters from Collins et al. that are not included are due to reclassification outside of the *Clostridiaceae* family.

levels of recombination, chromosomal rearrangement, and gene acquisition and loss.

Genomic analysis of other non-cluster I clostridial species, such as *C. bolteae*, *C. clostridioforme*, *C. histolyticum*, *C. celerecrescens*, *C. innocuum*, and *C. sphenoides*, clearly shows, just on the basis of G+C content, that these species should not be classified within the genus *Clostridium* (Table 1). *C. histolyticum* has been formally renamed *Hathewaya histolyticum*, but the others remain to be formally renamed.

CLOSTRIDIAL STRAINS THAT PRODUCE BOTULINUM NEUROTOXIN

A phylogenetically diverse collection of bacteria, representing at least four species (*C. botulinum*, *C. butyricum*,

C. argentinense, and *C. baratii*), express botulinum neurotoxins (BoNTs). BoNT-expressing isolates are further classified into six groups (I to VI) depending on which toxin types they produce. Groups I to IV encompass the *C. botulinum* isolates (Table 2), group V is the *C. baratii* isolates that encode type F BoNTs, and group VI covers the *C. butyricum* isolates that encode type E BoNTs (14). There are multiple clades within groups I, II, and III, and by normal phylogenetic considerations the genomically disparate groups of *C. botulinum* should not all have the same species names (Fig. 2). Each group encodes between one and three BoNTs from among the seven BoNT serotypes known (BoNT/A to BoNT/G), and there are also many subtypes (15, 16). Recently, other novel and hybrid BoNT variants have been characterized (17, 18). The BoNT serotype-encoding genes differ by ~25 to 45% at the nucleotide level and have diverse locations in the genome, on either chromosomes, plasmids, or bacteriophage loci, depending on the *C. botulinum* type (16, 19).

The genomes of BoNT-expressing isolates vary widely in size, with some as small as 2.4 Mb and others as large as 4.5 Mb (Table 1), indicating large differences in gene-coding potential. Williamson et al. carried out a comparative analysis of 170 genomes of BoNT-producing bacteria and other clostridial species (20). Proteolytic group I isolates are the most broadly represented bacteria among the whole-genome-sequenced *C. botulinum*. Using a variety of analytical approaches, including 16S rRNA gene, core genome, MLST, and concatenated marker gene comparisons, it has been demonstrated that there is a large amount of phylogenetic diversity not only across isolates carrying genes encoding the various BoNT serotypes but also between isolates of the same toxin type. For example, group III isolates were found to be evolutionarily distant from groups I and II (Fig. 2). Whole-genome comparisons using ANI found that some strains within groups I, II, and III have identities below the 95 to 96% level that is generally regarded as defining relatedness at the species level. Some strains within groups I and III have ANI values of less than 93% compared to other strains classified in the same group, indicating greater species-level diversity than had previously been recognized using conventional phenotypic classification methods. Other toxigenic clostridial species are much more closely related within the designated species; for example, the lowest ANI value for isolates classified as *C. perfringens* is 97.02%, and for *C. tetani* isolates, the lowest is 99.13%, indicating much tighter and coherent classification of these species than is the case for *C. botulinum* isolates (20).

Analyses comparing phylogenetic of *C. botulinum* genome sequences with those of other clostridial species have demonstrated a close genetic relationship between some strains that do not produce BoNTs and the toxigenic strains. For example, there is a high degree of similarity between *C. botulinum* group I strains and *C. sporogenes* and *C. tetani* strains; *C. taeniosporum* is genomically related to group II strains, and *C. novyi* is related to group III strains. The group II, V, and VI strains are more closely related to *C. perfringens* strains than to group III strains (20). There are also nontoxigenic representatives of BoNT-expressing species; i.e., there are toxigenic and nontoxigenic representatives of *C. argentinense*, *C. baratii* and *C. butyricum* (21).

Mechanisms such as conjugative plasmid transfer and phage infection and replication instability may account for some elements of the diverse BoNT carriage noted across this phylogenetically diverse collection of bacteria. Conjugative transfer of a large group I BoNT plasmid (pCLJ) has recently been demonstrated (22). Group III *C. botulinum* isolates are generally associated with cases of animal botulism, and they encode *bont* genes for types C or D BoNTs or chimeric C/D or D/C BoNTs. The *bont* genes are encoded by bacteriophages that replicate as unstable plasmids that are frequently lost during primary isolation and subsequent *in vitro* culture (23, 24). Recombination and mutation also shape the genomes, and SNP analysis of the core genomes indicates that recombination is more prevalent in group I isolates compared to group II isolates (20). It is not clear whether this dichotomy is due to actual differences in recombination rates or is a result of the varied evolutionary genesis and history of the groups.

Spore formation is important for *C. botulinum* survival in the environment, and efficient spore germination, leading to vegetative growth and BoNT production, occurs under favorable conditions. WGS analysis has demonstrated that each *C. botulinum* group encodes distinctive spore germination pathways. Groups I and III encode similar germination pathways that differ from the pathways of groups II and IV (25). Germination can be induced by a variety of amino acids and L-lactate. The genome analysis indicates a more diverse set of germinant receptor encoding genes in group I strains compared to the other groups, and this is in agreement with a greater range of amino acids that are known to be effective germinants (25).

C. tetani

C. tetani produces the tetanus neurotoxin (TeNT), the gene for which is encoded on a plasmid (26). The toxin has a similar mechanism of action and some structural similarity to the BoNTs, but the two types of toxin differ in the types of paralysis that they induce; TeNT causes rigidity of skeletal muscles, resulting in death in both humans and other

TABLE 2 Phenotypic groups of *C. botulinum*[a]

[a]+, present; –, absent;.

animals, whereas the BoNTs cause flaccid paralysis (27). Although effective vaccines against tetanus have been available for many years, there are still estimated to be several hundred thousand human deaths from tetanus each year (28). Phylogenomic analyses have shown that *C. tetani* is closely related to group I proteolytic *C. botulinum* strains (20). From the small number of WGSs available for *C. tetani*, it has been deduced that they are more highly conserved than *C. botulinum* genomes (29). WGS studies have investigated the genetic relatedness of vaccine strains from different laboratories and wild-type strains (29, 30). The original vaccine strain was isolated in the United States around 1917 to 1919 and was distributed to various vaccine manufacturers and laboratories around the world, so all vaccine strains are believed to have a common origin (29). WGS studies have demonstrated how these strains have changed in the intervening period, with the accumulation of varying numbers of SNPs, ranging from 25 to 281, among the 5 vaccine strains sequenced. More recent wild-type clinical isolates, unsurprisingly, are more divergent from the vaccine strains, with several thousand SNPs and diverse phage insertion sites and other genomic rearrangements. The chromosome of one strain, ATCC 19406, was very similar to the vaccine strains, but the strain was nontoxigenic due to the absence of the tetanus toxin-encoding plasmid (29). There appears to be more variation in the sequence of the large toxin-encoding plasmid than in the chromosome, with significant deletions and/or insertions in many areas.

C. novyi and *C. haemolyticum*

Comparison of 16S rRNA sequences indicated that both *C. novyi* and *C. haemolyticum* are closely related to group III *C. botulinum*, and this has been confirmed by WGS analysis, and hence these species have been referred to by the collective genospecies name *C. novyi sensu lato* (31, 32). *C. novyi* can cause gas gangrene/blackleg (myonecrosis) and toxic shock-like presentation. *C. haemolyticum* causes bacillary hemoglobinuria. There are pathogenic and nonpathogenic isolates of *C. novyi* that are genomically differentiated by the chromosomal carriage of beta-toxin (phospholipase C) and gamma-toxin (nontoxic phospholipase C) encoding genes respectively. The major virulence factor of *C. haemolyticum* isolates is a phospholipase similar to that found in beta-toxin of *C. novyi*. The similarity of the genomes within the *C. novyi sensu lato* group means that loss or acquisition of some mobile elements, such as the phages that encode BoNTs, can effectively result in conversion between the different species (33).

C. perfringens

C. perfringens is widely distributed in the environment. It can be isolated from soil and water samples and is often found within the gut microbiota of healthy animals. *C. perfringens* isolates can cause a variety of histotoxic and intestinal diseases in a wide variety of animals, including humans (34). *C. perfringens* isolates have been classified according to the combination of the four typing toxins (alpha, beta, epsilon, and iota) they carry. For many years five toxinotypes (A to E) were recognized, but the toxinotyping scheme has recently been expanded to include two more toxins, enterotoxin (CPE) and NetB, and two new toxinotypes, F and G, that these toxins are associated with (Table 3) (35). The typing toxins are just six of the many extracellular toxins and hydrolytic enzymes that are encoded within the *C. perfringens* pangenome. Because clostridial diseases are largely driven by the array of toxins that various isolates can produce, the toxinotyping scheme has some utility in differentiating isolates associated with particular diseases. All *C. perfringens* isolates carry the chromosomally encoded alpha-toxin gene, and those isolates that do not carry any of the other typing toxins are classified as toxinotype A isolates.

WGSs are available for strains of each toxinotype, although it is only poultry isolates of toxinotype A and the newly defined toxinotype G that have been studied in any depth. *C. perfringens* genomes range in size from 2.9 to 4.1 Mb (Table 1). A comparison of 51 *C. perfringens* genomes identified a core genome of 1,192 genes and a pangenome of 8,102 genes (36). The core genome is likely to be fairly well defined, although the sequencing statistics suggest that the number of genes within the pangenome has not plateaued and hence would be expected to expand as more isolates are sequenced. Comparative genomic studies have shown that there are no chromosomal differences which clearly delineate the different groups identified by toxinotyping, so a phylogenetic tree is not particularly informative regarding the pathogenic potential of isolates. The key differentiating feature of the toxinotypes is their carriage of large plasmids that encode the beta, epsilon, iota, CPE, and NetB toxins. These plasmids have large conserved gene clusters encoding conjugation machinery, and a number of the large clostridial plasmids, including those encoding typing toxins, nontyping toxins, and antibiotic resistance genes, have been shown to be conjugative (37, 38). Some nonpathogenic strains carry no large plasmids, whereas some pathogenic isolates have up to five large plasmids (32). A WGS study that compared pathogenic poultry isolates to nonpoultry isolates identified three DNA regions that were more often found in pathogenic chicken isolates and may therefore carry genes involved in

TABLE 3 Presence and absence of toxins within *C. perfringens* toxinotypes[a]

necrotic enteritis pathogenesis. Two of the regions were on large plasmids, and a third was chromosomal (39). A survey of WGSs of *C. perfringens* isolates from necrotic enteritis-diseased turkeys found that only one of the chicken-associated regions was commonly found in the turkey isolates, but a putative collagen adhesin was identified as having potential relevance to pathogenesis (40). It appears from the comparative genomic surveys that necrotic enteritis in chickens and turkeys is likely driven by different genetic factors.

The picture that is emerging from WGSs, whole-genome microarrays and MLST, multilocus variable-number tandem-repeat analysis, and pulsed field gel electrophoresis genomic typing studies is that of a species that can be characterized by a number of evolutionary lineages, each of which has variable carriage of a range of large plasmids (36, 41–43). Plasmid carriage, and hence the toxins encoded, is the most important determinant of disease-causing potential, but at least in the case of necrotic enteritis-causing isolates, genomic analysis and mutation studies have shown that chromosomally encoded genes are also critical determinants of strain virulence (41). Strains isolated from poultry include at least four evolutionarily distinct clades, and all carry a chromosomally encoded alpha-toxin gene. The few toxinotype B-E isolates that have been sequenced group within two of the toxinotype A clades and are only clearly differentiated by the toxin-encoding plasmids that they carry. Isolates can potentially interconvert between the different toxinotypes by acquisition and loss of toxin-encoding plasmids (37). Within toxinotype G isolates the plasmid-encoded genes are more highly conserved than chromosomal genes, indicating that there is either stronger selective pressure on their maintenance or they have a more recent origin (41, 42). The relative levels of sequence conservation between chromosomal and plasmid genes in *C. perfringens* are opposite to that seen in *C. tetani*, where plasmid sequences are less conserved (29).

There is a large pangenome, so each of the toxinotype strains that have been sequenced does carry unique genes, but a much larger collection of diverse *C. perfringens* isolates would need to be sequenced to determine which genes reliably characterize particular lineages and which may influence animal and tissue tropisms. A number of variable genomic regions have putative or known roles in capsular polysaccharide biogenesis, motility, antimicrobial activity, adhesion, and alternative metabolic pathways, and many of these regions are associated with mobile genetic elements such as transposase and recombinase genes and insertion elements (41, 42, 44). A significant proportion of the interisolate differences result from a large and diverse collection of phage insertion events, with some apparently intact prophages and many phage remnants throughout the genomes (41). Some nonpathogenic chicken isolates form a separate clade which is very distinct from the clades which include pathogenic chicken isolates and the toxinotypes isolated from different animals and diseases (36). Interestingly a nonpathogenic isolate from this divergent clade can be transformed into a pathogenic strain by conjugative transfer of the pNetB plasmid (37). It would be interesting to sequence a range of isolates from other animals and the environment to determine if this chicken nonpathogenic clade is an unusual outlier or whether each environment contains specialized isolates that have diverged from the other evolutionary lines.

Clostridioides difficile (*Clostridium difficile*)

C. difficile is the leading cause of antibiotic-associated diarrheal disease, and because of its clinical importance, the comparative genomics of *C. difficile* isolates have been extensively studied, as evidenced by the more than 1,000 genome sequences deposited in GenBank (Table 1) and some individual studies that have sequenced over 1,000 isolates (45). *C. difficile* has a diverse population structure with hundreds of strain types spread across at least six phylogenetic clades (46, 47). The clade structure was first defined by MLST studies (47–49) and was subsequently confirmed by WGS studies (46, 47, 51, 52). Recently, highly divergent isolates from animals and the environment have been assigned to three additional "cryptic" clades (53). Disease-causing isolates are found in a number of distinct lineages, indicating that virulence has evolved independently in the highly epidemic lineages, and it has been concluded that environmental and anthropogenic activities have influenced the rapid emergence and worldwide dissemination of virulent clonal lineages (47, 51). The *C. difficile* genomes range in size from 3.5 to 4.35 Mb. WGS studies have defined a large pangenome of almost 10,000 genes. Estimates of the size of the core genome have varied greatly, depending on the methods that have been used for its definition. Some studies have estimated the core genome to be comprised of approximately 1,000 genes, whereas others have estimated as many as 3,000 genes within the core genome (46, 54, 55). Although a large and diverse pangenome might indicate a specialized ability of isolates to respond to different environments in specific and different ways, a transcriptomics study found that the vast majority of genes that were differentially expressed following two different *in vitro* stress treatments were part of the core genome, indicating that the response to stress is a largely conserved process despite the great sequence plasticity of *C. difficile* (56).

WGS analysis of *C. difficile* isolates has resulted in an increasingly sophisticated understanding of the emergence and evolution of pathogenic strains. The first *C. difficile* comparative genomics study compared three strains: non-epidemic, epidemic, and hyper-virulent strains (57). The epidemic strain was found to have five unique regions, including a novel phage island, a two-component regulatory system, and transcription regulators. It was estimated that some of these genes were acquired over the past 20 years. Broader studies of animal and human isolates, including hyper-virulent isolates, have defined a large pangenome that has been formed by extensive horizontal gene transfer and recombination and has resulted in divergent *C. difficile* genomes in which there has been a high incidence of genome rearrangement and gene acquisition and loss (47, 51). These studies confirmed the important role of both homologous recombination and acquisition of mobile genetic elements in the evolution of the *C. difficile* species. Phylogenetic analysis has been used to estimate that the highly dynamic genome of *C. difficile* evolved within the last 1.1 to 85 million years and continues to rapidly adapt to environmental pressures and anthropogenic activities (51). Interestingly, a WGS study of *C. difficile* isolates from Costa Rica, which investigated microdiversification of isolates, suggested that for NAP1/ST01 strains, typically associated with high morbidity and mortality rates, mutation was an important driver, whereas in NAP_{CR1}/ST54 strains, also isolated from the outbreaks, lateral gene transfer played a more prominent role (58).

Disease-associated isolates have emerged from multiple lineages. Numerous point mutations have been found throughout the genomes of epidemic strains, including mutations in important genes such as that encoding the DNA gyrase, resulting in resistance to fluoroquinolone. WGS analysis of 151 isolates of *C. difficile* RT027, a clinically important ribotype, used 536 SNPs within the core genome to build a phylogenetic tree of strain relatedness (59). It was

found that the accumulation of SNPs was the main driving force in shaping the phylogeny, with no major role for genome rearrangements or gene loss or acquisition, indicating recent emergence of this *C. difficile* population, although acquisition of mobile elements associated with antibiotic resistance was also noted. The analysis indicated that fluoroquinolone resistance had arisen at least twice in North America to establish different epidemic lineages, one of which spread widely to the United Kingdom, Europe, and Australia (59). Other specific mutations have been suggested as driving forces in the emergence of more virulent epidemic strains. For example, Collins et al. showed that low concentrations of trehalose increase the virulence of some RT027 strains, due to mutation of a trehalose repressor gene (60). They noted that the emergence of RT027 and RT078 strains as major epidemic lineages occurred shortly after trehalose was introduced as a food additive, leading them to postulate that this helped to select for the emergence of these hypervirulent epidemic strains.

Isolates of ribotype RT017 have also been subjected to detailed WGS analysis. This ribotype is unusual in that isolates express only toxin A, rather than toxins A and B as commonly found in other lineages. Cairns et al. sequenced 277 RT017 isolates sourced from around the globe and from human and animal sources (61). They identified genetically diverse lineages, SL1 and SL2. RT017 had been thought to have arisen in Asia (62), but this detailed sequence study indicated that it probably had its origins in North America and then spread globally (61).

Mobile genetic elements account for a significant proportion of the genetic diversity of *C. difficile*, with as much as 11% of the genome of some isolates attributed to such elements (63). Mobile elements commonly found in the *C. difficile* genomes include a large and diverse group of intact and fragmented bacteriophage genomes, group I introns, insertion sequences, and transposons, including conjugative and mobilizable transposons, plasmids, clustered regularly interspersed short palindromic repeat (CRISPR)-cas elements, sigK intervening elements, and genomic islands (63–66). All these mobile elements occur in very diverse forms, and isolate surveys have indicated that insertion and rearrangement events have occurred many times in a wide range of lineages. For example, many inducible prophages have been identified, and at least some of them can have significant impacts on host biology. *C. difficile* phages have been shown to repress and induce toxin production, encode elements of quorum sensing systems, and contribute to drug resistance (67, 68). The pathogenicity locus (PaLoc) genomic island, encoding the major virulence factors toxins A and B, is flanked by phage-like integrase genes, and hence it has been suggested that it may have a phage origin (69).

The PaLoc is a key feature of the genomes of toxigenic isolates. In its normal configuration it is a 19.6-kb region that carries the *tcdA* and *tcdB* genes, encoding toxins A and B, as well as four other genes: *tcdR* encodes a sigma factor, *tcdE* encodes a holin-like protein, *tcdC* encodes a negative regulator of toxin expression, and there is a gene encoding a putative amidase (70, 71). The PaLoc is absent in nontoxigenic isolates, and instead there is a 115-bp sequence known as the integration site (72). The PaLoc region of RT017 isolates is unusual in that it contains mutations in the *tcdA* gene, rendering it inactive; therefore, RT017 isolates express only TcdB (61, 73).

Genome studies have also been conducted to investigate the transmission of *C. difficile* in both animal-human contacts and hospital settings. Didelot et al. (74) undertook WGS analysis of 486 *C. difficile* isolates taken from serial samples from patients over a 4-year period to determine the mutation rate and estimated the rate of microevolution to be 1.4 mutations per genome per year. This information was then used to construct time-scaled genealogies that could be used to identify potential transmission of infection between patients in the hospital setting. A similar but larger study of 1,223 sequenced isolates from hospital patients estimated the evolutionary rate to be 0.74 mutations per genome per year (45). WGS analysis of isolates from another hospital was used, in combination with patient movement records, to identify transmission events likely to have occurred within hospital wards and by direct donor-recipient contact, as well as recurrent infections in some patients (75). WGS analysis of isolates from recurrent infections indicated that almost 80% of cases could be attributed to the original infecting isolate (18). This tracking of very closely related strains is not possible with the other, previously used, typing methods (e.g., ribotyping, MLST, pulsed field gel electrophoresis, etc.); it is only with the use of WGS that such high-resolution identification of differences between isolates is possible. The epidemiological story emerging from these studies is that there appears to be a lower rate of direct transmission (35%) of *C. difficile* in the hospital environment than previously thought, and many infections (45%) involve genetically distinct isolates that are not obviously sourced from the immediate hospital environment. WGSs of isolates from asymptomatic carriers of *C. difficile* have also been investigated to estimate transmission rates. It was concluded that although transmission from asymptomatic carriers is probably rare, it is still probably of significant clinical importance because there are so many carriers within the population and many of the isolates found were toxigenic (76). A WGS comparison of *C. difficile* isolates from humans and animals on Dutch pig farms (77) estimated a mutation rate (1.1 mutations per genome per year) similar to that estimated in the human hospital isolates mentioned above. In some instances the human and pig isolates from the same farms were identical or nearly so, supporting the view that *C. difficile* infection is zoonotic, although not identifying the direction of transmission. An Australian WGS study has also found that some human isolates showed a clonal relationship with pig isolates, further supporting the transfer of isolates between humans and animals (78).

Groß et al. sequenced the genomes of three *C. difficile* strains isolated from a single patient with a mixed infection (79). They found that there was evidence of horizontal gene transfer, including transfer of virulence-related genes and antibiotic resistance genes between the strains within the mixed infection. The analysis of *C. difficile* isolates from a patient with recurrent infections over 13 months identified 10 *C. difficile* isolates of 6 ribotypes. Relapses and reinfections were indicated, and at one sampling point three isolates were recovered, indicating a mixed infection, but with little indication of any microevolution within the patient (80). Another interesting use of WGSs of isolates obtained from repeat investigation of particular patients was directed toward understanding the comparative value of two antibiotic treatments in preventing reinfection and relapse. Investigation of paired isolates from 93 patients before and after antibiotic treatment demonstrated that fidaxomicin was more effective than vancomycin in reducing both relapse and reinfection (81).

Paeniclostridium sordellii (*C. sordellii*)

P. sordellii infections can result in toxic shock-like presentation. The genome size ranges from 3.4 to 3.7 Mb, and

phylogenetic analysis of WGSs has placed isolates into four clades, with a number of isolates that do not belong to any of the clades (82). Toxigenic isolates of *P. sordellii* produce two large clostridial cytotoxins (LCCs); the lethal toxin is encoded by *tcsL*, and a hemorrhagic toxin is encoded by *tcsH*. In addition to the LCCs, *P. sordellii* also encodes a number of other probable exotoxins and virulence factors, including a collagenase, a neuraminidase, a phospholipase C, a cholesterol-dependent cytolysin, a secreted metalloprotease, and an antimicrobial peptide, LL-37. *P. sordellii* is unusual among the clostridia in that most isolates carry a urease operon, although to date, it has not been shown to be a virulence factor such as is the case in *Helicobacter pylori* (82, 83).

Although *P. sordellii* is phylogenetically related to *C. difficile*, a comparison of the coding potential of the genomes of the two species, supported by phenotypic analysis, revealed differences in the metabolism of the related species, with *C. difficile* being more capable of using carbohydrates as carbon sources and *P. sordellii* able to utilize amino acids and fatty acids as carbon sources (83). Genomic differences in pathogenicity loci, substrate utilization genes, and pH tolerance mechanisms indicate the genetic basis of the broader tissue tropisms of *P. sordellii* compared to *C. difficile*. WGS analysis of 44 animal- and human-derived isolates from 3 continents classified the *P. sordellii* isolates into 4 clades, with some outlier isolates that could not be assigned to a clade (82). There were no apparent correlations between clade and geographic or animal origin.

The major virulence factors, the LCCs (lethal toxin and hemorrhagic toxin), are localized on plasmids, in contrast to the chromosomal location found in *P. difficile* for the two LCCs which it produces (toxins A and B) (84). However, the LCC genes were only found to be present in a few *P. sordellii* isolates, and it was speculated that the large plasmids that carry the LCCs may be susceptible to loss during primary isolation or continued culturing in the laboratory (82). Such loss of toxin plasmids during primary isolation of bacteria has also been speculated to occur in chicken necrotic enteritis-causing strains of *C. perfringens* (85). The LLC-carrying plasmids of *P. sordellii* were recently shown to be conjugative (86).

GENOMICS OF OTHER PATHOGENIC CLOSTRIDIA

A number of other pathogenic clostridia are either well controlled by vaccination or are only occasionally isolated from clinical cases. Hence, there is a less pressing need to understand the virulence and survival mechanisms of the organisms, and therefore there are generally few genomic studies available beyond the sequencing of type strains and small isolate collections.

Clostridium bolteae and *Clostridium clostridioforme*

These two species can be found in the normal intestinal microbiota of humans and can cause disease when normal gut barrier function is compromised and they escape the confines of the gut to cause intra-abdominal infections. A comparative genomic analysis of *C. bolteae* and *C. clostridioforme* isolates was recently reported (87). Six isolates of each species were sequenced; the genomes were approximately 6 Mb, with the *C. bolteaea* genomes being larger than the *C. clostridioforme* genomes (Table 1). The two species are similar as determined by normal phenotypic methods used to classify bacteria but differ in their ability to ferment lactose. This difference in metabolic potential is evident in the coding potential of the genomes, with *C. bolteae* containing a lactose utilization operon which is absent from the *C. clostridioforme* genome. *C. clostridioforme* encodes an acetyl-CoA pathway and hence is likely to produce more butyrate than *C. bolteae*. Both species are notable for carrying antimicrobial resistance genes to a broad array of antibiotics (87).

Clostridium chauvoei

C. chauvoei can be highly pathogenic and causes blackleg, a histotoxic myonecrotic disease of ruminants (88). Simple bacterin or toxoid vaccines have been used to try to control the disease, but their effectiveness has been questioned (89). Human infections have been reported but are rare (90). The first complete genome sequence of *C. chauvoei* identified an absence of genes for the citric acid cycle and some amino acid metabolism paths, but there was a rich collection of genes for tissue-damaging toxins and pathways involved in protein degradation and amino acid assimilation (91). Presumably, some amino acid metabolism pathways have been lost because the bacteria can scavenge the necessary amino acids from damaged host tissue. The *C. chauvoei* genome is most closely related to the *C. septicum* genome, with gene homologies for key sporulation genes ranging between 77 and 99% (92). A recent analysis of the genomes of a geographically and temporally diverse collection of 20 *C. chauvoei* isolates showed that the genomes are highly homologous (93). The isolate collection spanned 64 years and 5 continents, yet there were very few differences in the genomes, with most genes encoding metabolic pathways and major virulence factors highly conserved. There was an array of single nucleotide variants throughout the genomes, but mainly located in intergenic areas, a few allelic variants in genes encoding flagellin proteins, and differences in some CRISPR sequences, with a large number of variable spacer elements. The WGS analysis indicated that *C. chauvoei* is highly specialized for survival in its host animals (sheep and cattle) and in the pastures in which they graze. The *C. chauvoei* genome (~2.9 Mb) is one of the smaller clostridial genomes. Smaller genomes are typical of bacteria that have evolved to occupy specific narrow environmental niches (5). Interestingly, from WGS analysis Rychener et al. (93) concluded that "*C. chauvoei* is a successful pathogen whose evolution has reached a dead end."

C. septicum

C. septicum is a rarer cause of gas gangrene (myonecrosis) following traumatic injury than *C. perfringens* but is becoming the leading cause of spontaneous gas gangrene in humans (94). *C. septicum* can also cause blackleg in animals. It produces four main toxins: a hemolytic alpha-toxin, a DNase beta-toxin, a hyaluronidase gamma-toxin, and the septicolysin delta-toxin (95). The single WGS that has been published reported a genome size of 3.27 Mb with a G+C content of 27.5% (96). Notably, the genome was found to have 22 rRNA operons, making it the clostridial genome with the highest rRNA operon count. The pathogenic clostridial species generally have approximately 10 rRNA operons, and there are no other bacterial species reported with such a high number of rRNA operons (97).

