FIGURE 3 Binding and entry of *C. difficile* toxins into colonic epithelial cells. TcdA and TcdB bind to the cell surface via interaction of the binding region and one or more cell surface receptors, including the α-Gal-(1,3)-β-Gal-(1,4)-β-GlcNAcO$(CH_2)_8CO_2CH_3$ carbohydrate moiety and glycoprotein 96 (gp96) or surface receptors including frizzled (FZD), chondroitin sulfate proteoglycan 4 (CSPG4), and poliovirus-like receptor 3 (PVLR3) respectively, resulting in receptor-mediated endocytosis. Binding can occur via CROPS (green)-dependent and -independent mechanisms. Once internalized, the endosome acidifies, resulting in a conformational change and membrane insertion of the delivery domain and translocation of the auto-protease domain (APD; gray) and glucosyltransferase (GTD; red) into the cytosol. The APD then interacts with host inositol hexakisphosphate (InsP6; blue), cleaving the GTD, which can interact with the Rho family of GTPases. Reprinted from *Annual Review of Microbiology* (254).

domains may account for some of the disparity in disease associated with the two toxins, either altering the binding of each toxin to its receptors or resulting in steric hindrance differences which may influence functional capacity within the complex gastrointestinal compartment.

The role of TcdA and TcdB in the development and progression of *C. difficile* disease has been contentious. Early research in this area, involving the intragastric administration of TcdA and TcdB to hamsters, suggested that TcdA was the major virulence factor in the development of severe *C. difficile* disease, with TcdB thought to be unable to induce disease in the absence of TcdA despite being a potent cytotoxin in cell-based *in vitro* assays (119). In hamsters, toxin coadministration, using sublethal doses of TcdA together with TcdB, was able to induce severe disease symptoms, indicating possible synergy between TcdA and TcdB (119). Similar results were seen in a rabbit ileal loop model, where exposure to TcdA but not TcdB was able to induce intestinal hemorrhage, fluid secretion, and inflammation (4). However, the isolation of clinical *C. difficile* variant strains that encoded only TcdB suggested that, at least in humans, TcdB alone is sufficient to induce disease, raising questions about the clinical relevance of previous studies using purified toxins (178, 179). Early studies did not assess the role of the toxins in the context of infection but instead used purified toxins and the intragastric administration of the toxins to animals to a site that is not where colonization and infection occur. A true representation of CDI and disease was therefore not achieved in these studies.

More recently, multiple laboratories have used various CDI animal models together with genetically engineered isogenic *C. difficile* toxin mutants to elucidate the role of TcdA and TcdB in disease. Each of these studies, which utilized hamsters and mice together with historical or epidemic *C. difficile* isolates and their isogenic toxin gene mutants, showed that TcdB induced severe disease in both the absence and presence of TcdA, highlighting the important role that TcdB plays in disease (33, 111, 118, 180). Although these studies have redefined TcdB as a key mediator of *C. difficile* disease, the role of TcdA in disease remains somewhat unclear. In two of the studies, TcdA was shown to have a minor role in disease, with hamsters or mice infected with TcdA-producing ($TcdA^+B^-$) strains not progressing to severe diarrhea or mortality and with mild pathology and damage seen in mouse colonic tissue (111, 118). In the other two studies, TcdA appeared to have a more intermediate role in disease, with $TcdA^+B^-$*C. difficile* strains inducing some disease or mortality but at a slower rate in comparison to the wild-type (WT) and $TcdA^-B^+$ strains (33, 180). Nevertheless, a key finding from these studies was that TcdB plays a

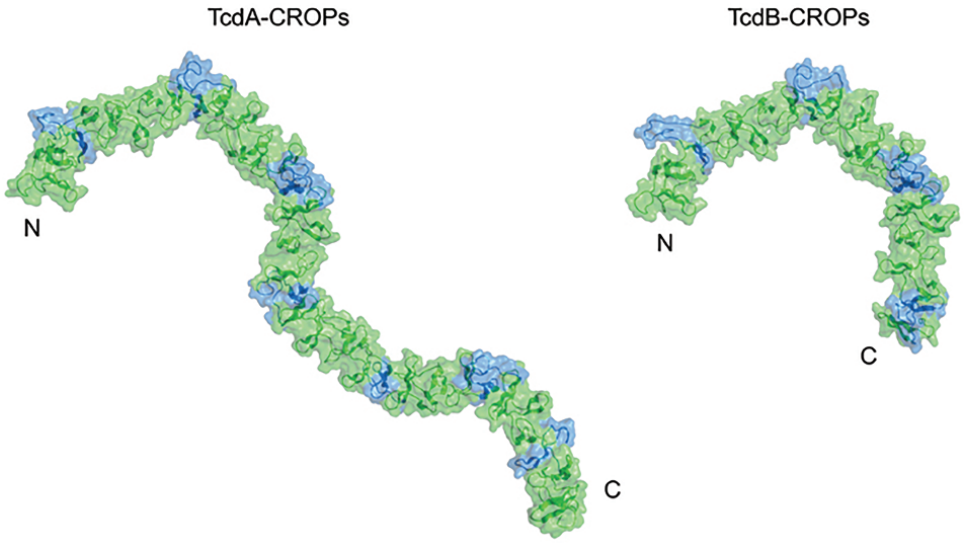

FIGURE 4 Comparison of the TcdA and TcdB combined repetitive oligopeptides (CROPS) domains. Three-dimensional models of the TcdA and TcdB CROPS domains based on the crystal structure of a 127-amino acid fragment from the C-terminal region of TcdA characterized in reference 177. Long repeats are in green; short repeats are in blue. N, N terminus; C, C terminus. Modified from *Frontiers in Cellular and Infection Microbiology* (157).

key role in disease, which is supported by the high number of clinical $TcdA^{-}B^{+}$ *C. difficile* strains that are isolated from patients with CDI, which currently comprise between 0.2 to 40% of all strains isolated, dependent on geographical location (64–68, 90). The recent emergence of a single $TcdA^{+}B^{-}$ *C. difficile* isolate is interesting since historically no such strains have been isolated; the clinical importance of this strain type remains to be determined, but future epidemiological tracking will be important to determine if such a strain type disseminates further (72).

C. difficile transferase

Some *C. difficile* strains, including ribotype 027 strains, produce a third toxin known as binary toxin or *C. difficile* transferase (CDT) (77, 181). CDT is an ADP-ribosyltransferase encoded by a 6.2-kb chromosomal locus, defined as the CdtLoc, which is independent of the PaLoc region (Fig. 1b) (77, 182, 183). CDT shares similarity with other clostridial binary toxins including *C. botulinum* C2 toxin, *C. perfringens* iota toxin and the *Clostridium spiroforme* CST toxin (184, 185). The locus encodes the *cdtA* and *cdtB* genes, which produce the enzymatic (CDTa) and binding (CDTb) components of the toxin, respectively. Similar to other clostridial binary toxins, CDTb is proteolytically activated prior to oligomerization into a predicted heptamer, which may occur prior to attachment to the cell surface via lipolysis-stimulated lipoprotein receptor or upon monomer binding (185). Once oligomerized, CDTa may bind, allowing for entry into the cell via endocytosis (185). Upon endosome acidification, CDTa is translocated into the cytosol, where it ADP-ribosylates actin, disrupting the cell cytoskeleton and inducing microtubule protrusions in intoxicated cells (181).

CDTLoc also encodes *cdtR*, producing CdtR, an orphan LytTR family response regulator responsible for regulation of CDT production (Fig. 1b) (183, 186). Interestingly, CdtR has recently been shown to also regulate the production of TcdA and TcdB in some strains of *C. difficile*, because insertional inactivation of *cdtR* resulted in reduced levels of TcdA/TcdB production and significantly reduced virulence in a mouse model of CDI (187). Although CdtR appears to regulate toxin production and virulence in some CDT-producing strains, the exact role of CDT in disease remains unclear.

Overall, CDT was found to be present in approximately 5% of historical isolates, but the prevalence of this toxin in *C. difficile* has steadily increased over the last 2 decades, with CDT detected in clinical strains at levels ranging from 17 to 45% (185). CDT was found to be highly prevalent in animal strains and is encoded by 23 to 100% of such isolates (92, 183). Importantly, CDT is also now found in approximately one-third of human clinical isolates (187, 188). CDT alone was thought to be unable to induce disease since clinical isolates producing only CDT, but not TcdA or TcdB, were unable to induce diarrhea or death in hamsters (189). However, the isolation of clinical strains that only produce CDT has raised questions about the role of this toxin in disease.

Since infection with strains producing only CDT and not TcdA or TcdB appears able to induce diarrhea in some patients, the role of this toxin in disease is still unclear (190). It may be that CDT acts synergistically with TcdA and TcdB to promote colonization and induce severe disease (181, 189, 191). Work by Schwan et al. (181) suggests that CDT may act as a colonization factor by inducing the formation of microtubule structures at the host cell surface, aiding in the adherence of the bacterium to the host cell. CDT also appears to increase the virulence of a TcdB mutant of strain R20291 in a hamster model of disease, but the mechanism by which this occurs is unknown (180). Recent work by Cowardin et al. (191) has also shown that CDT can enhance virulence to some degree, with CDTa mutants of two *C. difficile* isolates and a single CDTb mutant inducing less severe disease than the WT strains in a mouse model of CDI. This difference in disease profile associated with the CDT mutants was linked with increased levels of eosinophils in the colons of mice infected with the CDTb mutant of strain R20291 and suggests that eosinophils may play a protective role in CDI (191). Thus, it appears that CDT may play a synergistic role

with TcdA and TcdB to enhance virulence by decreasing eosinophil recruitment. Analysis of eosinophil involvement in disease progression in naturally occurring CDT-negative strains has yet to be investigated, and may provide further insights into this phenomenon. With the prevalence of CDT-positive animal isolates and the increasing emergence of these CDT-positive strains in humans (185), the enhanced virulence associated with CDT could have severe consequences on disease profiles and severity.

Immune Response to *C. difficile*

Our current understanding of the role of the host immune system during CDI is limited, particularly with respect to the cytokine response and the changes that occur to immune cell populations in gut tissues during infection in response to each toxin. Clinical observations show that humoral immunity is induced during CDI, specifically, increased levels of IgG and IgM are detected in response to infection with strains producing TcdA and TcdB and in response to nontoxin antigens (192, 193). An additional hallmark of CDI seen in humans, mice, and pigs is an abundant influx of polymorphonuclear leukocytes into infected gut tissues (114, 120).

Cytokine and Chemokine Responses to Toxins

The immune response to *C. difficile* and its toxins has been previously investigated, but most of this work was performed through the application of purified toxins or *C. difficile* antigens to cell lines or rabbit and mouse ileal loop models (194–200). In several studies, purified TcdA was shown to induce the release of the key neutrophil and monocyte chemoattractants interleukin 8 (IL-8) and monocyte-chemoattractant protein 1 from HT-29 cells, a human colonic adenocarcinoma cell line (195, 201, 202), and T84 cells, a human intestinal epithelial cell line (197, 201). TcdA also induced tumor necrosis factor α (TNF-α) release in murine and human monocytes (198, 203), and TcdA stimulation of human monocytes induced IL-1 and IL-6 production (203). Purified TcdA has also been shown to induce the synthesis and release of IL-8 in a human xenograft ileal loop intoxication model (199). Exposure of tissues in a mouse ileal loop intoxication model to purified TcdA also promotes the transcription of proinflammatory cytokines and chemokines, including interferon-γ, macrophage inflammatory protein 1α (MIP-1α), MIP-2, and TNF-α (200), and in a rat ileal loop intoxication model, MIP-2, within 2 to 6 hours of toxin exposure (194). When injected directly into the cecum, TcdA also alters the expression of several chemokines involved in neutrophil chemotaxis, including chemokine (C-X-C motif) ligand 1 (CXCL1), IL-1β, and IL-6 (204, 205). Taken together, these data suggest that the production of TcdA during infection will alter the cytokine milieu to induce a highly inflammatory environment, most likely contributing to the inflammatory pathology observed during CDI. However, infection studies of the immune response that occurs with strains that only produce TcdA have not been performed.

Less is known about the immunomodulatory role of TcdB compared to knowledge of this role for TcdA. TcdB can induce IL-8 release in a human xenograft ileal loop model (199), IL-1β release in a mouse ileal loop model (196), TNF-α in rat macrophages (206), and TNF-α, IL-1, and IL-6 production in human macrophages (203). TcdB has also been shown to induce IL-1β via the pyrin inflammasome in mouse bone marrow-derived macrophages (207). As for TcdA, infection studies on the immune response that occurs with TcdB-producing strains in the absence of the other toxins have not been performed.

Cytokine and Chemokine Responses to Nontoxin Antigens

Nontoxin antigens of *C. difficile* have also been investigated for their role in the induction of the host immune response. A recent investigation into the interaction between nontoxin *C. difficile* antigens, including surface layer proteins (SLPs), flagella, and heat shock proteins 42 and 60, isolated from several *C. difficile* isolates, and the human macrophage cell line THP-1 showed that a number of proinflammatory cytokines were induced (208). These nontoxin antigens were isolated from a diverse group of strains belonging to ribotypes 012, 087, 027, 011, and 106, and antigens from all isolates promoted IL-1β, IL-6, IL-8, IL-10, IL-12p70, and TNF-α synthesis in THP-1 cells, to similar levels (208). However, a comparison to an untreated control was not included in this study (208); these results therefore require validation through additional research. SLPs isolated from *C. difficile* strains have also been shown to induce the release of several cytokines, including IL-1β, IL-6, IL-10, IL-12, IL-23, monocyte-chemoattractant protein, MIP-2, and TNF-α (125, 209–211). *C. difficile*-mediated cytokine induction during infection is not the result of toxin action alone and results from stimulation of the host immune response to numerous *C. difficile* factors. Further investigation of these effects is clearly needed.

Immune Response During CDI

The role of myeloid differentiation factor 88 (MyD88), an adaptor molecule critical for Toll-like receptor (TLR) signaling, in CDI was assessed using $MyD88^{-/-}$ mice (122). When compared to WT ($MyD88^{+/+}$) mice, $MyD88^{-/-}$ mice infected with *C. difficile* strain M68, a TcdA- and TcdB-producing virulent human isolate, developed more severe disease with pronounced weight loss and a moribund appearance, together with edema and epithelial hyperplasia detected upon microscopic examination of cecal tissues. Furthermore, the survival rate of $MyD88^{-/-}$ infected mice was significantly less than WT infected mice, with 48% of the $MyD88^{-/-}$ infected mice not surviving the infection, compared to 100% survival in the WT mice (122). Considering the critical role that MyD88 plays in the downstream signaling of several TLRs and nuclear factor-κB activation, it is not surprising that infected $MyD88^{-/-}$ mice developed more severe disease pathology (212). This important study confirmed the critical role that the innate immune system plays in CDI, providing an appropriate platform on which to base other studies of the immune response to CDI.

Building on the MyD88 studies, recent investigations have explored the mechanism by which MyD88 deficiency increased disease severity and mortality during CDI (213). A detailed analysis of cecal and colonic histopathology of WT ($MyD88^{+/+}$) and $MyD88^{-/-}$ mice following *C. difficile* challenge was performed, which showed a significant reduction in neutrophil and monocyte infiltration into the colonic lamina propria of $MyD88^{-/-}$ mice (213). Furthermore, $MyD88^{-/-}$ mice had impaired CXCL1 transcription, which is an important observation since CXCL1 is a mouse homologue of the human chemokine IL-8, which is responsible for neutrophil trafficking (213). To study the role of neutrophils in CDI, neutrophils were depleted from mice by injection of a neutrophil-specific, Ly6G monoclonal antibody 1A8 (213). Mice depleted of neutrophils showed a 70% mortality rate

following C. *difficile* challenge compared to 25% mortality in mice with intact neutrophils (213). By contrast, little mortality was observed in C-C chemokine receptor type 2-deficient mice ($CCR2^{-/-}$, which are deficient in monocyte chemotaxis) infected with C. *difficile*, suggesting that CCR2 and, in turn, monocyte recruitment, are not important for protection from fulminant C. *difficile* disease progression (213). Collectively, these results suggest that neutrophils, and neutrophil chemotaxis mediated by CXCL1, play an important role in preventing severe CDI (213, 214). The increased disease severity and mortality associated with neutrophil depletion during CDI was speculated to be linked with the translocation of microbiota to extraintestinal sites. Depletion of neutrophils and monocytes via monoclonal antibody blockage of their receptor, Gr-1, resulted in substantial increases in microbiota translocation to the mesenteric lymph nodes of C. *difficile*-infected mice compared to untreated infected mice (213). Together, these data suggested that neutrophil, and to a lesser extent, monocyte, recruitment to the colon plays a crucial role in preventing excessive microbial dissemination, thereby reducing the broader host effects of CDI and highlighting the complex nature of this infectious disease (213).

An earlier study also showed a link between reduced neutrophil infiltration and the dissemination of the commensal microbiota during severe CDI, under conditions in which the host was immunocompromised (124). In this study, the involvement of the intracellular pattern recognition receptor nucleotide-binding oligomerization domain 1 (NOD1) in C. *difficile* disease was assessed (124). NOD1 detects *meso*-diaminopimelic acid peptidoglycans common to Gram-negative bacteria, while a second receptor, NOD2, detects muramyl dipeptide, a component of Gram-positive and Gram-negative peptidoglycans (215). Strikingly, NOD1 is critical in protection from life-threatening CDI, with $NOD1^{-/-}$ mice succumbing to infection at a more rapid rate than WT mice (124). By contrast, $NOD2^{-/-}$ mice were not more susceptible to C. *difficile* disease despite the association between Gram-positive bacteria and NOD2 (124). Increased mortality in C. *difficile*-infected $NOD1^{-/-}$ mice was associated with reduced neutrophil trafficking to the intestine as well as reduced CXCL1 expression in comparison to infected WT ($NOD1^{+/+}$) mice (124). The reduction in CXCL1 expression coincided with an increase in commensal microbiota contamination in the lungs, kidneys, mesenteric lymph nodes, and spleen of $NOD1^{-/-}$ mice, suggesting that neutrophilic infiltration of gut tissues plays an important role in preventing the dissemination of the commensal microbiota when C. *difficile*-mediated tissue damage occurs (124). The association between NOD1 and C. *difficile* defined in this study was unexpected since, at the time, Gram-positive bacteria were not believed to produce *meso*-diaminopimelic acid peptidoglycans. However, it now appears that *Bacillus* and many other clostridia, including C. *difficile*, do produce *meso*-diaminopimelic acid peptidoglycans, so this phenotype now appears not to be exclusive to Gram-negative bacteria and may provide an explanation for the link between NOD1 and CDI (124, 215, 216).

The association between severe C. *difficile* disease, reduced neutrophil infiltration, and commensal microbiota dissemination has also been shown in infection studies involving apoptosis-associated speck-like protein containing a caspase activation and recruitment domain (CARD) $(ASC)^{-/-}$ mice, which lack a key component of the inflammasome, an immune factor which is involved in CDI (123, 196). The inflammasome is an intracellular caspase-activating complex often consisting of the pattern recognition receptor NOD-like receptor family, pyrin domain-containing 1 (NLRP1) or NLRP3, the adaptor protein ASC, and caspase-1, which is responsible for the cleavage of pro-IL-1β and pro-IL-18 into their active forms (196, 217). $ASC^{-/-}$ mice infected with C. *difficile* display impaired neutrophil recruitment to the cecum and colon in addition to higher levels of commensal microbiota dissemination to the spleen, liver, and lungs upon development of fulminant disease compared to WT ($ASC^{+/+}$) infected mice (123). These differences in pathology resulted in an increased mortality in $ASC^{-/-}$ mice, with 54% of infected mice succumbing to disease, compared to mortality in 3% of $ASC^{+/+}$ infected mice (123). The reduction in neutrophil recruitment in this study was linked to a deficiency in CXCL1 production in $ASC^{-/-}$ mice following C. *difficile* challenge (123). Work performed prior to these studies had shown that the NLRP3 inflammasome was involved in TcdA- and TcdB-mediated IL-1β release in a mouse ileal loop intoxication model (196). It was therefore not surprising that $ASC^{-/-}$ mice infected with C. *difficile* had reduced IL-1β levels compared to WT ($ASC^{+/+}$) infected mice, and it has been suggested that the reduction in CXCL1 expression in $ASC^{-/-}$ infected mice results from the disruption of an IL-1β-mediated positive feedback loop for CXCL1 release (123).

In addition to NOD1 and NLRP3, TLRs also appear to be important in the host response to CDI. TLR4 interacts with C. *difficile* SLPs and induces the release of several cytokines, including IL-23, IL-1β, and TNF-α (125). $TLR4^{-/-}$ mice develop severe C. *difficile* disease, with dramatic weight loss and increased mortality occurring following CDI, compared to WT ($TLR4^{+/+}$) infected mice, which showed moderate weight loss and pathology (125). TLR5 also plays an important role in the prevention of severe CDI, with stimulation of TLR5 via exogenous flagellin, a TLR5 ligand, promoting increased survival following C. *difficile* challenge (218). More recently, infection of mice with an R20291 *fliC* mutant, which lacks flagella, resulted in less severe disease than WT ($fliC^{+/+}$) CDI, characterized by less goblet cell loss and epithelial damage, and a 50% increase in survival (219). Furthermore, infection of $TLR5^{-/-}$ mice with WT R20291 resulted in little epithelial damage, further supporting the role of TLR5 in CDI and in the induction of the inflammatory response (219). This was confirmed on cytokine gene analysis, which showed that WT infection induced significant upregulation of CXCL1, IL-6, IL-1β, IL-22, CXCL10, and TNF-α expression compared to infection with the *fliC* mutant, which only induced a significant change in CXCL1 expression (219).