Other Clostridial Species

Some clostridial species that are only occasionally seen as pathogens in humans or animals, such as *C. carnis*, *C. colinum*, and *C. limosum* (*Hathewaya limosum*), have still not had any whole genomes sequenced. There are a number of other clostridial species that may be pathogenic in humans

and/or animals but have been only rarely documented or are generally regarded as nonpathogenic species but have, rarely, caused human infections. These bacteria have attracted little research, but WGSs are available for some of them, some published and some just as GenBank entries. These include *C. ramosum* (*Erysipelatoclostridium ramosum*), *C. bifermentans* (*Paraclostridium bifermentans*), *C. cadaveris*, *C. celerecrescens*, *C. fallax*, *C. innocuum*, *C. paraputrificum*, *C. sphenoides*, *C. spiroforme*, *C. taeniosporum*, and *C. tertium* (97–99). These genomes are useful resources for the comparative analysis of clostridial gene content and for investigating features such as genes encoding antibiotic resistance, toxins, degradative enzymes, sporulation, and phages. A comparison of 40 clostridial genomes, including both pathogenic and nonpathogenic species, concluded that there were only 169 orthologous gene groups shared by all strains, and a pangenome of 22,668 genes (100). It was concluded that this was consistent with a group of bacteria that live in very diverse environments and hence have evolved a large and diverse gene pool allowing specific adaptation to different environments.

CONCLUSIONS

Advances in DNA sequencing technology have precipitated an avalanche of bacterial WGS information. The study of pathogenic clostridia has benefited enormously from this information explosion. Thousands of clostridial genomes have been sequenced, with most of the effort directed toward those species that present the most serious or intractable clinical challenges. Comparative genomic analysis within species has informed our understanding of strain evolution. By estimating mutation rates and then applying this to the level of variation found within species, evolutionary timelines can be hypothesized, and the likely origins of clades can be deduced. A particularly valuable application of within-species comparative genomics has been its use in epidemiological studies to trace the movement of isolates within the hospital environment, between patients, and in zoonotic transfers between humans and animals. With *C. difficile*, this has provided valuable information about bacterial spread and evolution in the clinical environment and the relative importance of new infections and recurrence of existing infections in recurrently infected patients.

Genomic analysis clearly shows the polyphyletic nature of the pathogenic clostridia. This issue is being addressed by renaming many of the clostridia, but there is still some way to go with this rationalization. Different levels of genomic plasticity have been noted across the phylogenetic lineages, with the cluster XI species, most notably *C. difficile*, showing high levels of sequence variation driven by mobile elements, chromosomal rearrangement, deletions and insertions, and SNPs. The genomes of true clostridia (cluster I) appear to be more stable, with most variation driven by mobile elements and the accumulation of SNPs. Plasmids play a major role in strain variation, with the large conjugative toxin gene-carrying plasmids often determining the virulence of isolates.

The gene contents of isolates provide clues to the survival strategies that are used. For example, species adapted to survival in the gastrointestinal tract differ from those that have a more saprophytic lifestyle in the carriage of adhesion factors, extracellular degradative enzymes (e.g., proteases, chitinases), sporulation and germination pathways, and toxins involved in rapid killing (e.g., neurotoxins), and this determines the biotic and abiotic environments in which they can survive and proliferate. The WGSs of clostridia provide a wealth of information about the metabolic capabilities and the regulatory pathways (e.g., alternative sigma factors, two-component regulators) that these organisms utilize to adapt to varying environments and growth substrates. The genomes can be bioinformatically mined to identify the secretome, surface-exposed proteins, and other gene products involved in pathogenesis. These represent targets that may be used for therapeutic and vaccine development. There is a wealth of information within the already available genomes that is yet to be fully exploited, and of course, the volume of new WGSs available for analysis and exploitation will greatly expand in the coming years. This, complemented with laboratory studies, will drive our knowledge of the pathogenesis of the clostridia and help in the control and treatment of infections.

Virulence Plasmids of the Pathogenic Clostridia

SARAH A. REVITT-MILLS, CALLUM J. VIDOR, THOMAS D. WATTS, DENA LYRAS, JULIAN I. ROOD AND VICKI ADAMS

59

Many clostridial species are ubiquitous in the environment and in the intestinal tracts of birds, fish, and mammals. Commensal species are often carried asymptomatically within a host. However, if the immune status of the host is compromised, due to either age, illness or a change in diet, disease can result from toxigenic strains. Alternatively, some clostridial species or strains don't require predisposing factors. They can cause disease simply if they gain entry into the host either through damage to the skin or through the gastrointestinal tract, often *via* poorly prepared or incorrectly stored food. These clostridia then overgrow and cause cell and tissue damage. Diseases mediated by the clostridial species discussed in this review are predominantly mediated by potent protein toxins, many of which are located extrachromosomally. These toxins have diverse mechanisms of action and include pore-forming cytotoxins, phospholipases, metalloproteases, ADP-ribosyltransferases and large glycosyltransferases. This review focuses on these toxins and the elements that carry the toxin structural genes. For ease of discussion it has been structured on a bacterial species-specific basis.

PAENICLOSTRIDIUM (CLOSTRIDIUM) SORDELLII

Virulence Properties of *P. sordellii*

Paeniclostridium (formerly *Clostridium*) *sordellii* causes several severe diseases in both humans and animals. Most documented animal infections caused by *P. sordellii* are edemic or enterotoxic diseases of livestock and poultry, but they also include rare myonecrotic infections of other animals (1). Human infections are infrequent, but severe in nature, with mortality rates approaching 70% overall (2). The majority of *P. sordellii* human infections are soft tissue infections that occur after trauma or surgery (2). Sporadic, yet severe cases of post-partum and post-medical abortion uterine *P. sordellii* infections have occurred over the last 20 years, with almost every case resulting in the death of the patient (1, 2).

Due to the rare nature of *P. sordellii* infections, the pathogenesis of disease is still poorly understood. The major virulence factors involved in *P. sordellii* infection, however, are the production of two large clostridial toxins (LCTs): TcsH (hemorrhagic toxin) and TcsL (lethal toxin) (1). The LCTs enter mammalian host cells and glycosylate small GTPases such as Ras, leading to an altered cytoskeletal arrangement, cellular rounding and eventual death of the cell (3). Interestingly, while being highly potent, both *P. sordellii* LCTs are produced by only ~5- to 13% of isolates tested (4–6), with the majority of toxigenic isolates producing only TcsL and containing a truncated *tcsH* gene (6). Despite these findings, TcsL has been shown to be the major virulence factor responsible for the production of uterine-infection related toxic shock using an animal model of infection (7). In *P. sordellii*, the LCTs are encoded within a region called the pathogenicity locus (PaLoc), alongside genes that are likely to be required for their regulation and release (8). A recent phylogenetic analysis found that in all toxigenic isolates the PaLoc is carried on a group of related plasmids called the pCS1 family (6), which is the major focus of this section. Other virulence factors of *P. sordellii* include a pore-forming phospholipase SDL, the sialidase NanS, and the production of unique endospores (1, 9–11).

Bioinformatic Characterization of Plasmids in *P. sordellii*

The pCS1 family is a group of large plasmids carried by both toxigenic and non-toxigenic *P. sordellii* isolates. Seven such plasmids have been identified to date (12). The pCS1 plasmids encode a putative replication initiation (Rep) protein (Fig. 1), which, based on conserved amino acid motifs, falls within the RepA family that was first identified from the theta-replicating *Escherichia coli* plasmid P1 (6, 13). However, neither the function of this protein nor the location of an origin of replication (*ori*V) region has been experimentally determined. All members of the pCS1 family also encode a number of predicted surface exposed proteins that may behave as adhesion molecules (6). A number of these predicted surface proteins contain an LPxTG-like sortase motif (6, 13). Sortases mediate the attachment of specific proteins via the LPxTG motif to the peptidoglycan of the cell wall (14). A type B sortase enzyme is encoded (*srtB*, Fig. 1) in the vicinity of the majority of these surface protein genes and may therefore facilitate their attachment to the *P. sordellii* cell wall (6, 12), however, the role of these surface proteins is yet to be explored.

While there is a large degree of nucleotide sequence identity between the characterized plasmids (Fig. 1), significant differences also have been observed, both in plasmid size and in the presence of unique open reading frames (ORFs) (6, 12). The paradigm element is pCS1-1, which is encoded by the *P. sordellii* type strain ATCC 9714. This plasmid is 103 kb

doi:10.1128/microbiolspec.GPP3-0034-2018

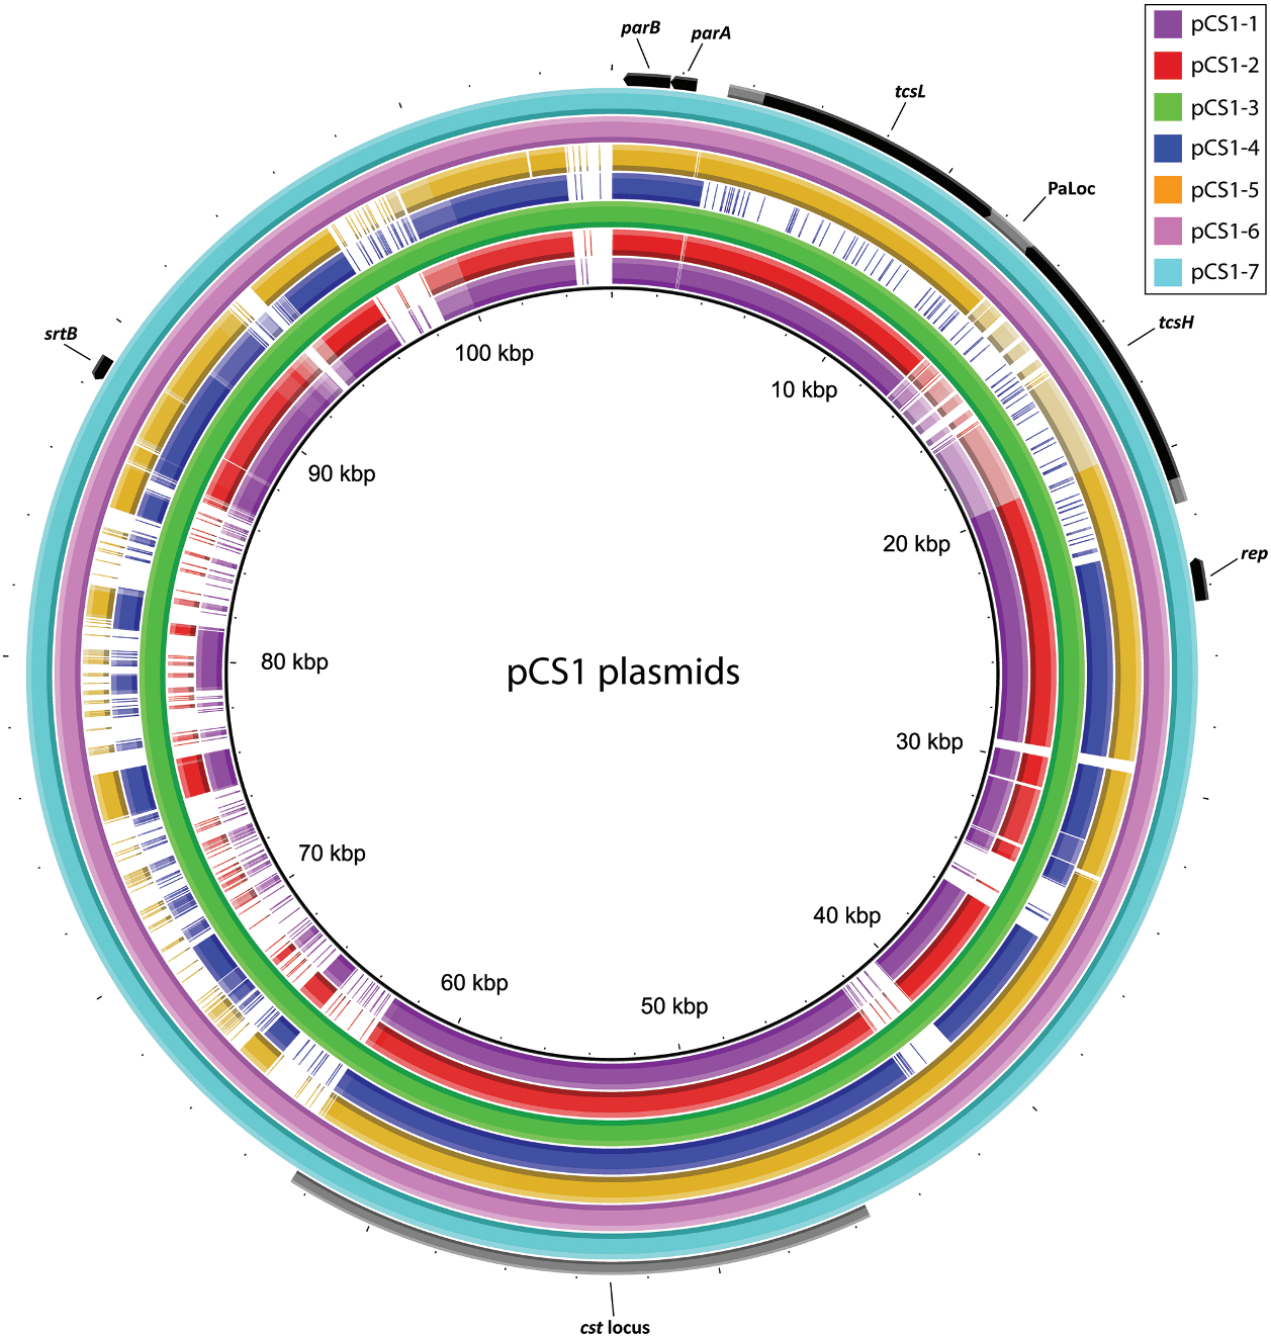

FIGURE 1 The pCS1 family plasmids of *P. sordellii*. Shown is a visual representation of a blastn analysis comparing each of the seven sequenced pCS1 plasmids to the reference sequence of pCS1-3 from strain JGS6382. The third ring from the center (green) and the coordinates (in kb) correspond to pCS1-3. Plasmids displaying 70 to 100% identity to pCS1-3 at a particular locus are shown with a solid block of colour on their respective ring. Identity to pCS1-3 between 50 and 70% is represented as a pale block of colour and if the identity is lower than 50% it is represented as a gap in the corresponding ring. Conserved loci on pCS1-3 are indicated as a gray arc on the outermost ring and labeled. Genes of interest are annotated as black arrows on the outermost ring and also labeled. Sequences analyzed and accession numbers: pCS1-1 (LN679999), pCS1-2 (LN681232), pCS1-3 (LN681235), pCS1-4 (LN681233), pCS1-5 (MG205643), pCS1-6 (MG205642), pCS1-7 (MG205641). Produced using BRIG (224).

in size and carries the PaLoc with a truncated version of the *tcsH* gene, just upstream of the hypothetical *rep* gene (6). The pCS1-2 and pCS1-5 plasmids carry a PaLoc almost identical to that of pCS1-1 (6, 12). pCS1-2 is the largest member of the family at 112 kb and while their PaLocs are identical, pCS1-2 is missing a number of genes, including genes encoding a transcriptional regulator and a cold shock protein (6). A large insertion that carries a putative lantibiotic synthesis cluster is present on pCS1-2 (6). On the other end of the spectrum is the smallest plasmid member, pCS1-5, at 92 kb (12). pCS1-5 displays regions of high identity to the other pCS1 members, but also contains two small unique

regions (12). The plasmids that carry a full-length *tcsH* gene, pCS1-3, -6 and -7, are very closely related (Fig. 1), displaying 99% identity across their ~106-kb sequences (12). Major differences between these plasmids and the other pCS1 members include an absence of the genes encoding subunits of an anaerobic sulfite reductase and the presence of a number of putative transposases (6). Non-toxigenic isolates of *P. sordellii* also carry pCS1 family plasmids, such as pCS1-4 from strain UMC2 (6). This plasmid is 100 kb in size and in place of the PaLoc is a string of ORFS with unknown functions, with the exception of a single putative transposase-encoding gene (6).

A second type of extrachromosomal element, named pCS2, has been identified in *P. sordellii* (6). This ~37-kb circular element has not been as thoroughly characterized as the pCS1 plasmids and appears to encode a number of bacteriophage-related genes (6). Putative plasmid-related genes are present, however, in the form of partitioning and replication initiation genes (6). Related elements appear to be present in another four strains of *P. sordellii*, two of which also carry a pCS1-like plasmid (6). Whether pCS2-like elements represent plasmids, cryptic plasmids, or phage is currently unclear, but no virulence genes have been identified within this plasmid family to date.

Stability and Conjugative Transfer of the pCS1 Family of Plasmids

A recent study has functionally characterized conserved genes of the pCS1 family plasmids, using pCS1-1 as a model (12). All pCS1 plasmids carry *parA* and *parB* genes, which are putative members of a ParABS plasmid partitioning system (6). Such systems are utilized by low-copy-number plasmids to ensure stable inheritance of the plasmid in each daughter cell upon cellular division (15). Stability assays conducted on a marked version of pCS1-1 in different strain backgrounds showed that the plasmid is stable across ~120 generations (12). Independent insertional inactivation mutants of the pCS1-1 *parB* gene displayed gradual loss of the plasmid during continual subculture, providing evidence that ParA and ParB represent a true plasmid partitioning system (12).

Bioinformatic analysis of pCS1-1 also leads to the identification of an ~17.3-kb region, subsequently named the *cst* (for *C. sordellii* transfer) locus (Fig. 1), that encoded proteins with similarity to components of a plasmid conjugation system (12). The conjugative transfer of a marked derivative of pCS1-1, from type strain ATCC 9714 to a *P. sordellii* isolate from a distant clade, was subsequently demonstrated (12). The *cst* locus is conserved between all members of the pCS1 family so far characterized (Fig. 1) (12). Encoded within the *cst* region is a putative relaxase protein belonging to the MobMG family of relaxases, along with a cognate origin of transfer (*oriT*) located upstream of the relaxase gene (12). A number of genes encoding components of a type IV secretion system are also located within the *cst* locus. Two of these, the putative coupling protein, CstD4, and the putative ATPase, CstB4, were demonstrated experimentally to be required for conjugative transfer, confirming the *cst* region to be a true conjugation locus (12). Regions with significant similarity to the *cst* locus also have been identified in plasmids of *Clostridium perfringens* and *Clostridium botulinum*, and within plasmid or conjugative transposon-like regions of the genomes of *Clostridioides* (previously *Clostridium*) *difficile* isolates, indicating that *cst* represents a variant of a common clostridial conjugation locus (12).

CLOSTRIDIUM PERFRINGENS

C. perfringens is ubiquitously distributed among animals, humans and the environment (16, 17), but is also the causative agent of numerous opportunistic infections (16). The diseases caused by *C. perfringens* range from typically mild, self-limiting human food poisoning, to the more severe pathologies of human gas gangrene, and enterotoxemia and necrotic enteritis in domestic livestock (18). It is this broad spectrum of disease that makes this bacterium of particular interest to both veterinary and human medicine. Enteric disease caused by *C. perfringens* is estimated to cost the poultry industry in excess of $6 billion globally as well as $466 million in human health service costs in the United States alone (19, 20). What makes *C. perfringens* such a successful pathogen is its ability to encode and produce up to 20 toxins, many of which are associated with conjugative plasmids (21, 22).

The *C. perfringens* Typing Toxins

Strains differ in their carriage and expression of toxins, and this forms the basis of the *C. perfringens* toxinotype classification scheme (23). This scheme previously categorized *C. perfringens* strains into one of five toxinotypes based on the expression of four lethal typing toxins: alpha, beta, epsilon and iota (23). However, this scheme recently was expanded to include two new typing toxins, *C. perfringens* enterotoxin (CPE) and NetB toxin (Table 1) (24). This toxinotype classification is unique because particular "types" are often associated with specific diseases in humans and animals, for

TABLE 1 The *C. perfringens* toxinotype classification scheme

type	Toxins Produced[a]						Associated Diseases
	Alpha	Beta	Epsilon	Iota	CPE	NetB	
A	+	–	–	–	–	–	Gas gangrene in humans and animals Canine and equine enteric disease
B	+	+	+	–	–	–	Lamb dysentery
C	+	+	–	–	+/–	–	Necrotic enteritis in humans, sheep, horse, cattle and pigs
D	+	–	+	–	+/–	–	Enterotoxemia of sheep and goats
E	+	–	–	+	+/–	–	Enterotoxemias of rabbits, canines and cattle
F	+	–	–	–	+	–	Food poisoning and nonfoodborne gastrointestinal disease in humans
G	+	–	–	–	–	+	Chicken necrotic enteritis

[a]+, Produced; –, not produced; +/–, as produced by some strains.

example; type A strains typically cause gas-gangrene, whereas type D strains are typically associated with enterotoxemia in sheep and goats (25).

Alpha toxin is encoded by all strains of C. *perfringens* and is the major toxin involved in the pathogenesis of gas gangrene infections (26). In all C. *perfringens* strains, the alpha toxin structural gene, *plc*, is chromosomally encoded with basal levels of *plc* mRNA always transcribed (27). The relative amount of toxin produced varies based on the strain background, with type A strains producing the highest levels of alpha toxin *in vitro* (28, 29). This toxinotype-specific control of toxin expression is said to be dependent on strain-specific global control elements, such as the two-component regulatory system VirR/VirS, as well as the structure of the promoter sequences preceding the *plc* gene (27, 28, 30, 31). Alpha toxin is a zinc-metalloenzyme that possesses both phospholipase C and sphingomyelinase activity, and functions by cleaving the phosphatidylcholine and ceramide head groups from the components of membrane phospholipid bilayers (32, 33). It is this targeted membrane disruption that leads to the severe disease often seen in gas gangrene infections (32, 34, 35).

Beta toxin, like many of the C. *perfringens* toxins, is a pore-forming toxin and is produced by both type B and C strains of C. *perfringens* (36). Beta toxin is responsible for disease development in C. *perfringens* type C infections; with beta toxin null mutant strains displaying avirulent phenotypes in animal models of enterotoxemia and necrotizing enteritis (37–39). The precise mechanism of action of beta toxin has not been fully elucidated, but, the hypothesis is that the toxin forms pores in the membranes of susceptible cells leading to cell lysis (40–42).

Beta toxin is encoded by the *cpb* gene, which is located on large conjugative plasmids (43–45). In type B stains, *cpb* is encoded on one of two plasmids: either ~65 kb or ~90 kb in size (44). More commonly the *cpb* gene is found on the larger ~90-kb plasmid (44). Preceding the *cpb* gene is the insertion sequence (IS) element, IS*1151* (44, 45). The presence of IS elements co-located in the toxin gene region may facilitate mobilization of these gene regions and may explain the presence of this toxin gene on multiple different plasmids (44, 45). The potential for mobilization is further supported by the detection of toxin-encoding circular intermediates in these strains (44, 45). In type B strains of C. *perfringens* there appears to be a strong association between carriage of *cpb* and the gene encoding the LCT, TpeL, which has no demonstrated role in disease (44). This study found that in all type B strains examined, the *tpeL* gene was always encoded ~3 kb after the *cpb* gene. The *cpb* plasmids of type B strains co-exist with at least one other virulence plasmid, an epsilon toxin (*etx*)-encoding plasmid, and sometimes another accessory toxin plasmid, encoding lambda toxin (*lam*) and a putative urease operon (44). In these strains the size of the *etx*-encoding plasmid and other accessory plasmids is consistent, with the only variable plasmid being the *cpb*-encoding plasmid (44). The limited variation of these plasmid combinations may be due to incompatibility issues with resident plasmids present in type B isolates. No type B plasmids have been identified that encode both the *cpb* and *etx* genes (44).

In contrast, the *cpb*-encoding plasmids of type C strains demonstrate much greater size variation (45). In these strains, the beta toxin gene is encoded on plasmids ranging in size from 65 kb to 110 kb (45). Restriction analysis suggests that some type C isolates may carry the same *cpb* plasmids found in type B strains (90- and 65-kb plasmids) (45). However, in addition to size differences, the *cpb*-encoding plasmids of type C strains also differ in their carriage of accessory toxin genes (45). As in type B strains, *cpb* is often associated with *tpeL* (45), although *tpeL* and *cpb* are not always encoded on the same plasmid (45). This result suggests potential movement of either of these IS-associated toxin genes (45). In addition to *tpeL*, *cpb*-plasmids can also encode other toxin genes, such as the CPE structural gene, *cpe* (45).

Epsilon toxin is the most potent of all toxins produced by C. *perfringens* (40, 46). It is the third most potent bacterial toxin, after tetanus and botulinum toxins (47). During infection, epsilon toxin is secreted as a pro-toxin from type B and D C. *perfringens* strains and is proteolytically cleaved to produce the active toxin (48, 49). Activation of epsilon toxin can be facilitated by proteolytic cleavage catalyzed by the C. *perfringens* protease lambda toxin (*lam*), but has been shown to be more commonly activated by chymotrypsin, trypsin or other carboxypeptidases encountered within the gut of the host organism (49–52). Once active, epsilon toxin primarily targets endothelial cells near the intestinal border, forming a prepore complex before inserting itself into cell membrane regions following binding to specific cellular receptors (53, 54). The toxin oligomerizes, forming a pore in the cell wall and inducing cellular damage (55). These damaged endothelial cells then allow epsilon toxin to be absorbed, where it systemically targets organs such as the lungs, and kidneys and in the brain, where it induces the release of the excitatory neurotransmitter, glutamate (47, 56, 57). Excessive glutamate release and subsequent overstimulation of neurons results in altered neurological capabilities, which are commonly observed in animals suffering from epsilon toxin-induced enterotoxemia (47, 57, 58).

Epsilon toxin is encoded by the *etx* gene (57). The *etx* gene is harbored on conjugative plasmids found in both type B and D strains of C. *perfringens* (44, 59, 60). The *etx* plasmids of type B strains again appear to have a limited degree of plasmid diversity, with the *etx* gene only encoded on an ~65-kb plasmid (44). In contrast, the *etx* plasmids of type D strains are more variable in size, ranging from ~45 to ~110 kb (60). In addition to the size variability observed for type D *etx* plasmids, they are also more diverse in their toxin gene carriage (60). Some of the larger *etx* plasmids have been found to encode numerous other toxin genes such as *cpe*, *lam*, and *cpb2*, which encodes beta2 toxin (60). Whether the toxin genotype of a type D strain is simple (carrying only *plc* and *etx*) or more complex (possessing other toxin genes such as *cpe* or *cpb2*) appears to delineate the size of the plasmid on which the *etx* gene is located (44). 'Simple' strains tend to encode *etx* on plasmids ranging in size from ~45 to ~75 kb. Conversely, more 'complex' strains tend to encode *etx* on larger plasmids of roughly 75 to 110kb (44).

Iota toxin is a binary toxin encoded by type E strains of C. *perfringens*, which infrequently cause enterotoxemia in rabbits, lambs and calves (61). It comprises two protein components: Ia -(the enzymatic component) and Ib -(the binding component) (62, 63). Each component alone is non-toxic, but when combined the intact toxin produces rapid cytotoxic effects that often result in death (64, 65).

Iota toxin is encoded by two genes, *iap* and *ibp*, which form an operon (62). These genes are located on large virulence plasmid that range in size from 65 kb to ~135 kb (66, 67). Like many other C. *perfringens* toxins, the genes encoding iota toxin can be associated with the insertion sequence element, IS*1151* (66), with a complete element upstream of *iap* and *ibp* and a partial element downstream (66). The association of the toxin genes with IS*1151* may explain the existence of a highly conserved silent *cpe* gene upstream of the iota toxin operon in some strains (68). Current theories suggest that an insertion event on a *cpe*-encoding plasmid

with the IS*1151*-associated iota toxin operon resulted in the formation of the type E iota toxin plasmids (66, 68). However, surveys of environmental strains and isolates from healthy humans has indicated that some type E strains derived from these sources encode an intact, but variant *cpe* gene that is not associated with IS elements (67).

Many type E strains carry additional genes, such as those encoding for urease and lambda toxin, on their iota plasmid (66). The components of iota toxin, like epsilon toxin, are activated by proteolytic processing (64), and the lambda toxin protease is known to process iota toxin into an active form (64, 69). The carriage of both toxin genes on a single plasmid would be considered advantageous because it would be beneficial for cells expressing iota toxin to also encode its activator, lambda toxin (66). In all strains characterized both *lam* and *iap/ibp* were encoded on the same large conjugative plasmid (66).

CPE is responsible for C. *perfringens*-mediated food poisoning in humans (70, 71) and is produced by the newly designated C. *perfringens* type F strains during sporulation in the small intestine, following the ingestion of a large number of C. *perfringens* cells from contaminated food (24, 72). Once released, CPE binds to enterocytes and forms a range of complexes on the cell surface (70). These complexes then form pores in the cell membrane, activating cell death pathways that result in cellular destruction (71). Like epsilon and iota toxins, CPE requires proteolytic cleavage for activation (73). It is encoded by the *cpe* gene, which can be located both chromosomally and on conjugative plasmids (74, 75), which appears to play a role in the epidemiology of disease (75, 76). C. *perfringens* type F food poisoning isolates generally possess chromosomally-encoded *cpe* genes, whereas isolates from nonfood borne gastrointestinal infections, such as antibiotic-associated diarrhea, have plasmid-encoded *cpe* genes (75). In fact, the *cpe* encoding plasmid from strain CPF4969, pCPF4969, was the first toxin plasmid of C. *perfringens* demonstrated to be conjugative (74). It is thought that the carriage of *cpe* on conjugative plasmids is a key factor in the disease phenotype observed during nonfood born gastrointestinal infections (40). In this syndrome, unlike C. *perfringens*-food poisoning, only a small number of *cpe*-positive C. *perfringens* cells are required to be ingested for disease establishment, which is postulated to be facilitated by the conjugative transfer of the plasmid to commensal C. *perfringens* strains in the gastrointestinal tract (40, 74).

The *cpe* gene is encoded on numerous plasmids that range in size from ~70 kb up to ~110 kb (45, 60, 66, 77). Plasmids encoding *cpe* have been found in type C, D, E and F strains, but not in any type B isolates (45, 60, 66, 77). In the newly designated type F strains (24), whether chromosomal or plasmid-borne, there is an IS*1469* element directly upstream of the *cpe* gene (78). However, the sequence downstream of *cpe* differs greatly, depending on the different genetic locations (78). Chromosomal *cpe* loci possess flanking IS*1470* sequences, which are proposed to comprise a larger mobile element (74, 77, 78). Plasmid-encoded *cpe* genes can have either a downstream IS*1151* or IS*1470*-like element, which forms the basis of the two *cpe* plasmid families: pCPF4969-like (IS*1470*-like) and pCPF5603-like (IS*1151* and *cpb2*) (77). The *cpe* plasmids show significant diversity and can differ in their carriage of other toxin genes (45, 60). In some type C strains *cpe* can either be carried on the same plasmid as *cpb* or on a separate plasmid (45). The larger *etx*-encoding plasmids characterized in type D strains tend also to carry *cpe* genes (60).

NetB is a β-pore forming toxin which is the causative agent of necrotic enteritis in chickens and forms the basis for the new toxinotype G. NetB was discovered after C. *perfringens* strains isolated from necrotic lesions were found to still induce disease after inactivation of the *plc* gene, which previously was thought to be the primary toxin involved in this syndrome (79, 80). Sequencing of these strains identified a putative toxin which was denoted NetB, Necrotic Enteritis Toxin B-like (80). Deletion of *netB* resulted in the formation of a strain that was unable to produce necrotic lesions in chickens (80). Complementation with the *netB* gene *in trans* restored the strain to wild-type virulence (80). NetB is produced by type G strains of C. *perfringens* and is encoded on large plasmids ranging in size from 82 to 95 kb (81), which like pCPF4969, have been shown to be conjugative (81, 82). Strains harboring *netB* plasmids can also contain two other closely related conjugative plasmids, encoding *cpb2* and tetracycline resistance (80–82).

Other Plasmid-Encoded *C. perfringens* Toxins

C. *perfringens* strains can harbor and express numerous other toxins and extracellular enzymes. The toxins of C. *perfringens* are functionally classified into four broad categories: pore-forming toxins, intracellular toxins, membrane damaging enzymes and hydrolytic enzymes (36). With some exceptions, most of the toxins and hydrolytic enzymes produced by C. *perfringens* are encoded on large conjugative plasmids (36, 83).

The beta2 toxin gene, *cpb2*, is possibly the most promiscuous of all toxin genes, because it can be found on plasmids from all C. *perfringens* strain types (44, 45, 60, 66). Despite its name, beta2 toxin has little amino acid sequence identity (less than 15%) to beta toxin (84). The involvement of beta2 toxin in disease is often debated because there is no direct evidence of beta2 toxin-induced virulence (85). However, there is a correlation between the prevalence of C. *perfringens* strains expressing beta2 toxin among animals with enteritis, particularly piglets, suggesting that it may play a role in the pathogenesis of this disease, but no genetic studies have been carried out (85).

The *cpb2* gene is carried by numerous plasmids ranging in size from 45 to 90 kb (44, 45, 60, 81, 82). These plasmids can carry numerous other toxin genes such as *cpe* and *etx*, with one plasmid characterized in a type D strain carrying all three toxin genes (60). In many strains *cpb2* is carried on a conjugative plasmid distinct from other toxin plasmids, as is seen in many type B to G strains (44, 45, 66, 81, 82).

Delta toxin is another β-pore forming toxin produced by C. *perfringens* (86, 87). Although it has not been shown to be involved in disease, it is thought that there may be a synergistic effect between delta and beta toxins, because they are often produced by the same strains (88, 89). Delta toxin is produced primarily by type C strains and possibly some type B strains (89, 90). Delta toxin is encoded by the *cpd* gene, which has so far only been characterized from two type C strains, CP24-03 and NCTC8131 (88). Not much information regarding the genetics of delta toxin is currently available, however, Southern blot analysis has shown that a *cpd* probe hybridizes to both total DNA and plasmid DNA preparations, suggesting that the *cpd* gene is likely carried on a plasmid (88). Further sequencing determined that *cpd* was encoded within a region flanked by ORFs that could make up a mobile genetic element, as is seen for other C. *perfringens* toxins (88).

NetE, NetF and NetG are putative β-pore forming toxins recently discovered in C. *perfringens* type A strains from dogs and foals presenting with enteric disease (91). Sequencing of the strains identified three genes—*netE, netF*, and *net*G—that were predicted to encode pore forming toxins with

sequence similarity to NetB (91). In the first *netE/F/G*-positive type A strain characterized, both *netE* and *netF* were found to be encoded on the same large conjugative plasmid (92, 93), whereas *net*G was located on a second large conjugative plasmid that also carried the *cpe* gene (91). Sequencing of other *netF*-positive strains showed that co-carriage of *netE* and *netF* on the same plasmid remained consistent; however, carriage of the *net*G plasmid was variable among these isolates (92, 93).

NetF is cytolytic for equine ovary cells (91). There is also a strong association of *netF*-positive strains isolated from diseased dogs and foals which, along with the cytotoxicity assays, suggests that NetF is involved in these diseases (91). Further genetic characterization of *netF*-positive strains has demonstrated that *netE/netF* and *net*G are encoded on two distinct and relatively large pathogenicity loci on their respective plasmids (92, 93).

TpeL is a large glycosylating toxin, closely related to the LCTs, toxin A and toxin B from *C. difficile*, as well as TcsH and TcsL from *P. sordellii*. A role for TpeL in *C. perfringens*-associated disease has not yet been established (94). However, due to the presence of TpeL in some hypervirulent type G avian necrotic enteritis strains it has been suggested that TpeL may play a synergistic role with other toxins such as NetB (95). TpeL is encoded by the *tpeL* gene, which is located on a series of large conjugative plasmids from type B, C and G strains (44, 45, 96, 97). To date, *tpeL* has not been found in any type D or type E strains (96). In type B strains, *tpeL* is consistently encoded on plasmids in a location downstream of the *cpb* gene (44). In contrast, in type C strains that also carry the *cpb* and *tpeL* genes plasmid carriage is more diverse, and TpeL can be encoded on plasmids with *cpb*, or *cpb2* or on entirely separate plasmids (45).

Lambda toxin is a thermolysin-like metalloprotease produced by type B, D and E strains of *C. perfringens* (69). Lambda toxin possesses casein-hydrolyzing activity and has been demonstrated to degrade biological substances such as fibrinogen, collagen and complement component C3 (69). Purified lambda toxin increases vascular permeability, resulting in edema in an *in vivo* model, suggesting that the toxin is potentially involved in pathogenesis of *C. perfringens* infections (69). Lambda toxin is encoded by the *lam* gene, which is located on large conjugative plasmids of varying size (44, 69). In many type B strains it is encoded with the urease genes on a plasmid of approximately 80 kb (44). The carriage of lambda toxin is not as prevalent in type D strains, even though it has been shown experimentally that lambda toxin can activate epsilon toxin, however, host proteases also can activate epsilon toxin (60). The majority of type E strains carry lambda toxin on the same plasmid as the iota toxin and urease genes (66).

Numerous type B, D and E strains possess the ability to produce urease, which is encoded by a plasmid-encoded *ure*ABC operon (98). These plasmids also may carry toxin genes, such as *cpe*, *lam*, *iap*, *ibp*, and *etx* (44, 60, 66, 98).

Toxin Association with Insertion Sequences

A common theme among the toxin genes of *C. perfringens* is the strong association with insertion sequence elements even though none of these genes have been shown to be located on a genetically confirmed transposon (60, 66). Frequently, toxin genes are located in close proximity to elements such as IS*1151*, IS*1470*, IS*1469*, and IS*406* (44, 45, 60, 68). The presence of these elements near toxin genes raises the possibility that toxin genes of *C. perfringens* can be easily mobilized and indeed circular DNA molecules that encompass toxin genes have been detected (44, 60, 66, 74). This theory could explain why several toxin genes, such as *cpb*, are found on numerous diverse plasmids and why toxin genes such as *cpe* are encoded both chromosomally and on plasmids (45, 74, 76).

Other *C. perfringens* Plasmids

Plasmids were first described in *C. perfringens* in 1973 (99) with the identification of a small bacteriocin-encoding plasmid, pIP404, in a type A strain (100). This plasmid forms the basis for most of the current *C. perfringens* cloning vectors (101). Other studies then focused on the identification and characterization of plasmids encoding antibiotic resistance determinants and bacteriocins (102–105). The first conjugative plasmid to be identified in *C. perfringens* was the tetracycline and chloramphenicol resistance plasmid pIP401 (102), in which the chloramphenicol resistance gene was later shown to be encoded on the integrative mobilizable element Tn*4451* (106, 107). Early studies also led to the identification and characterization of the conjugative tetracycline resistance plasmid pCW3 (108) and a series of plasmids that are closely related to pCW3 and pIP401 (109–112). Toxins were first associated with plasmids after a beta toxin-producing strain lost the ability to produce toxin after the loss of an uncharacterized plasmid (113).

Many of the antibiotic resistance and toxin plasmids of *C. perfringens* were initially characterised by methods such as pulsed-field gel electrophoresis, restriction analysis and Southern hybridization (44, 45, 60, 66, 105, 109–111, 114). It was through this analysis that the great diversity of toxin plasmids harbored by *C. perfringens* strains was demonstrated. The first known conjugative *C. perfringens* antibiotic resistance plasmid to be sequenced was the 47.3 kb plasmid pCW3 (115). Comparative analysis of this sequence revealed that there was a region that was common to many large *C. perfringens* plasmids (115). The first toxin plasmids to be sequenced were the *cpe*-encoding plasmids, pCPF4969 and pCPF5603, which were derived from two type F food poisoning isolates (77). Sequence analysis showed that the *cpe* plasmids had ~35 kb of conserved sequence, indicating that these two plasmids may have been derived from a single common ancestor (77). Subsequently, several other toxin and antibiotic resistance plasmids of *C. perfringens* have been sequenced and characterized (74, 81, 82, 91, 97, 115, 116). As was seen for the *cpe*-encoding plasmids, approximately 35 to 40 kb of plasmid sequence remained highly conserved, despite these plasmids arising from different strain types. This analysis demonstrated that there was a significant similarity between the toxin plasmids and the tetracycline resistance plasmid, pCW3 (83, 115) and this plasmid has become the paradigm for the genetic analysis of this family of toxin and antibiotic resistance plasmids (Fig. 2).

Sequencing of pCW3 identified novel replication and conjugation regions within the 35- to 40-kb conserved *C. perfringens* plasmid backbone (115). Within this conserved backbone there were regions identified with sequence similarity to another *C. perfringens* plasmid, pCP13 (115, 117). pCP13 is a resident plasmid of *C. perfringens* strain 13 and carries a *cpb2* gene (117). Sequence analysis showed that these two plasmids are unrelated, apart from nine similar genes (115). Until recently pCP13 was not considered important to toxin gene carriage, because the *cpb2* gene located on this plasmid was defective, due to the presence of a premature stop codon (117). However, it is now apparent that pCP13-like plasmids can encode other toxin genes, including a new *C. perfringens* binary toxin, BEC (also called

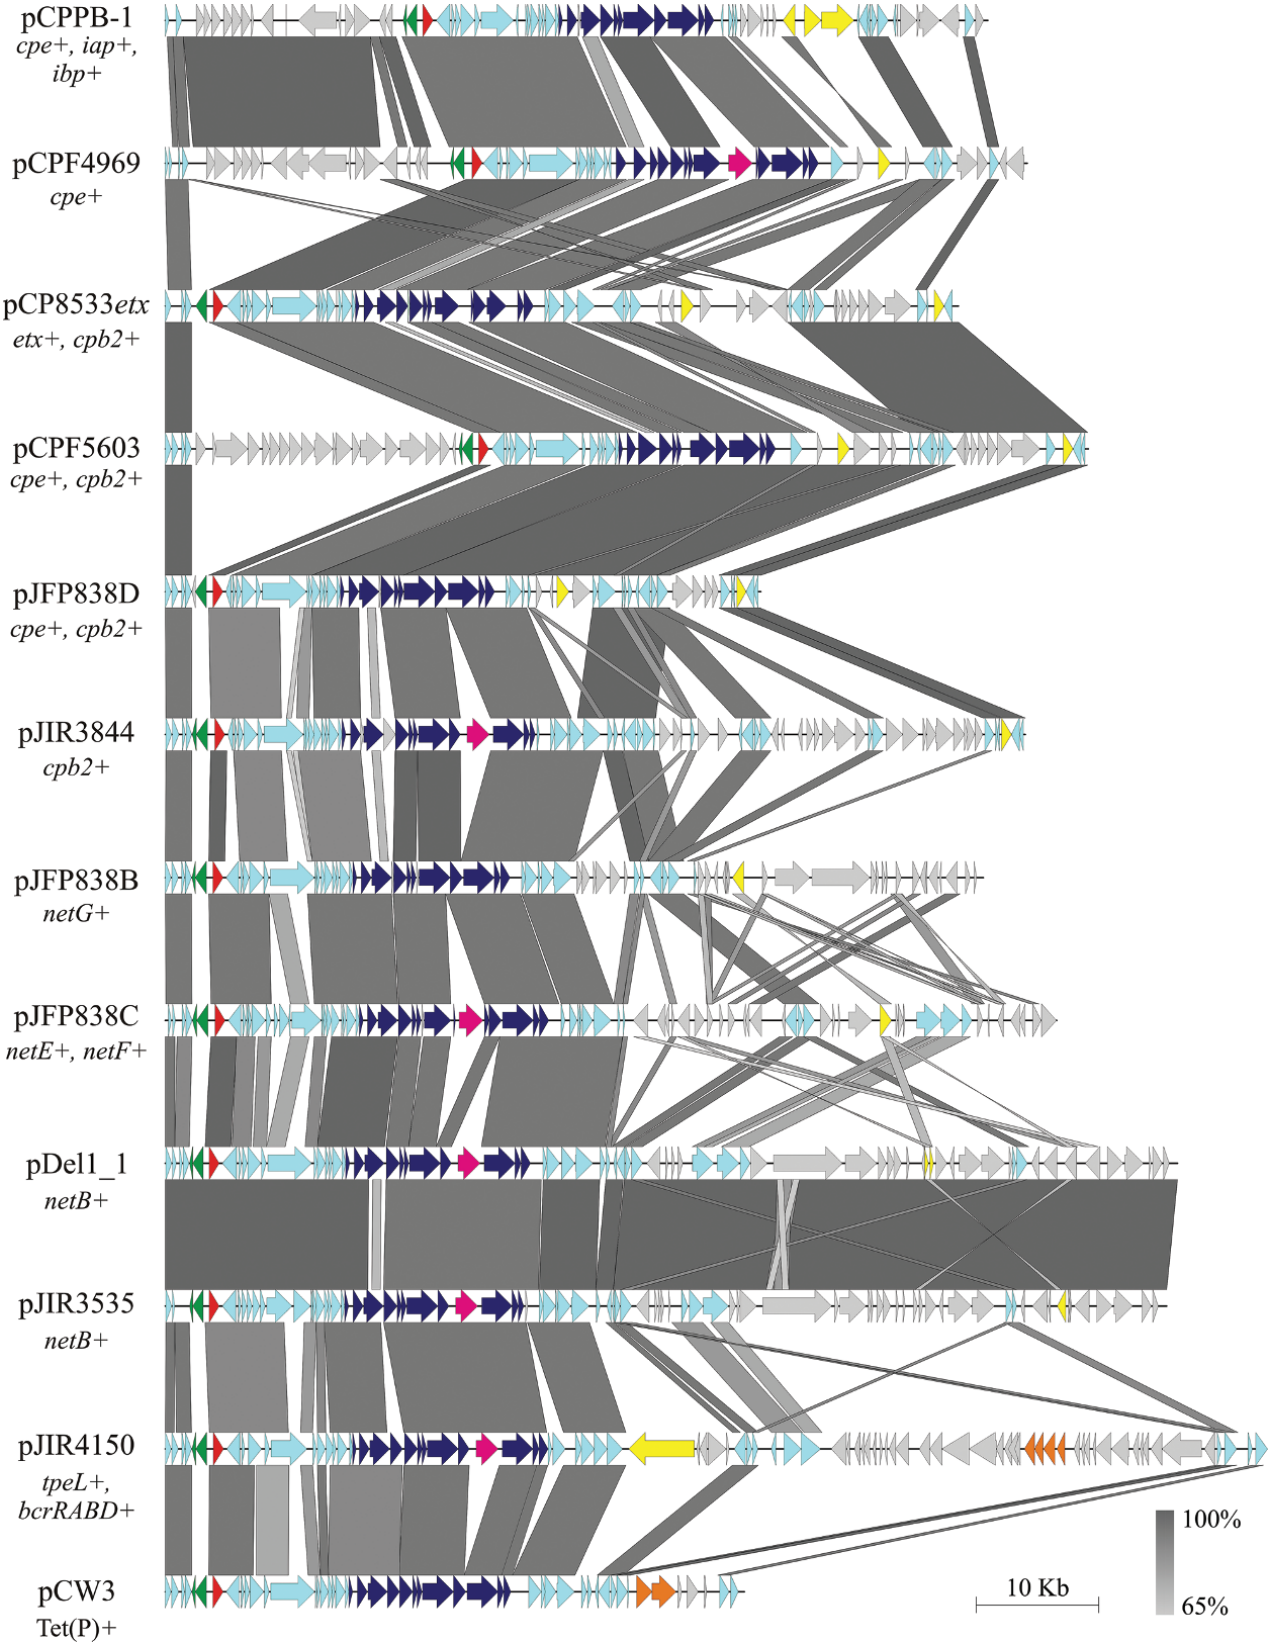

FIGURE 2 Nucleotide alignment of pCW3-like plasmids from *C. perfringens*. Full plasmid sequences were aligned using the blastn algorithm (225) and Easyfig for visualization (226). The plasmid names are noted on the left along with the toxin or antibiotic resistance determinants encoded within each plasmid sequence. Predicted (ORFs) are indicated by arrows with the following color code: conserved ORFs (light blue), *tcp* conjugation genes, dark blue; toxin genes, yellow; *parMR* partitioning genes, green; *rep* red; group II introns, pink; antibiotic resistance genes (orange) less-conserved ORFs, gray. The scale bar and key for nucleotide identity are shown.

CPILE), which appears to be involved in non-CPE mediated human food poisoning in Japan (118, 119). Now, *C. perfringens* toxin plasmids can be broadly categorized into two families: the well characterized pCW3-like plasmids and the less well-characterized pCP13-like plasmids. All the toxin plasmids mentioned so far, other than the BEC plasmids, belong to the pCW3-like plasmid family.

Comparative Analysis of pCW3-Like Antibiotic Resistance and Toxin Plasmids

Two key genetic loci were identified on the conserved backbone of pCW3 following sequence analysis: the plasmid replication and maintenance region (81, 82, 115, 120) and the putative conjugation locus, denoted as the transfer clostridial plasmid, or *tcp* locus (115). The *tcp* locus encodes a novel transfer mechanism that is common to pCW3-like plasmids of *C. perfringens* (Fig. 2) (115, 121–127). To date, six large toxin plasmids (*cpe, netB, cpb2, etx, net* G, and the plasmid carrying the *netE, and netF* genes) and many antibiotic resistance plasmids have been shown experimentally to be conjugative (59, 74, 82, 91, 97, 106, 108, 109, 111). Furthermore, sequencing, pulsed-field gel electrophoresis, and subsequent Southern hybridization have demonstrated that virtually all large toxin plasmids carry a *tcp* locus that is closely related to that of pCW3, albeit with some minor variations in genetic organization and sequence, meaning that these plasmids are highly likely to be conjugative (44, 59, 60, 66, 74, 77, 82, 116).

The biological importance of the toxins being encoded on conjugative plasmids is the potential of *C. perfringens* strains, particularly non-toxigenic commensals, to be converted to virulent isolates following the acquisition of a toxin plasmid(s) (59, 74, 128). Recently, this concept was validated *in vivo* in the gastrointestinal tracts of chickens, whereby non-pathogenic strains of *C. perfringens* were converted to disease causing isolates, following the horizontal transfer of a NetB toxin-encoding plasmid (129).

Current Model for Tcp-Mediated Conjugation

pCW3 is the smallest sequenced conjugative plasmid in *C. perfringens*, it contains a complete *tcp* locus and its transfer can easily be tracked by monitoring the acquisition of tetracycline resistance. Therefore, it has become the archetypal plasmid for conjugation studies in this bacterium (115, 128). The *tcp* locus of pCW3 encodes 11 genes, *tcp*M and *tcp*A to *tcpJ* (115). Many of the genes within the *tcp* locus were predicted to encode functional or structural components of the mating pair formation or transferosome complex. By contrast, no relaxase or other relaxosome components were identified from these initial investigations. Functional mutagenesis and complementation studies on each of the *tcp* encoded genes showed that most of these genes were required for efficient pCW3 conjugation (115, 121–127).

The pCW3 relaxosome

Prior to transport into the recipient cell pCW3 DNA must first be processed by the relaxosome. Typically, the relaxosome complex comprises a relaxase enzyme, which nicks DNA at the origin of transfer (*oriT*) of the plasmid to be transferred; in most cases, accessory proteins are also required (130). Initial analysis of the pCW3 *tcp* locus did not identify a typical relaxase gene, nor were any sequences identified with similarity to known *oriT* sites (115). However, the first gene encoded in the putative *tcp* operon, *tcp*M, encodes a protein showing limited similarity to tyrosine recombinase enzymes and was hypothesized to function as an atypical relaxase (83, 115, 127). Mutagenesis and complementation studies have shown that TcpM is necessary for efficient transfer (127). Subsequent complementation with site-directed mutants revealed that a single C-terminal tyrosine (Y259) residue was essential for TcpM function, in contrast to typical tyrosine recombinases, which require seven conserved arginine, histidine and tyrosine residues for catalytic function (127, 131). Therefore, it was concluded that TcpM was a unique relaxase enzyme with Y259 postulated to be responsible for the essential nucleophilic attack on the sugar-phosphate backbone at the *oriT* site of pCW3 (127).

In many conjugation systems, the *oriT* site is located adjacent to genes involved in the relaxosome complex (132). It was postulated that the pCW3 *oriT* was located within a 391-bp intergenic region located upstream of *tcp*M (127). Mobilization assays using the 391-bp region cloned into a non-conjugative shuttle-vector confirmed that the *oriT* sequence was located within this region and defined the minimal *oriT* site (127).

The pCW3 transferosome

Transferosomes are large multi-protein membrane-associated complexes, or type 4 secretion systems, that physically transfer the relaxase-plasmid DNA complex into a recipient cell using ATPase activity to power the process (133). Initial bioinformatic analysis of the pCW3 *tcp* locus identified several putative proteins predicted to assemble as part of the transferosome complex (115). TcpF is a putative hexameric ATPase (115); ATPases are common components of conjugation systems, and are required to power DNA translocation and to assist in the formation of the transferosome complex (134, 135). TcpH is a putative structural protein with eight putative transmembrane domains; it is predicted to comprise a large proportion of the transmembrane channel that spans from the donor cell into the recipient (115). TcpF and TcpH were the first proteins tested for their involvement in pCW3 conjugation. Mutation by allelic exchange of the genes encoding these proteins and subsequent complementation and conjugation analysis demonstrated that the TcpF and TcpH proteins are essential for the conjugative transfer of pCW3 (115). In a later study, functional domains of TcpH were determined by deletion and site-directed mutagenesis. It was concluded that a region located between amino acids 514 and 581 was essential for TcpH function *in vivo* (125). Despite being essential for pCW3 transfer, TcpF remains to be functionally characterized.

*tcp*G and *tcpI* are both predicted to encode peptidoglycan hydrolase enzymes, which are predicted to function by hydrolyzing local regions of the thick peptidoglycan layers of the donor and recipient cells to allow for the formation of the transferosome. Mutation and complementation analysis determined that TcpG, but not TcpI, was required for efficient pCW3 transfer (121). Further analysis confirmed that TcpG had peptidoglycan hydrolase activity (121).

*tcp*C, *tcpD*, *tcpE*, and *tcpJ* all encode hypothetical proteins of unknown function (115, 123, 126). With the exception of *tcpJ*, they all are required for maximal pCW3 transfer. Analysis of the crystal structure of the C-terminal portion of TcpC (123) showed that although it had no conserved domains or similarity to other protein sequences, TcpC had a structure similar to VirB8, a conserved structural protein of the *Agrobacterium tumefaciens* type 4 secretion system (123). The structural similarities between VirB8 and TcpC suggest that TcpC plays a structural role in the pCW3 transferosome (123). The small transmembrane proteins TcpD and TcpE are essential for pCW3 transfer, because plasmids with mutations

in either of these genes are non-conjugative (126). Their function remains to be elucidated, but immunofluorescence imaging showed that these proteins localize to the cellular poles, such as TcpF and TcpH (125, 126). It is highly likely that TcpD and TcpE also compose part of the transferosome.