Several immune cells, including eosinophils (220), neutrophils (221), and innate lymphoid cells (222), have also been shown to play a key role in modulating disease severity during CDI. Reduced levels of eosinophil infiltration to the colon in mice (linked to reduced IL-25 signaling) during CDI were shown to promote severe disease, resulting in greater than 50% mortality, compared to mice pretreated with recombinant IL-25 (to induce eosinophil infiltration), which showed ~20% mortality following infection (220). Neutrophil recruitment to the site of infection during CDI has been shown to have various effects on disease severity during CDI in different studies. Chronic neutrophil inflammation exacerbates disease by inducing nonspecific damage to the colon (221), but neutropenia patients have a higher incidence of severe and potentially fatal CDI (223). Furthermore, blocking neutrophil recruitment to the colon promotes systemic dissemination of the gut microbiota and increased mortality during CDI (213). The role of neutrophils in disease is therefore complex. With respect to other immune cell types,

C. difficile-infection of Rag$\gamma c^{-/-}$ mice, which lack innate lymphoid cells, results in ~90% mortality, compared to an ~30% survival rate in WT mice, suggesting that innate lymphoid cells play a critical role in protecting mice from severe *C. difficile* disease (222).

Recent clinical data have also provided insights into the human host response during CDI. Diarrheal specimens from CDI patients were compared to those collected from non-CDI AAD patients and healthy people and were found to have higher levels of complement component 5a, granulocyte-colony stimulating factor, IL-8, IL-13, IL-16, IL-27, monocyte-chemoattractant protein 1, and TNF-α (224), suggesting that the human host immune response to CDI involves many different pathways, most of which have not been examined in detail. In a separate study, a comparative analysis of serum cytokine levels in CDI and uninfected patients showed that CDI induced a significant increase in cytokine release into the blood system (225). Infection with *C. difficile* resulted in a greater than 2-fold increase in IL-1β, IL-2, IL-5, IL-6, IL-8, IL-10, IL-13, IL-15, IL-16, IL-17A, and TNF-α release into the blood when compared to uninfected donors, with elevated levels of IL-2 and IL-15 associated with increased disease severity (225). Collectively, these studies highlight the importance of the innate immune response in CDI and disease.

TREATMENT, PREVENTION, AND DISEASE RECCURENCE

Antibiotic Treatment of CDI

Depending on disease severity, CDI may require antibiotic treatment to ensure infection clearance. Antibiotic interventions for CDI include oral metronidazole, vancomycin, and more recently, fidaxomicin, in most cases for 10 days (226). For cases of mild and moderate CDI, the European Society of Clinical Microbiology and Infectious Diseases recommends oral metronidazole (either 250 mg four times a day or 500 mg three times a day), because it is less expensive than vancomycin and fidaxomicin while reducing the risk of developing antibiotic resistance in other pathogens associated with the use of the clinically important vancomycin (226). When treating severe CDI, vancomycin is preferred over metronidazole (226). Vancomycin is usually administered at >125 mg at least two to four times a day and has a reduced oral availability and colonic absorption compared to metronidazole, enabling retention in the gut lumen, which facilitates more efficient *C. difficile* clearance (226). Treatment of CDI with fidaxomicin is as effective as vancomycin treatment, with dosage between 50 mg to 200 mg twice a day being sufficient to clear infection (226). Importantly, treatment with fidaxomicin is associated with less recurrent disease compared to metronidazole and vancomycin treatment of CDI. This is because it has a high level of activity against *C. difficile* but a narrow spectrum of activity against other bacteria, particularly Gram-negative bacteria, which results in a reduced impact on the protective colonic microbiota (227, 228).

Prevention

Because there is currently no effective vaccine against *C. difficile* disease, prevention strategies are mainly focused on controlling spread in high-risk environments, including hospitals and nursing homes, and antibiotic stewardship. Although *C. difficile* spores are nearly ubiquitous in health care facilities, infection control guidelines suggested by Vonberg et al. (229) indicate that early diagnosis, extensive education of hospital staff, isolation of infected patients, proper hand hygiene, and hospital surface and equipment disinfection are measures that limit the spread of *C. difficile*. Improving true-positive diagnosis also reduces the unnecessary use of antibiotics, which has been successful in reducing CDI incidence in hospitalized patients (229).

The normal microbiota of the colon prevents overgrowth of *C. difficile* in colonized individuals, although this protective effect can be disrupted following treatment with antibiotics (230). *C. difficile* cell proliferation and toxin production follows, resulting in the symptoms associated with CDI (230). Probiotics have been investigated as a potential preventative therapy for cases of noninfectious AAD with some success, yet studies in the context of primary CDI have proven inconclusive (231). Patients age 65 and older that received a multistrain preparation of lactobacilli and bifidobacteria in a multicenter trial exhibited no reduction in AAD and *C. difficile*-associated diarrhea compared to a placebo group (232). Similarly, provision of the yeast *Saccharomyces boulardii* to hospitalized patients age 50 or over along with prophylactic antibiotic treatment resulted in *C. difficile*-associated diarrhea in 2.1% of patients, compared to 1.5% receiving the placebo, in a single-center trial (233).

Recurrent CDI and Alternative Therapeutics

Although antibiotic treatment of *C. difficile* can effectively clear a primary infection, recurrence of disease occurs in roughly 25% of patients (234). Antibiotic treatment, which depletes colonic microbiota, is a key risk factor for CDI (234). CDI recurrence may occur through infection relapse, either with the same infectious strain causing disease or through infection with a different strain not related to the first infection (235–237). In both cases recurrence is related to disruption of the host microbiota and probably also due to damage that has occurred to the colonic epithelium, the latter of which may contribute to patient susceptibility (238, 239).

The broad-spectrum microbial activity of both metronidazole and vancomycin, although efficient at treating CDI, also allows these antibiotics to continue to disrupt the protective microbiota (240), consequently resulting in patient relapse rates of 19 to 23% and 18 to 32%, respectively (234). Following an initial recurrence of CDI, the risk of a second recurrence increases to approximately 45%, which is also likely to be linked to treatment-mediated depletion of the colonic microbiota (234). The risk of a third CDI recurrence increases to roughly 65% when vancomycin or metronidazole are used to treat the earlier CDI episodes (234). With recurrence rates of roughly 13% and a narrower spectrum of activity on the microbiota compared to vancomycin and metronidazole, fidaxomicin has emerged as a more promising treatment for CDI. The high cost of this antibiotic has unfortunately prevented broad clinical implementation, with a cost more than two times that of vancomycin and over 100 times that of generic metronidazole (241).

The relatively high levels of relapse associated with antibiotic treatment of CDI have resulted in the investigation of alternative therapeutics which aim to treat CDI without disrupting the microbiota. One such therapy, fecal microbiota transplant (FMT), aims to replace or replenish the microbiota of the gastrointestinal tract in times of dysbiosis and is used almost exclusively to treat CDI, particularly after several relapse events (8). By reintroducing "healthy" microbiota from a donor to the colon of CDI patients, in most cases following a failure to treat CDI with antibiotics, the resolution of symptoms and eradication of

C. difficile can be achieved in approximately 80 to 100% of patients (242). However, with a majority of previous FMT work being conducted without effective controls, its efficacy as a treatment for CDI has been a contentious subject. In a recent randomized controlled trial, FMT was highly superior to standard antibiotic treatment of CDI (243). However, because FMT is inherently difficult to standardize and control, due to variation in the microbiota of each individual, Food and Drug Administration (FDA) approval can be difficult to achieve (244). Despite the effectiveness of FMT at reducing recurrent disease, this treatment may not be suitable for all patients, including some immunocompromised individuals for whom organisms from another individual's microbiota may present as pathogenic under these conditions. However, several recent cases have used FMT to treat recurrent CDI in immunocompromised individuals, including solid organ transplant patients, without substantial consequences (245), suggesting that the use of FMT may be a viable treatment for recurrent CDI in select cases. There is undoubtedly a need for alternative treatments for CDI with fewer secondary consequences on the microbiota, and FMT is one such treatment, which has provided a starting point for the development and optimization of microbiota therapy-based approaches (246).

Interestingly, patients with low serum antibody levels are more prone to severe CDI and disease recurrence, while asymptomatic carriers of *C. difficile* have elevated serum IgG levels (247, 248). This observation led to studies of the provision of passive immunization via intravenous immunoglobulin (IVIG) supplementation in the treatment of both severe primary CDI and recurrent disease. This potential therapeutic is prepared from pooled human serum and contains *C. difficile* toxin antibodies (249). Leung et al. (250) demonstrated that IVIG treatment of five children experiencing recurrent CDI who had low serum IgG levels against TcdA resulted in resolution of all clinical signs of colitis with treatment every 3 weeks for up to 6 months, with a rise in IgG TcdA antibodies following therapy. Furthermore, clinical symptoms of CDI were resolved in two adult patients with severe pseudomembranous colitis that did not respond to standard-of-care metronidazole and vancomycin treatment when treated with pooled normal human immunoglobulin (251). However, the mechanism of IVIG-mediated symptom relief is still unknown because only a handful of small-scale case studies have been conducted. IVIG could be beneficial as a therapeutic option for patients that do not respond to treatment with traditional antibiotics or those that cannot be given FMT, although there is an urgent need for randomized trials to understand dosage and timing of treatment, as well as possible side effects.

More recent alternative therapies include the TcdB-specific monoclonal antibody therapy bezlotoxumab, which has recently obtained FDA approval and has been suggested for use in patients with relapsing disease since it does not disrupt the protective microbiota like antibiotics do (238). More recently, work by Hutton et al. (252) has shown that hyper-immune bovine colostrum directed toward TcdB, as well as a combination of TcdB, SLP, and spore exosporium-directed colostrum, is effective at treating and preventing severe disease progression in primary CDI in approximately 70 to 75% of *C. difficile*-infected mice, compared to mice treated with nonimmune colostrum, of which >90% succumbed to disease. Furthermore, the combination therapy also prevented relapse of CDI in roughly 80% of mice, compared to the roughly 90% of mice that relapsed without secondary treatment (252). Both bezlotoxumab and colostrum antibody approaches represent viable alternative therapies for CDI that may help to minimize disease and the recurrence of CDI, which has become increasingly urgent since the emergence of the epidemic 027 strains. The clinical link between increased CDI recurrence and the emergence of ribotype 027 strains is supported by studies identifying higher recurrence rates in patients infected with ribotype 027 strains compared to infections with other strains (253). Disease recurrence has therefore become a focus of CDI treatment and prevention strategies in recent years.

CONCLUSION

Although there has been a substantial increase in our knowledge of *C. difficile* pathogenesis and treatment of infection which has resulted from the development of suitable animal disease models and advances in technology, several key aspects of disease and recurrent infection have yet to be investigated in detail. With the ever-changing epidemiology of CDI and the complexity of *C. difficile*-mediated disease, coupled with the recent listing of *C. difficile* as an urgent public health threat by the CDC, there is a need for an improvement of our understanding of disease pathogenesis and for the development of effective alternative therapeutics for the treatment of infection to provide a better standard-of-care for patients suffering from CDI.

Histotoxic Clostridial Infections

MASAHIRO NAGAHAMA, MASAYA TAKEHARA AND JULIAN I. ROOD

62

GENERAL CHARACTERISTICS OF HISTOTOXIC CLOSTRIDIAL INFECTIONS

Many pathogenic clostridial species cause potentially fatal soft tissue infections in humans and animals because of their ability to produce extracellular protein toxins (1, 2). The ability of these pathogens to produce spores that are resistant to environmental stress is an important factor in the epidemiology of these diseases. Disease pathogenesis involves the growth of the clostridial pathogen in the tissues and extensive tissue destruction, which is the result of the action of extracellular toxins. Typical histotoxic clostridial diseases include human gas gangrene or myonecrosis and blackleg in cattle. Although there are several clostridial species that are responsible for these syndromes (Table 1), this review will focus on histotoxic infections caused by *Clostridium perfringens* and *Clostridium septicum*, primarily because these are the species that have been the subject of the most extensive molecular and functional studies.

Although the histotoxic clostridia cause severe, rapidly developing infections, these potent toxigenic bacteria still must be regarded as opportunistic pathogens. All of these infections require predisposing conditions to cause disease, often a traumatic wound that enables the entry of spores from the soil or gastrointestinal tract to gain access to ischemic internal organs or soft tissues of the body. Alternatively, in nontraumatic myonecrosis caused by *C. septicum*, gastrointestinal malignancy is commonly associated with the onset of disease, with tumor development leading to ulceration and necrosis of the gastrointestinal mucosa and entry of the gastrointestinal microbiota into the circulation and subsequent infection at distal sites (3, 4). Clostridial necrotizing soft tissue infections, especially those caused by *C. perfringens*, *Clostridium sordellii*, and *Clostridium novyi*, also have resulted from the subcutaneous injection of contaminated black tar heroin (5–7).

PATHOGENESIS OF CLOSTRIDIAL MYONECROSIS CAUSED BY *C. PERFRINGENS* AND *C. SEPTICUM*

As previously described (8), the pathogenesis of these infections involves three distinct stages, irrespective of whether the source of infection involves a traumatic wound. Stage 1 involves an interruption to the blood supply such that the redox potential in the tissues drops to a level that facilitates spore germination and/or the growth of the infecting clostridial cells. Stage 2 involves bacterial growth and establishment of the conditions for toxin production. In *C. perfringens*, regulation of toxin production primarily utilizes the VirSR two-component signal transduction system (9) and an accessory growth regulator-like quorum sensing system (10, 11), as well as other regulatory networks. Stage 3 encompasses the toxin-mediated cell and tissue damage that leads to necrosis, systemic toxicity, and clinical disease (8).

C. perfringens type A is the major cause of traumatic gas gangrene, although other histotoxic clostridia may also be responsible for this sporadic, but fulminant and often fatal, disease (Table 1) (1). The major toxin produced by gas gangrene strains of *C. perfringens* is α-toxin, a zinc metallophospholipase that has both phospholipase C and sphingomyelinase activity (12). α-Toxin was the first bacterial toxin to be shown to have enzymatic activity (13). Two independent studies using different experimental approaches have shown that α-toxin is essential for *C. perfringens*-mediated myonecrosis. First, immunization studies in mice using recombinant α-toxin variants purified from *Escherichia coli*, and therefore devoid of any other *C. perfringens* toxins, showed that the C-terminal domain of α-toxin was immunoprotective (14). Second, mutation of the α-toxin structural gene (*plc* or *cpa*) abrogated the ability of the bacterium to cause clostridial myonecrosis in a murine model. Virulence was restored by complementation *in trans* with a recombinant plasmid containing the wild-type *plc* gene (15), thereby fulfilling molecular Koch's postulates and providing proof of the essential role of this toxin in disease.

The other major toxin produced by *C. perfringens* type A is perfringolysin O, or θ-toxin, a pore-forming toxin that is a member of the cholesterol-dependent cytolysin family (16, 17). Although mutation of the perfringolysin O structural gene, *pfoA*, did not eliminate the ability to cause disease (18, 19) subsequent studies of *plcpfoA* double mutants (20) provided evidence that perfringolysin O has a synergistic effect with α-toxin on disease pathogenesis (20, 21).

Recent studies have involved the concurrent analysis of the transcriptomes of both the host and *C. perfringens* in a murine myonecrosis infection (22). The results showed that many host genes involved in the innate immune response to infection were upregulated in *C. perfringens*-infected muscle tissues. In the *C. perfringens* cells, upregulated genes included those encoding potential adhesins and proteins associated with the cell envelope.

C. septicum is the major causative agent of nontraumatic gas gangrene, often associated with a gastrointestinal

doi:10.1128/microbiolspec.GPP3-0024-2018

TABLE 1 Histotoxic clostridial infections

Syndrome[a]	Causative agent	Host	Major toxins[b]	References
Traumatic gas gangrene	C. *perfringens* type A	Humans	α-toxin	12, 17
			Perfringolysin O (θ-toxin)	
Traumatic gas gangrene	C. *novyi*	Humans	α-toxin	151
	C. *septicum*		α-toxin	129
	C. *histolyticum*		Lethal factor	152
	C. *sordellii*		Lethal toxin (TcsL)	153
			Hemorrhagic toxin (TcsH)	
Nontraumatic gas gangrene	C. *septicum*	Humans	α-toxin	3, 4
	C. *fallax*	Humans and animals	Not known	154
Necrotizing pancreatitis	C. *perfringens* type A	Humans	α-toxin	155
Clostridial myonecrosis	C. *perfringens* types A, B, C, and D	Sheep, cattle, and other animals	α-toxin	29
			β-toxin	
			ε-toxin	
Blackleg	C. *chauvoei*	Cattle, sheep, and other ruminants	Cytolysin A (CctA)	156

[a]The terms "gas gangrene" and "clostridial myonecrosis" are used interchangeably in this review.
[b]Note that the different α-toxins referred to in this column are not necessarily structurally or functionally related.

malignancy (4). The major toxin produced by C. *septicum* is also called α-toxin, but it is not related to C. *perfringens* α-toxin. C. *septicum* α-toxin is an aerolysin-like pore-forming toxin that is secreted as an inactive prototoxin that is cleaved near the C terminus by membrane-bound furin or furin-like proteases to form the active toxin (23). The toxin then oligomerizes on the membrane and subsequently inserts to form a membrane pore, which ultimately leads to cell lysis (24). Genetic studies have shown that α-toxin is essential for C. *septicum*-mediated myonecrosis in mice (25). Mutation of the α-toxin structural gene, *csa*, leads to a loss of virulence, which is restored by complementation with the wild-type *csa* gene.

STRUCTURE AND FUNCTION OF *C. PERFRINGENS* α-TOXIN

α-Toxin is a 43-kDa single polypeptide that is a hemolytic, cytotoxic, dermonecrotic, and lethal extracellular toxin (26–29). Moreover, it induces contractions of blood vessels and smooth muscle, aggregation of platelets, superoxide production, and cytokine release. Importantly, together with perfringolysin O, it is responsible for the hallmark histopathological feature of C. *perfringens*-mediated myonecrosis, the paucity of the polymorphonuclear leukocyte (PMNL) influx into the infected lesion (15, 19–21, 30).

Determination of the crystal structure of α-toxin revealed that it has an α-helical N-terminal domain (amino acids 1 to 246) that is responsible for its enzymatic activity, a flexible linker (amino acids 247 to 255), and a C-terminal (amino acids 256 to 370) β-sandwich membrane-binding domain (31) (Fig. 1). The two domains also are linked by hydrophobic surface interactions between their neighboring faces. The N-terminal domain has significant sequence similarity to phospholipase C enzymes from *Bacillus cereus* (32), *Clostridium bifermentans* (33), and *Listeria monocytogenes* (34). It comprises nine densely packed α-helices and resembles the structure of *B. cereus* phospholipase C (31, 35), which has enzymatic activity, but is neither toxic nor hemolytic. There are three loops in the N-terminal domain: loop 1 (residues 70 to 90), loop 2 (residues 135 to 150), and loop 3 (residues 205 to 215). These loops serve a vital role in the direct interaction between the toxin and the membrane-binding component. The C-terminal domain comprises eight-stranded antiparallel β-sheets (31). This domain plays a role in membrane binding and is required for hemolytic and toxic activity (28, 36). It is absent from nontoxic phospholipase C enzymes (31). It has structural similarity to the C-terminal domain of pancreatic lipase, the N-terminal domain of soybean lipoxygenase, and the C2 phospholipid-binding domains of

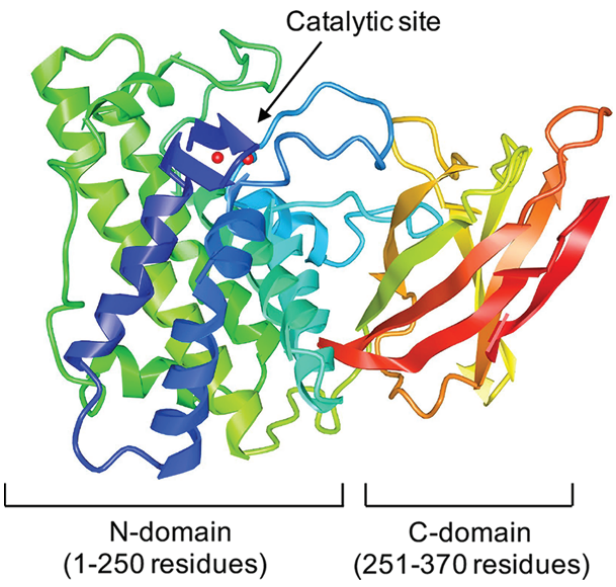

FIGURE 1 Structure of α-toxin. The structure of α-toxin was obtained from the Protein Data Bank (code 1QM6) and was created using MacPyMOL. A ribbon representation is shown, colored from blue (N-terminal) to red (C-terminal). Two zinc metal ions in the active site are shown as red spheres.

eukaryotic intracellular proteins, such as synaptotagmin I, which are involved in signal transduction and vesicular transport (37, 38).

The active site in the N-terminal domain is situated within a solvent-accessible cleft that contains two zinc ions and an exchangeable divalent cation. His-148 and Glu-152 dock with one zinc ion, which is critical for the catalytic site of the toxin. His-11 and Asp-130 tightly dock with the other zinc ion, which is needed for maintenance of the structure. His-68, His-126, and His-136 dock with an exchangeable divalent cation, which is required for binding to target cell membranes (39). The external loop regions (residues 70 to 90, 135 to 150, 205 to 215, 265 to 275, 290 to 300, and 330 to 340) bind to phospholipids in the host cell membranes (31). Thr-74 is present in one of these loops, and although the substitution derivative T74I is still active and can cleave a water-soluble substrate, its membrane-damaging activity toward red blood cells and phosphatidylcholine-cholesterol liposomes is decreased compared to wild-type toxin (40, 41). However, the structure of the T74I variant is identical to that of the wild-type toxin (41). The T74I substitution results in altered recognition of the glycerol moiety in the phospholipid, without affecting the function of the active site, supporting the hypothesis that the amino acid 70 to 90 loop is important for phospholipid recognition (42, 43).

Computational modeling of α-toxin and phosphatidylcholine revealed that Tyr-57 and Tyr-65, which exist at an external site near the catalytic cleft and are in proximity with the 70 to 90 loop, are responsible for substrate interaction (44). The replacement of these Tyr residues with Ala did not have any effect on phospholipase C and sphingomyelinase activity but had a marked effect on the membrane-damaging activity (hemolysis of sheep red cells and disruption of liposomes). These residues exist in or near the entrance of the catalytic cleft and are essential for the membrane-damaging effect of α-toxin, because they are required for entry of the catalytic cleft into the hydrophobic region of plasma membranes (44).