The second gene in the *tcp* operon, *tcp*A, encodes a putative integral membrane protein, with a conserved FtsK/SpoIIIE domain (122). Proteins within the FtsK/SpoIIIE family bind DNA in cellular processes such as chromosomal segregation and the transfer of genetic material into the forespore during sporulation (136). Therefore, TcpA was postulated to function as a coupling protein in pCW3 conjugative transfer (122). Subsequent mutation and complementation analysis confirmed that TcpA was essential for pCW3 transfer (122). As the coupling protein, it was assumed that TcpA mediated a range of protein-protein interactions with other Tcp proteins in both the relaxosome and transferosome complexes (124). Through chemical cross-linking and bacterial two-hybrid analysis, TcpA was found to self-associate, as well as to interact with the transferosome components TcpC, TcpG and TcpH (124). At the time of this study no relaxosome components had been identified, and thus, interactions with pCW3 relaxosome components have not yet been assessed (124). Based on these studies and other protein-protein interaction studies, including structural studies (121–125) a model for the conjugative apparatus utilized by pCW3 has been constructed (Fig. 3) (128).

Although a large body of work has been conducted on the *tcp* locus of pCW3, there are still large gaps in our knowledge and understanding of the structure and function of the conjugation apparatus. To date, it is still not certain whether pCW3 DNA transport occurs in a single-stranded or double-stranded manner. Additionally, the precise processing reactions that are catalyzed by the relaxosome remain uncharacterized and the protein composition of this structure remains to be elucidated. Finally, the mechanism of direct cell-to-cell contact between *C. perfringens* cells remains elusive. These genetic and functional studies of pCW3 are important because they serve as a model system for the analysis of the pCW3-like toxin plasmids.

Multiple pCW3-Like Toxin Plasmids Are Often Present in the Same Strain

Plasmid incompatibility is defined as the inability of two plasmids to coexist in the same cell without the application of

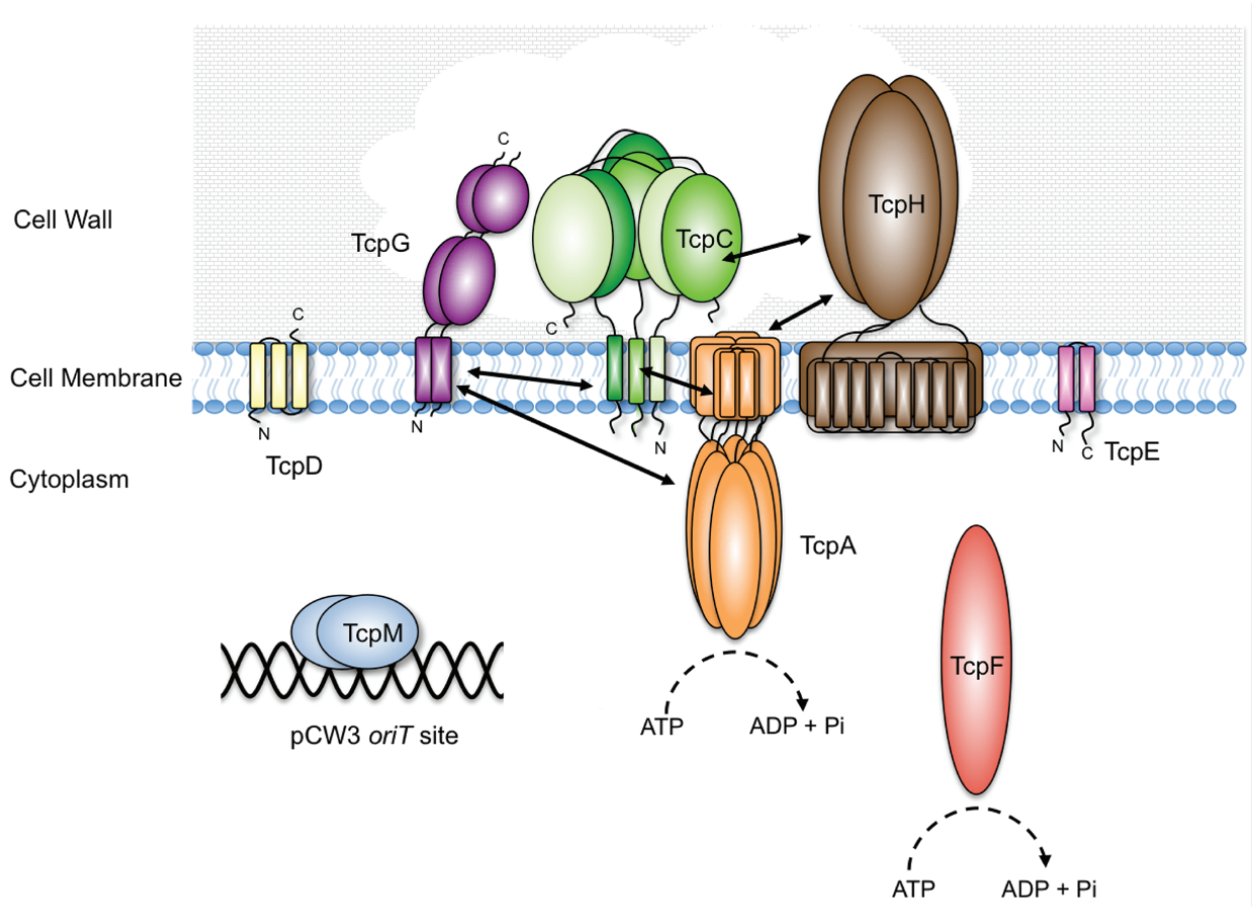

FIGURE 3 Model of the pCW3 conjugation apparatus. The arrangement of the proteins within the model is based on protein localization studies and bioinformatics analysis. Black arrows indicate confirmed protein interactions between Tcp proteins and only Tcp proteins required for wild-type transfer of pCW3 are shown. Indicated within the membrane are the integral membrane proteins TcpH (brown), the peptidoglycan hydrolase TcpG (purple), the assembly factor TcpC (green; monomers as different shades), the proteins of unknown function, TcpD (yellow) and TcpE (pink) and the putative coupling protein TcpA (orange). Within the cytoplasm are a putative ATPase TcpF (red) and the novel relaxase TcpM (blue) in complex with the double stranded pCW3 *oriT* site. Dotted arrows indicate putative ATPase activity. Reproduced with permission from Wisniewski and Rood (2017).

external selection (137). Plasmid incompatibility usually arises when two plasmids encode similar essential plasmid encoded factors such as replication initiation factors, replication control mechanisms or partitioning machineries.

All plasmids must replicate and maintain a stable copy number relative to the host chromosome to be faithfully inherited by the daughter cells at cell division (138). The copy number of a plasmid is related to the properties of the replication machinery and other factors. Initial attempts to identify the pCW3 replication gene could not identify an ORF with significant similarity to any known plasmid replication proteins (115). Therefore, a functional genetics approach was employed to determine which plasmid encoded regions were involved in plasmid replication. A combination of deletion and transposon mutagenesis studies led to the identification of the *rep* gene, which was essential for the replication of pCW3 (115). The intergenic region upstream of the *rep* gene had five pairs of inverted repeats and a series of conserved 17-bp direct repeats that were postulated to act as iterons or as a centromeric binding site for partitioning proteins (115). Comparative bioinformatic analysis of the available *C. perfringens* conjugative plasmid sequences revealed that the pCW3-like replication protein is highly conserved (120).

As already mentioned, many strains of *C. perfringens* carry more than one pCW3-like toxin or antibiotic resistance plasmid, each of which encodes a similar replication protein (82, 115, 120). These plasmids are stably maintained in the same cell, which is unexpected given the conventional relationship between plasmid incompatibility and plasmid replication functions (137). The best studied example of this phenomenon is the avian necrotic enteritis type G isolate, EHE-NE18. This strain stably harbours three highly similar pCW3-like conjugative plasmids: a NetB plasmid, a beta2-toxin plasmid and a tetracycline resistance plasmid. These plasmids each encode an almost identical replication protein (≥ 98% amino acid sequence identity) (82, 120). The apparent stability of this plasmid combination, and other toxin plasmid combinations in strains from other toxinotypes, suggested that factors other than the replication machinery were involved in the determination of plasmid incompatibility in *C. perfringens*.

pCW3 is a low-copy number plasmid (~5 plasmid copies/chromosome) (T. Stent, X. Han, R. Moore, V. Adams and J. Rood, personal communication) and therefore most likely requires an active maintenance system to ensure that it is inherited correctly (139). Closer inspection of the pCW3 sequence revealed two genes that were adjacent to, but divergently transcribed from, the *rep* gene. These genes encoded putative partitioning system homologues, ParM and ParR, and a putative *par*C centromere site (115).

Partitioning systems act as positioning systems to ensure that sister plasmids are positioned at the cell poles thus ensuring that the plasmid is maintained in daughter cells when cell division occurs (139). Type II or ParMRC-like plasmid partitioning systems encode three components: ParM, an actin-like ATPase that polymerizes to form filaments, ParR, a DNA-binding adaptor protein, and *par*C, a centromeric ParR binding region that usually comprises a series of direct repeats located upstream of the *par*M gene (140). ParMRC systems segregate plasmids via a pushing mechanism in which two sister plasmids are linked through a bundle of ParM filaments that recognize and interact with ParR adaptor proteins bound to the *par*C centromere sites (140). *C. perfringens* ParMRC-like plasmid partitioning systems have not been thoroughly investigated, although a *parMRC*$_B$ family partitioning system from the *C. perfringens* isolate JGS1987 has been demonstrated to stabilize a mini-replicon in *E. coli* (141).

An extensive survey of sequenced pCW3-like plasmids showed that there were at least 10 distinct families of *parMRC*-like partitioning systems (*parMRC*$_{A\text{-}J}$) present in *C. perfringens* (81, 82, 115, 120, 142). Comparative analysis showed that ParM homologues had upwards of 90% amino acid sequence identity within a family, but only 15- to 54% identity between the various groups (120). ParR homologues clustered into the same phylogenetic groups as the ParM homologues, but showed more amino acid sequence variation within a family (120). The *par*C centromere sites also clustered with their cognate ParM and ParR family groups, although the *par*C sites are very AT-rich and have a lot more sequence variability between the 10 groups than the ParM and ParR components (120). It was observed that *C. perfringens* strains that house multiple pCW3-like plasmids generally do not have plasmids that encode the same *parMRC* allele (120). This observation suggested that *parMRC* partitioning families were responsible for maintenance within the same strain of multiple pCW3-like plasmids that encode a highly similar replication region.

There now is experimental evidence to support this hypothesis (143). In this study different combinations of genetically marked, *parMRC*-encoding, pCW3-like plasmids were introduced into the same *C. perfringens* strain. These strains were constructed so that they housed either two plasmids with the same *parMRC* locus, or two plasmids with *parMRC* loci from different families. Analysis of these isolates showed that plasmids with the same *parMRC* families were unable to stably coexist in the same cell, whereas plasmids with different *parMRC* families could stably coexist even though they encoded similar Rep proteins (143).

pCP13-Like Plasmids

Most studies of *C. perfringens* plasmids have focused on the pCW3-like family of toxin and antimicrobial resistance plasmids, but another class of toxin plasmids is beginning to garner more interest in the field (144). Genome mapping and whole genome sequencing of the *C. perfringens* type A isolate, strain 13, revealed the presence of a 54.3 kb plasmid called pCP13 (117, 145). pCP13 encodes 63 putative ORFs, many of which encode proteins of unknown function. Several ORFs could be assigned a predicted function including ORFs encoding a defective, consensus beta2-toxin, a predicted collagen adhesin called CnaB (146), and plasmid partitioning homologues, ParA (Soj) and ParB (117). Both the consensus and atypical beta2-toxins have been implicated as accessory virulence factors becuase they are found in various *C. perfringens* disease isolates (81, 82, 84). However, beta2-toxin has no confirmed association with disease. Cna proteins are known to act as adhesins and virulence factors in other Gram positive pathogens such as *Staphylococcus aureus* (147–149). A Cna homologue, CnaC, encoded on pCW3 and recently CnaA, which is produced by several avian necrotic enteritis isolates of *C. perfringens*, was shown to be important for gastrointestinal colonization and subsequent infection in chickens (146, 150).

pCP13-like BEC (CPILE)-encoding plasmids

Recently, three *cpe*-negative *C. perfringens* strains, OS1, TS1 and W5052, were isolated from three separate food poisoning outbreaks in Japan (118, 119). The supernatants of two of these isolates showed enterotoxic activity in a rabbit ileal loop model, even though no CPE was produced (119). Sequence analysis led to the discovery of two 54.5 kb plas-

mids, pCP-OS1 and pCP-TS1, each of which had 38 kb sequence identity with pCP13 (Fig. 4). Sequencing of these pCP13-like plasmids led to the identification of a novel clostridial binary toxin designated BEC (or CPILE, see reference 119 for a discussion of the terminology). BEC comprises two components, BECa and BECb, which show 43% and 44% amino acid identity to iota-toxin components Ia and Ib, respectively (118, 119). The BECb component is responsible for some of the enterotoxic effects, however its activity is enhanced by the BECa component, which has been shown to have ADP-ribosyltransferase activity on purified actin (119). In addition, both BECa and BECb components are required to cause Vero cell rounding *in vitro* (119). X-ray crystal structures of BECa have been solved, revealing a fold and substrate recognition mechanism similar to other ADP-ribosyltransferase toxins (151, 152).

Comparative analysis of pCP13 plasmids

The BEC plasmids, pCP-TS1 and pCP-OS1, were isolated from different strains, but are almost identical at the nucleotide sequence level (99% identity) (Fig. 4), which suggests that a recent horizontal gene transfer event occurred (119). The original sequencing of pCP13 did not initially reveal any ORFs with homology to known conjugation proteins (117). However, more recent comparative analysis of clostridial plasmid sequences has shown that pCP13 has several genes that encode proteins with amino acid sequence identity to conjugation proteins from the conjugative toxin plasmids pCS1-1 (12) and pCLL (153) from *P. sordellii* and C. *botulinum*, respectively. These proteins include a putative coupling protein with VirB4 domains, a putative essential ATPase with predicted VirD4 domains and a potential membrane scaffold protein with predicted VirB6-like domains (12). The presence of these conjugation machinery homologues on pCP13 together with the identification of almost identical BEC plasmids pCP-TS1 and pCP-OS1 in two distinct strains suggested that pCP13-like plasmids may be conjugative. We now have experimental evidence that pCP13 is indeed conjugative (T. Watts, C. Vidor, M. Awad, D. Lyras, J Rood and V. Adams, unpublished results). These studies highlighted the importance of the pCP13 plasmid family to the toxin armory of C. *perfringens* and to the dissemination of the toxin genes.

The most recent addition to the pCP13-like family is the bacteriocin-encoding plasmid pBCNF5603, a plasmid found to coexist with a pCW3-like, CPE-plasmid in the type F isolate F5603 (144). Bacteriocins are antibacterial factors produced by bacteria to inhibit the growth of similar bacterial strains (154). C. *perfringens* strains often produce bacteriocins (155), some of which have been implicated in strain competition in the gastrointestinal tracts of broiler chickens (129, 144, 156, 157). pBCNF5603 was recently sequenced and found to have genes with a high level of similarity to homologues on pCP13 and on the small bacteriocin plasmid pIP404, suggesting that pBCNF5603 arose from a recombination event between these two C. *perfringens* plasmids (144) (Fig. 4). Sequencing of this plasmid has provided insight into the replication functions of pCP13-like plasmids by identifying two potential replication regions (144). The first replication region showed homology to the *rep* and *cop* genes of pIP404, whereas the second region displayed similarity to the *parA* and *parB* gene regions of pCP13, pCP-TS1 and pCP-OS1. The 5.5 kb gene cluster with similarity to pCP13 supported replication of a recombinant plasmid in C. *perfringens*, whereas the replication region with similarity to pIP404 did not (144). Analysis of subsequent deletion derivatives showed that the homologue to PCP63 may be the pBCNF5603 Rep protein (144). The region upstream of the putative *rep* gene was AT-rich, with a series of inverted repeats that are likely to be important for replication initiation.

THE TOXIN PLASMID OF *C. TETANI*

The neurotoxic clostridia comprise the C. *botulinum* complex, the causative agents of botulism, and C. *tetani*, which causes tetanus in both humans and animals. Both the

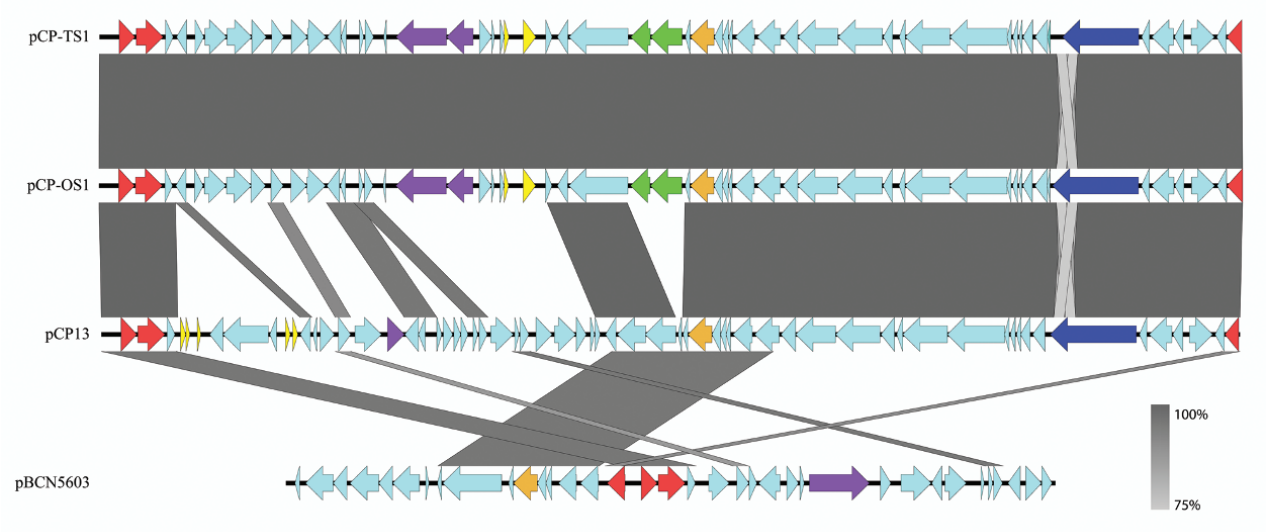

FIGURE 4 Sequence alignment of pCP13-like plasmids from C. *perfringens*. The plasmid sequences of pCP-TS1, pCP-OS1, pCP13 and pBCNF5603 were aligned using the Blastn algorithm using Easyfig (226). The percentage identity is indicated by the scale bar at the bottom right and each sequence is compared separately to the sequences above and below. ORFs are indicated by arrows and ORFs of particular interest are colored as follows: green, restriction modification systems; red, replication and maintenance; purple, toxin genes; yellow, transposase genes; dark blue, putative collagen adhesins; orange, putative relaxase enzymes.

clostridial species that comprise the C. *botulinum* complex and C. *tetani* are renowned for their ability to produce potent neurotoxins, botulinum toxin (BoNT) and tetanus toxin (TeNT), respectively (158). The various BoNT structural genes can be encoded on the chromosome, on a temperate bacteriophage or on a plasmid, whereas the TeNT structural gene is plasmid encoded (159).

TeNT is a zinc metalloprotease that acts on the SNARE protein VAMP/synaptobrevin at the synaptic junction of the nerve relaxation pathway in the spinal cord. Cleavage of VAMP/synaptobrevin means that it is unable to form a complex with other SNARE proteins, preventing fusion of the synaptic vesicle with the cellular membrane at the synaptic nerve junction and preventing release of the neurotransmitter from the inhibitory interneurons to the motor neurons in the spinal cord. The net effect is inhibition of the muscle relaxation pathway and a rigid muscular paralysis that may be fatal (158, 160).

The first C. *tetani* strain that was sequenced, the Harvard vaccine strain E88, carries a 74,082 bp plasmid, pE88, that encodes 61 putative genes (159). These genes include the TeNT structural gene, *tetX*, and the *tetR* gene, which encodes an alternative sigma factor that is required for *tetX* expression and consequently for TeNT production (161). TetR belongs to a family of alternative sigma factors together with BotR from C. *botulinum*, TcdR from C. *difficile*, TcsR from *P. sordellii*, and UviA and TpeR from C. *perfringens* and (162, 163). Little is known about the function of other genes encoded on the TeNT plasmid, although there is another potential virulence factor gene, the *colT* collagenase gene, and genes encoding five distinct ABC transporter complexes (159). The regulatory proteins encoded by pE88 include TetR, two other putative alternative sigma factors, a putative two-component signal transduction system (CTP21/22) and a homologue of the bacteriocin plasmid pIP404-encoded UviB protein from C. *perfringens*. pE88 encodes two IS*200*-family transposases and an IS*605*-like transposase. It has *parMR*-like plasmid partitioning genes and a duplicated replication gene, the product of which is related to the replication protein encoded by pIP404. The structure of the actin-like ParM protein, Alp12, has been determined and shown to be compose of a four-stranded filament that is in a different conformation than other actin-like proteins (164, 165). Note that there is no genetic or bioinformatic evidence that pE88 or its homologs are conjugative or mobilizable.

A transcriptomics study that included plasmid-encoded genes has been carried out on strain E88 grown in fermentation bioreactors (166). The results showed that most of the pE88 genes have a transcriptional profile similar to the *tetX* and *tetR* genes, with gene expression increasing over time. No significant expression of the *colT* collagenase gene is observed under these conditions.

Since the publication of the genome sequence of strain E88 (159), the sequences of 10 other C. *tetani* strains have been reported (167–169). The chromosomes of these strains are highly conserved, with variations occurring at putative bacteriophage insertion sites, and CRISPR loci and within a flagellar glycosylation genomic island. Therefore, the C. *tetani* pan-genome can be considered closed, supporting the concept that C. *tetani* has only limited genetic exchange with other bacteria (170).

All of the sequenced strains, with the exception of the non-toxigenic isolate ATCC 19406, carry a pE88-like plasmid (168, 169) (Fig. 5). Another non-toxigenic strain, ATCC 454, carries a plasmid that has >95% identity to pE88, but has a 20 kb deletion that encompasses both the *tetX* and *tetR* genes (Fig. 5). The remaining plasmids have considerable conservation as well as specific pE88 regions that are not present (Fig. 5). The *tetX* genes are highly conserved (99.3 to 99.4% identity) and the *tetR* genes are all identical (169). The lack of genetic tools for the analysis of C. *tetani*, combined with the inherent difficulties in working with this anaerobic, very motile and highly toxigenic pathogen, have clearly limited the genetic and functional studies that can be carried out on these important plasmids.

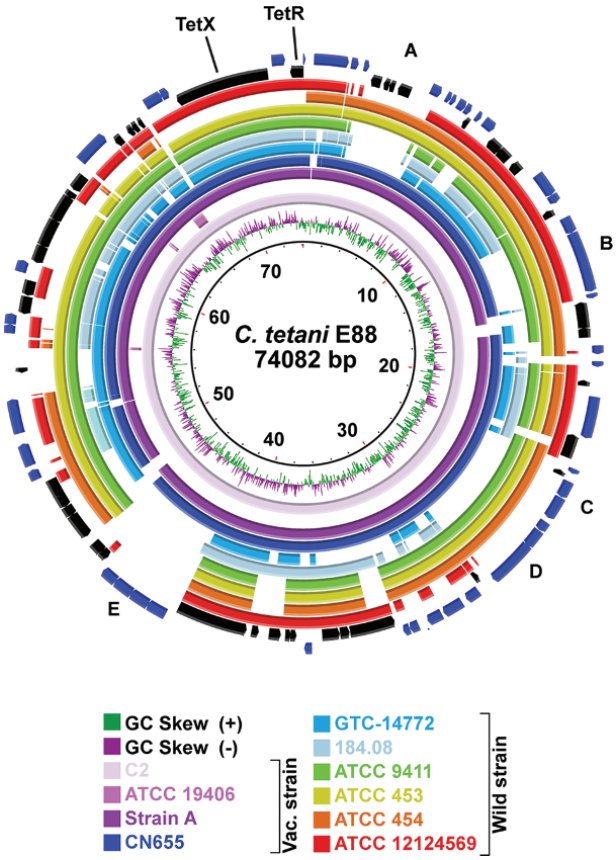

FIGURE 5 Blast analysis of the tetanus toxin plasmid family. Plasmid sequences derived from C. *tetani* were compared to the 74 kb pE88 plasmid (GenBank accession number NC 004565). The two outermost rings show predicted (ORFs) for both the (+) and (-) DNA strands. The position of the tetanus toxin gene (*tetX*) and the regulator (*tetR*) are shown. DNA regions with less than 80% sequence identity are indicated by gaps. Strain ATCC 454 does not encode either the *tetX* or *tetR* genes. The regions denoted A through E indicate deletions within plasmids found in wildtype strains and include *uviB* and DNA directed RNA polymerase sigma-70 factor (A), *ftsX* and an ABC anti-microbial transporter system (B), an *ompR*/*baeS* two-component system (C), *ftsX* and an ABC-type lipoprotein export system/permease complex (D), and another ABC multidrug-resistance transporter/permease complex (E). Reproduced with permission from Cohen *et al* (2017).

BOTULINUM TOXIN-ENCODING MOBILE GENETIC ELEMENTS

The production of BoNT neurotoxin is one of the defining features of the clostridial species C. *botulinum*. However, unlike TeNT-producing C. *tetani*, C. *botulinum* constitutes a highly heterologous group of organisms (171–175). This collection of strains consists of six groups (I- to VI), with

groups I- to III generally designated C. *botulinum* (171, 172, 175). Groups IV, V, and VI consist of BoNT-producing strains of C. *argentinense*, C. *baratii*, and C. *butyricum*, respectively (175). This highly divergent spread of related toxin genes suggested early on that mobile genetic elements may be involved in toxin gene dissemination and subsequent studies have demonstrated that multiple types of elements are involved (171, 173).

All of these different species are able to produce BoNT, which is related to TeNT in both sequence, structure and function (176, 177). Both BoNT and TeNT are highly specific zinc metalloproteases. However, unlike TeNT, BoNT associates with non-toxigenic proteins to form large complexes (178), which is related to the different routes of intoxication between TeNT and BoNT (wound versus intestinal absorption). The non-toxic components are involved in the protection and transport of the active proteolytic component of BoNT from the gut to its site of action within the synaptic vesicles of excitatory neurones, where it blocks the release of neurotransmitters at the neuromuscular junction (179). The resultant flaccid paralysis can be fatal without appropriate supportive treatment (180). Many species, including humans, livestock, aquatic birds and fish, have been demonstrated to be susceptible to botulism (171).

The BoNT protein sequences have conserved functional domains, but are still highly variable (between 29 and 64% amino acid sequence identity), and historically have been separated into seven serologically distinct types (A- to G) (161, 179, 181). Many of the BoNT types have been further segregated into subtypes, designated by a number (179, 182), for example, BoNT/F6. An eighth serotype designated H, was reported in 2014, but there is controversy about whether this serotype constitutes a chimeric protein between serotypes BoNT/F5 and BoNT/A or a distinct group (172, 183, 184). Subsequently, another BoNT type has been identified and named BoNT/X. This neurotoxin appears not to be a mosaic enzyme and constitutes a new class of BoNTs (185). A ninth class of BoNT, BoNT/En, has recently been identified after genome sequencing of an *Enterococcus faecium* isolate derived from a manure sample in South Carolina and appears most closely related to BoNT/X (38.7%) (181). The heterogeneity exhibited by BoNTs is intriguing because it has resulted in differences in the complexes that are formed prior to cellular uptake and in the mechanisms of transportation. Most importantly, they have different host targets, catalyzing the proteolytic cleavage of different SNARE proteins, which facilitate neurotransmitter vesicle fusion and therefore neurotransmitter release and propagation of the electrical signal from the nerve cell to the muscle cell (186). In spite of this diversity, the result is the same: inhibition of neurotransmitter vesicle fusion, leading to flaccid paralysis (186).

The BoNT structural (*bont*) genes are encoded within two distinct genetic regions, the *orfX+* (function unknown) and *ha+* (hemoglutinin) loci (Fig. 6) (173). Both loci contain conserved ORF's (*orfs*), including *bont*, found downstream, and in the same orientation, as the conserved *ntnh* (non-toxigenic, non-hemagglutinin) gene as well as the *botR* gene mentioned above (161, 178, 187). All BotR-related proteins are responsible for positively regulating the expression of toxin genes in their native hosts. Likewise, BotR has been shown to regulate transcription of the *bont* gene (161, 162, 188).

The variable regions of the *bont* loci encode either the *orfX1-3* genes (*orfX+* loci) or the *ha17*, *-33*, and *-70* genes (*ha+* loci; Fig. 6, Table 2). The organization of these two loci is largely conserved between different strains, the surrounding nucleotide sequences having co-evolved with the variable *bont* gene (173). In addition to the nine serological BoNT types, hybrid *bont* genes have also been identified, such as serotype C/D and D/C derivatives (189). Certain BoNT positive strains encode multiple *bont* loci (173, 190), suggesting an easy mechanism for genetic exchange and explaining how recombination between *bont* loci could readily

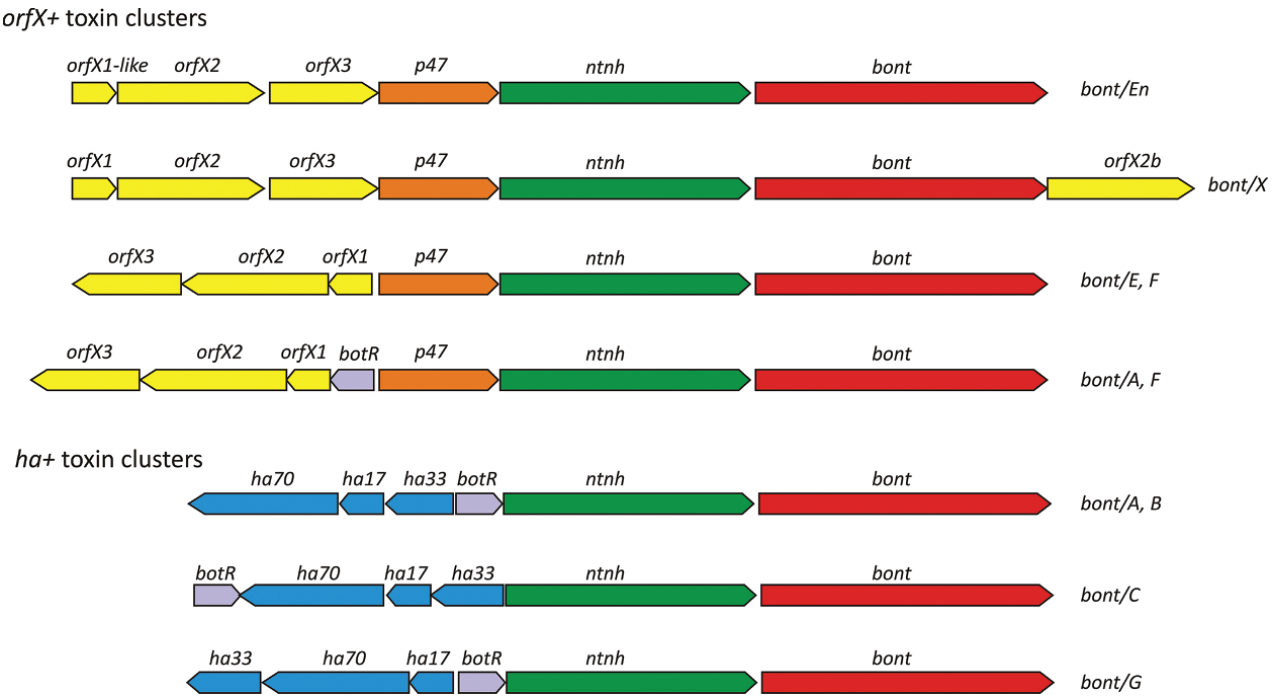

FIGURE 6 Gene arrangement for *bont* toxin loci. The two basic loci types, *orfX+* and *ha+*, are indicated. Similar genes are designated with the same color and the toxin gene serotype designation is given on the right.

TABLE 2 Summary of BoNT-producing species and toxin gene locations

[a]Bacterial clade designation: I-III *C. botulinum*, IV *C. argentinense*, V *C. baratii*, VI *C. butyricum*.
[b]Designation of serologically distinct BoNT proteins, the number of toxin subtypes are in parentheses.
[c]Genes encoding BoNT toxins are found associated with one of two distinct genetic loci; *orfX*+ or the *ha*+ loci (see Fig. 6).
[d]Chromosomal location of *bont* locus, often associated with a mobile genetic element (MGE). F6 is the *bont* subtype.
[e]The vertebrate species in which each toxin type is most frequently demonstrated to cause Botulism. Clade IV strains have not been definitively associated with botulism but have been associated with multiple sudden deaths (199).

occur. It has been shown that when multiple *bont* loci are present within the same strain, one particular BoNT toxin is expressed to a higher degree than the other(s) and is thereby designated with uppercase (indicating the more abundant toxin type) and lower case toxin types, for example BoNT/Ba (191).

Group I: — Proteolytic *C. botulinum*

Bacterial species belonging to this clade or group include C. *botulinum* as well as the non-neurotoxigenic, C*lostridium sporogenes* (173, 175). The toxin serotypes that have been identified within this clade include BoNT/A, /B, /F, /H (F5/A) and /X (172, 173, 184, 185) (Table 2). The serotype B *bont* loci (*ha*+ operon) has a chromosomal location within the *oppA*/*brnQ* site (172). Alternatively, some B subtypes such as *bont*/*B1*, */B2*, and */B5* are found within the "B" site of large plasmids (172, 191). Very similar plasmids have been shown to harbor *orfX*+ operons encoding either *bont*/*A2-4* or */F2* toxin genes integrated at another site known as the "A/F" site (172). Bivalent strains often carry one or even two plasmid encoded *bont* loci, where both the "B" site and the "A/F" sites are occupied (such as pCLJ from the bivalent strain 657 Ba) (191), for example, the *bont*/*F5* locus from the trivalent strain, Af84, also was found to be plasmid located (190, 192).

All clade I plasmids identified appear to be related and range in size from 149- to270 kb (173, 191, 193–195). A significant number of genes are conserved, including multiple genes involved in DNA replication (173, 194). In addition, there appear to be many genes show similarity to bacterial type II and IV secretion systems and two clade I plasmids, pBotCDC-A3 and pCLJ, are conjugative, with transfer demonstrated between plasmid-carrying donors and two different clade I recipients (153). The plasmids derived from clade I strains exhibit different degrees of stability, impacting the stability of toxin production as a result (194, 196). It is clear that the *bont* toxin genes of serotypes A, B, and F are commonly carried by highly related clade I conjugative plasmids capable of transfer between C. *botulinum* strains, but also to non-toxigenic C. *sporogenes* (197). Given the ability of the toxin loci to both recombine and move in the context of mobile genetic elements, there is significant capacity for the further spread either to other strains or to other locations within the same strain.

Group II: – Non-proteolytic *C. botulinum*

Group II strains produce BoNT serotypes B4, F6 and E (multiple subtypes; Table 2) (198, 199). The *bont*/*F6* loci are chromosomally located and found within what is thought to constitute a mobile genetic element that carries a recombinase gene, *topB* (172, 200). The *bont*/*B4* loci found within this clade are believed to be exclusively plasmid-borne (193, 198, 199). The first group II plasmid sequenced is derived from strain Eklund 17B and carries the *bont*/*B4* locus on the 48-kb plasmid, pCLL (173, 174). Subsequent studies demonstrated that *bont*/*B4* loci are carried by plasmids 47 to 63 kb in size that are unrelated to group I plasmids (198). These plasmids form two distinct plasmid groups, perhaps sharing a common ancestor (198). One group (class 1) is related to pCLL and its members are of similar size, whereas class 2 plasmids only have about 33% similarity to class 1 plasmids; this similarity is limited to the large neurotoxin gene cluster (198). Class 2 plasmids range in size from 58 to 63 kb (198). A third plasmid appears to be a hybrid of the two other plasmid classes (198). All plasmid types encoding *bont*/*B4* loci were found only in group II strains and related plasmids that were non-toxigenic have subsequently been found by analysis of genome sequence data from other group II strains (199).

Serotype E strains belonging to group II had previously been reported to encode only chromosomal *bont*/*E* loci, but recent pulsed-field gel electrophoresis studies showed that a proportion of type E strains (6-10%) carry *bont*/*E* loci on large plasmids in group II strains (199, 201). These plasmids range in size from 134 to 144 kb and are closely related (199). Functional CRISPR systems were identified on plasmids carrying *bont*/*E1* and *bont*/*E10* loci, but not on plasmids carrying the *bont*/*E3* loci (199). The type E toxigenic plasmids appear to be very low copy number as judged from sequencing read abundance, approximately one copy per chromosome (199). The *bont*/*E* plasmid loci are very similar to the chromosomal *bont*/*E* toxin clusters that have integrated into a chromosomal copy of the resolvase gene, *rarA*. The toxin loci in both cases consists of a 24-kb cassette that include genes outside of the normal toxin cluster. This region includes a second, related *rarA* gene that remains intact (199). The plasmid-borne type E toxin cassette is completely conserved, but the integration site is different. The plasmid gene that has been interrupted is a helicase gene and the insertion site appears to be a 6-bp sequence that is conserved between the chromosomal *rarA* gene and the plasmid-encoded helicase gene (199).

All of the toxin plasmids so far identified from group II organisms (class1 and 2 *bont*/*B4* and *bont*/*E* plasmids) have a significant number of ORFs whose predicted function involves conjugative transfer (198, 199). The smallest plasmid characterized so far, pCLL, which contains the least putative conjugation genes (198), is the only group II plasmid to have a demonstrated ability to transfer, remarkably, into a group I recipient (153). No group II- like plasmids have been detected in any other related strain and they show little conservation between themselves or plasmids from other groups, suggesting that these plasmids have a narrow host range (199). pCLL has a low level of similarity to pCS1-family plasmids from *P. sordellii* and pCP13-like plasmids from C. *perfringens* (12). The plasmid location of *bont* genes in this bacterial group explains how the *bont* genes have been so widely disseminated.

Group III: – *Clostridium novyi sensu lato*?

The clade designated type III includes a number of clostridial species and recently it was proposed that it be re-named from C. *botulinum* to C. *novyi sensu lato* (189). This designation includes three species depending on the toxins that each strain produces (189): C *novyi, Clostridium haemolyticum* and C. *botulinum*. C. *novyi* produces the lethal alpha toxin, which is related to the alpha toxin produced by *Clostridium septicum*. In C. *novyi*, the alpha toxin gene is located on a bacteriophage (202) and any particular C. *novyi* strain may also produce one of two phospholipases (beta and gamma) (189). C. *haemolyticum* produces a phospholipase serologically indistinguishable from the beta phospholipase of C. *novyi* (189). Group III C. *botulinum* strains are associated with the expression of BoNT/C and BoNT/D and the chimeric derivatives, C/D and D/C (203) (Table 2). The location of the *bont* locus within group III strains of C. *botulinum* has been known for many decades to be within temperate bacteriophage, called pseudolysogens, that could be readily cured from toxigenic strains (203). The curing mechanism was shown to be due to the unusual nature of the lysogenic state — that of a replicating plasmid (203). For example, the *bont*-encoding

bacteriophage from strain C-ST has a large (186-kb) linear genome with 404-bp terminal direct repeats when packaged within the phage particle (203), but the genome is found as a circular, self-replicating molecule within the bacterial cell (189, 203). Many other plasmid and phage-like molecules can be found not just in C. *botulinum* group III, but in all C. *novyi sensu lato* strains, indicating that this group is highly dependent on the accessory genome to determine the virulence of any particular strain (189, 202–205).

Group IV: – *Clostridium argentinense*

This group was renamed C. *argentinense* because it had very little similarity to other C. *botulinum* strains other than the production of BoNT (171). Only BoNT/G has been detected in C. *argentinense* and the *bont*/G toxin gene was demonstrated to be located on large plasmids in at least two strains (206) (Table 2). The first type G strain sequenced, CDC 2741, remains a draft assembly, but analysis of the sequence data indicated that the *bont*/G cluster was located on a large 1.1-Mb contig and was thought to be chromosomally located (172, 207). Recently, another completed genome sequence for a BoNT/G-expressing strain was released, strain 89G (208), and a circular plasmid sequence was obtained and shown to carry the *bont*/G locus. This plasmid, pRSJ17_1, is 140 kb in size and, although no further analysis of this sequence has been published (208), it appears to share little or no similarity to plasmids of group I or II C. *botulinum* strains. However, the entire pRSJ17-1 sequence appears to be located within the 1.1 Mb contig assembled from the genome sequence of strain CDC 2741 so it is possible that either the *bont*/G plasmid has become integrated into the chromosome in this strain or that the CDC 2741 draft assembly is erroneous and CDC 2741 contains a 140-kb plasmid almost identical to pRSJ17-1. Further analysis is required to confirm the toxin cluster location in strain CDC 2741.

Group V: – Neurotoxigenic *Clostridium baratii*

Type V BoNT-expressing strains are not designated as C. *botulinum* but are members of the non-neurotoxigenic species, C. *baratii* (172, 173). Again only one serotype of BoNT has been detected from this species: BoNT/F7, and the location of this gene is chromosomal, where it is flanked by directly repeated IS*1182* elements (207) (Table 2). The context of the *bont*/F7 locus in this strain suggests that it has been acquired by horizontal gene transfer (207).

Group VI: – Neurotoxigenic *Clostridium butyricum*

Neurotoxigenic C. *butyricum* strains have only been demonstrated to carry *bont*/*E* genes within *orfX*+ loci (173) (Table 2). The neurotoxin gene cluster was originally thought to be plasmid determined rather than chromosomal (209). However, more recent data have clearly indicated that the *bont*/*E* genes in C. *butyricum* are chromosomally located (173, 210, 211). The *rarA* gene is the position of insertion for the *bont*/*E* locus in both group II C. *botulinum* strains that carry *bont*/*E* as well as neurotoxigenic C. *butyricum* strains (172, 173, 199), which suggests that the *bont*/*E* locus has most likely been inserted *via* the same mechanism in both organisms, possibly via the recombinase RarA (172, 173).

CLOSTRIDIOIDES (*CLOSTRIDIUM*) *DIFFICILE* VIRULENCE PLASMIDS

C. *difficile* is a genomically diverse species, that consists of eight phylogenomic clades (212), and it contains many integrated and extrachromosomal genetic elements (213). The presence of numerous potentially mobile genetic elements suggests that horizontal gene transfer has played an important role in the evolution of C. *difficile*. Although C. *difficile* pathogenesis involves multiple factors (214), disease resulting from infection with this microbe is primarily toxin-mediated, and strains can encode up to three toxins. These toxins include toxin A (TcdA) and toxin B (TcdB), which are both encoded within the Pathogenicity Locus (PaLoc), and the C. *difficile* transferase or binary toxin (CDT), encoded within the CDT locus (CdtLoc) (215). Both the PaLoc (216) and CdtLoc (217, 218) were found in chromosomal locations when first identified. However, the chromosomal PaLoc is mobilizable, and can be transferred to a non-toxigenic recipient thereby converting it to a toxigenic strain, but neither a defined mobilizable or conjugative PaLoc element nor the mechanism of transfer have been determined (219).

Few studies have investigated plasmids in C. *difficile* and only a small number of native plasmids have been described or characterized to date. Unlike many other clostridial species, in which toxin genes are often encoded on extrachromosomal elements, as discussed earlier in this review, C. *difficile* toxins appeared to be encoded exclusively on the host chromosome (219, 220). However, a recent study using single-molecule real-time sequencing technology showed that the genome of a bacteriophage, designated phiSemix9P1, carries a complete functional binary toxin locus within its genome (221). The location of the CDT genes on this 56.6 kb bacteriophage suggests that a transduction-mediated mechanism may be involved in transferring these toxin genes across different C. *difficile* lineages. Of relevance to this review, the genome of phiSemix9P1 was found to encode a putative ParA-like protein and a gene for a protein that might play a role in the initiation of plasmid replication in addition to typical bacteriophage-encoded genes involved in DNA packaging, head and tail morphogenesis or host cell lysis, suggesting that this element may represent a bacteriophage-plasmid hybrid (221). Such hybrid elements have recently been identified in C. *difficile* (221), and the presence of these elements can sometimes modulate the virulence of strains by regulating the expression of the chromosomally located toxin genes (222). Genome sequencing studies are continuing to identify new and novel hybrids (223) which may impact phenotypes that influence strain virulence or lateral gene transfer processes, and therefore the evolution and dissemination of C. *difficile* variant strains. The ubiquity of mobile elements in C. *difficile* suggests that horizontal gene transfer plays an important role in the movement of DNA between strains, and the identification of plasmid-bacteriophage fusions may suggest that intra- and inter-species DNA exchange has occurred, probably within the diverse bacterial populations found in the gastrointestinal environment (213).

CONCLUSIONS

The importance of mobile genetic elements to toxin dissemination within the clostridia is clearly evident. These genera produce a large variety of protein toxins, including the three most potent toxins known to man: botulinum, tetanus and epsilon toxins. Many of these toxin genes are not only located on extrachromosomal elements, but also may be associated with mobile genetic elements that may facilitate their spread from one plasmid or bacteriophage to another. The carriage of these toxins on extrachromosomal elements greatly facilitates the spread of toxin genes either within a species or between species. No doubt the extent of the spread

detected to date is limited only by our survey capabilities and the advent of next generation sequencing will facilitate the identification of an even greater range of elements that can facilitate the movement of the genes encoding these important, and sometimes devastating, toxins.

Enterotoxic Clostridia: *Clostridium perfringens* Enteric Diseases

ARCHANA SHRESTHA, FRANCISCO A. UZAL AND BRUCE A. McCLANE

60

INTRODUCTION

Clostridium perfringens is a Gram-positive, spore-forming rod with ubiquitous environmental distribution, including a presence in soil and sewage (1–3). Given its anaerobic nature, it is unsurprising that C. *perfringens* is also a component of the normal gastrointestinal (GI) tract microbiota of humans and other animals (1, 2, 4). Additionally, this bacterium is an important cause of intestinal and histotoxic infections in humans and other animals (2, 5, 6).

The pathogenicity of C. *perfringens* largely reflects the toxin-producing proficiency of this bacterium, which can make at least 20 different toxins, including many with GI tract activity (6–10). However, toxin production patterns vary greatly among different strains. This variability permits classification of C. *perfringens* isolates based on their production of certain toxins referred to as typing toxins. Historically, five C. *perfringens* types were recognized, but this system was recently expanded (11) to include seven types (A to G), as shown in Table 1.

Due to their medical importance, this article will primarily focus on type F strains of C. *perfringens*. It will also briefly mention other C. *perfringens* strains that cause human or livestock GI diseases.

C. PERFRINGENS TYPE F FOOD POISONING

Epidemiology

Type F strains are the causative agents of C. *perfringens* type F food poisoning (formerly referred to as C. *perfringens* type A food poisoning prior to the recent typing system revision), which is the second most common bacterial foodborne illness (12, 13). A million cases of this disease occur annually in the United States, involving ~$400 million in economic losses (12–14). The high prevalence of C. *perfringens* type F food poisoning is attributable to several factors (1). First, type F strains are common in foods (15, 16), providing ample opportunity for infection if that food is incompletely cooked or held prior to ingestion. Second, this bacterium has a very short doubling time of ~10 minutes, which allows it to grow quickly in contaminated food to reach the bacterial load (>10^6 vegetative cells/gram of food) needed to initiate GI disease. Last, most C. *perfringens* type F food poisoning strains have an outstanding ability to survive in incompletely cooked or improperly held foods due to (i) the heat tolerance of their vegetative cells, which grow in up to at least 50°C (17) and (ii) the even greater heat, cold, and food preservative resistance of their spores, as discussed below.

C. *perfringens* type F food poisoning outbreaks are typically large, averaging ~100 cases (1). This large outbreak size is attributable to at least two factors. First, C. *perfringens* type F food poisoning is strongly associated with institutional settings because such facilities need to prepare and store foods in advance of serving, which provides sufficient time for C. *perfringens* to grow and reach pathogenic loads in improperly cooked or held foods. Second, public health officials often overlook small food poisoning outbreaks not involving fatalities; therefore, small outbreaks of this type of food poisoning typically go unidentified.

The most important contributing factor to C. *perfringens* type F food poisoning outbreaks is holding foods at improper temperatures (1, 13). Because of the relative heat tolerance of C. *perfringens* vegetative cells, food should either be stored under refrigeration or held at temperatures >65°C to prevent growth of this bacterium. Incomplete cooking is the second leading contributor to development of this type of food poisoning since it allows C. *perfringens* spores to survive and then germinate in undercooked foods. Beef roasts and turkey are among the most common vehicles for this type of food poisoning because those large food items are difficult to cook thoroughly (1, 13).

The laboratory plays an important role in identifying C. *perfringens* type F food poisoning outbreaks (1). The most reliable approach involves serologic demonstration of C. *perfringens* enterotoxin (CPE) in feces from food poisoning victims. Several commercial assays for fecal CPE detection are available. Alternatively, it can also be informative to demonstrate, by PCR, the presence of *cpe*-positive C. *perfringens* in foods or feces.

Pathogenesis

C. *perfringens* type F food poisoning begins with the ingestion of food contaminated with vegetative cells of a type F strain (1). Most of those bacteria die upon exposure to gastric acid but, if the ingested food was heavily contaminated (i.e., >10^6 to 10^7 vegetative cells/gram of food), some survive to pass into the intestines. After initial growth, those C. *perfringens* cells then undergo *in vivo* sporulation. The trigger for this response is unclear but may involve exposure of ingested

doi:10.1128/microbiolspec.GPP3-0003-2017

TABLE 1 Revised C. *perfringens* toxin-based typing scheme[a]

Toxinotype	Toxin production					
	α-Toxin (*plc* or *cpa*)	β-Toxin (*cpb*)	ε-Toxin (*etx*)	ι-Toxin (*iap* and *ipb*)	CPE (*cpe*)	NetB (*netB*)

F	+	–	–	–	+	–
G	+	–	–	–	–	+

[a]NetB, necrotic enteritis B-like toxin; +, toxin is produced; –, toxin is not produced.

C. *perfringens* cells to low pH in the stomach or to bile salts or phosphate in the intestines (18–20).

Considerable evidence implicates CPE as the toxin responsible for the GI symptoms of C. *perfringens* type F food poisoning (reviewed in reference 1). First, this toxin is detectable in the feces of nearly all C. *perfringens* food poisoning victims but is absent from the feces of healthy people. Second, the CPE concentrations present in the feces of food poisoning victims are similar to the CPE concentrations that cause GI effects in animal models. Third, type F strains are much more virulent in animal intestinal disease models than are most CPE-negative type A strains, which (like type F strains) produce alpha-toxin but (unlike type F strains) do not produce CPE. Importantly, the GI effects of type F strains can be neutralized with a CPE antibody. Fourth, human volunteers fed purified CPE developed the GI symptoms of C. *perfringens* type F food poisoning. Last, and perhaps most persuasive, are studies fulfilling molecular Koch's postulates, which showed that an isogenic *cpe* null mutant of a type F food poisoning strain is fully attenuated in a rabbit small intestinal loop model of GI disease, and complementation of that mutant to regain CPE production also fully restored virulence (21).

Only sporulating C. *perfringens* cells produce CPE (1, 22, 23). Once made, this toxin is not secreted but is instead freed into the intestinal lumen only when the mother cell lyses to release its mature endospore upon the completion of sporulation (24). CPE then binds to the intestinal epithelium and exerts its cytotoxic action, described below, causing villus shortening and intestinal epithelial desquamation. Animal model studies suggest that this intestinal damage is responsible for the onset of the GI symptoms associated with C. *perfringens* type F food poisoning (25–27), although contributions by other processes (such as CPE effects on paracellular permeability) cannot be excluded.

All regions of the small intestine respond to CPE, but the ileum is particularly sensitive (28, 29). Interestingly, while CPE binds to, and initially damages, villus tips in the small intestine, the toxin eventually damages the entire villus (25). Recent cell culture studies, described below, identified a bystander killing effect that may help to explain this *in vivo* observation (30).

Based upon an initial study in which CPE did not affect the rabbit colon (31), it was originally believed that C. *perfringens* type F food poisoning only involves the small intestine. However, later studies demonstrated that purified CPE does affect the rabbit colon (32) and it can also damage human colonic tissue *ex vivo* (33). Furthermore, colonic damage has been observed in some human C. *perfringens* type F food poisoning victims (34). Recent studies suggest that CPE acts focally in the human colon, mainly damaging cells with exposed receptors (35).

Clinically, C. *perfringens* type F food poisoning usually involves diarrhea and abdominal cramps that develop within ~8 to 16 h of ingesting contaminated food (1). This incubation period largely reflects the ~8 to 12 h needed for C. *perfringens* to complete sporulation and then release CPE into the intestinal lumen. In most cases, the GI symptoms of this type of food poisoning persist for 12 to 24 h before self-resolving. However, it has long been recognized that this disease can be fatal in the elderly or debilitated; it is estimated that ~26 people die from C. *perfringens* type F food poisoning every year in the United States (12).

In addition, two unusually severe C. *perfringens* type F food poisoning outbreaks occurred during the past 15 years, resulting in the deaths of several relatively healthy and younger people (34, 36). Both outbreaks involved psychiatric institutions, which is relevant because the severity of these outbreaks appears attributable to the victims having predisposing medical conditions prior to contracting C. *perfringens* type F food poisoning. Specifically, the severely affected individuals in both outbreaks had been receiving psychoactive medications that can induce severe constipation or fecal impaction side effects. Those side effects likely prevented the GI tract flushing effects of the diarrhea that typically occurs during C. *perfringens* type F food poisoning. The absence of diarrhea in these cases is thought to have prolonged intestinal contact with CPE, thus enhancing disease severity. Studies with a mouse model (37) supported this hypothesis by showing that prolonged intestinal contact with purified CPE increases uptake of this toxin into the circulation. This allowed CPE to damage internal organs, such as the liver and kidneys, resulting in a hyperpotassemia that induces cardiac arrest. Those mouse model studies suggest that pre-existing severe constipation or fecal impaction can facilitate development of a lethal enterotoxemia following C. *perfringens* type F food poisoning (37).

The CPE Protein

CPE is a single 319-amino acid polypeptide (M_r 35,317; pI, 4.3) (38). Its primary amino acid sequence lacks significant sequence homology with other proteins, except for some limited sequence homology (of unknown significance) with a nonneurotoxic protein of C. *botulinum* (39). The secondary structure of CPE is ~80% beta-pleated sheet and ~20% random coil (28).

The structure of CPE was solved in a series of studies that began with crystallization and X-ray diffraction analysis of the C-terminal domain of CPE, which mediates binding of the toxin to receptors, as discussed below. That initial study (40) showed that this CPE domain consists of a nine-stranded beta-sandwich, with most strands in an antiparallel arrangement. Tyrosine and leucine residues implicated (41) (described below) in receptor binding line a pocket located on the surface of this C-terminal CPE domain, where they can readily interact with receptors (40).

The complete structure of native CPE was solved independently by two groups in 2011 (42, 43). Those structural analyses (Fig. 1A) revealed that, in addition to the C-terminal domain mediating receptor binding activity, this pore-forming enterotoxin also has an N-terminal domain required for CPE oligomerization and pore formation. The 34 N-terminal amino acids of CPE appear to be disordered, explaining why their presence reduces CPE-induced cytotoxicity (see below). Although lacking primary sequence homology with other proteins, CPE structurally belongs to the aerolysin pore-forming toxin family, which also includes *C. perfringens* epsilon toxin. A region in the N-terminal domain named TM1 (for transmembrane 1), which is important for pore formation (as discussed below), is largely present in an α helix when the native CPE monomer is in solution. This is distinctive since comparable sequences in other members of the aerolysin pore-forming toxin family are present in a beta-strand (42, 43).