Several studies have shown that the calcium-binding C-terminal domain is responsible for membrane binding (28, 31, 36, 37). Two acrylodan-labeled C-terminal domain derivatives, S263C and S365C, bound to lipid bilayers and displayed a chromogenic shift, demonstrating entry of the C-domain of the toxin into the hydrophobic regions of the liposomes (36). The data provide evidence that the C-terminal domain of the toxin binds to the membrane and that the amino acid 70 to 90 loop and Tyr-57 and Tyr-65 serve an important role in the recognition of target membranes (Fig. 2). Other studies have shown that substitution of the C-terminal domain residues Asp-269, Asp-336, Tyr-275, and Tyr-331, which were predicted to be involved in membrane binding (31), were required for hemolytic and cytotoxic activity (45).

INTERACTION OF *C. PERFRINGENS* α-TOXIN WITH HOST CELLS

Membrane-Damaging Activity on Phospholipid Bilayers

The effect of α-toxin on host tissues is caused by the phospholipase C- and sphingomyelinase-mediated cleavage of

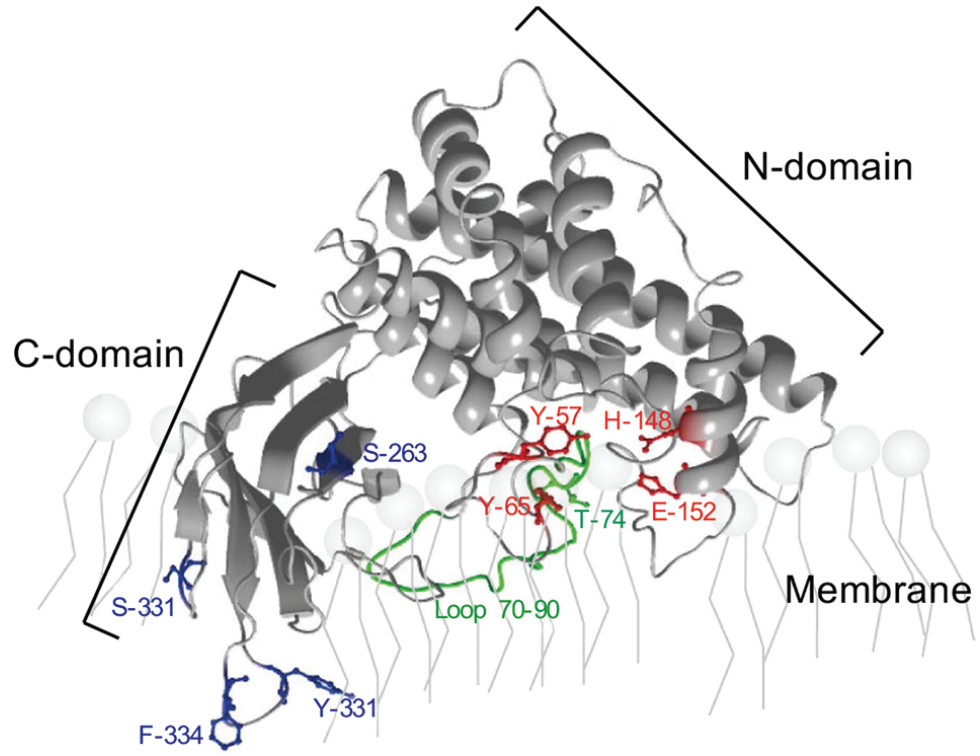

FIGURE 2 Binding model of α-toxin and membrane phospholipids. The structure of α-toxin was obtained from the Protein Data Bank (code 1QM6) and was created using MacPyMOL. Phospholipids are shown as light gray spheres for head groups and light gray lines for tail groups. The head group of a phospholipid, from the outer membrane into the active site of α-toxin, is displayed. Amino acids that may play a role in membrane interaction are shown.

phospholipids in the host cell membranes. The resultant disruption of the phospholipid bilayer together with the end products of these cleavage reactions, diacylglycerol and ceramide, respectively, activates lipid metabolism in host cell membranes and plays a role in host cell damage (27, 28).

The composition of the phospholipid bilayer modulates the extent of the α-toxin-mediated membrane disruption (46). In another study that measured the release of carboxyfluorescein from various liposomes, α-toxin-mediated release, or liposomal leakage, decreased with increasing chain length of the hydrocarbon residues in the phospholipid bilayer (40). It was concluded that membrane disruption was related to the fluidity of the membrane and double bonds in the acyl chain. Subsequently, several phosphatidylcholines (C18:0/C18:1) with a double bond in the *sn*-2 fatty acyl chain were prepared (47). The phase transition temperature value was lowest when the *cis*-double bond was positioned at the center of the C18:1 *sn*-2 acyl chain and increased continuously as the double bond was moved toward either end of the acyl chain. α-toxin-mediated carboxyfluorescein release from various liposomes was highest when the *cis*-double bond was positioned at the center of the *sn*-2 fatty acyl chain, resulting in a bell-shaped curve (47). Accordingly, the membrane-disrupting activity of the toxin is strongly associated with the membrane fluidity of target membranes.

There is evidence that α-toxin also promotes perfringolysin O-induced membrane damage in phospholipid bilayers. Hydrolysis of phosphatidylcholine residues of liposomes that contained cholesterol increased the amount of free cholesterol in the lipid bilayer and enhanced perfringolysin O-dependent cytolytic activity (48). These data may at least partly explain the synergistic effects of α-toxin and perfringolysin O that were previously observed in C. *perfringens* infections of mice (20).

Activation of Phospholipid Metabolism and Hemolysis

α-toxin provokes contraction of isolated rat ileum and aorta tissues in a dose-dependent manner through stimulation of the phospholipid metabolic pathway (49, 50). In isolated rat organs, α-toxin activates the phosphatidylinositol metabolic pathway and then the arachidonic acid cascade, thereby promoting thromboxane production. Contraction caused by the toxin was evoked by thromboxane A2 generation induced by arachidonic acid (49, 50). The metabolism of arachidonic acid results in the production of bioactive lipid mediators, including leukotrienes, thromboxanes, and prostaglandins (27). These bioactive lipid mediators play key roles in enhancing the local inflammatory reaction and lead to vasoconstriction, which is responsible for inducing anoxia in the early stages of bacterial infections. These effects presumably contribute to the capacity of C. *perfringens* to proliferate in the host and cause disease.

Treatment of rabbit neutrophils with α-toxin promotes the formation of diacylglycerol, which is followed by adhesion of the cells to extracellular matrix proteins and the generation of superoxide ions (Fig. 3B) (51). α-Toxin

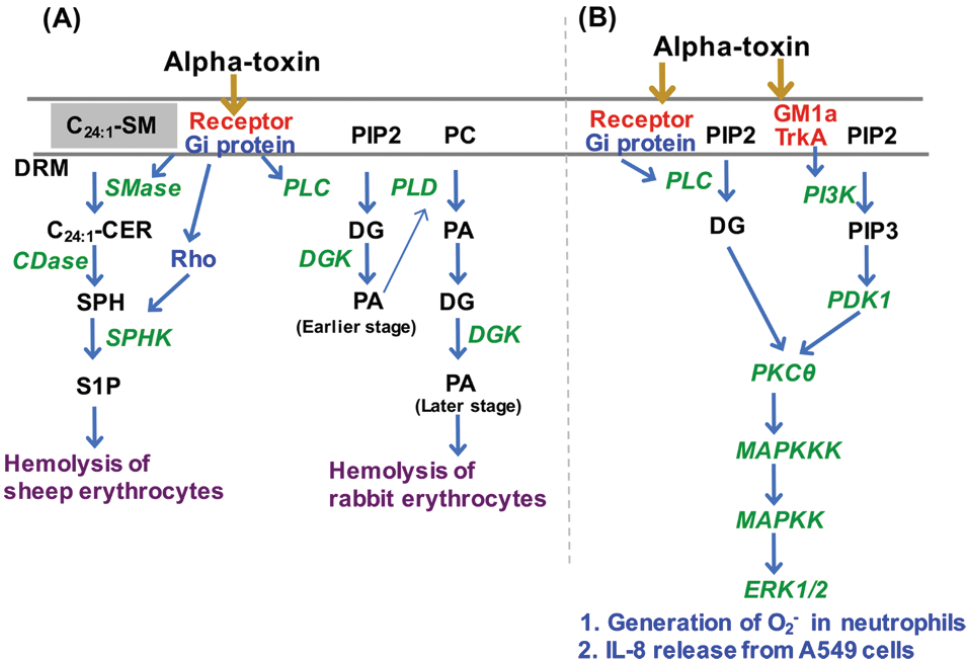

FIGURE 3 Relationship between phospholipid metabolism and the biological activities of α-toxin. (A) Signaling events involved in α-toxin-induced hemolysis of sheep or rabbit erythrocytes. (B) Signaling events involved in α-toxin-activated generation of O_2^- in neutrophils and in α-toxin-mediated release of IL-8 from A549 cells. Abbreviations: SM, sphingomyelin; PIP2, phosphatidylinositol 4,5-bisphosphate; PLC, phospholipase C; DG, diacylglycerol; PC, phosphatidylcholine; SMase, sphingomyelinase; PLD, phospholipase D; PA, phosphatidic acid; PKCθ, protein kinase Cθ; PI3K, phosphatidylinositol 3-kinase; PIP3, phosphatidylinositol 3,4,5-trisphosphate; CDase, ceramidase; CER, ceramide; SPH, sphingosine; S1P, sphingosine 1-phosphate; DGK, DG kinase; PDK1, phosphatidylinositide dependent kinase 1; DRM, detergent-resistant membrane; TrkA, neurotrophic tyrosine kinase receptor type1; MAPKK, mitogen-activated protein kinase kinase; Erk1/2, extracellular signal-regulated kinase 1/2.

induces diacylglycerol generation through activation of intrinsic phospholipase C enzymes by a pertussis toxin-sensitive GTP-binding protein. Moreover, it increases the phosphorylation of neurotrophic tyrosine kinase receptor type 1 (TrkA), leading to 3-phosphoinositide-dependent protein kinase 1 activation (52). Therefore, α-toxin independently causes stimulation of intrinsic phospholipase C and protein kinase 1 activity through TrkA receptor activation. Both phenomena synergistically augment the activity of protein kinase C θ, leading to the formation of superoxide ions via activation of the mitogen-activated protein kinase (MAPK) cascade (Fig. 3B) (52). In human lung carcinoma (A549) cells, α-toxin mediates the activation of the p38 MAPK, NF-κB, and extracellular signal-regulated kinase 1/2 (ERK1/2) through TrkA activation, which leads to interleukin-8 (IL-8) release (53) (Fig. 3B).

Treatment of rabbit erythrocytes with α-toxin induces the biphasic formation of phosphatidic acid (54) (Fig. 3A). α-Toxin-induced formation of phosphatidic acid is activated in the earlier stage (30 s) by intrinsic phospholipase C and in the later stage (ca. 25 min) by intrinsic phospholipase D. Both processes involve stimulation of the G-protein-signaling pathway by toxin-mediated membrane phospholipid cleavage (55) (Fig. 3A).

Sheep erythrocytes have higher amounts of sphingomyelin but do not contain phosphatidylcholine. Cleavage of sphingomyelin by α-toxin leads to increased levels of ceramide and sphingosine 1-phosphate (56), which is essential for toxin-induced hemolysis (57) and activates the sphingomyelin metabolism system (Fig. 3A) (56). The resultant cleavage of N-nervonoic sphingomyelin ($C_{24:1}$-SM) occurs in a detergent-resistant membrane component (57) (Fig. 3A). Pertussis toxin blocks the production of $C_{24:1}$-ceramide caused by α-toxin and blocks red cell hemolysis, which indicates that intrinsic sphingomyelinase, which can cleave $C_{24:1}$-SM to $C_{24:1}$-ceramide, is regulated by a pertussis toxin-sensitive G-protein in plasma membranes. In addition, the activation of Rho protein by α-toxin increases sphingosine kinase activity. Subsequently, the ceramides are quickly metabolized to sphingosine, indicating that the toxin also activates ceramidases (57). These results indicate that the cleavage of $C_{24:1}$-SM to sphingosine 1-phosphate by α-toxin in lipid rafts is essential for toxin-induced hemolysis of sheep red cells (Fig. 3A).

Interaction of α-Toxin with Gangliosides

Amino acid sequence analysis of botulinum toxin and tetanus toxin showed that the ganglioside-GT1b- and lactose-binding site is determined by the existence of the conserved peptide motif, H.....SXWY.....G (ca. 30 amino acids [aa]), with the Tyr and Trp residues being particularly critical (58). A similar motif (H.....SWY.....G, amino acids 68 to 93) is present in α-toxin (53), in the region (amino acids 55 to 93) that is located at the interface between the *N-terminal* and C-terminal domains (42). It has been demonstrated that the 70 to 90 loop in α-toxin plays a role in binding to the cell surface (43) (Fig. 2). Computational docking studies indicated that Trp-84 binds to the sialic acid residue on ganglioside GM1a via an aromatic stacking interaction and a hydrogen-bonding interaction and that Tyr-85 associates with the galactosamine residue on GM1a via an α-glycosidic bonding interaction (59). Replacement of Trp-84 and Tyr-85 in α-toxin, which correspond to the ganglioside recognition site of botulinum and tetanus toxins, significantly reduced binding to ganglioside GM1a-containing liposomes. W84A and Y85A derivatives had markedly decreased capabilities to stimulate TrkA (59). Ganglioside GM1a assembles with a TrkA molecule on the cell surface and stimulates TrkA and ERK1/2 (60). It has been reported that ganglioside GM1 clustering leads to the condensation of TrkA in lipid rafts and the stimulation of downstream signaling targets (61). α-Toxin-mediated diacylglycerol production leads to diacylglycerol flip-flop movement that affects the dynamics of cell membranes (Fig. 4). Therefore, it serves in GM1a clustering and intrinsic phospholipase C-γ1 activation through TrkA, triggering various signal transduction activities (62–64).

α-toxin causes higher cytotoxicity in a ganglioside-deficient cell line (Don Q) (65) and can be internalized by dynamin-mediated endocytosis (66, 67). The toxin binds to caveolin-1 both on the cell membranes and in endosomal vesicles, and it also induces ceramide production in the cell membrane (28), which generates negative membrane curvature and facilitates endocytosis (68). Internalized α-toxin is transported to the early and late endosomes and lysosomes. Lysosomes are damaged during progressive α-toxin internalization into Don Q cells. In addition, the internalization of α-toxin is also mediated through the stimulation of MEK/ERK signaling (66, 67). It has been reported that the toxin causes reactive oxygen species generation via PKC, MEK/ERK, and NF-κB signaling activities in Don Q cells (66, 67). Therefore, α-toxin perturbs the host cell signaling cascade and acts not only on the cell membrane, but also in the cytoplasm.

Effect of α-Toxin on Hematopoietic Cells

The first line of defense of the innate immune system involves neutrophils, which play an important role in the phagocytosis and subsequent elimination of pathogenic bacteria (69, 70). Normally, the number of neutrophils is sustained in a steady state through granulopoiesis, which is accelerated to replenish neutrophils during bacterial infection (71–73). Pattern recognition receptors, such as Toll-like receptors (TLRs), are responsible for the recognition of structural components of microorganisms (74, 75). TLR2 and TLR4 have been identified as being pivotal for the recognition of Gram-positive or Gram-negative bacteria by recognizing cell wall components such as peptidoglycan and bacterial endotoxin (lipopolysaccharide), respectively (76–79). During bacterial infection, these bacterial components stimulate the production of granulocyte colony-stimulating factor (G-CSF), which is a glycoprotein that promotes the proliferation, survival, and differentiation of neutrophils and their progenitor cells (80) from endothelial cells and monocytes, resulting in the acceleration of granulopoiesis (81). G-CSF-deficient and G-CSF receptor-deficient mice exhibit chronic neutropenia and reduced infection-driven granulopoiesis, leading to impaired ability to eliminate infecting bacteria (82, 83). Thus, granulopoiesis is precisely regulated to replenish neutrophils during bacterial infection. However, *C. perfringens* can still cause life-threatening infections, and the mechanisms by which *C. perfringens* avoids these host defenses are still not completely understood.

C. perfringens-mediated myonecrosis progresses so rapidly that death, which is associated with muscle destruction, shock, and multiple organ failure, sometimes precedes an accurate diagnosis (84). *C. perfringens* infection is characterized by a greatly reduced PMNL influx to the site of the infection (19, 85–87), suggesting that the bacteria disrupt neutrophil-based innate immunity to evade host defenses. α-Toxin mediates the formation of platelet-leukocyte aggregates, leading to vascular occlusion, and induces a marked

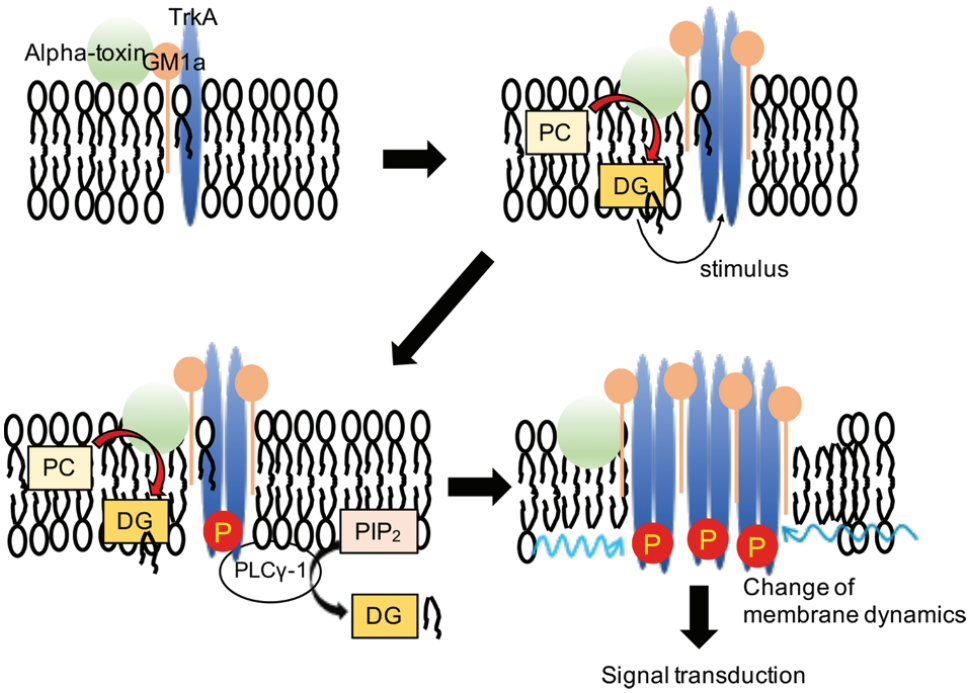

FIGURE 4 Model of α-toxin-induced membrane dynamics and clustering of the GM1a and TrkA complex. α-Toxin binds to GM1a and, through the phospholipase C activity of the toxin itself, causes diacylglycerol (DG) production at the outer membrane. The flip-flop movement of DG affects membrane dynamics, facilitating clustering of GM1a and TrkA activation by phosphorylation. Activation of TrkA results in the activation of PLCγ-1, leading to the increased production of DG. Finally, DG formation results in the enhanced activation of TrkA, triggering activation of signal transduction pathways, which induce neutrophil activation. Abbreviations: PIP_2, phosphatidylinositol 4,5-bisphosphate; PLC, phospholipase C; DG, diacylglycerol; PC, phosphatidylcholine; TrkA, neurotrophic tyrosine kinase receptor type 1.

reduction in microvascular perfusion (45, 86, 88), which is thought to impede neutrophil extravasation (89). Recently, it was shown using a mouse model of infection that *C. perfringens* infection reduced mature neutrophils in bone marrow, in peripheral blood, and in *C. perfringens*-infected muscle, in an α-toxin-dependent manner (90). α-Toxin inhibits neutrophil differentiation and impairs the replenishment of differentiated mature neutrophils in the peripheral circulation, resulting in reduced recruitment of neutrophils to the *C. perfringens* infection site. The half-life of peripheral neutrophils is less than 12 hours *in vivo* (91), meaning that the number of mature neutrophils required to counter a bacterial infection is sustained through continuous granulopoiesis. Therefore, blockage of both granulopoiesis and PMNL diapedesis into the tissues, as a result of platelet aggregation, leads to a reduction in cell numbers in a short period of time. Thus, *C. perfringens* infection impairs the host immune system, which could explain the both scarcity of PMNL at the site of infection and a propensity for polymicrobial infections in many patients (Fig. 5).

α-Toxin is essential for disease pathogenesis (18–21, 30), and blockage of neutrophil differentiation is dependent on its phospholipase C and sphingomyelinase activities (90). In human lymphocytes, *S. aureus* sphingomyelinase disrupts lipid rafts, which are cholesterol-rich plasma membrane microdomains (92). Lipid rafts function as platforms of signaling molecules involved in the regulation of cell differentiation in many cell types (93, 94). Ceramide, the hydrolysis product of sphingomyelinase, also is known to be a lipid messenger implicated in various cellular responses, including apoptosis, differentiation, and cell growth (95). Recently, *C. perfringens* α-toxin was reported to perturb the integrity of lipid rafts, leading to the blockage of neutrophil differentiation (90). The detailed molecular mechanism behind this blockage has not been elucidated, but it may be important to focus on the relationship between the role of sphingomyelinase and cell differentiation to shed further light on host-pathogen interactions in clostridial myonecrosis.

Effect of α-Toxin on Erythropoiesis

α-Toxin has been reported to lyse erythrocytes from various species. It activates T-type Ca^{2+} channels and increases intracellular Ca^{2+}, which plays an important role in the hemolysis of horse erythrocytes (96). The toxin activates the sphingomyelin metabolic system, leading to the hemolysis of sheep erythrocytes (56, 57), and the lysis of rabbit erythrocytes involves α-toxin-mediated activation of endogenous phospholipase C activity (54, 55). Recently, *Bacillus anthracis* lethal toxin was reported not only to induce hemolysis, but also to inhibit erythroid differentiation of cord blood-derived $CD34^+$ hematopoietic stem cells, leading to the suppression of erythropoiesis (97). The toxin-induced suppression of erythropoiesis is potentially part of a lethal toxin-mediated pathophysiology in anemia and hypoxia. Similarly, it was reported that mature erythroblasts were preferentially decreased when isolated mouse bone marrow cells were treated with α-toxin, and subsequent experiments revealed

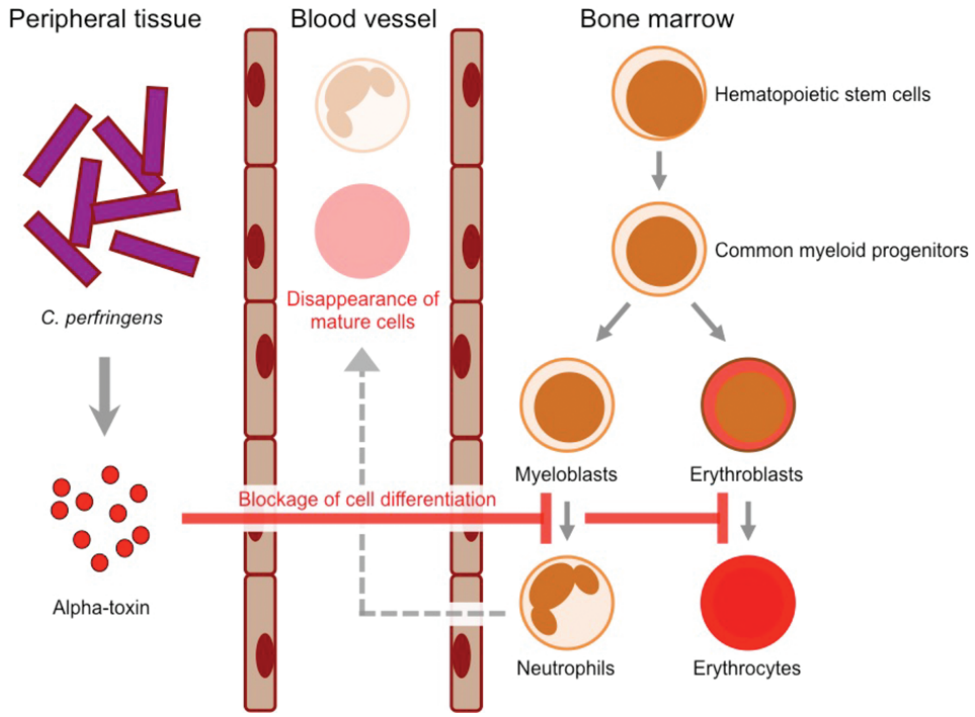

FIGURE 5 Inhibition of granulopoiesis and erythropoiesis in a C. *perfringens*-infected host. Infection with C. *perfringens* diminishes mature hematopoietic cells in the bone marrow, leading to impairment of replenishment of differentiated neutrophils and erythrocytes in the peripheral circulation and resulting in host innate immune deficiency. The major virulence factor of C. *perfringens*, α-toxin, plays an important role in this phenomenon by interfering with cell differentiation of myeloblasts and erythroblasts.

that the blockage of erythroid differentiation was involved in the reduction in mature erythroblasts by α-toxin (98). Massive intravascular hemolysis and severe anemia have been reported in C. *perfringens*-infected patients (99), although it is a relatively uncommon event. The detailed mechanisms by which C. *perfringens* infection causes severe anemia have not been elucidated, but blockage of erythropoiesis by α-toxin may be important (Fig. 5).

Experiments carried out using an inactive α-toxin H148G variant revealed that its enzymatic activity was required for the α-toxin-mediated reduction of erythroblast levels (98). Furthermore, the cell surface expression of a lipid raft marker, GM1, decreased in association with erythroid differentiation, and α-toxin affected lipid raft integrity in erythroid progenitors, leading to the impairment of erythroid differentiation. During erythroblast enucleation, the clustering of lipid rafts at the furrow between incipient reticulocytes and pyrenocytes is observed, and an inhibitor of lipid rafts impedes enucleation (100). Therefore, lipid rafts play an important role in the regulation of erythropoiesis, but the detailed mechanism by which the disturbance in lipid raft integrity by α-toxin impairs erythroid differentiation remains unclear.

STRUCTURE AND HOST CELL INTERACTIONS OF *C. PERFRINGENS* PERFRINGOLYSIN O

Perfringolysin O (θ-toxin) is a pore-forming hemolytic toxin that belongs to the cholesterol-dependent cytolysin (CDC) family (16, 101), which includes streptolysin O from *Streptococcus pyogenes*, listeriolysin O from *L. monocytogenes*, pneumolysin from *Streptococcus pneumoniae* (17), and related cytolysins produced by several other clostridia (102). The perfringolysin O structural gene, *pfo*A, is located on the chromosome (103, 104). Perfringolysin O is elaborated by most, but not all, strains of C. *perfringens* (104–107), and mature perfringolysin O (53 kDa, 473 aa) (108) is secreted as a water-soluble monomer and binds to host cell membranes in a cholesterol-dependent manner (102). Binding to the cell membrane initiates oligomerization and the formation of a pore complex that can contain up to 50 monomeric subunits and is responsible for cell lysis.

Perfringolysin O monomers have a hydrophilic, β-sheet-rich structure that can be divided into four distinct domains (109, 110) (Fig. 6). Domain 1 contains a seven-stranded antiparallel β-sheet flanked by helices and loops. Domain 2 forms an elongated β-sheet structure. Domain 3 comprises α-helices and β-sheets, and domain 4 (the C-terminal region) is divided into two distinct β-sandwich regions. Domain 4 also contains a highly conserved 11-aa Trp-rich motif (ECTGLAWEWWR) or undecapeptide loop that is near the C-terminus. This structure subsequently was shown to be similar to that of members of the eukaryotic membrane attack complex/perforin family (111).

Perfringolysin O and most of the other cholesterol-dependent cytolysins bind directly to cholesterol in the host cell membrane. Contrary to what was thought for many years, the undecapeptide is not the receptor-binding motif (112). Instead, there is a Thr-Ile pair located in a nearby loop (L1) of domain 4 that is responsible for binding to cholesterol (113). The role of the undecapeptide is to assist in anchoring the toxin monomer to the membrane and to couple membrane insertion with oligomerization (112). The next step in the

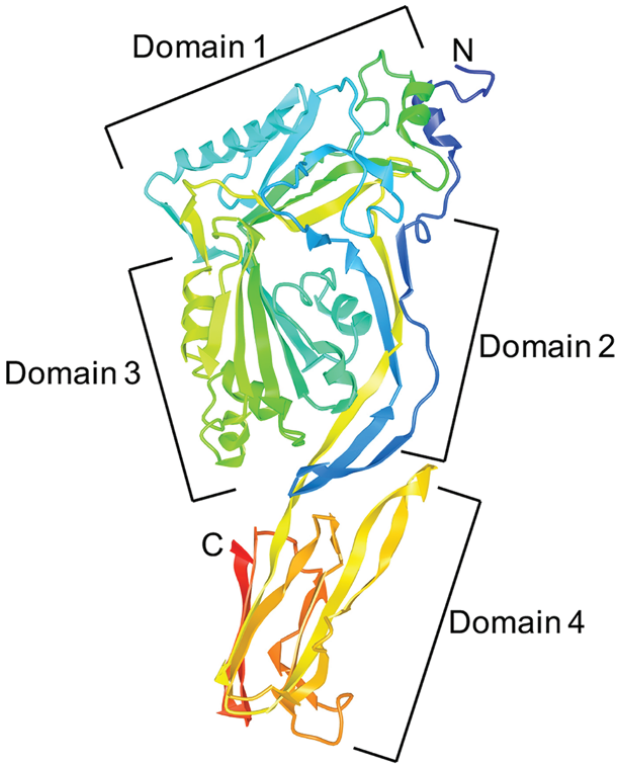

FIGURE 6 Structure of perfringolysin O. The structure of perfringolysin O was obtained from the Protein Data Bank (code 1PFO) and was created using MacPyMOL. A ribbon representation is shown, colored from blue (N-terminal) to red (C-terminal).

oligomerization process is a conformational change of two α-helical bundles in domain 3 to form two longer amphipathic β-hairpins; this extended β-hairpin structure inserts into the host cell membrane, initially to form toxin dimers and then to form a large oligomeric β-barrel pore that contains 35 to 45 monomers. The biological effect of large pore formation is to induce cell lysis by osmotic stress (114). In addition, perfringolysin O can interfere with cell signaling events by activating TLR4 and inducing inducible nitric oxide synthase expression and tumor necrosis factor-α (TNFα) secretion in bone marrow-derived macrophages (115) and by stimulating the degradation of Ubc9, thereby reducing the posttranslational SUMOylation of host proteins (116). Therefore, perfringolysin O has effects on both membrane integrity and internal cell signaling.

Perfringolysin O works synergistically with α-toxin to cause gas gangrene by promoting leukostasis and intravascular coagulation (19–21, 117). The result is decreased blood flow (87, 88) and the accumulation of PMNL and macrophages in the blood vessels around the site of infection, which leads to vascular leukostasis and contributes to the paucity of leukocyte infiltration to the site of infection (20, 21). Similarly, intramuscular injection of a crude *C. perfringens* toxin preparation causes and promotes the formation of intravascular platelet aggregates (87). Leukocytes and fibrin accumulate rapidly in the aggregate, leading to obstruction of the blood vessels and the production of thrombi that reduce local blood flow (87, 88).

Perfringolysin O upregulates the expression of adherence molecules, including platelet-activating factor, CD11b, and endothelial adherence molecules (118–120). In addition, it stimulates the expression of intercellular adherence molecule 1 and platelet-activating factor in endothelial cells (19, 118, 119, 121). The toxin triggers platelet/leukocyte and platelet/platelet aggregation by activating the platelet fibrinogen receptor gpIIb/IIIa synergistically with α-toxin (86, 122). Moreover, it has been reported to impair the polymerization of actin filaments in leukocytes and the migration of neutrophils in response to chemoattractants (118, 123). These events lead to the formation of intravascular platelet/leucocyte/fibrin aggregates, and the adherence of the aggregates to the vascular endothelial cells results in vascular injury, vessel obstruction, hypoxia, and tissue destruction (1, 30, 124). In addition, a direct cytotoxic effect of perfringolysin O on endothelial cells has been demonstrated, which also impairs leukocyte transmigration (30, 88). Disruption of the endothelium contributes to progressive edema (30). α-Toxin impairs granulopoiesis, leading to the reduction of neutrophils, and a direct cytolytic effect of perfringolysin O on leukocytes has been reported (123). Therefore, perfringolysin O works synergistically with α-toxin to reduce the level of leukocytes. Finally, *C. perfringens* cells can escape from the phagosome of macrophages and survive, and perfringolysin O is an important factor in this escape process (125, 126). These data are in agreement with genetic studies that showed that α-toxin and perfringolysin O act synergistically in the disease process (19, 20).

In the latter stage of clostridial gas gangrene, cardiovascular collapse, tachycardia, and multiorgan failure are observed in patients (1). Toxins such as perfringolysin O and α-toxin are released into the blood and can act at a distance from the site of infection. Perfringolysin O reduces systemic vascular resistance, increases cardiac output, and decreases the heart rate without a drop in mean arterial pressure (117, 127). In addition, it promotes the release of inflammatory cytokines, such as TNFα, IL-1, IL-6, platelet-activating factor, and prostaglandin I2, by acting synergistically with α-toxin, which contributes to the symptoms of toxic shock, including hypotension, hypoxia, and reduced cardiac output (30, 128).

FUNCTION AND HOST CELL INTERACTIONS OF *C. SEPTICUM* α-TOXIN

C. septicum is the primary causative agent of nontraumatic clostridial myonecrosis and enumerates an α-toxin that is essential for disease and is responsible for reduced PMNL influx into the infected lesions (25). *C. septicum* α-toxin is a member of the aerolysin family of pore-forming toxins (129, 130). These toxins include aerolysin from *Aeromonas hydrophila*, ε-toxin and *C. perfringens* enterotoxin (CPE) from *C. perfringens*, and parasporin toxins produced by *Bacillus thuringiensis*. These toxins all form small, often heptameric, β-barrel pores in host cell membranes (130). Although the crystal structures of several members of the aerolysin family have been determined, there is no such structure available for α-toxin. However, molecular modelling of α-toxin shows that it does not have the small-lobe lectin-binding domain (D1) of aerolysin, known as the aerolysin pertussis toxin domain (131), but has homologous domains to the other three aerolysin domains (Fig. 7) (132).

α-Toxin is synthesized as a preprototoxin, with a 31-aa leader sequence that is cleaved upon secretion from the bacterial cell and a 45-aa C-terminal extension that is cleaved by host proteases such as furin prior to pore formation (23, 102, 133). The resultant cleaved propeptide prevents premature oligomerization (134). The 46-kDa prototoxin

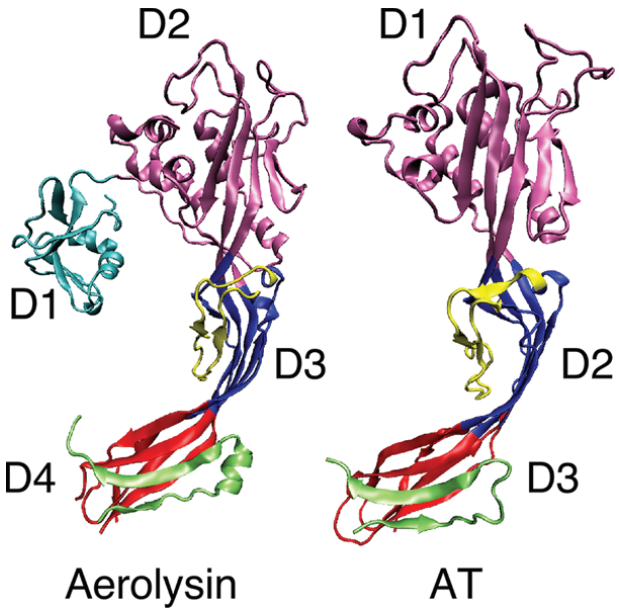

FIGURE 7 Crystal structure of aerolysin and molecular model of *C. septicum* α-toxin. Domains are indicated. Note that domain 1 (D1) of aerolysin is not present in α-toxin. AT, *C. septicum* α-toxin. Reprinted with permission from reference 137. Copyright (2006) American Chemical Society.

binds to glycophosphatidylinositol-anchored protein receptors located in lipid rafts in the host cell membrane (135). After protease cleavage on the cell membrane, the 43-kDa mature toxin undergoes a conformational change and oligomerizes to form a heptameric prepore complex that is required for pore formation (24). Cleavage of the C-terminal extension enables the formation of a transmembrane β-barrel structure, with each monomer contributing one extended β-hairpin loop to the β-barrel that forms the transmembrane pore (130, 132).

The analysis of substitution derivatives of α-toxin has yielded insights into the functional domains of the toxin (132, 136–138). Y155F and S189C α-toxin derivatives had reduced toxicity for CHO cells but were still cleaved by host proteases and could bind to glycophosphatidylinositol-anchored receptors and form oligomers. A S189C/S238C derivative retained its ability to bind, act as a substrate for furin cleavage, and form oligomers but was not toxic (136). Like aerolysin, α-toxin has a Trp-rich motif (amino acids 302 to 312) in its C-terminal domain (138). Several of the residues in this motif, including three Trp residues, are essential for binding and/or cytotoxic activity (137, 138). Fluorimetric studies using Cys-substituted derivatives led to the identification of the amphipathic transmembrane β-hairpin (Lys-203 to Gln-232) that spans the host cell membrane. Deletion of this region eliminated the toxin's ability to form pores and kill cells, but the resultant protein could still bind, undergo cleavage, and form oligomers (132). Subsequently, saturation Ala or Cys substitutions were made across the remaining residues in the α-toxin molecule, and the resultant proteins were purified and analyzed for their biological and biophysical properties (137). The results showed that the only α-toxin Cys residue, Cys-86 in domain 1, was required for receptor binding. In summary, derivatives altered in receptor binding all had substitutions in domain 1, but proteins with altered oligomerization properties had changes in domains 1 and 3. Several of these mutants have been examined in the mouse myonecrosis model (139). The results showed that both the amphipathic β-hairpin and Cys-86 were essential for disease, providing evidence that receptor binding and pore formation are important in pathogenesis.

Pore formation is essential for *C. septicum*-mediated myonecrosis (129, 140), but pore-mediated osmotic cell lysis is not the only consequence of intoxication by α-toxin. Treatment of C2C12 mouse myoblast cells with α-toxin leads to a rapid Ca^{2+} influx into the cell but does not induce apoptosis. Instead, α-toxin induces programmed cellular necrosis (140), which is consistent with the fact that it is more active against nucleated cells (141, 142). α-Toxin-mediated Ca^{2+} influx resulted in the activation of proteolytic calpain activity, a reduction in lysosomal integrity, leading to cathepsin release, mitochondrial dysfunction and ATP depletion, and release from the nucleus of the histone-binding protein HMGB1 (140). Induction of this programmed necrotic pathway was dependent on the ability to form pores; treatment with a substituted α-toxin lacking the β-hairpin loop did not induce a Ca^{2+} influx or programmed necrosis. All of these changes are consistent with α-toxin-mediated pore formation causing the induction of the programmed cellular necrosis pathway (140). Other studies have shown that α-toxin treatment of Madin-Darby Canine Kidney (MCDK) cells causes a rapid K^+ efflux, ATP depletion, and caspase-3-independent necrosis and nonapoptotic cell death (129). Subsequently, it was shown that pore formation by α-toxin led to ERK, c-Jun N-terminal protein kinase, and p38 phosphorylation and activation of their resultant MAPK pathways and the resultant dose-dependent release of TNFα (143). *C. septicum* α-toxin also leads to a significant reduction in vascular perfusion of muscle tissues, as shown by comparative intravital microscopy studies using culture supernatants from an isogenic series of *C. septicum* strains (88).

CONTROL AND TREATMENT OF HISTOTOXIC CLOSTRIDIAL INFECTIONS

The treatment of myonecrotic infections caused by *C. perfringens* and *C. septicum* is complicated by the rapid onset and progression of disease. Death can result within 24 hours of initial symptoms. Standard treatment regimens involve surgical debridement of the infected tissues, which needs to occur as early as possible (2), and treatment with penicillin and clindamycin (144). The effectiveness of the penicillin on its own has been questioned (145), and there is experimental evidence that clindamycin and metronidazole, alone or in combination with penicillin are more effective in mice (145, 146). Often, surgical removal of an infected limb is the only option available in life-threatening infections.

In other studies, mice lacking TNF-α were protected from *C. perfringens* α-toxin-induced lethality (147), demonstrating that TNF-α release is essential for the lethal effect of the toxin. Treatment with erythromycin blocked α-toxin-induced release of TNF-α from peripheral neutrophils and the activation of TrkA and ERK1/2, demonstrating that toxin-induced TNF-α release is related to stimulation of the ERK/MAPK signaling pathway through TrkA. Anti-TNF-α antibodies, but not anti-IL-1β or anti-IL-6 antibodies, blocked the death of mice and intravascular hemolysis by α-toxin. Compounds that block the release of TNF-α therefore may be valuable in treating patients with *C. perfringens* infection. Recently, experiments with *C. perfringens* infections in mice provided evidence that treatment with opioids such as buprenorphine stop the development of

disease (148), but this treatment option has not been tested in clinical settings.

Several studies have investigated the use of recombinant α-toxin variants to vaccinate against C. *perfringens*-mediated gas gangrene, primarily from a military or biosecurity perspective or for elderly patients that are at risk. Initial studies showed that the isolated nontoxic C-terminal C2 lipid-binding domain of α-toxin (amino acids 247 to 370) was highly immunoprotective in mice (14). Mice immunized with this formaldehyde-treated recombinant antigen were protected from the effects of α-toxin and from challenge with a 10× LD_{50} dose of C. *perfringens*. By contrast, mice immunized with the equivalent N-terminal enzymatic domain (amino acids 1 to 249) produced immunoreactive antibodies, but these antibodies did not protect against the toxin or disease. These results were confirmed in a subsequent, more detailed, vaccination study that also showed that mice vaccinated with the C-terminal domain and then challenged in a murine infection model had reduced thrombosis and an increased PMNL influx into the site of infection (149). To further define the immunoprotective region of the C-terminal domain, the potency of several recombinant fragments (amino acids 251 to 370, 281 to 370, and 311 to 370) fused to glutathione S-transferase (GST) were examined in an active vaccination model (150). Vaccination with the 251 to 370 and 281 to 370 GST-fusions protected against the toxicity of α-toxin and against C. *perfringens* challenge, whereas the amino acid 311 to 370 derivative yielded only partial protection. Despite these three promising studies, no commercial C. *perfringens* vaccine is currently available.

Research in Julian Rood's laboratory was supported by project grant GNT1082401 from the Australian National Health and Medical Research Council.

SECTION 6

Mycobacteria and Corynebacteria

Section Editor: **Miriam Braunstein**

Mycobacteria and corynebacteria are high-GC Gram-positive bacteria of the *Actinobacteria* phylum and *Corynebacteriales* order. Mycobacteria and corynebacteria share a novel cell envelope containing a highly impermeable crosslinked network of peptidoglycan, arabinogalactan and long-chain mycolic acids. In conjunction with non-covalently linked lipids and glycolipids, mycolic acids form an outer membrane bilayer, called the mycomembrane. The double-membrane, diderm, cell envelope of mycobacteria and corynebacteria is dramatically different from the monoderm cell envelope of most Gram-positive bacteria. Moreover, the mycomembrane is physically similar to that of Gram-negative bacteria, although its molecular composition differs completely from that of the Gram-negative outer membrane. Along with the distinctive cell envelope structure, mycobacteria and corynebacteria, are increasingly recognized as having novel mechanisms for critical processes such as cell division, protein export, and metabolism.