Structure versus function relationships have been extensively mapped for the CPE protein. Early deletion mutagenesis research (44), coupled with chemical cleavage analyses (45), revealed that the C-terminal domain of the toxin is sufficient for receptor binding. That research also showed that the N-terminal domain must also be present to obtain cytotoxicity and cause GI tract pathology. Later studies using recombinant CPE fragments and synthetic peptides showed that even the 30 C-terminal amino acids of CPE alone possess some receptor binding activity (46). Subsequent site-directed mutagenesis results identified three tyrosine residues (Y306/Y310/Y312) and a leucine triplet (L223/L254/L315) in the C-terminal half of CPE as being important for receptor binding (41).

While full-length CPE (amino acids 1 to 319) is cytotoxic, removing up to the first 45 amino acids from CPE by deletion mutagenesis increases cytotoxic activity by 2- to 3-fold (47). This activation effect, which does not correspond to removal of a leader sequence since CPE is not a secreted protein, may have pathologic relevance; i.e., purified trypsin and chymotrypsin also induce a 2- to 3-fold increase in CPE-induced cytotoxic activity by removing the first 25 or 37, respectively, N-terminal amino acids from the native toxin (48, 49). However, deleting amino acids beyond residue 45 renders CPE noncytotoxic (50). Subsequent site-directed mutagenesis studies identified several amino acids located between residues D45 and G53 of the native toxin as mediating CPE oligomerization (51). In particular, residue D48A is required for both CPE oligomerization and cytotoxicity (51).

Besides oligomerization, the N-terminal domain of CPE mediates a second function during CPE-induced cytotoxicity. This CPE domain contains TM1, a region consisting of alternating hydrophobic and hydrophilic residues spanning from amino acids 80 to 106 of native CPE (52, 53). As mentioned earlier, the TM1 region is mainly localized within an alpha-helix in the N-terminal domain of native CPE. However, once CPE oligomerizes, the TM1 α-helix is thought to unwind to form a beta-hairpin loop that participates in pore formation (as described in the next section).

CPE-Induced Cytotoxicity

CPE binding

The cytotoxic action of CPE begins (Fig. 2) with binding of this toxin to its receptors (54). Conclusive insights into CPE

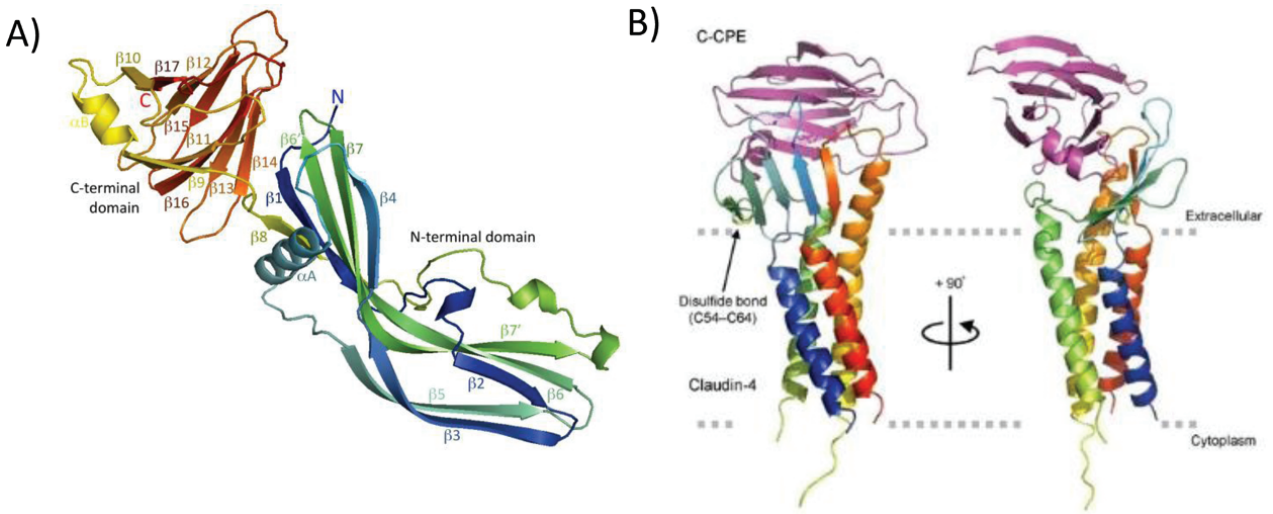

FIGURE 1 Structure of CPE and the C-terminal CPE structure bound to a claudin-4 receptor. (A) Structure of the CPE monomer, colored from blue at the N-terminus to red at the C-terminus. Note the presence of two distinct domains, including the C-terminal domain (red/yellow) mediating receptor binding and the blue-green N-terminal domain mediating oligomerization, membrane insertion, and pore formation. The alpha helix labeled αA is located at the TM1 region that becomes a beta-hairpin when CPE is assembled in the prepore. Beta-hairpins from the seven CPE molecules in the prepore are thought to then form a beta-barrel that inserts into membranes to form the active pore. (B) Structure of the C-terminal CPE region (C-CPE) bound to the human claudin-4 receptor. The claudin receptor is rainbow-colored and the C-CPE is purple. The membrane orientation of the claudin receptor, including the transmembrane helices, is also shown. Panels A and B are reproduced with permission from references 42 and 66, respectively.

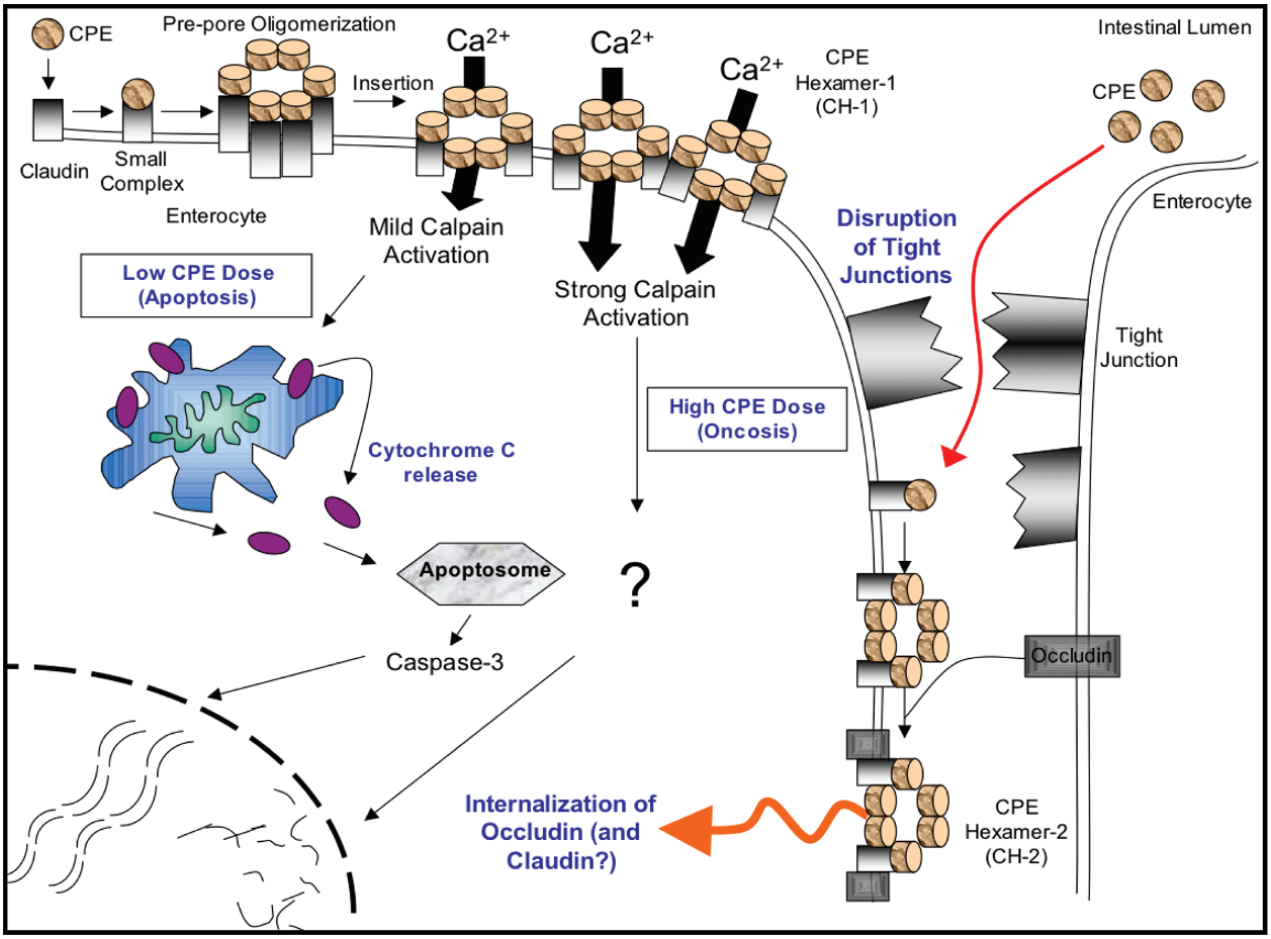

FIGURE 2 Model of the CPE mechanism of action. At the top left, CPE binds to receptors forming a small complex that contains both receptor claudins and nonreceptor claudins, as well as CPE. At 37°C, several small complexes interact to form a prepore on the membrane surface. Portions of CPE in the prepore insert into the membrane to form a pore that allows Ca^{2+} entry into the cytoplasm. With high CPE doses, there is a massive Ca^{+2} entry that causes strong calpain activation to trigger oncosis (a form of necrotic cell death). At low CPE doses, there is a more limited Ca^{2+} entry that causes a mild calpain activation; this results in mitochondrial membrane depolarization, cytochrome C release, and caspase-3 activation to cause death by apoptosis. Dying CPE-treated cells undergo morphologic damage that exposes their basolateral surface to CPE, resulting in formation of a second large complex containing occludin (as well as CPE and claudins), which induces internalization of these molecules. This effect may contribute to paracellular permeability changes, at least in cultured cells. Reproduced with permission from reference 54.

receptors were provided by expression cloning studies that identified two CPE-binding host proteins, later determined to be claudins-3 and -4 (55, 56). Claudins are a family of ~21- to 27-kDa single polypeptides that play a critical role in maintaining the normal barrier and fence properties of the tight junction (54). Humans are thought to produce 27 different claudins (54). Structural analyses (57) revealed that claudins consist of a four-transmembrane domain bundle and two extracellular loops, referred to as ECL-1 and ECL-2. Claudins also possess a short (~7-amino acid) N-terminal sequence and a C-terminal tail (~20 to 60 amino acids), both of which are located in the host cell cytoplasm. The sequence of the C-terminal tail is variable, allowing discrimination between different claudins using antibodies raised against synthetic peptides with a claudin tail sequence.

Experiments established that, in addition to claudin-3 and -4, CPE can use claudin-6, -7, -8-, -9, and -14 as receptors (54, 58, 59). The CPE binding affinity among those claudin receptors varies greatly, with some (e.g., claudin-3 and -4) binding CPE strongly but others (e.g., claudin-8 and -14) binding CPE with only moderate affinity (59, 60). Furthermore, not all claudins are CPE receptors, because claudin-1, -2, -5, -10, -13, and -20 to -24 cannot bind significant amounts of CPE at physiologically relevant toxin concentrations (54, 58, 59, 61, 62).

Substantial research has focused on the basis for the different CPE binding abilities among claudins. Early studies used chimeric claudins (54, 58) to demonstrate the importance of ECL-2 for CPE binding. Later work (54, 59, 62) identified specific amino acids in ECL-2 that contribute to CPE binding. In particular, an N residue is conserved in the ECL-2 of receptor binding claudins, while the corresponding residue is never an N (usually it is a D or S) in claudins that are unable to bind the toxin (62). Site-directed mutagenesis studies (62) directly confirmed the importance of this conserved N residue for CPE binding. ECL-2 residues adjacent to the essential N residue vary among the receptor claudins, and those variations modulate the CPE binding affinity of different receptor claudins (62–64). Structural biology studies demonstrated that the N residue and adjacent P and L/S

residues dock tightly in the tyrosine pocket of the C-terminal CPE domain (57, 65).

Recently, the structure of the CPE C-terminal domain bound to a claudin receptor was solved (57, 66) (Fig. 1B), which provided a major surprise by showing that CPE interacts with ECL-1, as well as with ECL-2. ECL-1 sequences are conserved in all claudins, explaining why previous chimeric claudin studies did not pick up CPE interactions with ECL-1. The strong sequence conservation among the ECL-1 of different claudins is also consistent with a model where ECL-2 is the primary determinant of CPE binding ability among the claudins, although CPE also interacts with the conserved ECL-1 in receptor claudins. Supporting the importance of CPE interactions with ECL-1 for receptor binding were site-directed mutagenesis studies showing that mutation of ECL-1 residues A39 to I41 affects CPE binding to claudin receptors (57).

Postbinding steps in CPE action

Binding of CPE to a claudin receptor results in the formation of a small complex of ~90 kDa (67). Coimmunoprecipitation and electroelution results (68) suggest that this small complex can contain a nonreceptor claudin (e.g., claudin-1), as well as CPE bound to the claudin receptor. Heteromer gel shift studies (68) indicated that 6 small CPE complexes then oligomerize to form the CH-1 large complex, with a molecular mass of ~425 to 500 kDa. It is believed that CH-1 is initially present as a prepore on the membrane surface of host cells, but each CPE in the prepore then unwinds its TM1 α-helix to form a beta-hairpin loop (52, 53). Similar loops likely extend from each of the 6 CPE molecules present in the prepore oligomer, forming a beta-barrel that inserts into the membrane to create an active pore. In support of this model, site-directed mutagenesis identified several TM1 variants that have normal binding and oligomerization properties but are impaired for membrane insertion or for formation of a functional pore (52).

CPE pore formation leads to a rapid efflux of some cytoplasmic ions (e.g., potassium) but an influx of other extracellular ions, including calcium (28, 69–72). CPE-induced calcium influx is particularly important since it activates, in a toxin dose-dependent manner, calpain and calmodulin to cause cell death (70, 73). At low CPE doses (~1 μg/ml), modest pore formation occurs to cause a limited calcium influx and a mild activation of calpain that triggers caspase-3 dependent apoptosis (70, 73). However, high CPE doses (~10 μg/ml) form large numbers of pores, allowing a massive calcium influx that results in strong calpain activation to cause necrotic death involving oncosis (70, 73).

Cells affected by CPE develop morphologic damage (71, 74). This allows even more CPE binding to the abundant claudin receptors present on the basolateral cell surface (75). In Caco-2 cells, CPE-induced cell damage also permits some receptor-bound CPE to interact with another tight junction protein named occludin to form an ~600-kDa complex named CH-2 (68, 75, 76). The importance of this complex for CPE activity, particularly *in vivo*, is not clear since only the CH-1, (i.e., not the CH-2) complex is detectable in CPE-treated rabbit small intestine (37).

CPE Induces a Bystander Killing Effect

The human body is a complex mixture of host cells, including cells that produce claudin CPE receptors and respond to this toxin, as well as other cells that do not make CPE receptors and are not directly sensitive to this toxin. Therefore, a recent study (30) asked whether CPE effects on sensitive host cells might impact nearby CPE-insensitive host cells. When a coculture of CPE-sensitive and CPE-insensitive cells was treated *in vitro* with the enterotoxin, many of the CPE-insensitive cells died. This bystander killing effect was shown to involve a factor, possibly a 10- to 30-kDa serine protease, that is released from CPE-sensitive cells when they undergo CPE-induced, caspase 3-mediated apoptosis. The cytotoxic host factor released from those dying cells then induces a caspase 3-mediated apoptosis in the naturally CPE-insensitive cells. Collectively, these results suggest that a similar bystander killing effect may amplify CPE action *in vivo* and thus contribute to disease.

CPE Genetics

Less than 5% of global *C. perfringens* isolates carry the gene (*cpe*) encoding the enterotoxin (77). Those *cpe*-positive strains belong to types C, D, and E, as well as type F (77–81). In type F strains, the *cpe* gene can be present on either the chromosome or large plasmids (82–84); no type F strain has been found that carries both a chromosomal and plasmid-borne *cpe* gene. In other types, the *cpe* gene is always present on large (>70-kb) plasmids (78, 79, 82, 85).

Whether located on plasmids or the chromosome, the *cpe* open reading frame sequence is highly conserved among type C, D, and F strains (84, 86). However, type E strains can possess either silent *cpe* sequences (due to loss of the *cpe* promoter and the presence of mutations, including a nonsense mutation, in the *cpe* ORF) or a functional *cpe* gene that encodes a variant CPE with ~10 amino acid sequence differences from the classical *cpe* ORF found in type C, D, and F strains (85, 87). Whether those amino acid sequence differences affect CPE cytotoxic activity is unknown.

Most (~70%) type F food poisoning strains carry a chromosomal *cpe* gene (1, 88–91). This association is not due to the chromosomal *cpe* strains producing either more CPE or a CPE variant with greater cytotoxicity (84). Instead, it is attributable to at least two factors: (i) the exceptional resistance of the spores made by most chromosomal *cpe* strains (17), which likely facilitates their survival in incompletely cooked foods, and (ii) the vast majority of *cpe*-positive strains present in retail raw meat/fish having a chromosomal as opposed to a plasmid-borne *cpe* gene, providing the chromosomal *cpe* strains with much greater opportunity to cause food poisoning (1, 16). The reason for the greater prevalence of chromosomal *cpe* strains in meat/fish is unknown but may be related, in part,to their better survival in foods (as explained above).

Genome sequencing of strain SM101, a transformable derivative of the type F food poisoning strain NCTC8798, showed that its *cpe* gene is located in a highly variable region of the chromosome (92). Other chromosomal *cpe* strains appear to carry a similarly organized *cpe* locus (86, 93, 94). The presence of the *cpe* gene in a highly variable chromosomal region is likely due to the integration of Tn*5565*, a putative 6.4 kb-transposon where the *cpe* gene and an upstream IS*1469* sequence are both flanked by IS*1470* sequences (95, 96). The putative Tn*5565* insertion event apparently occurred in the chromosomal locus between *nad*C, encoding a putative quinolate phosphoryltransferase gene, and *uap*C, encoding a putative purine permease (Fig. 3). The ability of adjacent insertion sequences to mobilize the chromosomal *cpe* gene is suggested by PCR studies, which detected circular DNA species carrying the *cpe* gene in DNA extracted from chromosomal *cpe* strains; those circular DNAs may be transposition intermediates carrying the *cpe* gene (95).

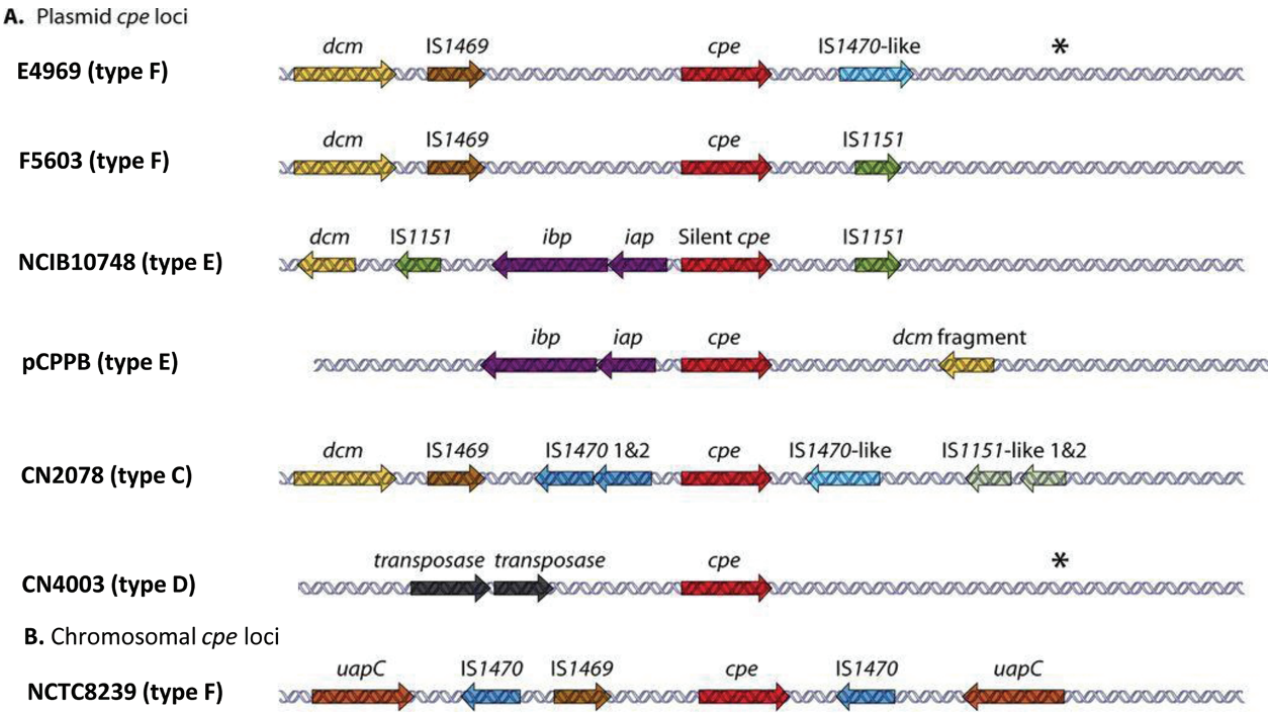

FIGURE 3 Organization of *cpe* loci in type C, D, E, and F strains of C. *perfringens*. (A) Organization of plasmid-borne *cpe* loci in type F, E, C, and D strains. (B) Organization of the type F chromosome *cpe* locus. Asterisks indicate a region with similarity to sequences present downstream of the *cpe* gene in F4969, except for the absence of an IS*1470*-like gene. Modified with permission from reference 82.

Multilocus sequence type studies (80, 97) showed that, beyond their *cpe* gene location, chromosomal *cpe* type F strains differ phylogenetically from type F plasmid *cpe* strains and most other C. *perfringens* strains, with the exception of the type C strains causing a form of enteritis necroticans (EN) known as Darmbrand in post-World War II Germany (discussed further below). Type F chromosomal *cpe* strains and type C Darmbrand strains are both also unusual (80) among C. *perfringens* strains in that they (i) lack the *pfoA* gene that encodes perfringolysin O and (ii) carry a *sasp4* gene that encodes a variant small acid-soluble protein-4 to impart exceptional spore heat resistance (described further below). However, an important distinction between the type F chromosomal *cpe* strains and the type C Darmbrand strains is that when Darmbrand strains carry a *cpe* gene, it is located on a large plasmid rather than on the chromosome (80).

The *cpe* plasmids of type F strains belong predominantly to the pCPF5603 and pCPF4969 plasmid families (82, 98). Both of those plasmid families likely evolved from a common precursor plasmid. The pCPF5603 family later acquired a cluster of metabolic genes, as well as the gene encoding beta2-toxin, while the pCPF4969 family picked up genes encoding a VirS/VirR-like two-component regulatory system and a putative bacteriocin. The *cpe* gene in both of these *cpe* plasmid families is associated with insertion sequences (Fig. 3), including the presence of a 5′ IS*1469* sequence near their *cpe* genes. However, the *cpe* loci in these two *cpe* plasmids lack the upstream IS*1470* sequence upstream found in the chromosomal *cpe* locus. In addition, while an IS*1470* sequence is located downstream of the *cpe* gene in pCPF4969 plasmids, that insertion sequence is absent from the *cpe* locus of the pCPF5603 plasmids. Instead, pCPF5603 plasmids carry an IS*1151* sequence downstream of their *cpe* gene. The presence of these insertion sequences near these *cpe* genes may help to mobilize this toxin gene into circular forms that could be transposition intermediates, as shown for type C and D strains carrying *cpe* plasmids (86).

Insertion sequences are also located adjacent to the plasmid *cpe* gene (Fig. 2) in type C, D, and E isolates (85, 86), as well as the silent *cpe* sequences present on plasmids in some type E strains (86). However, the *cpe* locus is organized differently in those strains compared to type F strains (Fig. 2). In addition, the plasmids carrying *cpe* genes or silent *cpe* sequences in non-type F strains are often larger, ranging up to ~135 Kb, than the pCPF5603 or pCPF4949 plasmids (82, 99). Some *cpe* plasmids in type C, D, and E strains share partial similarity with pCPF5603 or pCPF4969, and they can also carry other toxin genes (78, 79, 99), e.g., the *cpb* gene encoding beta-toxin, the *etx* gene encoding epsilon-toxin, or the *iap* and *ibp* genes encoding iota-toxin (78, 79, 82, 99).

Nearly all *cpe* plasmids, including the pCPF5603 and pCPF4969 plasmids, carry a region named *tcp*, for transfer of clostridial plasmids (82). This carriage is important because the *tcp* locus has been shown to mediate conjugative transfer of another C. *perfringens* plasmid, named pCP13 (82, 100). Those pCP13 results predicted that the pCPF5603 and pCPF4969 *cpe* plasmids should also be conjugative. This postulate was confirmed for pCPF4969 when mixed mating studies demonstrated conjugative plasmid transfer of this *cpe* plasmid (83, 101).

In summary, both the chromosomal and plasmid *cpe* genes are associated with insertion sequences, which may facilitate mobilization of the *cpe* gene within a C. *perfringens* cell. Additionally, the *cpe* gene is often present on conjugative plasmids, which allows transfer of the *cpe* gene from one C. *perfringens* strain to another. If this conjugative transfer

happens during infection, it could contribute to pathogenesis, as explained below in the nonfoodborne human GI disease section.

Regulation of CPE Production

When CPE is produced during sporulation, it can account for >15% of the total protein inside the sporulating C. *perfringens* cell (1). This abundant CPE production is not attributable to a gene dosage effect since most food poisoning strains carry only a single copy of the *cpe* gene. Instead, Northern blotting and reporter studies indicated that *cpe* expression is primarily regulated at the transcriptional level, with the *cpe* gene transcribed as a monocistronic message that becomes detectable soon after the onset of sporulation (1, 28, 102–104).

The presence of three promoters upstream of the *cpe* start codon likely explains the strong production of CPE during sporulation (1, 103). The close association between CPE production and sporulation is attributable to those *cpe* promoters sharing significant homology with SigK-or SigE-dependent promoters in *Bacillus subtilis* (103). Those promoter sequence homologies are important because SigK and SigF are sporulation-associated sigma factors in many *Bacillus* and *Clostridium* spp. (105). A direct role for SigK and SigE in regulating both CPE production and C. *perfringens* sporulation was demonstrated experimentally using *sigK* and *sigE* null mutants (106).