Among the diverse array of mycobacterial and corynebacterial species are two notorious bacterial pathogens: *Mycobacterium tuberculosis* (etiologic agent of tuberculosis) and *Corynebacterium diptheriae* (etiologic agent of diptheria). The chapters that follow cover a mix of topics on the physiology and pathogenesis of mycobacteria and corynebacteria. As a result of increased research attention and new molecular technologies, our understanding of the distinctive features of these bacteria has expanded greatly in recent years.

Mycobacteriophages

GRAHAM F. HATFULL

63

INTRODUCTION

Because of the importance of mycobacterial diseases such as tuberculosis and leprosy, mycobacteriophages have long been studied, with the first ones being isolated in the 1940s (1–3). At that time, it was recognized that bacteriophages display particular profiles of specificity for their bacterial hosts, nearly always distinguishing between bacteria in different genera and sometimes distinguishing between strains of the same bacterial species (4–7). Mycobacteriophages thus presented a plausible means of identifying (i.e., typing) clinical isolates by scoring for phage sensitivity profiles, with the prospects of obtaining data considerably faster than standard protocols that required extensive growth of the host. *Mycobacterium tuberculosis*—the causative agent of human tuberculosis—has a remarkably slow growth rate (24-hour doubling time), so phage typing can speed up diagnosis by several weeks. This general concept of exploiting the relatively rapid propagation of mycobacteriophages has been a common theme in their subsequent development (8–10).

Although the important role of *M. tuberculosis* in human health was known from the early studies by Koch, our knowledge of the organism was limited for many years because of the inability to genetically transform it with the uptake of DNA (11). An important breakthrough in the late 1980s occurred when it was demonstrated that phage DNA could be taken up by mycobacterial spheroplasts, followed by conversion into infectious units and plaque formation (12). The approach illustrated three additional aspects of working with the mycobacteria and their phages. First, Jacobs and colleagues used *Mycobacterium smegmatis* as a surrogate host, because of its much faster growth rate (~3-hour doubling time), coupled with mycobacteriophages which had been shown to infect both *M. smegmatis* and *M. tuberculosis*. Second, the construction of shuttle phasmids, which replicate as a large plasmid in *Escherichia coli* and as a phage in mycobacteria, facilitated the introduction of foreign DNA, because the shuttle phasmids could be manipulated readily in *E. coli* and then used as vectors in *M. smegmatis* and *M. tuberculosis*. Shuttle phasmids have found extensive uses for introduction of reporter genes, transposons, and allelic exchange substrates into a variety of mycobacterial hosts (11). Lastly, shuttle phasmids built with temperate phages enable stable introduction of gene cassettes that can be used to evaluate expression and activities of foreign genes such as those for antibiotic resistance (13).

Mycobacteriophages entered the genomics era in the early 1990s (14), opening up a variety of new tools that can be applied to studying the mycobacteria (15). As sequenced mycobacteriophage genomes emerged over the next 25 years, the extent of their considerable genetic diversity became apparent, culminating in a current collection of over 9,600 individual phages, of which 1,500 have been completely sequenced (16). Because all of these (with the exception of DS6A) infect a single bacterial strain (*M. smegmatis* mc^2155), they represent a unique perspective on viral diversity and bacteriophage evolution. These also encompass more than 150,000 genes and together provide a tremendous resource for advancing our understanding and control of their mycobacterial hosts.

In this article I will review our current understanding of mycobacteriophages, their roles in mycobacterial genetics, and the insights gained from their diversity. A number of other reviews of mycobacteriophages are available (8, 9, 15, 17–26) that provide a variety of perspectives, including a historical view of this field. Here, I will focus primarily on recent developments that have not been extensively covered in the earlier reviews, the most recent of which was 4 years ago (27).

GENERAL MYCOBACTERIOPHAGE FEATURES

Current Genomic Scope

As noted above, the total number of mycobacteriophages isolated is nearing 10,000, and over 1,500 have been completely sequenced. Further details about how these were isolated and characterized are provided below, but for the most part we will constrain the discussion here to the subset of genomes that are available in the public databases, totaling 899 genomes. As should be apparent from the discrepancies in these numbers, at the time of writing there are almost 700 genomes that have been sequenced but are not yet fully annotated and submitted to GenBank. The complete and up-to-date list of sequenced phages and their current status is available at the PhagesDB (http://phagesdb.org) and Phamerator (http://phamerator.org) databases (16). It should be noted that the annotation, quality control review, revision, and GenBank submission represents a current bottleneck in the pipeline and is relatively time-consuming compared to sequence determination. Nonetheless, the dataset of 899 genomes offers a representative view of the overall diversity, which does not change substantially if the larger dataset is considered.

It is also worth noting that there is a growing collection of genomically sequenced phages that infect other bacterial

doi:10.1128/microbiolspec.GPP3-0026-2018

hosts within the phylum *Actinobacteria*. This includes substantial numbers of phages of *Arthrobacter*, *Corynebacterium*, *Gordonia*, *Microbacterium*, *Propionibacterium*, *Rhodococcus*, and *Streptomyces* (16). These will not be discussed in detail here but are especially relevant in considering the processes by which bacteriophages evolve.

Phage Discovery and Genomics as a Platform for Advancing Science Education

Isolation of bacteriophages using a simple plaque assay has been performed successfully for the past 100 years (28). However, genomic analyses of these phages have only been available since about the early 1990s (14), and DNA sequencing technology has advanced rapidly since then. The coupling of phage isolation and genomic analysis facilitates defining viral diversity and provides insights into understanding their evolution (29). The finding that there are so many different phage genomes underpins the use of phage isolation and genomics as a powerful platform for integrating our missions in science education with those in phage exploration (30).

The Phage Hunters Integrating Research and Education (PHIRE) program was developed at the University of Pittsburgh in 2002 with the intent of using phage discovery and genomics to introduce high school and undergraduate students to authentic scientific research (31). The PHIRE program provides strong evidence not only that students can readily successfully engage in research, but that it is inclusive and does not require either prerequisite understanding of bacteriophages or technical skills in microbiology (30, 32). Since its inception, students in the PHIRE program have isolated over 300 individual mycobacteriophages, about one-half of which have been sequenced. However, PHIRE is essentially a local program mostly confined to the Pittsburgh region where our research laboratory is located.

The demonstration that this discovery-rich platform is well suited to scientific novices provided the rationale for broader dissemination and expansion to a nationwide program organized as a course-based research experience for first-year undergraduate students. In 2008, in collaboration with the Science Education Alliance (SEA) program at the Howard Hughes Medical Institute (HHMI), we developed the Science Education Alliance Phage Hunters Advancing Genomics and Evolutionary Science (SEA-PHAGES) program (33). SEA-PHAGES is an example of a general model for transforming science education—an inclusive research education community—in which a program infrastructure supports inclusion of different types of institutions and students from all types of backgrounds (Fig. 1). In its first year (2008) there were 12 participating institutions, but additional schools have joined SEA-PHAGES each year, and currently there are over 120 member schools, with more than 4,500 student researchers each year (33, 34). The SEA-PHAGES experience strongly promotes student engagement in studying science, with project ownership and networking being prominent contributing elements (34). It has also had a major impact on our understanding of bacteriophages, and SEA-PHAGES students and faculty have isolated a total of 9,600 actinobacteriophages, of which 1,880 have been sequenced. Of these, 8,800 are mycobacteriophages, of which over 1,200 have been sequenced (16).

In general, we have adopted a nonsystematic scheme for naming these newly isolated phages. The reasons are threefold. First, the genomes are clearly constructed as architectural mosaics, with individual genomes composed of specific assemblages of individual genes (35) (see below). It is thus unclear how to use a systematic naming system that reflects the genomic constitution of the phages. Second, naming a newly discovered phage is interesting and stimulating for PHIRE and SEA-PHAGES students and provides an opportunity for them to define their discoveries and their contributions, expanding the sense of project ownership that is important to the impact of these programs (34). Third, from a purely practical perspective, it is much easier to remember names such as Corndog, Rosebush, Patience, Daenerys, RedRock, Phayonce, or Snazzy than some tedious series of meaningless letters and numbers. Science doesn't have to be dull and boring all the time.

Databases

The large sizes of both the SEA-PHAGES program and the growing phage collections require data management that is accomplished with three interconnected databases with front-end web interfaces. One is available at http://seaphages.org and contains information about the SEA-PHAGES program, including institutional participation, contact information, protocols, forums, news events, etc. The second is at http://phagesdb.org (16) and contains all of the information associated with individual phages, including genome sequences, GPS location coordinates, BLAST functions, and many other resources. It is a place where information on newly isolated phages is deposited and where data on all of the phages is available.

The third is the Phamerator database at http://phamerator.org. The database was designed as a means of organizing mycobacteriophage-encoded genes into "phamilies," or sequence-related groups, together with the nucleotide sequence data (36). This information can then be used for comparative genomics, such as displaying sets of genome maps in which the genes are colored according to their phamily membership and pairwise nucleotide sequence similarity can be displayed. The Phamerator database includes some genome-associated information that is not present in the other databases, and a web browser interface provides facile database usage. It liaises with both phagesdb.org and GenBank to help maintain data consistency and is also used by other programs such as Starterator and the Phage Evidence Collection and Annotation Network (PECAAN). As such, Phamerator plays a central role in the annotation pipeline, from genome sequence to GenBank submission (Fig. 1). Phamerator databases containing different numbers of genomes can be downloaded and "frozen" so that they can be archived and used for publication preparation.

Mycobacteriophage Morphologies

All of the mycobacteriophages isolated to date are tailed phages with double-stranded DNA (dsDNA) genomes; no single-stranded DNA (ssDNA) or RNA phages have been found. Three families of such *Caudovirales* have been described for other bacterial hosts (*Siphoviridae*, *Myoviridae*, and *Podoviridae*) but only siphoviral and myoviral morphotypes are present among the mycobacteriophages (Fig. 2). Because such a large number have been morphologically examined, it seems unlikely that mycobacteriophages with podoviral morphologies exist. Interestingly, phages with podoviral morphologies have been described for other actinobacterial hosts, including *Arthrobacter* and *Streptomyces* (37, 38), suggesting that the absence of podoviral mycobacteriophages is due to a physical blockage presented by mycobacterial cell walls, rather than being evolutionarily inaccessible.

The mycobacteriophage myoviruses, which have contractile tails, are all confined to a single genomic type, with

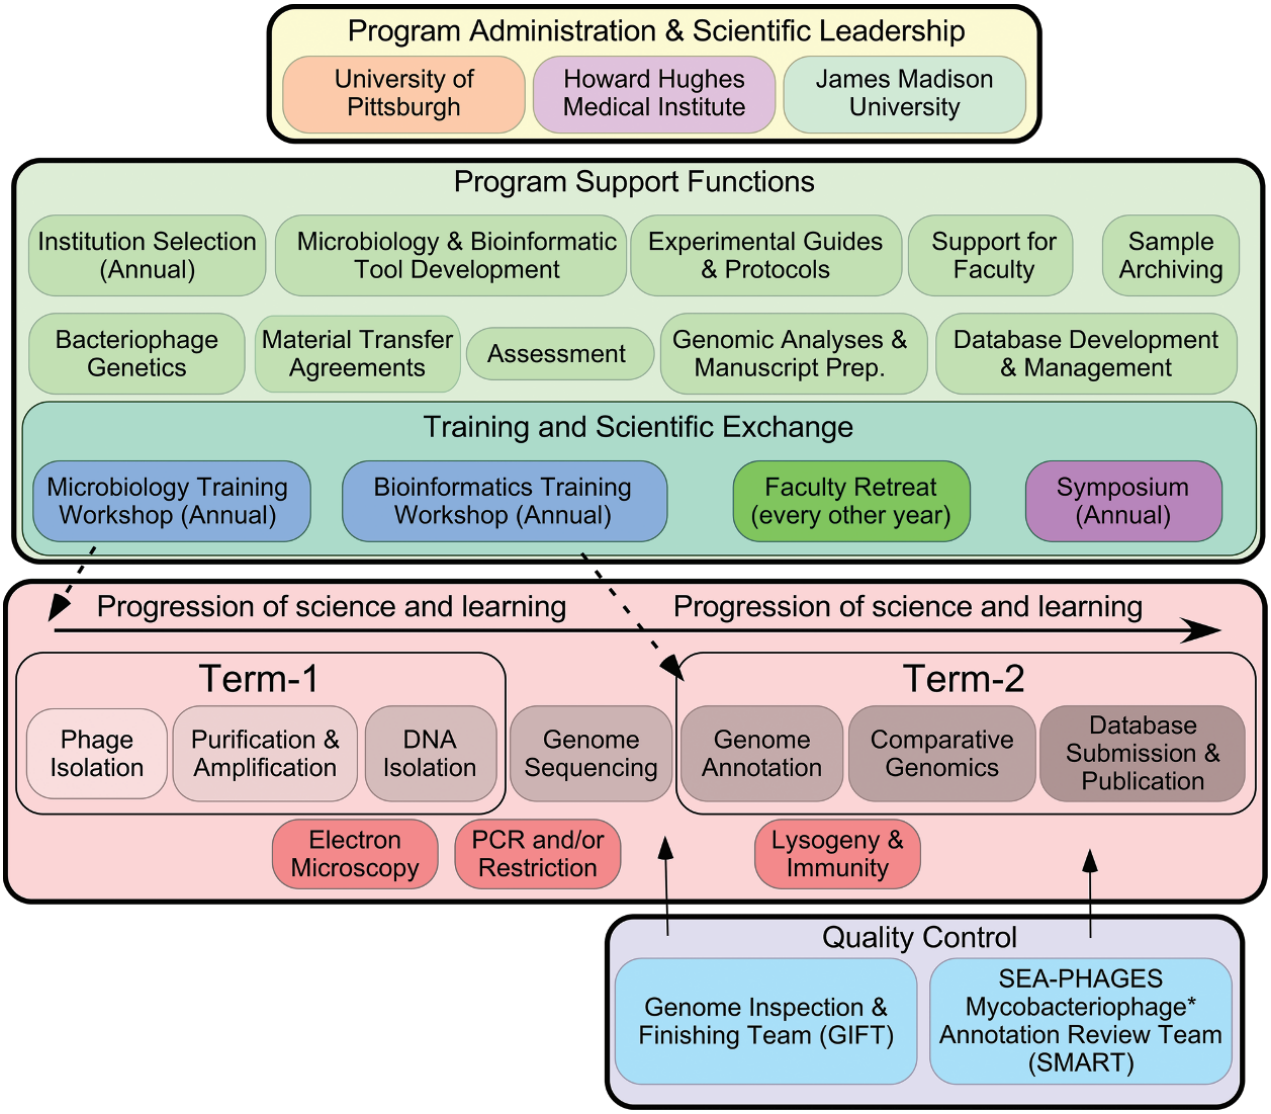

FIGURE 1 Organization and structure of the SEA-PHAGES program. SEA-PHAGES program administrators (yellow box, top) oversee support components critical to program implementation (green box, upper middle). The typical two-term course structure (red box, lower middle) includes phage isolation through comparative genomics; additional characterization includes electron microscopy, PCR/restriction analysis, and lysogeny assays (red ovals). Sequence and annotation quality control is shared with SEA-PHAGES faculty teams (purple box, bottom right). Reproduced with permission from reference 34.

phages grouped within cluster C (Fig. 2; see below). All of the other mycobacteriophages are siphoviruses, with long flexible noncontractile tails, and these span considerable genetic diversity (Fig. 2). Most mycobacteriophages have isometric capsids (i.e., like a soccer ball) with sizes varying from a diameter of about 40 nm to about 80 nm, correlating with their genome sizes. However, some have prolate heads with the length:width ratios varying from about 2.5:1 to about 4:1 (Fig. 2). Tail length also varies considerably, ranging from about 135 nm to more than 350 nm.

MYCOBACTERIOPHAGE GENOMIC DIVERSITY

Clusters, Subclusters, and Singletons

When the first few mycobacteriophage genome sequences were determined in the 1990s, it became apparent that they do not simply represent variants of a common sequence type (14, 35, 39–41). As the number of sequenced genomes grew, it became clear that these could be grouped according to their overall nucleotide sequence similarity. These groups are referred to as "clusters," and in general, phages within a cluster share evident DNA sequence similarity to each other that spans more than 50% of their genome lengths; phages in different clusters share little if any DNA sequence similarity (42). When 30 genome sequences were available (42), these could be assembled into six clusters (clusters A to F); nine phages were not closely related to the others and are referred to as singletons. Within 4 years, the number of genomes had doubled, and these 60 phages were grouped into 9 clusters (clusters A to I), and five singletons (43). It also became clear that within some clusters there are boundaries justifying a separation into subclusters, and average nucleotide identity values reflect these divisions. Thus, for the 9 clusters formed with 60 sequenced mycobacteriophages, 5 could be divided

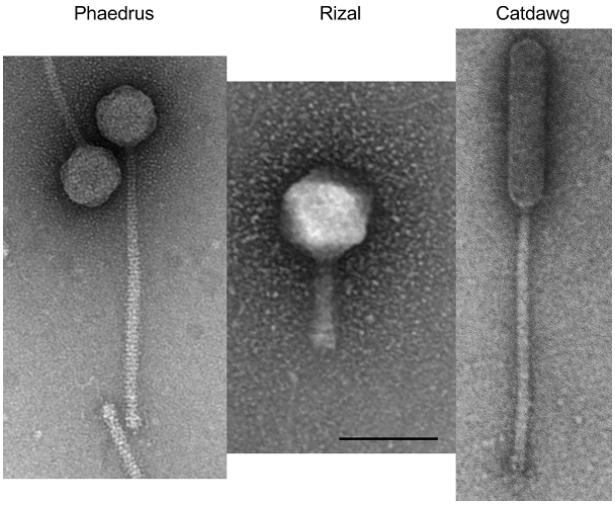

FIGURE 2 Mycobacteriophage viral morphotypes. Mycobacteriophages generally fall into two morphological families, the *Siphoviridae* with long flexible tails (e.g., Phaedrus and Catdawg) and the *Myoviridae* with contractile tails (e.g., Rizal). Most of the siphoviral phages have isometric heads (e.g., Phaedrus), but some (e.g., Catdawg) have prolate heads. Scale marker is 100 nm.

into subclusters. For example, cluster A contained a total of 13 phages at that time, 8 of which are in subcluster A1, and 5 are in subcluster A2 (43). As noted at the time (43), the nature of the relationships within clusters is not uniform, such that the apparent divisions revolve around different ANI values for different clusters. A similar pattern has been reported for phages of the *Enterobacteriaceae* (44).

The 899 mycobacteriophages considered here assemble into a total of 28 clusters together with 5 singletons (Table 1). These clusters are designated clusters A to Z and clusters AB and AC (note that cluster AA is constituted with genomes that are yet to be submitted to GenBank and are thus excluded from the current list). Twelve of these clusters (A, B, C, D, F, G, H, I, K, L, M, and P) are currently divided into subclusters (Table 1). The largest of the clusters is cluster A with 322 phages, and this is split into 18 subclusters (A1 to A14 and A16 to A19; note that A15 is made up solely of *Gordonia* phages). The largest of the clusters that is not subdivided is cluster E, with 52 members (Table 1). These all share substantial nucleotide sequence similarity but are far from identical and differ with numerous small insertions/deletions/substitutions relative to each other, often constrained to a single gene or a small group of genes. Although it typically requires two or more members to constitute a cluster, three of the clusters in the dataset discussed here (X, Y, AC) contain only a single member, and the other members of these are sequenced but are not yet publicly available in GenBank (Table 1).

Cluster assignments simplify the analyses and descriptions of phage genomes, but clusters represent groupings of convenience rather than hard biological boundaries, consistent with them having mosaic architectures (45). As more phage genomes are sequenced, the boundaries between different clusters and subclusters have become more obscure. Thus, these divisions likely reflect unequal sampling of phages from an underlying continual spectrum of diversity, of which not all parts are equally prevalent in the biosphere (45). Thus, while the vast majority of mycobacteriophages within a cluster do indeed share nucleotide sequence similarity spanning greater than 50% of the genome lengths, some phages have genomes that fall only just below that, complicating their cluster assignment. This has become especially apparent in the comparative genomic analyses of *Gordonia* phages (46, 47). As a consequence, for those genomes that have partially shared sequences where nucleotide-based assignments are difficult, it is recommended that the encoded genes be first grouped into phamilies using Phamerator and the proportions of shared genes be calculated (http://phagesdb.org). Phages sharing more than 35% of their genes should be grouped into the same cluster, and those with fewer than 35% should be in different clusters (46).

Allocation of Cluster Designations

When only a relatively modest number of mycobacteriophages were sequenced and the first few clusters were designated, their naming was simple, using ordered alphabetical names (cluster A, cluster B, etc.). Three events prompted further consideration of this naming system. First, as the numbers of clusters grew, the possibility arose that new clusters would be designated even after cluster Z was named. How should these be designated? Second, as our attention shifted to actinobacterial hosts in other genera, how should these be termed? Third, phages isolated on different host genera might group into the same cluster either frequently or very rarely. How should this be accommodated?

We decided to implement a scheme in which blocks of letters are set aside for clusters of phages isolated on particular hosts (Table 2). In brief, the alphabetical series is extended beyond clusters A to Z into two-letter (e.g., AA, AB, AC, etc.) and then three-letter (AAA, AAB, AAC, etc.) names as needed, and a block is assigned to each host. For example, phages isolated on mycobacteria have a reserved block of clusters A to Z and AA to AJ. Currently, only clusters up to AC are actually used, so there are seven unoccupied clusters. The size of the initial block (40 for mycobacteriophages; Table 2) is mostly a guess based on an estimate of how many phages may be isolated for that host and their predicted diversity. For example, a relatively small block is set aside for *Cutibacterium* (including the formerly named *Propionibacterium acnes*) phages, because the phages of *Cutibacterium acnes* are very similar to each other and are all in a single cluster (48). If a block of cluster allocations becomes fully used, then additional blocks can be added, even though they are likely to be nonsequential. For example, phages of *Arthrobacter* were initially assigned clusters AK to AZ, but these were quickly used, and an additional block of FA to FZ was added (Table 2). Similarly, *Gordonia* phages were found to be quite diverse, and the initial allocation of clusters CQ to CZ was quickly populated. However, this could be easily extended to clusters DA to DZ, because these had not been previously assigned (Table 2), preserving a series of consecutive letters.

This scheme works in large part because most of the phages isolated on a host of a different genus form new clusters from those previously described. However, we do not expect a strict correlation between the genus of the host and the phage cluster designation. An excellent example is provided by cluster A. Cluster A is highly populated (Table 1) with individual phages, by far the majority of which were isolated on *M. smegmatis*. However, some cluster A phages were isolated on *Gordonia* strains, all of which constitute subcluster A15; it is noteworthy, however, that in spite of the genomic relationships, subcluster A15 phages do not infect *M. smegmatis*, and other cluster A phages that have been

TABLE 1 Mycobacteriophage clusters and subclusters

[a]The numbers of subclusters are shown but are not applicable (N/A) for singleton phages.
[b]Singleton phages with no close relatives. Phage names are provided.

tested do not infect *Gordonia terrae*. Likewise, we note that several *Gordonia* phages described previously also infect *Nocardia* strains (49). In general, we predict that the more closely related the bacterial hosts are phylogenetically, the more likely it is that their phages may be grouped into the same clusters.

We have constrained these cluster allocations to phages of hosts in the phylum *Actinobacteria*. However, this could plausibly be extended to phages of hosts in other phyla using a similar scheme and designations, using a prefix to denote the phylum in circumstances where confusion might arise.

Mycobacteriophage Gene Phamilies

The central questions in deciphering these mycobacteriophage genomes are how are they architecturally structured and how have they evolved? To simplify the comparative genomic analyses, we can take the total gene set, compare each gene to all other genes pairwise at the amino acid sequence level, and place similar genes into groups that we call phamilies (43), often abbreviated to phams. This is a different strategy to using a hidden Markov model, in part in an attempt to accommodate the complexity arising from the substantial number of modular genes. When the dataset was small, phamilies were constructed using BlastP and ClustalW, using cutoff values of 10^{-50} (E value) and 32.5% (amino acid identity), respectively (36). These values were set to capture distantly related homologues into the same phamily but to minimize false-positive inclusion of non-homologues in phamilies (36). As the dataset expanded, the use of BlastP and ClustalW became computationally prohibitive, and they were substituted with a kmer-based

TABLE 2 Allocation of cluster designations

Host phylum	Host genus	Designations	Number
Actinobacteria	*Mycobacterium*	A–Z, AA–AJ	40
	Arthrobacter	AK–AZ, FA–FZ	42
	Streptomyces	BA–BT	20
	Propionibacterium	BU–BZ	6
	Rhodococcus	CA–CP	14
	Gordonia	CQ–DZ	36
	Microbacterium	EA–EM	13
	Corynebacterium	EN–EZ	13

method for phamily assembly (45). Different phams are identified by numbers (pham 1, pham 2, pham 3, etc.), and we attempt to maintain pham designations as additional phages are added to the databases. The program Phamerator uses k-clust to sort genes into phamilies and displays genome maps that include pham designations and other genome and gene information (36). The web-based version of Phamerator is available at http://phamerator.org, which uses a default database(Actino_Draft) that contains information on all sequenced phages of actinobacterial hosts. The Actino_Draft database is constantly updated as new phages are isolated and their genomes sequenced, and as such contains genomes of several different status classes including "draft" (auto-annotated) annotations, "final" annotations that have been manually reviewed and revised, and "Gbk," whose annotation history is unknown.

A Phamerator database (Mycobacteriophage_899) was constructed for the 899 phages discussed here, which contains only genomes that are available in GenBank. This database contains 96,979 genes, which are sorted into 6,046 phamilies. The average number of genes per phamily is 16.03, and approximately 25% (1,506) contain only a single gene and are designated as "orphams." The largest phamily has 337 gene members.

MYCOBACTERIOPHAGE GENOME ORGANIZATION AND EXPRESSION

Genome Annotation and Gene Naming

When phage genomes are sequenced within the PHIRE or SEA-PHAGES program, they can be autoannotated simply with Glimmer (50) and GeneMark (51) using the program DNA Master (http://cobamide2.bio.pitt.edu/). Although these programs are quite good at identifying coding regions and predicting translational start sites, they do this incorrectly for about 10% of the genes. To obtain as well-supported an annotation as possible, each of the predicted genes is manually inspected, and putative functional assignments are made. The genomes are also inspected for missing genes and for tRNA genes and other features. All annotated genomes are reviewed through a quality control process prior to submission to GenBank (Fig. 1).

To simplify the gene naming process, each open reading frame or RNA gene is assigned a gene name as a number, sequentially starting with 1 at the left end of the genome and proceeding rightward. It is important to note that gene names (e.g., 1, 2, 3, etc.) and their gene products (e.g., gp1, gp2, gp3, etc.) have no functional meaning. Thus, for example, both phage Corndog and phage Rosebush have a gene *20*, each coding for a protein, gp20, but Corndog gp20 and Rosebush gp20 are unrelated at the sequence level and are not functionally related.

Genome Organization

Although there is great sequence diversity among the mycobacteriophages, there are several common themes arising in their overall organization and genomic architecture. An example is shown in Fig. 3. First, there is a common organization of virion structural genes in all of the phages with siphoviral morphologies, which includes all of the clusters and singletons, with the exception of cluster C. The genomes are typically presented such that these structural genes are at the left end of the genome and transcribed rightward (Fig. 3). The gene order is typically terminase (small and large subunit genes), portal, capsid maturation protease, scaffold, capsid, tail capping and head-tail connectors, major tail subunit, tail assembly chaperones (typically expressed via a programmed translational frameshift), tape measure protein, and minor tail genes (of which there may be 4 to 10) (Fig. 3).

In some genomes, usually those that are relatively short (40 to 45 kbp), the 20 to 25 closely packed virion structure and assembly genes span about 22 to 23 kbp, occupying ~50% of the whole genome (Fig. 3). In such phages, the terminase small subunit gene is usually very close to the physical left end of the genome (in phage Taheera, the translation start site of the small terminase subunit genes is predicted to be at coordinate 47). In other genomes, the gene order may be conserved, but the virion structure and assembly genes are interspersed with nonstructural genes. In phage Omega and its relatives (52), the virion structure and assembly genes span over 35 kbp, and the inserted genes include a glycosyl transferase, an *O*-methyl transferase, and an IS*110*-like transposon. In phage Marvin and its relatives two of the minor tail protein genes are atypically located near the right end of the genome, separated by about 20 kbp from the other structural genes (53).

All of the phages code for a lysis system that typically includes three components: a holin, an endolysin (lysin A), and a serine-esterase, referred to as lysin B or lysterase (see Fig. 3). The lysis cassette is located in one of two genomic positions. In most phages it is immediately downstream (to the right) of the virion structural genes (Fig. 3). However, in the cluster A phages it is positioned to the left of the structural genes, between the leftmost *cos* end and the terminase genes (14, 54). Within the lysis cassettes, the holin gene is sometimes difficult to assign, because of there being several genes with predicted transmembrane domains near the lysin A gene; it is plausible that several of them play some role in the regulation of lysis. The endolysin genes are constructed modularly, with individual modules shared between otherwise distantly related phages (55). The lysin B genes code for esterases that cleave the mycolic acids from the cell wall to promote efficient lysis, and at least in phage Giles the lysin B is not essential for plaque formation, although it forms smaller plaques with fewer particles (56). Some of the mycobacteriophages appear to lack a lysin B gene altogether (e.g., Rosebush), and it is unclear if other genes substitute for its function (56).

Over one-half of the clusters of mycobacteriophages appear to be temperate and contain an integration cassette (e.g., clusters A, E, F, G, I, J, K, L, M, N, O, P, Q, T, X, Y, Z; singletons DS6A, Dori, Kumao, MooMoo, and Sparky). Typically, the integration cassette is located near the center of the genome and contains an integrase gene and an *attP* site

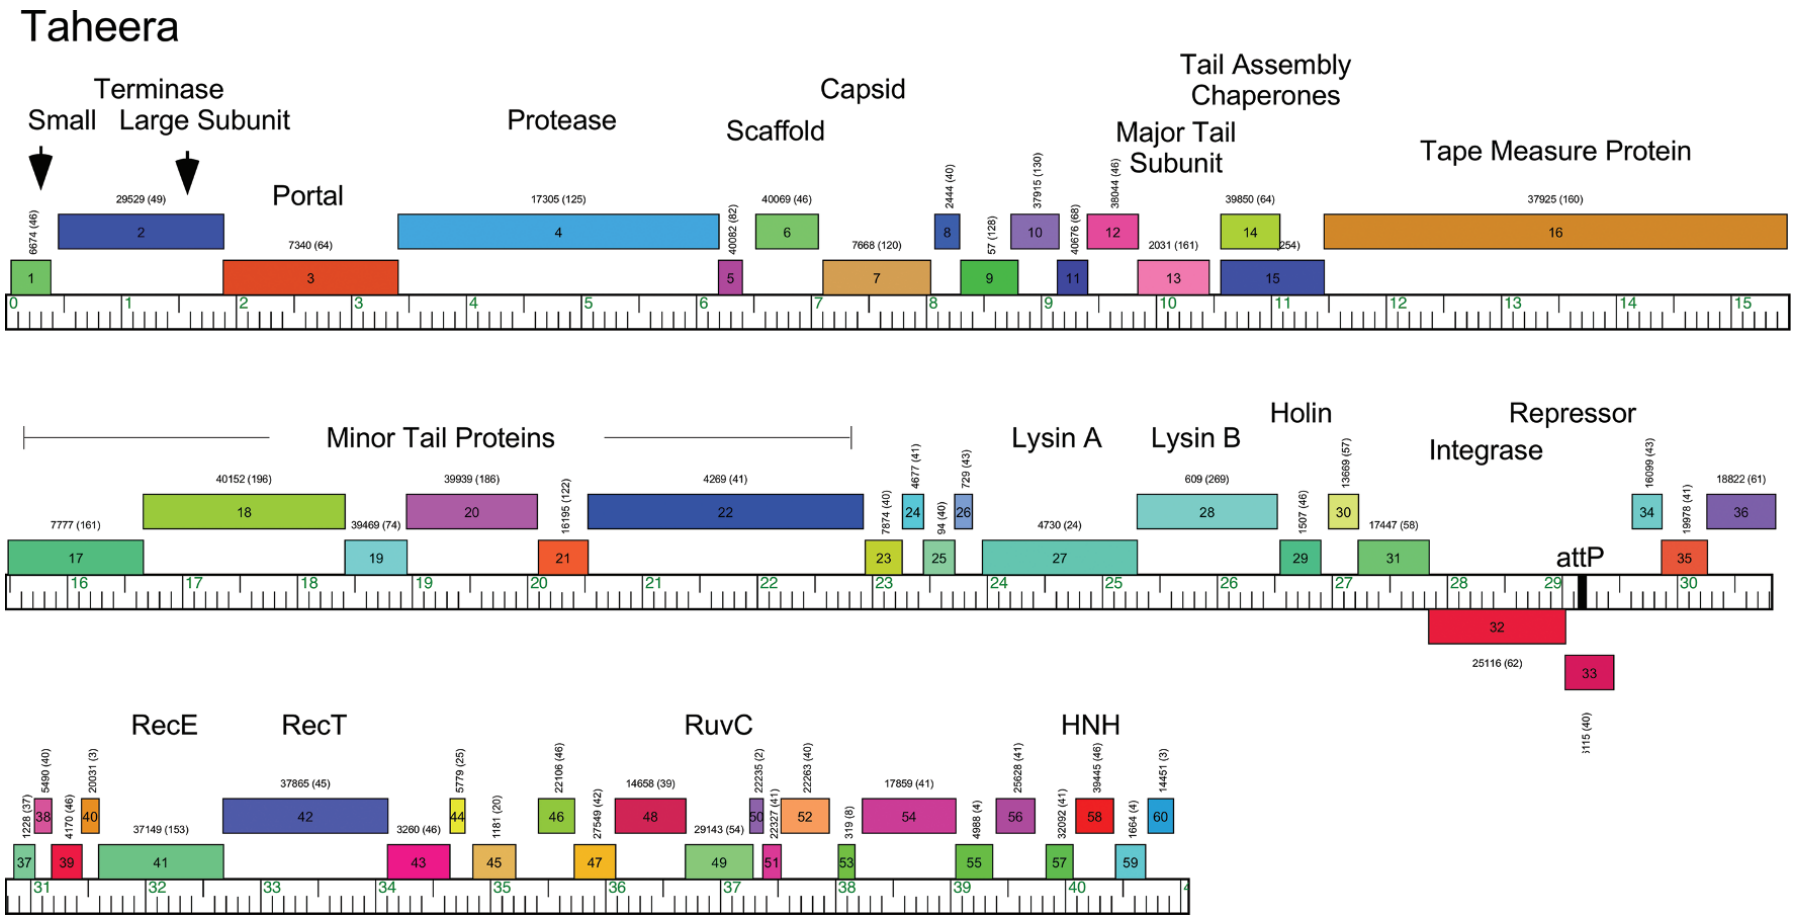

FIGURE 3 Genome organization of mycobacteriophage Taheera. The genome of phage Taheera (cluster G) is represented as a scale bar (major intervals: 1 kbp) with predicted genes shown as boxes either above (rightward transcribed) or below (leftward transcribed). Gene numbers are shown within each box, and the phamily designation is shown either above or below with the number of phamily members shown in parentheses. Putative gene functions are indicated.

(see Fig. 3). Both major families of integrases—tyrosine integrases and serine-integrases—are represented, although the serine-integrases are typically found in cluster A and K genomes. Over a dozen *attB* sites are predicted to be used for prophage integration (22). Interestingly, some phages—predominantly members of cluster A—do not have an integration cassette and instead code for a *parABS* partitioning system (57, 58). In lysogeny, these phages replicate extrachromosomally at low copy number, although the replication functions have yet to be determined (58).

The mycobacteriophages have a variable number of genes that are not involved in virion structure and assembly, lysis, or integration, depending on the overall genome size. Thus, the smallest of the mycobacteriophages (e.g., clusters G, N, T) may have only 25 to 30 additional genes (Fig. 3), whereas larger genomes (e.g., cluster J) may have over 150 such genes. A few of these have predicted functions in DNA metabolism, including replication and recombination, but the vast majority are relatively small and are of unknown function. In phage Giles, it has been shown that about half of the nonstructural genes are dispensable for lytic growth (59). Little is known about the essentiality of any of the predicted DNA replication functions, including the Pol I type genes and Pol III alpha genes present in some of the phages. Many mycobacteriophages do not encode any DNA polymerase, so those that do may need them to synthesize genomes with altered chemistry or because the host polymerases are degraded or inactivated. However, this has yet to be investigated.

Mycobacteriophage Gene Expression

A general picture of mycobacteriophage gene expression is emerging, although only a rather small subset of phages has been examined. Lytic gene expression has been described for several cluster A phages including L5, D29, StarStuff, Kampy, and SWU1 (54, 60, 61); Giles (cluster Q) (59); Fruitloop (cluster F) (62); and several cluster N phages (63). In general, there appear to be two major types of transcription that occur, in early and late periods. Early gene expression occurs in the first 30 minutes, with late transcription initiating about 30 minutes after infection and continuing until lysis, typically about 180 minutes after infection. These general profiles are in agreement with patterns of phage protein synthesis detected by radiolabeling (14, 40).

Early gene transcription usually encompasses nonstructural genes in the right arm, and the virion structure and assembly genes and the lysis cassette are expressed late. In phages such as Fruitloop (Fig. 4), late transcription starts ~5 kbp from the right genome end (in the 113-bp intergenic region between genes *91* and *92*) and proceeds rightward through *cos* into the structural genes (62) (Fig. 4). Of the 11 right arm genes (*92* to *102*) at the beginning of the late operon, 4 of the gene products have predicted functions. One (gp92) is a predicted transcriptional regulator, two (gp99 and gp102) are putative glycosyltransferases, and gp100 is a putative kinase. It is plausible that several of these may be involved in postreplication DNA modification as protection against host defenses. Currently, very little is understood about the factors needed to activate late transcription in any of the mycobacteriophages. Presumably, they are encoded as early genes, but they have not been identified.

Curiously, in the cluster A phages that have been transcriptionally characterized (L5, D29, StarStuff, RedRock, Kampe, SWU1), a noncoding region near the right genome end is transcribed extremely high very early in lytic growth (54, 58, 60, 61). Several small transcripts may be made, but their functions are not known. However, they appear to be quite toxic to *M. smegmatis*, and even *E. coli*, somewhat complicating their study (54). It was previously shown that host gene expression is shut down during L5 early lytic growth (14), and a role for these early RNAs in host shutdown would be consistent with their severe toxicity.

Lysogenic gene expression has been explored in a few mycobacteriophages, primarily those in clusters A, F, Q, and N (58, 59, 62, 63). Not unexpectedly, the repressor is typically expressed, and the lytic genes are switched off. However, it is not uncommon for additional genes—typically located near the repressor—to also be expressed (see below). The cluster A phages are unusual in that they contain a large number of putative repressor binding sites (54, 64–66), spanning the entire genome. These sites are 13 to 14 bp long, asymmetric, and predominantly present in short intergenic regions. Furthermore, the sites are mostly oriented in one direction relative to the direction of transcription (64). It is proposed that at least one of these sites acts as a true operator site for regulation of the early lytic promoter P_{left} (67), whereas the others, termed "stoperators," act to promote transcription termination, primarily to prevent expression of toxic genes during lysogeny (64).

Unusual Life Cycle Regulation

Some of the mycobacteriophages employ an interesting and noncanonical system for the establishment of lysogeny that differs from the well-studied paradigms such as in coliphage lambda. Examples of integration-dependent immunity are found in mycobacteriophages in clusters G, N, and P, and the best studied is that of phage BPs (cluster G) (68). However, these systems have specific bioinformatic features that are readily recognizable in a variety of other temperate phages (46).

Perhaps the most striking feature of the integration-dependent immunity systems is that the phage attachment site (*attP*) is located within the coding region of the immunity repressor (Fig. 5). At first, this is seemingly a bizarre organization, because integrase-mediated site-specific recombination between the phage *attP* and host *attB* sites results in disruption of the repressor gene, even though repressor synthesis is absolutely required for maintenance of lysogeny (68). A rationalization of this emerges from a second common feature, a C-terminal tag in the virally encoded repressor gene product that promotes degradation, typically via *ssr*A-like proteolysis. Because of this *ssr*A-like tag, the virally encoded form of the repressor is rapidly turned over, and insufficient repressor is made to maintain lysogeny or confer superinfection immunity (68). Integration results in removal of the C-terminal 30 to 35 amino acids, including the *ssr*A-like tag, such that the prophage-encoded form of the repressor is active for maintaining lysogeny and immunity to superinfection (Fig. 5). These phages thus require integration as a prerequisite for lysogeny, and the efficiency of lysogeny is determined by the level of integration, which in turn is modulated by a tag for proteolysis at the C-terminus of integrase (68).

These features impose constraints on other aspects of immunity regulation and are accompanied by some notable consequences. First, we should note that in all of the systems studied to date, the integrases are of the tyrosine-recombinase family and use an *attB* site that overlaps a host tRNA gene (Fig. 5). The common core, a region of sequence identity between *attP* and *attB*, is typically 25 to 45 bp and contains not only the region at which strand-exchange occurs, but also

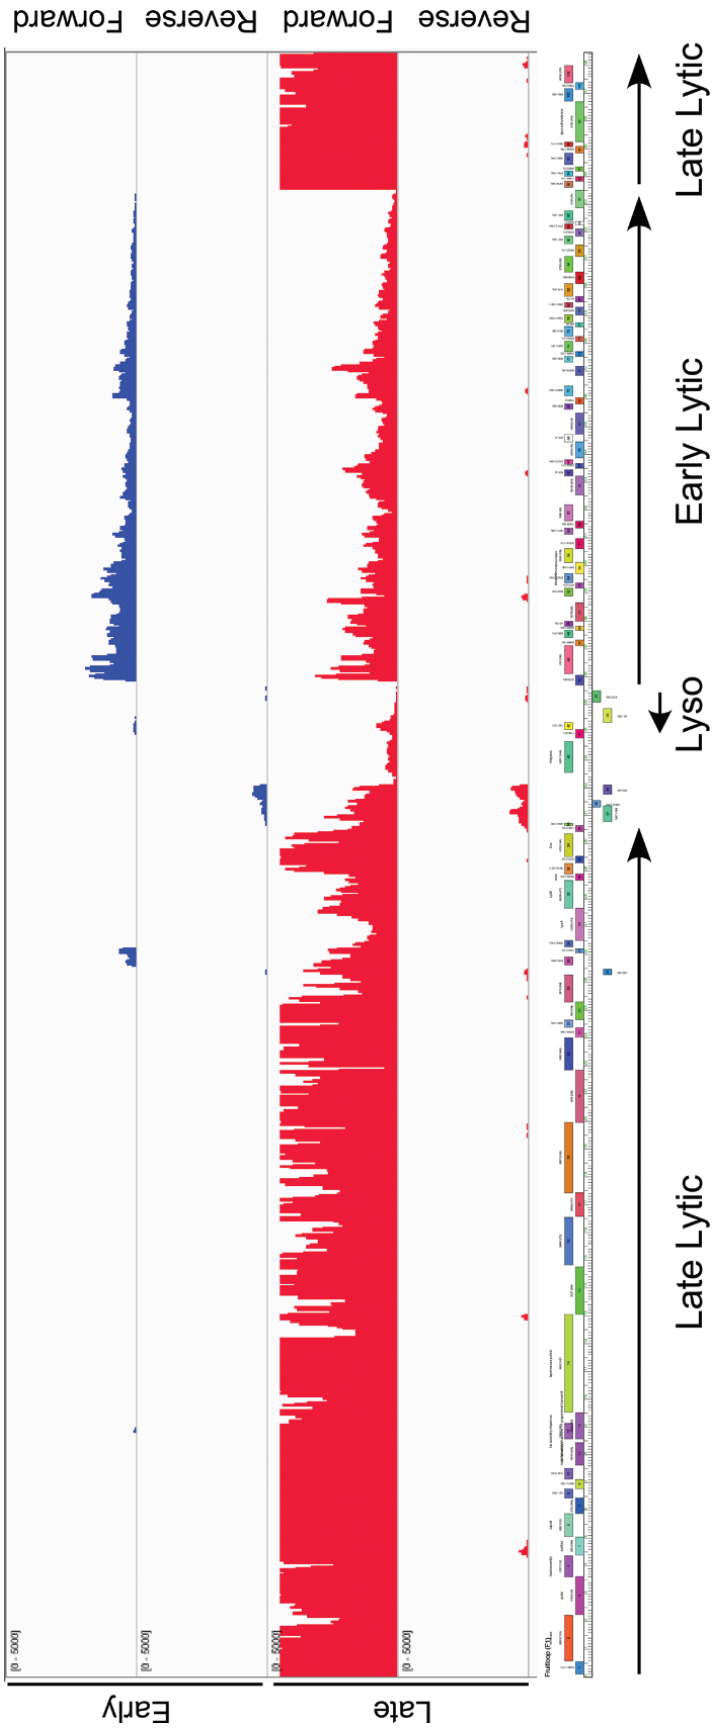

FIGURE 4 Gene expression in mycobacteriophage Fruitloop. RNA was isolated from *M. smegmatis* infected with phage Fruitloop at either early (30 min) or late (150 min) time points after infection. Following strand-specific RNAseq analysis, sequence reads were mapped to the Fruitloop genome (shown below). Reads mapping to the forward and reverse strands are indicated on the right. Scales for the numbers of sequence reads are from 0 to 5,000. Reproduced with permission from reference 62.