A later study (107) established a role for SigF, another sporulation-associated sigma factor, in regulating both CPE production and C. *perfringens* sporulation. In contrast to early PCR studies (106) suggesting that SigK is the first sporulation-associated sigma factor made during C. *perfringens* sporulation, the later study (107) using Western blotting detected no SigK or SigE production by a *sigF* null mutant. Those Western blot results indicate that during early sporulation, either (i) SigF controls production of both SigK and SigE or (ii) only very low (below Western blot levels of detection) SigK levels are produced before SigF is made. In addition, those Western blot studies (107) demonstrated that SigF controls production of a fourth sporulation-associated sigma factor, named SigG. It was also shown that SigG is necessary for C. *perfringens* sporulation but not for CPE production (107). An emerging model from these and other studies is shown in Fig. 4. Briefly, C. *perfringens* sporulation initiates with phosphorylation of Spo0A by an unknown kinase. Phosphorylation of Spo0A (108), a master regulator

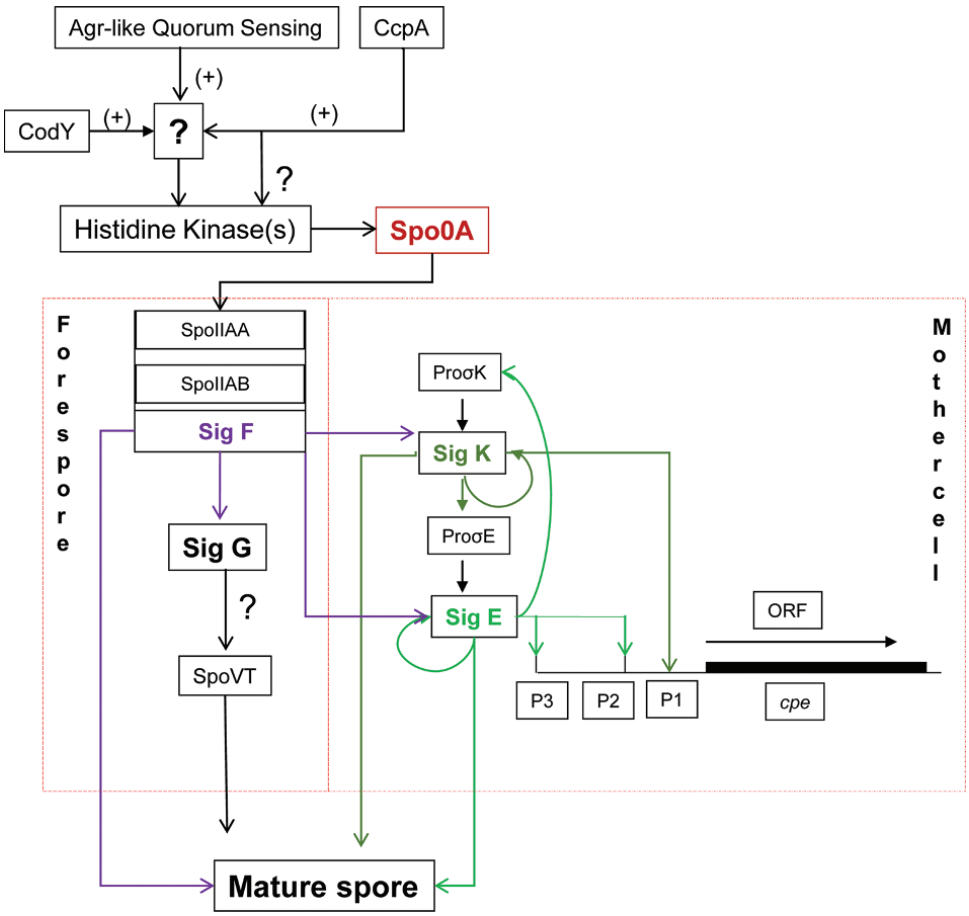

FIGURE 4 Model of C. *perfringens* sporulation and enterotoxin production. Via the Agr-like quorum sensing system, CcpA and CodY, and unidentified intermediates, a histidine kinase(s) affects spoOA expression and/or possibly Spo0A phosphorylation to initiate sporulation. This triggers a sigma factor cascade, where SigF controls production of three other sporulation-associated sigma factors (SigE, SigG, and SigK). SigE and SigK then regulate CPE production during sporulation by enhancing *cpe* expression. All four sigma factors are needed for sporulation. Reproduced with permission from reference 142.

of stationary phase gene expression, leads to production of SigF (107). Once produced, SigF signals the sporulating cell to make SigE, SigG, and SigK. SigE and SigK then direct expression of the *cpe* gene in the sporulating C. *perfringens* cell. All four sporulation-associated sigma factors contribute to the gene expression needed for sporulation (106, 107).

Several other regulators, i.e., CcpA, CodY, and the Agr-like quorum sensing system, have been shown to regulate sporulation and CPE production, but the precise nature of their involvement is unclear at present (109–111).

Other Virulence Factors: Small Acid-Soluble Protein 4

The vegetative cells and, especially, spores of type F strains carrying a chromosomal *cpe* gene are usually much more resistant to heating (cooking), cold (storage in refrigerators/freezers), and food preservatives than cells and spores of most other C. *perfringens* strains (17, 112, 113). The exceptions are type C Darmbrand strains, which also form highly resistant spores and cause human food-borne disease (80). For example, the spores of both type F chromosomal *cpe* strains and type C Darmbrand strains have a D_{100} value (the time needed at 100°C to reduce viability by 1 log) of ~1 h versus a D_{100} value of only ~1 to 2 min for spores made by other C. *perfringens* strains (17, 80).

Small acid-soluble proteins (SASPs) provide important protection to spore DNA. C. *perfringens* produces four SASPs (114, 115). Early studies (114) showed that differences in SASPs 1 to 3 do not explain the exceptional heat resistance properties of spores made by type A chromosomal *cpe* strains or type C Darmbrand strains. Instead, later studies demonstrated that those chromosomal *cpe* type F strains and type C Darmbrand strains forming highly heat-resistant spores produce a variant SASP-4 with an Asp at residue 36, unlike the SASP-4 of other C. *perfringens* strains, which have a Gly at this residue (80, 115). Studies with isogenic mutants and complementing strains confirmed the importance of this variant SASP-4 for the extreme spore resistance properties of type F chromosomal *cpe* stains and, presumably, type C Darmbrand strains (114). The greater protection offered by the SASP-4 Asp_{36} variant appears to involve tighter DNA binding, particularly to AT-rich DNA sequences, by the Asp_{36} compared to the Gly_{36} SASP-4 variant (116). While their SASP-4 variant plays a major role in the strong spore resistance properties of type A chromosomal *cpe* strains, other factors may also contribute (117, 118).

Immunology

There is no evidence that immune responses contribute substantially to the rapid resolution of most C. *perfringens* type F food poisoning cases. Instead, symptoms of this illness are thought to quickly abate due to CPE-induced diarrhea flushing unbound toxin and C. *perfringens* from the GI tract. Most people have CPE antibodies in their serum, but there is no evidence that prior exposure to C. *perfringens* type F food poisoning provides long-term protection against future acquisition of this illness (119, 120).

Treatment and Prevention

Treatment of C. *perfringens* type F food poisoning is symptomatic. However, recent studies showed that mepacrine could be a potential therapeutic since it can inhibit CPE action *in vitro* (121).

As mentioned earlier, the best approach to prevent this type of food poisoning is to thoroughly cook foods and then hold them at temperatures of <4°C or >65°C. No vaccine is licensed for prevention of C. *perfringens* type F food poisoning. However, the C-terminal domain of CPE, which is noncytotoxic and does not cause GI tract effects, contains a neutralizing epitope (1, 48). Immunization of mice with a conjugate consisting of a peptide containing this CPE epitope coupled to a thyroglobulin carrier induced high titers of CPE-neutralizing antibodies in mice, suggesting that this epitope could be a vaccine candidate (122).

CPE-ASSOCIATED NONFOODBORNE HUMAN GI DISEASES

C. *perfringens* type F isolates are also responsible for 5 to 15% of all nonfoodborne human GI disease cases (2, 123, 124), which include antibiotic-associated diarrhea and sporadic diarrhea. In CPE-associated antibiotic-associated diarrhea, patients receiving antibiotics become colonized, often from the nosocomial environment, by type F strains of C. *perfringens* (124–126). CPE-associated nonfoodborne GI disease cases often last longer (up to several weeks) and are typically more severe than most cases of C. *perfringens* type F food poisoning, particularly in the elderly (124–126).

The more chronic duration of CPE-associated nonfoodborne GI diseases may be attributable to the organisms' superior intestinal colonizing ability compared to type F food poisoning strains. *In vitro* studies (127) showed that nonfoodborne human GI disease strains adhere much better than type A chromosomal *cpe* strains to human enterocyte-like Caco-2 cells. This enhanced adherence correlates with the ability of the CPE-associated nonfoodborne GI disease strains, but not chromosomal *cpe* type F food poisoning strains, to produce NanI sialidase (127). Studies (127) of *nanI* null mutants of a nonfoodborne human GI disease strain confirmed a role for this sialidase in Caco-2 cell adherence, where it likely trims the host cell surface to promote bacterial adherence via a combination of surface charge reduction and exposure of adhesin receptors. In addition, sialic acid generated by NanI from host sources such as enterocyte/colonocyte surfaces or GI tract mucus may facilitate the intestinal growth of C. *perfringens* (128). Interestingly, NanI can also increase the activity of CPE and several other intestinally active C. *perfringens* toxins by enhancing their binding to host cells (129, 130).

As mentioned earlier, virtually all C. *perfringens* type F isolates causing CPE-associated nonfoodborne human GI diseases carry a plasmid *cpe* gene, in contrast to the chromosomal *cpe* gene present in most C. *perfringens* type F food poisoning isolates (82, 83, 89, 93, 94). The presence of the *cpe* gene on plasmids, which are conjugative (101), may contribute to the development of CPE-associated nonfoodborne diseases. Unlike C. *perfringens* type F food poisoning, which develops following the ingestion of massive numbers of bacteria, CPE associated nonfoodborne GI diseases likely involve ingestion of low numbers of C. *perfringens* (2). Therefore, inside the GI tract, the presence of the *cpe* gene on plasmids may result in conjugative transfer of this toxin gene to C. *perfringens* in the normal intestinal microbiota, thereby helping to establish and amplify the infection during CPE-associated nonfoodborne GI disease.

OTHER HUMAN GI DISEASES CAUSED BY *C. PERFRINGENS*

Enteritis Necroticans

C. *perfringens* type C strains cause a disease named enteritis necroticans (EN), which was first identified in malnourished

TABLE 2 C. *perfringens* enteric diseases of livestock and poultry

Type	Main enteric disease	Toxin
A	Possible necrotizing and hemorrhagic enteritis in dogs and foals	NetF? (necrotic enteritis F-like toxin)
B	Lamb dysentery; possible necrotizing enteritis in horses	CPB (beta-toxin), ETX (epsilon-toxin)
C	Necrotizing enteritis in neonatal calves, foals, lambs, piglets, and possibly other species	CPB (CPE may be synergistic in some cases)
D	Enterotoxemia in sheep, goats, and cattle	ETX
E	Possible hemorrhagic enteritis in cattle and rabbits	ITX (iota-toxin)
F	Possible enteric disease in horses, dogs, and other species	CPE (enterotoxin?)
G	Necrotic enteritis in chickens, turkeys, and possibly other avian species	NetB (necrotic enteritis B-like toxin)

people in post-World War II Germany, where it was known as Darmbrand (80). EN, known locally as pigbel, was the leading cause of childhood death in Papua New Guinea during the 1960s to 1970s (131, 132). For special occasions, villagers in the Papua New Guinea highlands would barbecue a pig in a pit dug in the ground, thus allowing contamination of the meat with type C strains present in the environment (soil or pigs). When that food was ingested, beta-toxin (CPB) was produced in the intestines and then caused both a necrohemorrhagic enteritis and enterotoxemia. While the presence of high trypsin levels in the intestines of well-fed people with a normal diet rapidly inactivates CPB, the diet in the highlands population was poor in protein (which reduces trypsin production) but rich in sweet potatoes (which have a trypsin inhibitor), rendering the local people (especially children) highly susceptible to CPB. Type C-induced EN outbreaks occur sporadically in malnourished populations in other developing countries (131). Individual cases are observed occasionally in developed countries, particularly in people with underlying pancreatic diseases such as diabetes (133).

CPB is necessary for type C strains to cause EN (134). However, some strains (including many Darmbrand strains) produce only low amounts of CPB, often along with low amounts of CPE (135). For those strains, it has been shown (135) that CPB and CPE can act synergistically in the intestines to cause pathology. CPB, also a pore-forming toxin (6), has been poorly studied. For example, the receptor for this toxin remains unknown.

The *cpb* gene is always plasmid borne in type C strains; occasionally this gene is located on the same plasmid carrying a *cpe* gene (79, 82). Plasmids carrying the *cpb* gene are predicted to be conjugative since they typically carry the *tcp* locus; however, this has not yet been evaluated (82). Adjacent to the *cpb* gene are insertion sequences that may mobilize the *cpb* gene (79, 82).

The only treatment for EN is prompt intestinal surgery to remove affected portions of the small intestine (131). Immunization with a CPB toxoid during the 1980s to 1990s greatly reduced the prevalence of EN in Papua New Guinea (131, 132).

Another *C. perfringens* Foodborne Human Disease?

Recently, there were reports (7, 8) of several Japanese food poisoning outbreaks that apparently involved *cpe*-negative C. *perfringens* type A strains. Analysis of those strains determined that they produce a binary toxin whose A and B components share 44% and 37% identity, respectively, with C. *perfringens* iota-toxin. This new binary toxin (named CPILE or BEC by different groups) structurally resembles iota-toxin and, like iota-toxin, can ADP-ribosylate actin (136, 137). It causes fluid accumulation in rabbit ileal loops, and null mutants that do not produce the binary toxin lose their intestinal virulence, but complementation of those mutants has not yet been performed (7). Additional research is needed to address the overall importance of strains producing CPILE/BEC for human foodborne disease; e.g., how common are outbreaks caused by these bacteria both inside and outside of Japan?

C. PERFRINGENS ANIMAL DISEASES OF INTESTINAL ORIGIN

C. *perfringens* type B, C, and D strains, and perhaps certain type A and E strains, can cause enteritis, colitis, enterocolitis, and/or enterotoxemia in livestock, while type G strains are responsible for necrotic enteritis of poultry (Table 2). Like C. *perfringens* human enteric diseases, these animal diseases are not intoxications but true infections resulting from C. *perfringens* producing toxins in the intestines. Molecular Koch's postulate analyses have confirmed a role for epsilon-toxin in type D infections, CPB in type C infections, and necrotic enteritis B-like toxin in avian necrotic enteritis (9, 134, 138). Each of those pore-forming toxins is plasmid encoded (82). Detailed discussion of these animal diseases is beyond the scope of this chapter, so readers are directed to several recent reviews on this subject (6, 139–141).

Preparation of this chapter was generously supported, in part, by grant R01 AI019844-35 from the National Institute of Allergy and Infectious Diseases.

The content is solely the responsibility of the authors and does not necessarily represent the official views of the National Institutes of Health.

Because of page limitations, this chapter has cited published reviews for many older studies.

Enterotoxic Clostridia: *Clostridioides difficile* Infections

S. MILETO, A. DAS AND D. LYRAS

61

INTRODUCTION

Clostridioides difficile is a Gram-positive anaerobic, spore-forming bacterium and the most common identifiable infectious agent of nosocomial antibiotic-associated diarrhea (AAD) (1, 2). This bacterium is also linked to several life-threatening syndromes in humans, including pseudomembranous colitis and toxic megacolon (1, 2). Disease symptoms associated with *C. difficile* infection (CDI), including diarrhea, fluid loss, and inflammation, result from the production and activity of two exotoxins, toxin A (TcdA) and toxin B (TcdB) (2). These toxins disrupt the Rho family of GTPases within the host cell, which eventually results in cell rounding and death (3, 4). *C. difficile* was originally discovered by Hall and O'Toole as *Bacillus difficilis* during their 1935 study of neonatal fecal microbiota and was named "*difficilis*" due to the difficulty of its cultivation and isolation (5). At the time of its initial isolation, *C. difficile* was not considered pathogenic, with recognition of *C. difficile* as a human pathogen occurring roughly 40 years after its initial discovery (5). With time, identification of the obligately anaerobic nature of this organism ultimately resulted in reclassification from *B. difficilis* to *Clostridium difficile*. More recently, with an update to the classification of the clostridia, it was first suggested that *C. difficile* be reclassified as *Peptoclostridium difficile* (6) and, more recently, to *Clostridioides difficile* (7). However, as recently highlighted in Smits et al. (8), there is reluctance for reclassification, because there currently exists a large knowledge base surrounding *Clostridium difficile*, in addition to a strong public awareness which could be lost upon reclassification. Despite these reservations, *Clostridioides difficile* has now been officially approved by the *International Journal of Systematic and Evolutionary Microbiology* and International Committee on Systematics of Prokaryotes and has begun to be used more commonly (9–11).

An increase in clinical CDI rates has been occurring for over a decade, coinciding with the emergence of new epidemic strains, including the BI/NAP1/027 group (referred to as ribotype 027 strains from here on), which appear to have enhanced virulence properties in comparison to historical isolates (8, 12, 13). The emergence of these epidemic *C. difficile* strains has resulted in increased disease severity in infected patients which has been recorded globally and has placed a great financial and administrative burden on hospitals worldwide (14–18).

BACTERIOLOGY, DIAGNOSIS, AND TYPING

Bacteriology and Diagnosis

As a strict anaerobe, the ability of *C. difficile* to form spores is important for disease transmission and recurrence (2). Spores facilitate the survival of *C. difficile* in harsh conditions, including in aerobic environments or in the acidic stomach during transit to the large intestine. Sporulation and spore persistence are major challenges, particularly in nosocomial environments, resulting from the resistance of spores to many commonly used disinfection regimens (19). Spores of *C. difficile* can be induced to germinate at a higher frequency when cultured in media supplemented with bile salts that are usually found in the intestine, which also greatly improves organism recovery from clinical samples (20).

Although *C. difficile* has been established as the leading identifiable cause of infectious AAD in the hospital setting, disease diagnosis remains a contentious issue (21, 22). CDI is defined as acute diarrhea accompanied by the presence of either toxigenic *C. difficile* or its toxins in stool samples (23). However, the lack of a clear distinction between specific clinical CDI and more general non-CDI symptoms in all patients prevents the accurate diagnosis of *C. difficile* disease. Current diagnostic methods for *C. difficile* disease include bacterial culture, enzyme immunoassays (EIAs), cell cytotoxicity neutralization assays (CCNAs), toxin detection tests, and nucleic acid amplification tests (NAATs).

Isolation of *C. difficile* from stool samples requires bacterial culture in an anaerobic environment on selective media such as cycloserine-cefoxitin fructose agar (CCFA) (24). The addition of sodium taurocholate and horse blood to CCFA results in enhanced spore germination and enables colony fluorescence, respectively, allowing for accurate identification (25, 26). However, nontoxigenic *C. difficile* strains also grow in these conditions, and culturing on CCFA can take up to 48 hours, delaying the reporting of results.

Toxigenic and nontoxigenic strains of *C. difficile* constitutively produce the cell wall-associated enzyme glutamate dehydrogenase (GDH), which is highly conserved across different ribotypes (27). A recent large-scale meta-analysis indicated that GDH EIAs are highly sensitive, accurate, and relatively cheap to conduct as screening tests, returning positive results for all strains of *C. difficile*, regardless of the presence or absence of toxin in stool samples (28). These

doi:10.1128/microbiolspec.GPP3-0015-2018

assays are often utilized as initial screening tools for the presence of C. *difficile* because they are quicker and more sensitive than toxin EIAs (29). However, GDH EIAs are not recommended as the sole form of diagnosis (30, 31).

CCNAs have historically been viewed as the "gold standard" of CDI detection because they can detect the presence of TcdA and TcdB at picogram levels (31, 32). Cell lines such as Vero (African green monkey kidney epithelial cells) and HT29 (human colorectal adenocarcinoma cells) are cultured in the presence of fecal filtrates, with and without toxin-neutralizing antibodies, and observed for characteristic toxin-induced cell rounding over 24 to 48 hours (33, 34). Although the sensitivity of these assays is very high, CCNAs are more expensive than EIAs and bacterial culture, can take between 72 and 96 hours to complete, and require a high level of technical expertise to perform, making them impractical for routine diagnostic use or during CDI outbreaks (35).

NAATs detect the presence of C. *difficile*-specific nucleic acid sequences in fecal samples, primarily through PCR amplification of conserved regions within the genes that produce TcdA and TcdB (35). In recent years, NAATs have been commonly accepted as the most sensitive form of diagnosis relative to the other methods discussed above and are increasingly used in hospitals despite being more expensive than bacterial culture and GDH EIAs (36). However, NAATs are less specific for CDI compared to CCNAs, because they detect toxin genes instead of active toxin within fecal samples and thus cannot differentiate between asymptomatic carriage of C. *difficile* and CDI, potentially leading to overdiagnosis and overtreatment (36, 37).

Due to the differing degrees of sensitivity and specificity between these individual diagnostic tests, a multistep algorithm is likely to be the most effective strategy for accurate CDI diagnosis and case surveillance. Guidelines released in 2016 for Europe and the United Kingdom recommend the use of the more specific TcdA or TcdB EIAs to confirm CDI in patients that initially yield a positive result for the more sensitive NAATs or GDH EIAs and suggest the consideration of other factors such as the onset of disease symptoms and progression prior to diagnosis and subsequent treatment of CDI (38). Correlating disease symptoms with positive molecular tests could prove vital for accurate CDI diagnosis, because asymptomatic C. *difficile* colonization in otherwise healthy individuals has been reported to be between 4 and 15% via PCR ribotyping and stool culture in geographically distinct regions (39–41). The use of such algorithms is proposed to provide a quicker and more accurate diagnosis of positive CDI cases and to decrease false-positive results. Importantly, reducing false-positive cases decreases the risk of susceptible patients being physically grouped together with true CDI patients in hospitals, thereby exposing them to C. *difficile* (36). This also prevents unnecessary antibiotic treatment for CDI, which may lead to the rise of multidrug-resistant organisms such as vancomycin-resistant enterococci (42). Overall, algorithm-based diagnoses provide a more accurate representation of C. *difficile*-induced diarrhea, although the composition of each algorithm may vary between hospitals (22).

Strain Typing

Typing of C. *difficile* isolates is essential for identifying the strains responsible for CDI outbreaks and for monitoring the spread and emergence of new strain types. Several typing schemes have been developed for C. *difficile*, utilizing the molecular and serological differences that exist between strains (43, 44). Although several schemes have been developed, in recent years molecular techniques, specifically PCR-based methodologies, have been favored due to their reproducibility and relative low cost (44).

With respect to the recent epidemic ribotype 027 strains, three molecular techniques have primarily been used in their typing (44). The first technique, restriction endonuclease analysis (REA), identifies ribotype 027 strains as the REA type BI (44). In this typing scheme, whole genomic DNA extracts are fragmented by the restriction enzyme *Hin*dIII, followed by agarose gel electrophoresis to separate the resulting DNA fragments (45). The banding pattern obtained is then compared to that of a reference strain, and the strain under question is typed accordingly, utilizing the results obtained through other typing methods to further confirm the strain type (45). The second technique uses pulsed-field gel electrophoresis and results in the ribotype 027 strain belonging to the NAP1 (North American pulsed-field type 1) pulsotype (44). This technique works in a similar way to REA, but it uses the *Sma*I or *Sac*II restriction enzymes to fragment whole genomic DNA, after which pulsed-field gel electrophoresis is performed (44). As with REA, analysis of the resulting banding pattern occurs through comparison to known reference strains, which is then used to classify each isolate (46). The third technique is ribotyping, which has become the typing method of choice in recent times because it is quick, sensitive, and reproducible, effectively distinguishing between different strain types (44, 47). Ribotyping relies on differences in the number of copies and overall length of the rRNA genes within the genome of C. *difficile* strains (47, 48). Due to these differences, amplification by PCR between the 16S and 23S rRNA intergenic spaces results in the production of distinct and characteristic banding or fingerprint patterns which are compared to those produced by reference strains to identify the ribotype to which each isolate belongs (48, 49). Over 400 ribotypes have been identified and, as with the other two typing schemes just described, comparative analysis between the typing schemes can be used to confirm each strain type (47–49).

In addition to the three major schemes used to type C. *difficile* strains, toxinotyping may be used to differentiate between strains (47). Toxinotyping assesses the genetic differences within a discrete 19.6-kb genomic region defined as the pathogenicity locus (PaLoc) (Fig. 1a), with a focus on the *tcdA* and *tcdB* genes, and a comparison is generally made to the PaLoc region of the reference strain VPI10463, which is classed as toxinotype 0 (50, 51). Toxinotypes range from I to XXXI, and new toxinotypes are frequently identified; some of these toxinotypes contain subsets which serve to subdivide toxinotypes with a small number of differences between them (52).

Another technique, multilocus sequence typing, analyzes several C. *difficile* housekeeping and toxin genes to define strains based on their sequence type, which characterizes C. *difficile* strains into 6 distinct phylogenetic clades: clades 1 to 5 and clade C-I (53–58). Each clade represents a variety of both toxigenic and nontoxigenic C. *difficile* isolates, from many different ribotypes (53–58). Clade 1 is the most diverse of the 6 clades, with over 100 sequence types, including several ribotypes of clinical significance, such as ribotypes 001, 012, and 014, which are frequently associated with CDI throughout Europe (59) and throughout Asia and the United States (60, 61). Clade 2 includes the epidemic ribotype 027 strains associated with recent outbreaks and the related ribotype 244, which has a variant TcdB that shows cytopathic effects more similar to *Paeniclostridium sordellii* (previously *Clostridium sordellii*) TcsL, and is associated with more

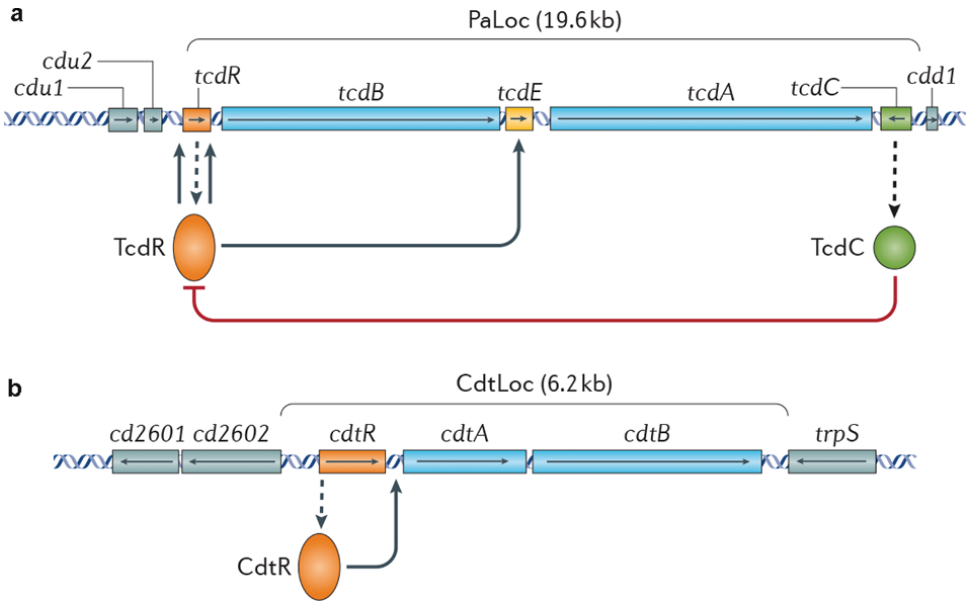

FIGURE 1 Schematic representation of the C. *difficile* pathogenicity locus (PaLoc) and C. *difficile* transferase locus (CDTLoc) and flanking genes. (a) The PaLoc chromosomal region is responsible for both the production and regulation of the major toxins TcdA and TcdB (encoded by *tcdA* and *tcdB*), which are critical for pathogenesis, virulence, and the disease symptoms of CDI. PaLoc also encodes genes involved in the positive (*tcdR*) and negative (*tcdC*) regulation of toxin production, as well as a gene (*tcdE*) encoding a holin-like protein, TcdE, which may be involved in the release of toxins from the cell. Nontoxigenic strains lack this region and are consequently avirulent. (b) The CDTLoc chromosomal region is responsible for both the production and regulation of CDT/binary toxin (encoded by *cdtA* and *cdtB*). CDTLoc also encodes a gene involved in the positive regulation of CDT (*cdtR*). Modified from *Nature Reviews Disease Primers* (8).

severe disease (62, 63). Analysis of clade 3 is less comprehensive, and it appears to be less diverse (62, 63). Clade 4 includes strains from ribotype 017, a $TcdA^{-}TcdB^{+}CDT^{-}$ variant strain that has caused significant disease throughout Asia, as well as being a predominant strain throughout Europe (64–68). Like the ribotype 244 TcdB variant, TcdB from ribotype 017 strains also has similarity to TcsL from *P. sordellii*, specifically in the enzymatic domain of the variant TcdB, which alters the cytopathic effects of the toxin (69). Clade 5 contains C. *difficile* strains from ribotype 078, a ribotype commonly associated with disease in animals, particularly livestock, including pigs and cows; however, in recent times ribotype 078 strains have also been associated with community-acquired cases of human CDI (59, 70, 71).

Clade C-I is a more significantly divergent clade than the other 5 clades and was originally thought to encompass several nontoxigenic strains; however, some recent variant toxigenic strains have been found to cluster with other clade C-I strains (56, 72). Recent work analyzing environmental C. *difficile* isolates has suggested a need for further classification of the clades, with the considerable divergence of clade C-I resulting in 3 distinct clades, C-I, C-II, and C-III (73). Strains belonging to clade C-I/II/III also show considerable divergence from the remaining 5 clades, which has brought into question if these strains are indeed C. *difficile* or if they represent a new species that is distinct from the other 5 clades (74).

Other typing schemes for C. *difficile* include multilocus variable-number tandem repeat analysis, whole-genome sequencing, and single nucleotide polymorphism analysis, all of which provide different genetic perspectives and degrees of sensitivity for strain typing (48). Use of the different typing schemes available for C. *difficile* has shown that a broad diversity of strains exists, and this is true for human clinical and animal isolates. In particular, whole-genome sequencing has provided new insights into the epidemiology and spread of C. *difficile* strains and has changed our understanding of the dissemination and transmission of this bacterium, allowing new and more effective infection control strategies to be developed (75).

EPIDEMIOLOGY

Over the last 2 decades the incidence of CDI has increased dramatically, correlating with the emergence of epidemic isolates of C. *difficile* in hospitals worldwide, in particular, ribotype 027 strains which have gained fluoroquinolone resistance (76). Nosocomial outbreaks of ribotype 027 C. *difficile* strains have undoubtedly contributed to the global increase in CDI rates (13, 77). In late 2002, an outbreak of C. *difficile* occurred in Quebec, Canada, which resulted in a dramatic increase in CDI rates (78). In Quebec, the overall incidence of CDI had increased nearly 4-fold from 1991 to 2003 (78). Furthermore, rates of infection in those above the age of 65 increased roughly 4-fold from 2002 to 2003 during the Quebec outbreak, which resulted in CDI rates increasing 8-fold from 1991 to 2003 in this age group (78). Complications from infection and mortality also increased during this time (78). The ribotype 027 strain responsible for the outbreak spread quickly, leading to several outbreaks across the United States, the United Kingdom, and Europe and highlighting the difficulty in containing CDIs and preventing the spread of disease (17, 77, 79). Interestingly, the increasing use of dietary trehalose has contributed to the dissemination of ribotype 027 strains because their ability to metabolize this

sugar may be an additional factor contributing to the changing epidemiology of this strain type (80).

REA and pulsed-field gel electrophoresis analysis of isolates collected from clinical outbreaks across the United States from 2000 to 2003 highlighted the prevalence of BI/NAP1/027 strains, with an average of 51% of isolates classified as belonging to this class (13). Although the current incidence of ribotype 027 strains appears to be declining in the United States, indicated by surveillance of 10 of the Centers for Disease Control and Prevention (CDC) Emerging Infections Program sites in 2011, the prevalence of this strain type remains high (81). In this study, ribotype 027 strains accounted for 20.6% of community-associated CDI and 33.9% of hospital-acquired CDI in the United States, with ribotype 002, 020, and 106 strains also contributing considerably to CDI, albeit at lower rates of 10 to 10.7%, 10.3 to 11.4%, and 4.3 to 7.6%, respectively (81). Nevertheless, infection rates and mortality resulting from CDI still remain high in the United States. In 2013, the CDC estimated that *C. difficile* caused 250,000 infections per year and 14,000 deaths in the United States, but these numbers are likely underestimates (18). Estimates from CDC data in 2015 by Lessa et al. suggest that over 450,000 CDIs occurred in the United States, accounting for over 29,000 deaths annually (81). The disparity between the two estimates highlights an ever-growing need for more stringent detection of infections and subsequent analysis of CDI rates.

Similar to the United States, in the United Kingdom *C. difficile* disease rates were reported to be four times greater than those seen in the late 1990s in both England and Wales, reaching a peak between 2007 and 2010 and coinciding with outbreaks of ribotype 027 strains (82–84). From late 2003 to 2005, two severe and devastating outbreaks of *C. difficile* were documented in the Stoke Mandeville Hospital in England, in which a total of 334 cases of CDI were recorded, resulting in 38 fatalities (85). Strain R20291 was isolated during this outbreak and was identified as a ribotype 027 strain (86). These outbreaks were associated with several contributing factors, including insufficient isolation of infected individuals and poor implementation of infection control measures and practices by staff, which would have minimized and prevented *C. difficile* spread and contamination (85). In the years following this outbreak, rates of CDI appeared to be declining in the United Kingdom, from 164.8 deaths per million people in 2008 to 34.3 deaths per million people in 2015, as a result of increased awareness and infection control management; however, infections and mortalities resulting from CDI still occur at high rates in the United Kingdom (82).

Several other European countries, including France, Germany, and the Netherlands, have experienced similar recent outbreaks of *C. difficile*, with ribotype 027 strains found to be prevalent during these outbreaks (87, 88). Although ribotype 027 isolates are still highly prevalent throughout Europe, accounting for 19% of the reported CDIs, a wide diversity of *C. difficile* ribotypes also contribute to these infections, highlighting the diverse global epidemiology of *C. difficile* (89). The diversity of *C. difficile* throughout Asia is dramatically different and is dominated by a high number of variant *C. difficile* strains, in particular, ribotype 017 *C. difficile*, a $TcdA^{-}TcdB^{+}CDT^{-}$ variant strain which, for example, comprises up to 40% of all strains isolated in Korea and China (65, 67, 68, 90).

Although *C. difficile* is an important nosocomial pathogen, it can also cause community-acquired infections, which occur without recent exposure to *C. difficile* during hospitalization or during a hospital stay. Interestingly, community-acquired CDIs often occur without the presence of risk factors commonly associated with nosocomial CDI, such as advanced age or prior antibiotic use (8, 70). Furthermore, community-acquired CDI rates appear to be on the rise, accounting for 20 to 27% of all CDI cases, with an increasing number of cases detected in the United States and Europe (70). Although ribotype 027 strains do contribute to community-acquired CDI, other isolates, including ribotype 078 strains which are often isolated from pigs and cows, also contribute to community-acquired CDI in high numbers (59, 70, 71). This may be linked to the shedding of spores within feces of livestock and domesticated animals, which contributes to the transmission and spread of disease from animal to animal (91) and may also aid in potential zoonotic transmission from animals to humans (92). This potential zoonotic transmission probably occurs via the ingestion of spore-contaminated meat products derived from *C. difficile*-infected livestock (92). In the United States, *C. difficile* spores have been detected in up to 42.4% and 41.3% of tested beef and pork products, respectively, with ribotype 078 and 027 strains being isolated in high frequencies from these samples. Similar *C. difficile* spore contamination of meat products occurs in Canada, albeit at lower levels, with levels of detection ranging from 6.1 to 20% for beef and 1.8 to 12.2% for pork products (93). Detection of *C. difficile* spores in meat products throughout Europe is considerably lower, with less than 5% of tested samples yielding a positive *C. difficile* culture (93). Nevertheless, detection of *C. difficile* spores within retail meat products has the potential to aid in transmission from animal to human host and may account for the emergence of typically animal-associated *C. difficile* strains in humans (70, 71).

PATHOGENESIS

Susceptibility to CDI

Following the ingestion of *C. difficile* spores, infection may be established within the host upon spore germination and vegetative cell colonization of the colon (94). However, susceptibility to colonization and disease is generally not seen in healthy individuals who have an established and diverse gastrointestinal microbiota, which provides a physical barrier to colonization and contributes to the induction and maintenance of a protective immune response to invading pathogens (95–97). The commensal microbiota provides colonization resistance by occupying and interacting with the colonic niche but becomes disrupted in individuals undergoing antibiotic treatment (98).

A number of factors may contribute to reduced colonization resistance in antibiotic-treated hosts. Disruption to the microbiota may change the nutrient profile within the gastrointestinal tract, which may create a niche that is more suitable for *C. difficile* (99). Furthermore, with reduced microbiota-mediated priming of the innate immune system following antibiotic disruption, recognition of invading pathogens such as *C. difficile* may be compromised, thereby increasing host susceptibility to opportunistic infection (98). Under normal conditions when the microbiota is intact, immune responses occur within the host which promote the production of several gastric and immune molecules, including mucus/mucin and antimicrobial peptides such as defensins and immunoglobulin A (IgA), which help to prevent gut colonization by pathogens (98). Although significant disruption of the host microbiota may occur following multiple doses of antibiotics, a single dose is sufficient to "shift" the microbiota and promote CDI (98, 100). For example, depletion of the microbiota can change the cleavage of sugar substrates within the gut, resulting in higher

levels of sialic acid and succinate, promoting the growth of *C. difficile* (99). Antibiotic resistance of *C. difficile* strains exacerbates this problem, as has been seen with fluoroquinolone resistance in the epidemic ribotype 027 strains following the overuse of this group of antibiotics (101).

Colonization and infection with *C. difficile* occurs in people from a range of age groups, but increased risk of infection, infection rates, and disease severity occurs in elderly and in immune-compromised patients (23, 76, 102). *C. difficile* often presents as a nosocomial infection and is the leading cause of infectious AAD, accounting for about 25% of all cases (21). More recently, substantial increases in CDI rates have been recorded, with the persistence of *C. difficile* in hospitals and spore-mediated transmission likely to play a fundamental role in this phenomenon (13, 76). In addition to this, rates of community-acquired CDI are also increasing and often occur in patients that are not typically at risk of infection such as children, pregnant women, and individuals with no recent antibiotic use (8, 70).

Disease Associated with CDI

CDI is associated with a variety of disease symptoms, ranging from asymptomatic carriage of *C. difficile* to severe and life-threatening disease complications (2). The spectrum of disease that is observed in CDI patients begins as mild diarrhea and may increase in severity with the progression of infection. Mild diarrhea associated with CDI often resolves following the cessation of antibiotic therapy; however, it may progress to severe diarrhea, leading to dehydration and mild inflammation of the colon with the possible development of fever (103). The progression of disease in severe cases of CDI may lead to the development of pseudomembranous colitis, with toxin-mediated damage resulting in the formation of plaques throughout the colon, consisting of cellular debris, fibrin, and neutrophils (104). Patients may also present with fever, abdominal pain, and elevated white blood cell counts (104).

A rare yet significant complication of severe disease is toxic megacolon, which results in detrimental inflammation and swelling of the colon, colonic perforation, sepsis, and in many individuals, death (105). Disease complications may be compounded by the onset of multiple organ dysfunction syndrome, promoting patient fatality (106). This syndrome can be defined as "the development of potentially reversible physiologic derangement involving two or more organ systems not involved in the disorder that resulted in ICU admission," which includes damage to the lungs, kidneys, heart, liver, or brain (107). Extraintestinal infections may occur following CDI, presenting as abdominal abscess and wounds, ascites, bacteremia, brain abscess, catheter infection, perianal abscess, peritonitis, and toxemia (106, 108–110). Recent work by Carter et al. (111) has shown that damage and architectural disorganization occurs in the kidneys, lymph nodes, spleen, and thymus during murine CDI. Toxemia, or escape of toxins into the blood, in *C. difficile*-infected piglets has also been shown to result in systemic pathologies of the lungs, which seemingly occurs via TcdB-mediated damage of the colonic epithelium, because neutralizing antibodies to TcdB, but not TcdA, were able to block colonic damage and systemic pathology progression (112). Although this level of disease severity is considered rare in humans, the increasing incidence of CDI and the more severe disease symptoms associated with ribotype 027 strain infections has resulted in more cases involving life-threatening complications (105).

Disease in *C. difficile*-infected animals shares many of the characteristics seen in human disease. One of the most well-characterized CDI-associated diseases in animals is *C. difficile*-associated enteritis in piglets (113). As in humans, CDI often leads to diarrhea in piglets, which may be yellow and pus-like, and may progress into severe life-threatening disease (113). As a result of these disease symptoms, weight-loss, difficulties digesting food, dehydration, and weakness often occur, which over time may result in piglet death (114). On examination of the colon tissue, swelling and edema of the epithelium may also be observed, with colonic dilation and hemorrhage also common (114). As seen in humans, neutrophil infiltration and pseudomembranous formations throughout the colon are common, particularly in severe enteritis (114). Disease in animals is not restricted to pigs, with infection and disease occurring in other animals including horses, cows, and domesticated dogs, as well as exotic and wild animals including penguins and elephants (115–117).

Animal Models of CDI

Studies of *C. difficile* and CDI have used specific animal models to provide key insights into the role played by virulence factors in disease pathogenesis (33, 118, 119). The hamster model of *C. difficile*-associated disease was used extensively in early research because of the sensitivity of hamsters to the *C. difficile* toxins, with infections almost always resulting in hamster death (120). Most other animals (including humans) are not as sensitive to the effects of the toxins (120); thus, the extreme sensitivity of hamsters to the *C. difficile* toxins has prevented the more subtle aspects of infection and disease from being teased out. The use of hamsters in infection studies is also limiting because of a lack of reagents such as specific antibodies, or hamster genetic variant strains, making more detailed research using this animal model difficult (120).

The more recent development of a murine model of CDI by Chen et al. in 2008 (120), which mimics *C. difficile* susceptibility and disease in humans, has overcome many of the limitations associated with the hamster model of CDI (121). The murine CDI model provides the opportunity to analyze *C. difficile* disease from a new and more detailed perspective (120). In the model by Chen et al. mice are pretreated with an antibiotic cocktail prior to infection challenge and, following infection, animals develop many of the characteristic disease pathologies associated with clinical CDI, including diarrhea and weight loss (120). Infection also induces severe colonic pathology, with epithelial damage, submucosal inflammation, and neutrophil influx seen, similar to human disease, further supporting the utility of this model in developing a better understanding of *C. difficile* disease (120). *C. difficile*-infected mice also succumb to disease quickly and exhibit observable signs of disease 2 to 3 days postinfection. This model of CDI and the availability of reagents and genetically manipulated mice has facilitated recent studies focused on defining the contribution of key immune pathways to *C. difficile* disease, which are described in more detail below, providing important new insights into the progression of CDI and the host response (120, 122–125).

Following the development of the Chen et al. model, additional murine models of CDI were developed which utilize different pretreatment regimes and result in different disease pathology and outcomes (126). In 2009, Lawley et al. developed a less severe CDI model through disruption of the intestinal microbiota via oral administration of clindamycin for four consecutive days prior to infection (122). Infection in these mice was established following exposure to "carrier state" mice, which were induced to carry *C. difficile* in their

microbiota through the administration of neomycin 24 hours prior to challenge. Mice infected with *C. difficile* in this model show some weight loss, diarrhea, and damage to the intestinal epithelium, albeit at lower levels than in the Chen et al. model (122). In 2012, Buffie et al. showed that a single dosage of clindamycin by intraperitoneal injection was sufficient to induce CDI with disease pathology and outcome similar to the other models (127). The third murine CDI model, developed by Theriot et al. in 2011, induces *C. difficile* susceptibility through the oral administration of cefoperazone for 10 days, 12 days prior to infection (128). Dependent on the *C. difficile* strain and dosage used for infection, mice developed severe disease within 2 days of infection, characterized by weight loss, diarrhea, and damage/inflammation of the intestinal epithelium (128). More recently, the oral administration of either metronidazole or streptomycin to mice has been shown to induce susceptibility to CDI, allowing for high levels of *C. difficile* colonization (129). Gnotobiotic mice, which are void of colonic microbiota, have also been used to model CDI, presenting similar disease profiles to the aforementioned models; however, since a complete lack of colonic microbiota is unlikely in human CDI, this model does not accurately represent human CDI (130). More recently, a mouse model of CDI has been established in mice with humanized microbiota, allowing for the analysis of disease under conditions more similar to human CDI (131). Together, these different murine models of CDI have provided valuable insights into CDI and disease progression under different circumstances and conditions.

Other *C. difficile* disease models include the porcine model, which emulates human disease symptoms and severity and which has provided new insights into the understanding of *C. difficile* disease (114). Through the infection of gnotobiotic piglets with *C. difficile* spores, Steele et al. (114) were able to replicate natural *C. difficile* disease, with infected pigs developing diarrhea 48 hours after infection. Severe colonic pathologies and lesions were also observed, leading to the formation of pseudomembranes in some animals, much like those seen during severe CDI in humans. With these similarities to human disease, this model provides a valuable resource for the development of our understanding of CDI and provides an appropriate model for the testing of potential therapeutics and treatments for CDI (114).

C. difficile Toxins

TcdA and TcdB

Several *C. difficile* virulence factors have been identified, the most important of which are TcdA and TcdB (33, 111, 118, 132). Typically, the 19.6-kb PaLoc encodes both the *tcdA* and *tcdB* genes, producing TcdA (308 kD) and TcdB (270 kD), respectively, and also encodes genes involved in the positive (*tcdR*) and negative (*tcdC*) regulation of toxin production (Fig. 1a) (133, 134). TcdR is an alternative RNA polymerase sigma factor, which shares similarity to the alternative sigma factors BotR in *Clostridium botulinum* (135), TetR in *Clostridium tetani* (136), TpeR and UviA in *Clostridium perfringens* (137–139), and TcsR in *P. sordellii* (140). TcdR positively regulates the transcription of *tcdA*, *tcdB*, and *tcdR*; however, this process is influenced by various environmental stimuli, including changes in the metabolism of amino acids via CodY (141) and carbon sources such as glucose via CcpA (142). Other regulatory proteins involved in aspects of the *C. difficile* life cycle, including Spo0A, a master regulator of sporulation, and SigD, a regulator of flagella, also regulate toxin transcription (143, 144). TcdC is an anti-sigma factor, which is thought to negatively regulate toxin transcription by disrupting the function of TcdR, but this occurs with considerable variability across different strain backgrounds (145–147). PaLoc also carries a gene (*tcdE*) encoding a holin-like protein, TcdE, which may be involved in the release of toxins from the cell, but this hypothesis is contentious (148–150). Variants of the *C. difficile* PaLoc exist, which contain mutations or deletions within the locus, altering the toxin profile of these strains (72). More recently, the PaLoc has been found in alternate genomic locations in specific strains, although such strains do not appear to be common (72).

TcdA and TcdB are members of the large clostridial glucosylating toxin family, members of which are also found in several other pathogenic clostridia (132). These include the hemorrhagic (TcsH) and lethal (TcsL) toxins produced by *P. sordellii* (151), α-toxin (TcnA) produced by *Clostridium novyi* (152), and TpeL produced by *C. perfringens* (153), all of which function in a similar way to the *C. difficile* toxins and inactivate Rho, Rac, or Ras small GTPases. These small GTPases play a vital role in maintaining cellular architecture and are involved in the maintenance of the actin cytoskeleton, cellular migration, and division (154). Inactivation of these small GTPases via the covalent transfer of a glucose moiety by one of the large clostridial toxins, or an acetylglucosamine moiety only by TcnA and TpeL, leads to the disruption of their normal function and consequently results in cell rounding and cell death (152, 153, 155, 156).

TcdA and TcdB, which have 63% amino acid similarity, share an overall conserved structure (Fig. 2), with four functional domains that are involved in cellular binding, entry, and enzymatic activity of the toxins (157–159). The C-terminal ends of TcdA and TcdB, consisting of the combined repetitive oligo-peptides (CROPS) domain, are thought to facilitate receptor binding for each toxin (157); however, toxins which lack this domain can still induce cell rounding in tissue culture, suggesting that there are CROPS-dependent and -independent receptor binding regions within each toxin (160–165). CROPS-mediated receptor binding has been shown to increase TcdA-mediated cytotoxicity compared to a CROPS deletion mutant (165), while recombinant C-terminal-TcdA (REP321) blocks cytotoxicity in F9 cells when used to saturate the cell surface prior to intoxication (166). Immunization of mice with REP231 also protected mice against subcutaneous lethal dosing with TcdA (166), highlighting the importance of the CROPS in receptor binding and cell entry. Several receptors have been proposed for TcdA, including the α-Gal-(1,3)-β-Gal-(1,4)-β-GlcNAcO$(CH_2)_8CO_2CH_3$ carbohydrate moiety (167) and glycoprotein 96 (gp96) (160) on human cells, but the exact mechanism of binding still remains unclear. Three potential host receptors have been identified for TcdB: poliovirus receptor-like protein 3 (162), chondroitin sulfate proteoglycan 4 (161), and members of the frizzled family receptors (163). Binding to these receptors occurs in a CROPS-independent manner at regions adjacent to the CROPS domain; however, further *in vivo* characterization of the role for these receptors in CDI is required (161–164). Thus, it appears that receptor-mediated binding of TcdA and TcdB is a complex process involving multiple binding regions within the C-terminal portion of each toxin, which interact with an array of receptors that are not yet fully characterized.

Following receptor binding, both TcdA and TcdB enter the cell via clathrin-mediated endocytosis, with acidification of the endosome resulting in a conformational change in the pore-forming domain of the toxin, allowing insertion of the toxin into the membrane and facilitating toxin entry into

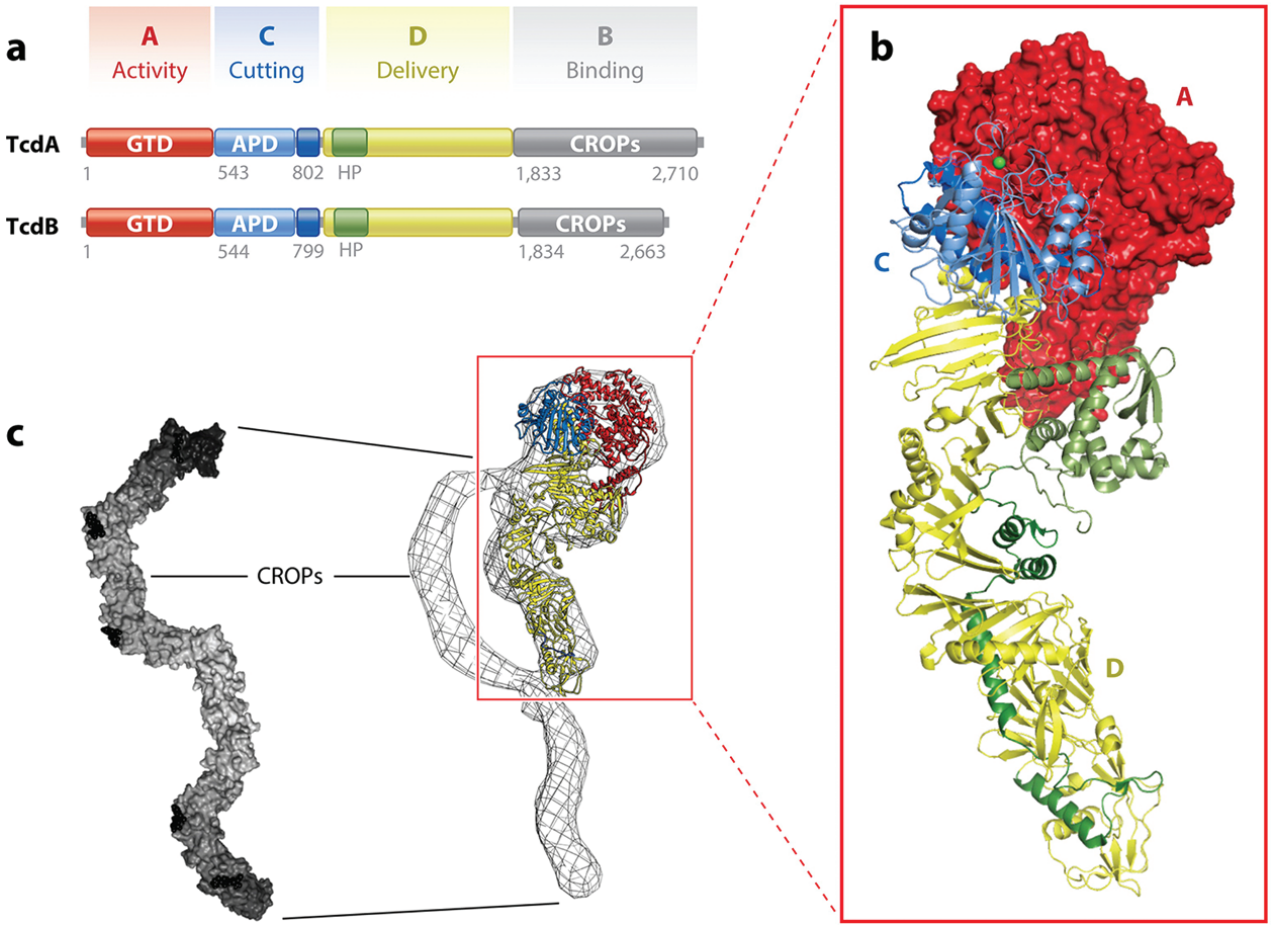

FIGURE 2 Schematic representation of C. *difficile* TcdA and TcdB. (a) Comparison of TcdA and TcdB functional domains. Comparison of the four functional domains of the toxins, including the glucosyltransferase domain (GTD) (red), auto-protease domain (APD) (blue), delivery domain (yellow), and combined repetitive oligo-peptides (CROPS) domain (gray). (b) The crystal structure of the TcdA GTD (red), APD (blue), and delivery domains (yellow) in the absence of the binding domain. (c) Three-dimensional structure of TcdA, superimposed with the crystal structure of TcdA. Reprinted from *Annual Review of Microbiology* (254).

the cytosol (Fig. 3) (157, 168). Once translocated across the endosomal membrane, the glucosyltransferase domain (GTD) of each toxin is cleaved off by the auto-protease domain, following activation of this domain by host inositol hexakisphosphate (InsP6), which releases the enzymatic GTD into the cytosol (169, 170). Once in the cytosol, the GTD then inactivates host cell Rho family GTPases. A conserved tryptophan residue at amino acid position 102 and a DXD motif at position 286 to 288 are located in the GTD of TcdA and TcdB and are essential for binding to UDP-glucose and for the catalytic function of the monoglucosyltransferase domain (171). Inactivation of Rho family GTPases induces cell rounding and death (172). These outcomes occur because of a lack of regulation in actin polymerization within the intoxicated cell, resulting in the disruption of a number of essential host cell features, including the actin cytoskeleton, stress fibers, and tight junctions (173). TcdB has also been shown to promote the formation of NADPH oxidase complexes, releasing reactive oxygen and leading to necrotic cell death (174). TcdB from ribotype 027 strains appears dissimilar to historical TcdB in some aspects, with variations in the CROPS domain (175). The differences between the binding domains of ribotype 027 TcdB and historical TcdB are thought to provide an increase in tissue tropism, because ribotype 027 TcdB induced more severe and extensive pathologies when used to treat embryonic zebra fish (175). Specifically, ribotype 027 TcdB displayed increased cardiotoxicity, resulting in severe cardiac damage and necrosis after 24 hours compared to historical TcdB in this model, which induced swelling and bleeding of the cardiac tissue at a slower rate (175).

Recent work by Chumbler et al. (176) has also shown that TcdA and TcdB induce cell damage in distinct ways, with TcdA inducing apoptosis via glucosyltransferase activity and TcdB via two modes of action that are dependent on toxin concentration. At low concentrations, TcdB induced apoptosis in young adult mouse colonic cells, in a similar way to TcdA (176). Unlike TcdA, which only induced apoptosis, high concentrations of TcdB (≥100 pM) induced necrosis, which, from analysis using an enzymatically inactive TcdB, occurs independently of glucosyltransferase activity (176). Despite these insights, the exact mechanism for the vastly different roles of TcdA and TcdB in disease still remains unclear. Notably, TcdB has a substantially smaller CROPS domain than TcdA, which may confer a largely different three-dimensional structure, as depicted in modeling of the CROPS region from smaller crystalized fragments (Fig. 4) (157, 177). The difference in physical size between these