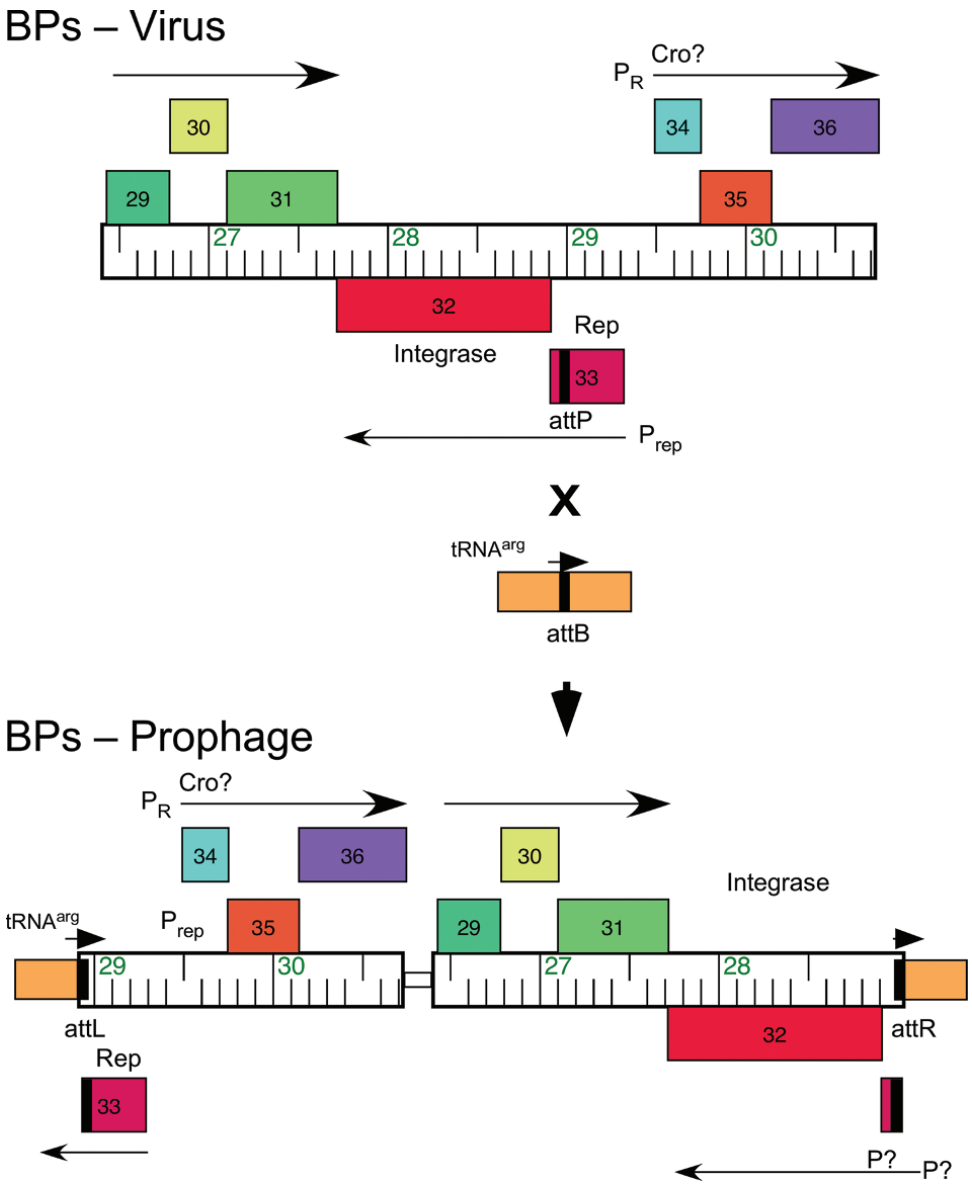

FIGURE 5 Integration-dependent immunity regulation. BPs is a cluster G phage, and a central ~4 kbp segment of the genome is shown at the top. Genes are shown as colored boxes, transcribed rightward or leftward as depicted above or below the genome, respectively. The repressor and integrase genes (*33* and *32*, respectively) are transcribed leftward from the P_{rep} promoter. The *attP* site (black bar) is located within the repressor open reading frame and can recombine with an *attB* site overlapping an *M. smegmatis* $tRNA^{arg}$ gene. Establishment of lysogeny involves formation of an integrated prophage in which an active form of the repressor is expressed from near *attL*, and the 3′ end of the gene is near *attR*. The virally encoded form of the repressor contains a C-terminal *ssrA*-like tag that targets it for degradation, and it fails to confer immunity. Integration results in removal of the C-terminal tag such that the prophage-expressed form of the repressor is stable and confers immunity.

the sequences corresponding to the 3′ end of the tRNA gene; tRNA gene integrity is thus maintained at the attachment junction (*attL* or *attR*) following integration (Fig. 5). In phage BPs, the common core is 35 bp long and positioned 33 codons from the 3′ end of the viral repressor gene. Following integration, the first base of the bacterial sequence joined at *attL* changes a cysteine codon (5′-TGT) to a translation terminal codon (5′-TGA), so the prophage-encoded form of the repressor lacks the C-terminal 33 amino acid residues of the virally encoded form (68).

Canonical tyrosine integration systems such as in phage lambda and mycobacteriophage L5 (69, 70) use complex *attP* sites containing secondary integrase-binding sites flanking the common core (i.e., arm-type Int-binding sites) and thus span up to 250 bp. Not only is there no evidence of similar arm-type binding sites in BPs or other integration-dependent systems, but the integrase proteins lack an N-terminal arm-type binding domain (68). As such, these are simple site-specific recombination systems reminiscent of FLP or Cre. This in turn raises the question of how directionality (i.e., integration

versus excision) is regulated, because without the ability to use arm-type binding to form higher-order protein-DNA architectures, there is no obvious role for a recombination directionality factor such as Xis (71). It is likely that directionality is regulated at least in part by the availability of active integrase, because the integrases in these systems also contain an *ssr*A-like C-terminal proteolysis tag. Removing the tag leads to higher rates of excisive recombination even in the absence of additional phage-encoded proteins (68).

The relationship between the *attP* site and the repressor gene also results in an unusual expression pattern (Fig. 6). This is illustrated by transcriptome sequencing (RNAseq) analysis of an *M. smegmatis* lysogen carrying a prophage, the cluster N phage Panchino, which integrates at the *attB*-4 site overlapping a tRNA-lys gene (22). The truncated prophage form of the repressor (gene *33*) is expressed as expected, but the host tRNA-lys gene is also expressed, generating RNA on both strands within the repressor gene (Fig. 6). These rightward transcripts terminate before they proceed through to gene *34*, which is a candidate for a *cro* gene, whose expression could result in interference with lysogeny and induction of lytic growth. It is somewhat surprising that the transcripts originating from the tRNA do not act as antisense inhibitors of repressor expression. This unusual expression pattern is observed in all the integration-dependent systems that have been examined by RNAseq (63).

Finally, these immunity systems can be used to construct integration vectors for inserting genes into mycobacterial chromosomes at *attB* loci, as has been described for other integration vectors (72–74). However, they transform at very low frequency because of the *ssr*A-like tags on the integrase. Removal of these tags gives higher transformation frequencies, but this may be accompanied by instability of the integrated vector if the integrase gene is still present in the recombinant strains (68).

INSIGHTS INTO PHAGE EVOLUTION

Mosaicism: The Hallmark of Phage Genomes

Comparative genomic analysis of phages clearly shows them to have modular structures, with segments assembled to form distinct genomes (35, 75). This is evident at the nucleotide sequence level when comparing phages grouped within particular clusters or subclusters, where otherwise closely related segments are interspersed with regions that are unrelated or more distantly related. An example illustrated by some genomes grouped in subcluster A2 is shown in Fig. 7. It is strikingly common for the boundaries between shared and nonshared sequences to coincide with gene boundaries. A vast number of discontinuities are identifiable, and rarely are there signs of sequence homology that could have promoted recombination through a homology-dependent mechanism, although such events have been described (54). This has led to the suggestion that the recombination events are likely to predominantly occur without extensive sequence dependence but with selection for function (76). It is plausible that very small regions of homology (3 to 5 bp) are favored, and these could be mediated by phage-encoded recombinases, which often have relaxed sequence requirements (77–79).

Genomic mosaicism is also evident when comparing genes at the amino acid sequence level, where distant homologues can be identified (Fig. 8). There are numerous examples in which gene members of a phamily are present in two otherwise unrelated genomes, such that the flanking genes to its left and its right are quite different (Fig. 8).

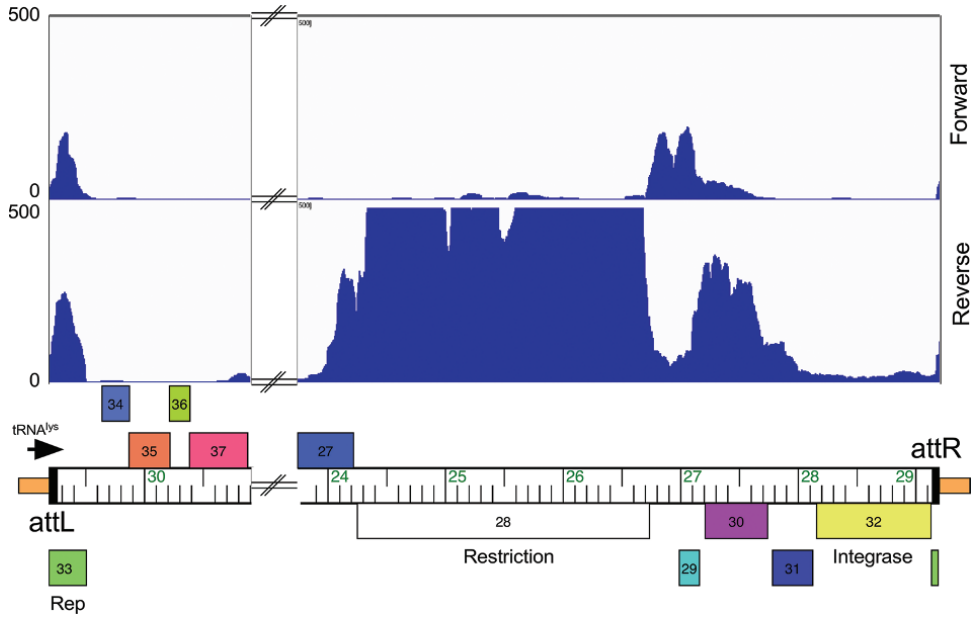

FIGURE 6 Gene expression in a Panchino lysogen of *M. smegmatis*. RNA was isolated from a lysogen of mycobacteriophage Panchino and strand-specific RNAseq reads were mapped to the Panchino prophage. Only the genome segments at the ends of the prophage near *attL* and *attR* are shown. Sequence reads for forward and reverse DNA direction are shown, and the scales are 0 to 500 reads. Genes below the genome are transcribed leftward, and those above are transcribed rightward. Panchino uses an integration-dependent immunity system similar to that in phage BPs (see Fig. 5). Genes *31* to *28* are also expressed; the lytic genes are not expressed (not shown). Reproduced with permission from reference 63.

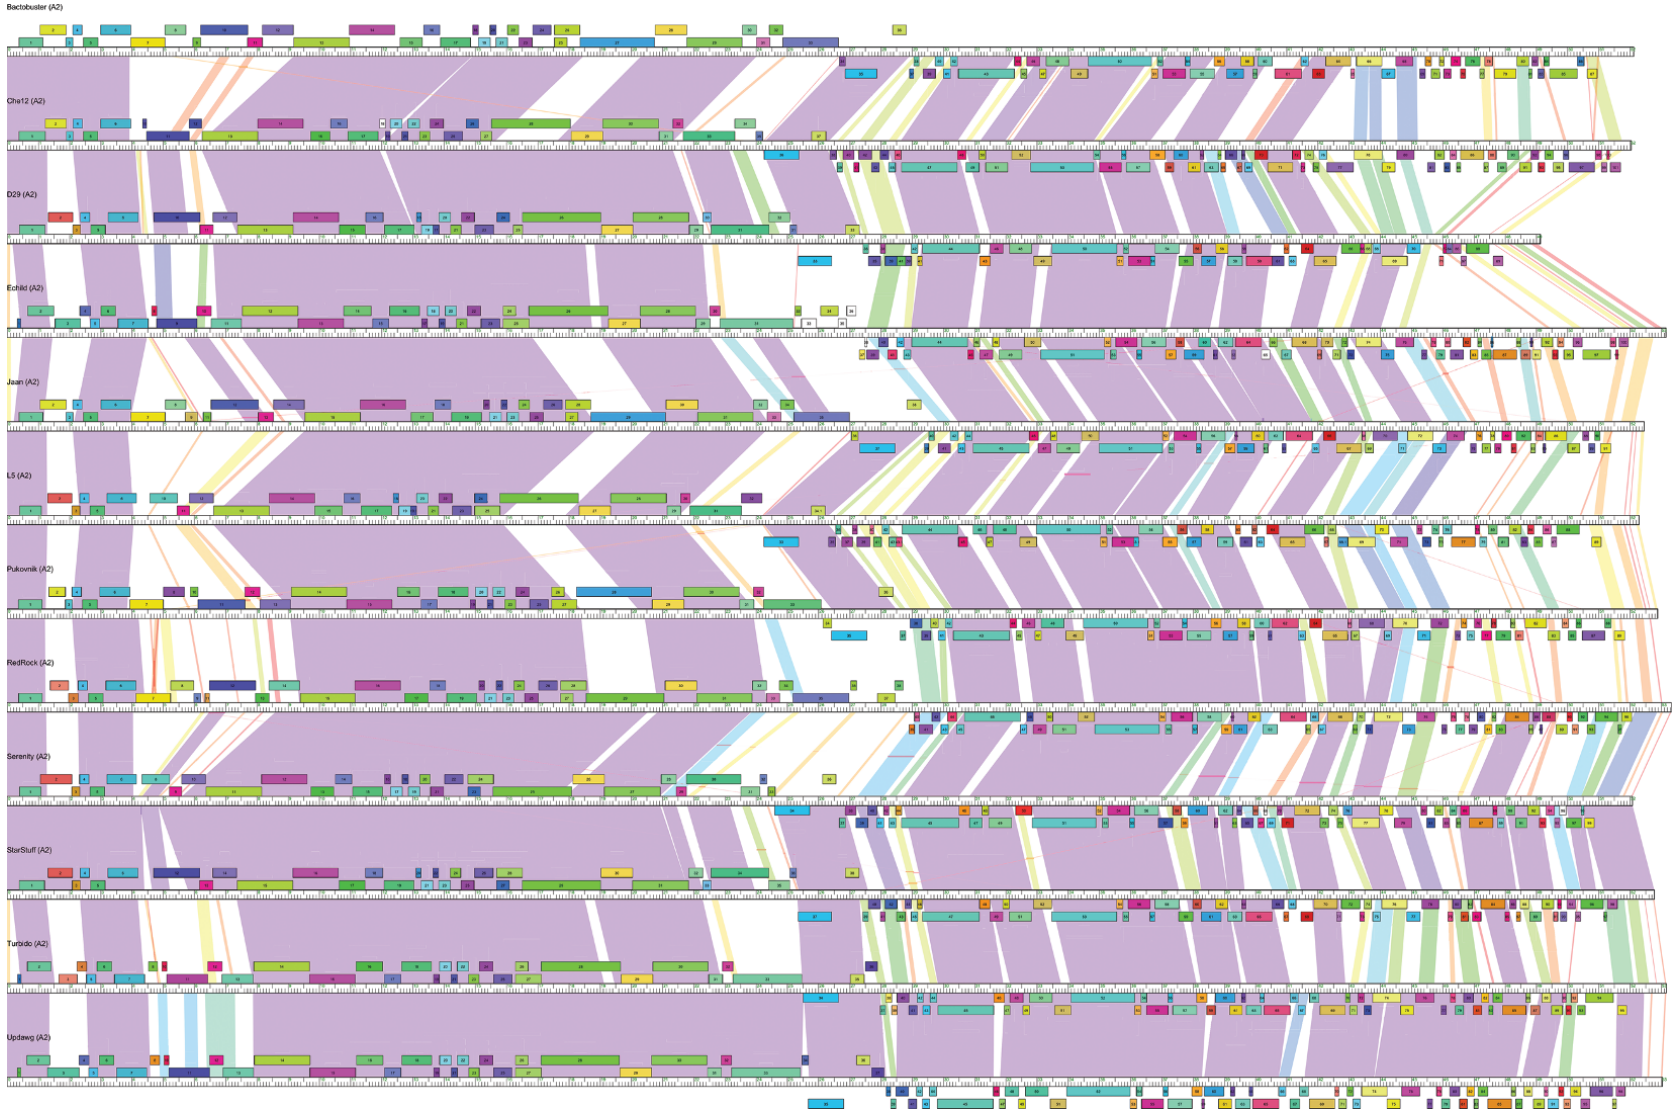

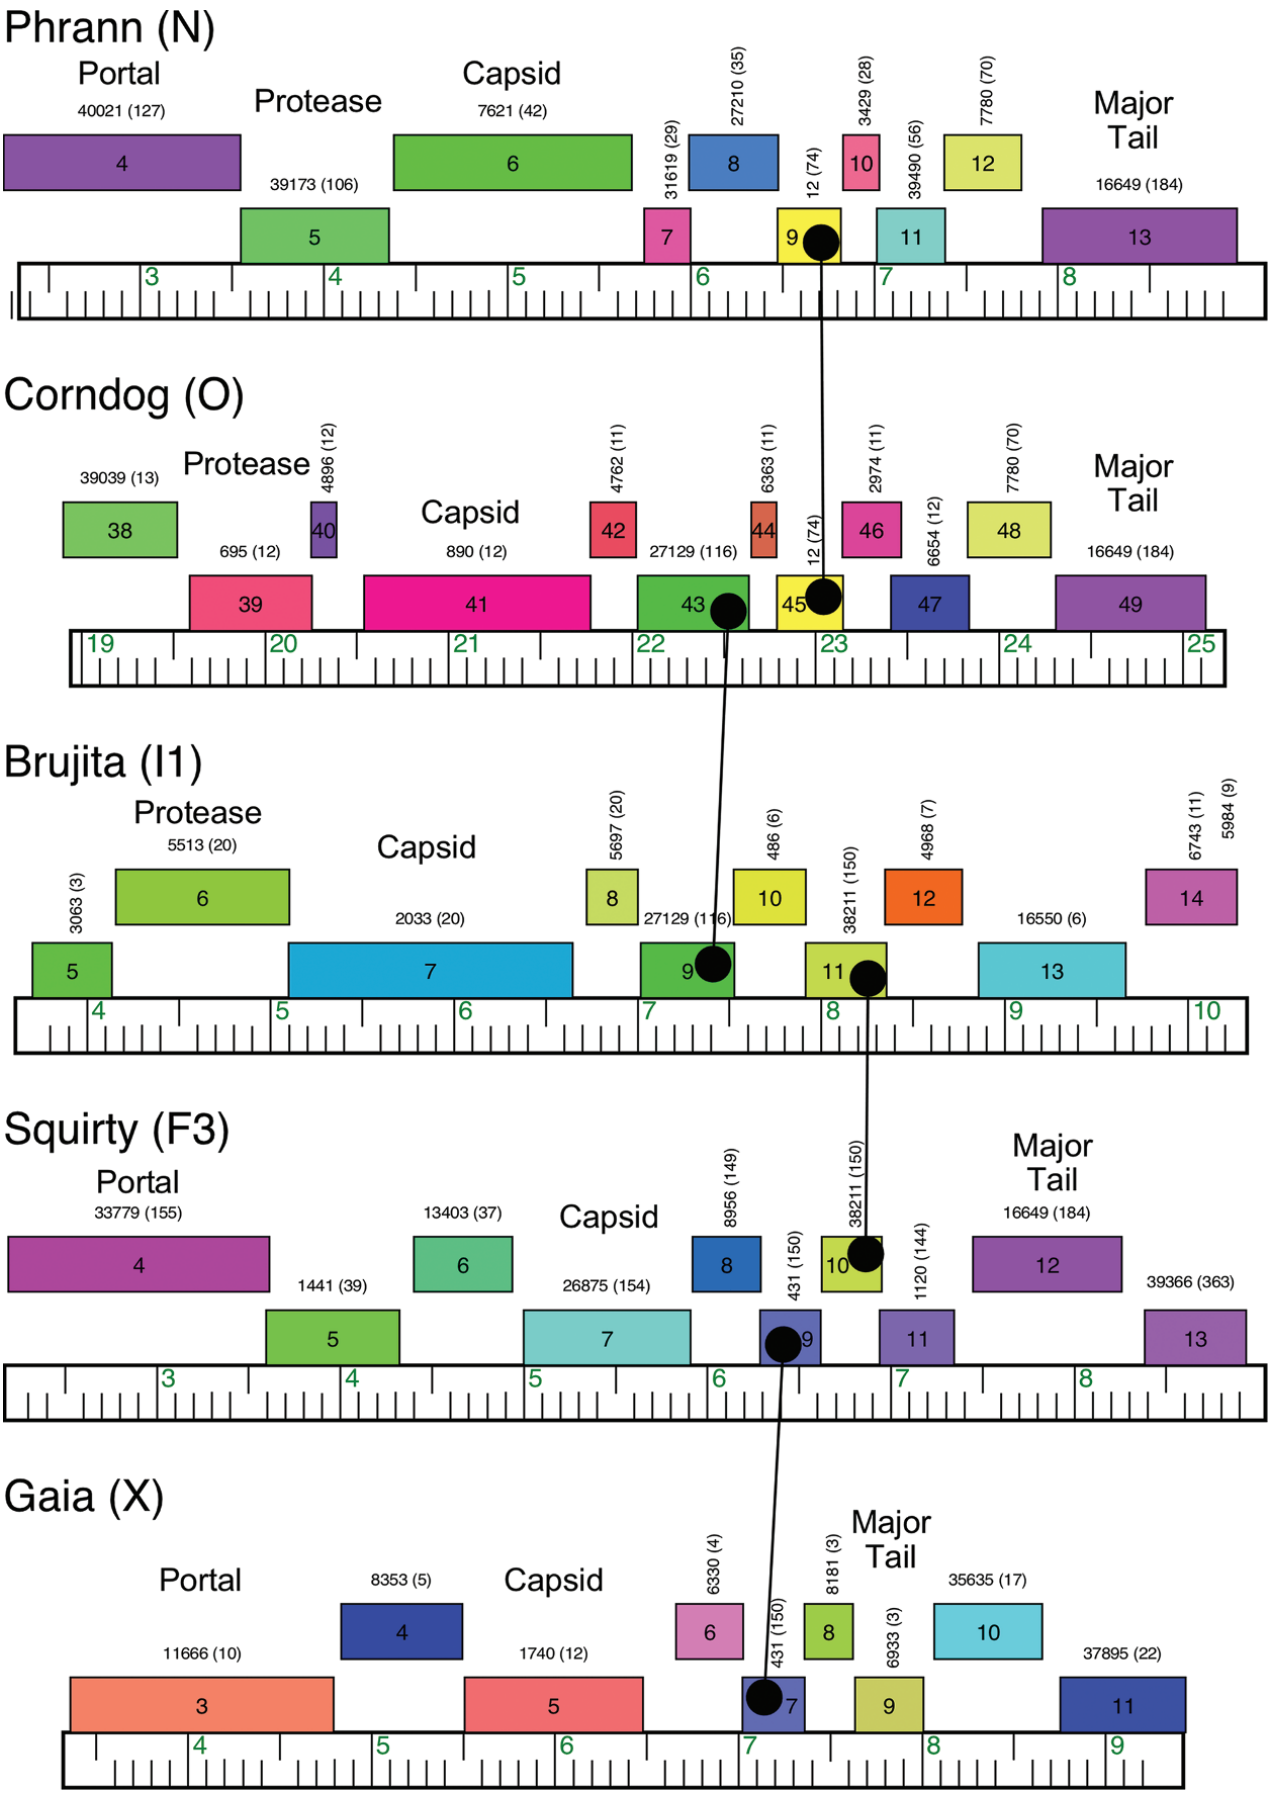

FIGURE 7 Genomic mosaicism in subcluster A2 phages. Mycobacteriophages are characteristically mosaic, with shared genome segments interspersed with nonhomologous regions. The genomes of 12 subcluster A2 phages are shown (Bactobuster, Che12, D29, Echild, Jaan, L5, Pukovnik, RedRock, Serenity, StarStuff, Turbido, and Updawg), with pairwise nucleotide sequence similarities shown as shadings between the genomes; shading is spectrum colored, with violet being the most closely related and red being just above the threshold E value of 10^{-5}. Genes are shown as colored boxes, and genes within the same phamily are similarly colored. Note the segments with close sequence similarity (violet-shaded regions) interspersed with dissimilar regions (white-shaded segments).

Although sometimes two or more genes may be coevolving and are shared between genomes, it is very common to observe single genes as units within the mosaic architecture. This mosaicism is particularly pervasive among the large number of small nonstructural genes, most of which are of unknown function. However, it is also evident in some of the virion structure and assembly genes, especially those located between the capsid and major tail subunit genes (Fig. 8).

Mobile Elements

Although it is anticipated that mobile genetic elements contribute to mosaicism, transposons, introns, and inteins are relatively rare in mycobacteriophage genomes. There is an IS*110*-like element in phage Omega and some other cluster J phages (52), IS*605*-like elements in phage Llij and several other subcluster F1 phages (although inserted at several distinct locations), an IS*1096*-like element in the cluster G phage LouisV14, and an IS*1380*-like element in Guillsminger (subcluster K5). There are instances of introns (e.g., in Omega and other cluster J phages) (52) and inteins, especially in terminase large subunit genes (65). However, there are more genes appearing to code for stand-alone homing endonucleases or HNH proteins (65). These are expected to be mobile, and it is not unusual to find HNH genes sharing high levels of amino acid sequence and sometimes nucleotide sequence similarity located in different genomic contexts, indicative of recent mobility.

The most common mobile elements are small mycobacteriophage mobile elements (MPMEs) that form two main classes, MPME1 and MPME2, which share about 85% nucleotide identity with each other (80). These were first identified by comparison of genomes in cluster G, where some pairs of genomes are very closely related and differ primarily by insertion of the MPME (80). These comparisons reveal the sequence of the preintegration site and thus the consequences of insertion. The MPMEs are small (~440 bp) and have short (11 bp) imperfectly conserved inverted repeats (IRs) at each end (IR right [IR-R] and IR left [IR-L]), and IR-R is joined to the target DNA. However, the junction at IR-L contains six additional base pairs that are not evidently part of the transposon and are not derived from the target sequence. Neither the origin of these nucleotides nor the mechanism giving rise to their inclusion is known. The MPMEs contain a small opening reading frame coding for a putative 125-residue protein, although it has no motifs commonly found in other transposases or recombinases (80). Many instances of these MPMEs have been identified (over 120 MPME1 and over 35 MPME2) in a variety of genomes (including those in clusters F, G, I, O, T, and W); within a group they are either completely identical or differ by one nucleotide difference. Thus, even though there has been no experimental demonstration of mobility, there is strong evidence that they are indeed mobile, and their small size and unusual features suggest that they warrant further investigation.

Multiple Modes of Evolution

The pervasive mosaicism of the genomes likely arises because of a relatively high level of horizontal genetic exchange relative to the mutational clock. However, the rates have not been simple to quantify, in part because of the challenges in determining the number of horizontal genetic exchange events and estimating mutation rates that likely differ among different phages, especially those that may deploy their own DNA replication machinery. Pairwise comparisons of NCBI phage reference sequences (whose annotations should be reasonably reliable), determining both nucleotide distances and shared gene content, shed some light on these parameters. Phages of all hosts were included (not just mycobacteriophages) (81). Traditional comparison methods are too computationally intensive to measure nucleotide distances, so a kmer-based Mash method was used (82). Although there is not universal agreement that Mash distances reflect nucleotide divergence, a variety of validation strategies supported its application in this analysis (81). Because phage genome diversity is high, most genomes are not related, and pairwise comparisons have Mash scores above 0.5 (Fig. 9) and are insufficiently similar to be informative (81). The second parameter is an estimate of gene content similarity (Fig. 9), which was determined by grouping the genes into phams and then determining what proportion of phams are shared pairwise between genome pairs (81).

This analysis provides an interesting insight, in that there appear to be two major modes of phage genome evolution, one in which gene content varies broadly in proportion to nucleotide distances (low gene content flux [LGCF]) and a second in which gene content appears to vary substantially more over shorter nucleotide distance changes (high gene content flux [HGCF]) (81) (Fig. 9A). In general, lytic phages follow the LGCF evolutionary mode, whereas temperate phages distribute between the LGCF and HGCF modes. Moreover, phage genomes fall into one of the two modes based on their genomic type, such that clusters of phages tend to follow one or the other but not both modes (81). This is well illustrated by three clusters of mycobacteriophages (Fig. 9B,C,D).Cluster B phages are lytic, do not form stable lysogens, and do not contain integrase or repressor genes. These generally distribute throughout the LGCF profile (Fig. 9B). In contrast, clusters F and K are both temperate (Fig. 9C,D), stable lysogens can be recovered, and repressors and integrases have been characterized (73, 83). Cluster F genomes clearly distribute in the HGCF mode (Fig. 9C), whereas cluster K phages lie in the LGCF mode (Fig. 9D). The drivers of these evolutionary modes are unclear, but it is plausible that the HGCF temperate phages strongly participate in the acquisition of genes that benefit their host when expressed in lysogeny and may contribute directly to pathogenesis (81).

Evolution and Host Range

The great genetic diversity of the mycobacteriophages, with many types sharing little or no DNA sequence information, is unexpected, given that they all infect the same host bacterial strain and therefore should be in genetic communication with each other. A simple model to explain this is that phage host preferences are quite mutable, and there is a low barrier to switching from one host to another (84). Moreover, there must be strong pressure to do so, because phages must mutate

FIGURE 8 Single-gene mosaics in mycobacteriophage genomes. Segments of five phage genomes (Phrann, Corndog, Brujita, Squirty, and Gaia) are shown, which are unrelated at the nucleotide sequence level and are grouped in different clusters, as shown (in clusters, N, O, I1, F3, and X, respectively). Genes are shown as colored boxes, with genes in the same phamilies colored similarly and pham numbers shown above with the number of phamily members in parentheses. Pairwise-shared homologues are indicated with dumbbells. Note that the homologues are situated in different genomic contexts and the flanking genes are not homologous.

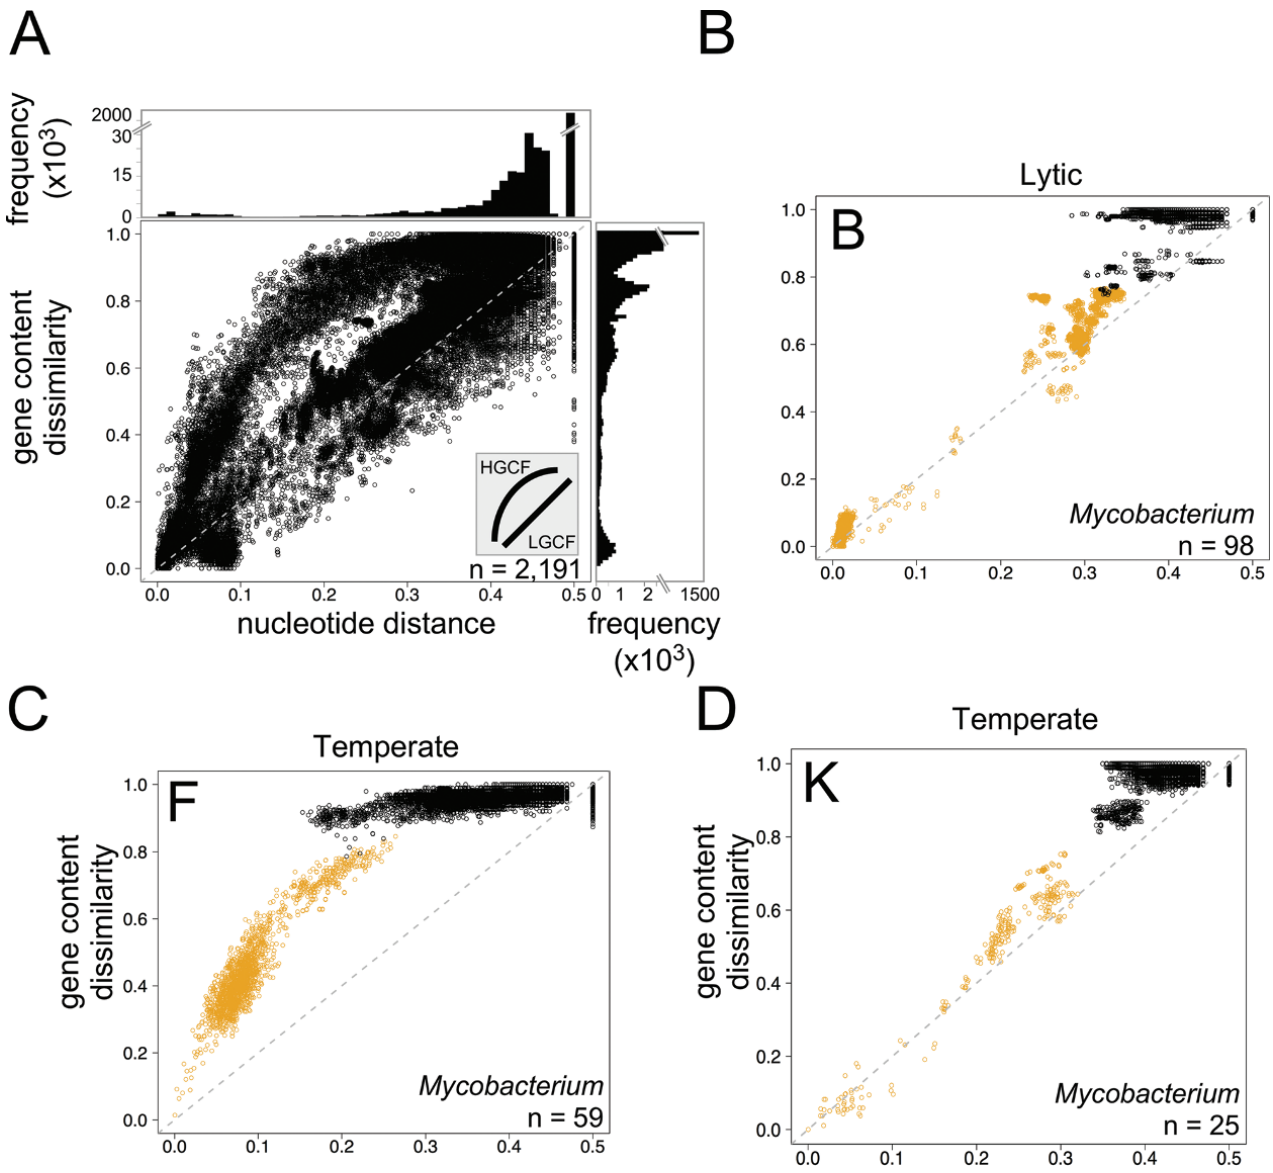

FIGURE 9 Modes of phage evolution. (A) Nucleotide distance (using Mash) and gene content dissimilarity (using phams from Phamerator) are plotted for ~2.4 × 10^6 dsDNA phage comparisons to reveal two evolutionary modes, HGCF and LGCF (inset). The line at y = 2x is plotted for reference. Marginal frequency histograms emphasize densely plotted regions, with truncated y axes for viewability. (B–D) Cluster-specific intracluster (orange) and intercluster (black) comparisons are plotted as in Fig. 1A for actinobacteriophage clusters B (panel B), F (panel C), and K (panel D). Phages in clusters F and K are temperate, and phages in cluster B are lytic, as indicated. n, number of phages present in the specific cluster. Reproduced with permission from reference 81.

to survive viral attack, and phages must coevolve to access hosts for replication. We thus envisage pathways by which phages migrate across bacterial host landscapes, such that phages pursuing different paths have different access to the large common gene pool (Fig. 10).

Several lines of evidence support this model. First, several examples demonstrate that mycobacteriophages can expand their host ranges at reasonably high frequencies (e.g., 10^{-5}), including acquiring the ability to infect M. *tuberculosis* or a different strain of M. *smegmatis* (84). In each case, this requires just a single base pair change resulting in single amino acid substitutions in phage tail proteins. Second, characterization of the cluster U phage Patience identified features consistent with the hypothesis that it acquired the ability to infect mycobacteriophage hosts relatively recently (85). Patience has an unusually low G+C content (50.3%), substantially different than most other mycobacteriophages (Table 1) and its M. *smegmatis* host (67.3%). Perhaps not surprisingly, it also has a radically different codon usage profile than M. *smegmatis*, including preferred use of some codons that are only rarely used in the host. A seemingly obvious route to adapting to this situation would be for Patience to acquire tRNA genes that would recognize the rare codons, but this has not happened, and Patience has just a single tRNA gene (tRNA-gln). Instead, the genome appears to be in the process of adapting to its new host, such that the most highly expressed genes are more quickly adapting to match the coding profiles of host genes (85).

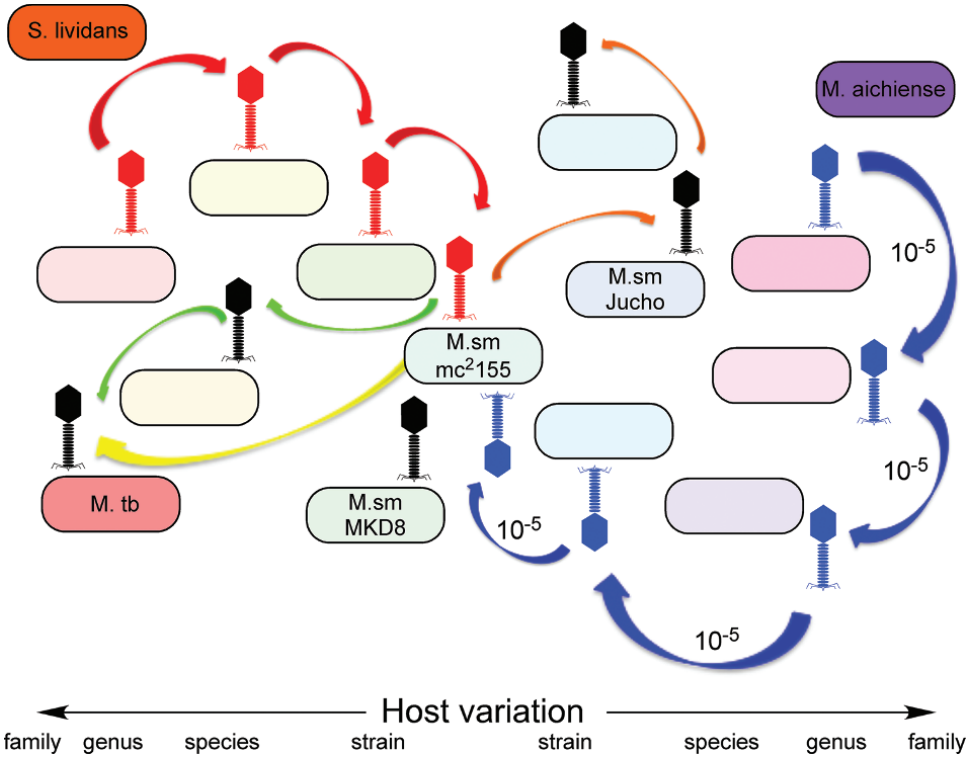

FIGURE 10 A model for mycobacteriophage diversity. The diversity of mycobacteriophages isolated on *M. smegmatis* mc^{2}155 can be explained by a model in which (i) phages can readily infect a new bacterial host, by either a switch or an expansion of host range, and (ii) there is a highly diverse bacterial population, including many closely related strains, in the environments from which the phages are isolated. As such, phages with distinctly different genome sequences and GC contents infecting distantly related bacterial hosts, such as those to the left (red) or right (blue) extremes of a spectrum of hosts, can migrate across a microbial landscape through multiple steps. Each host switch occurs at a relatively high frequency (~1 in 10^5 particles, or an average of about one every 10^3 bursts of lytic growth) and much faster than either amelioration of phage GC content to its new host or genetic recombination. Two phages (such as those shown in red and blue) can thus "arrive" at a common host (*M. smegmatis* mc^{2}155) but be of distinctly different types (clusters, subclusters, and singletons). The variety of hosts is shown two-dimensionally for simplicity; the actual relationships among bacteria in environments such as soil and compost is likely to be considerably more complicated. Because host range variation is a common feature of bacteriophages, the model predicts that a high degree of phage diversity will be seen for any particular host if the microbial population from which the phages are isolated is also highly diverse and rich in closely related strains. Reproduced with permission from reference 84.

DRIVERS OF MYCOBACTERIAL AND MYCOBACTERIOPHAGE DYNAMICS

Prophage-Mediated Defense against Viral Attack

Because bacteria are under constant attack from viral infection, there is a strong selection for survival and acquisition of systems for viral defense. These include the well-studied restriction-modification and CRISPR-Cas systems, but there are numerous examples of defense by abortive infection, and a plethora of new defense systems have been identified (86, 87). Some mycobacterial strains—including *M. tuberculosis*—have CRISPR-Cas-like arrays, although their functionality in defense and spacer acquisition is unclear (88); mycobacterial restriction-modifications have also been described (89–92). However, *M. smegmatis* mc^{2}155, which has been used extensively for phage isolation, appears to be free of both restriction and CRISPR-Cas systems (93).

Mycobacteriophages have been useful for demonstrating that phage defense systems can also be expressed from the prophages of temperate phages (63). This phenomenon has also been described for *Pseudomonas* phages and is likely to be widespread (94). Although it has been known for some time that phages and plasmids can carry restriction and abortive infection systems (95, 96), the number and variety of prophage-encoded systems is quite impressive. These have been best characterized in the mycobacteriophages within cluster N but are predicted to be present in many other temperate phages and other phages of actinobacterial hosts (63). It is simple to envisage how such defense systems would play key roles in microbial dynamics, because lysogeny is common, and prophage acquisition and recruitment of critical defense systems can occur at relatively high frequency in bacterial populations (97).

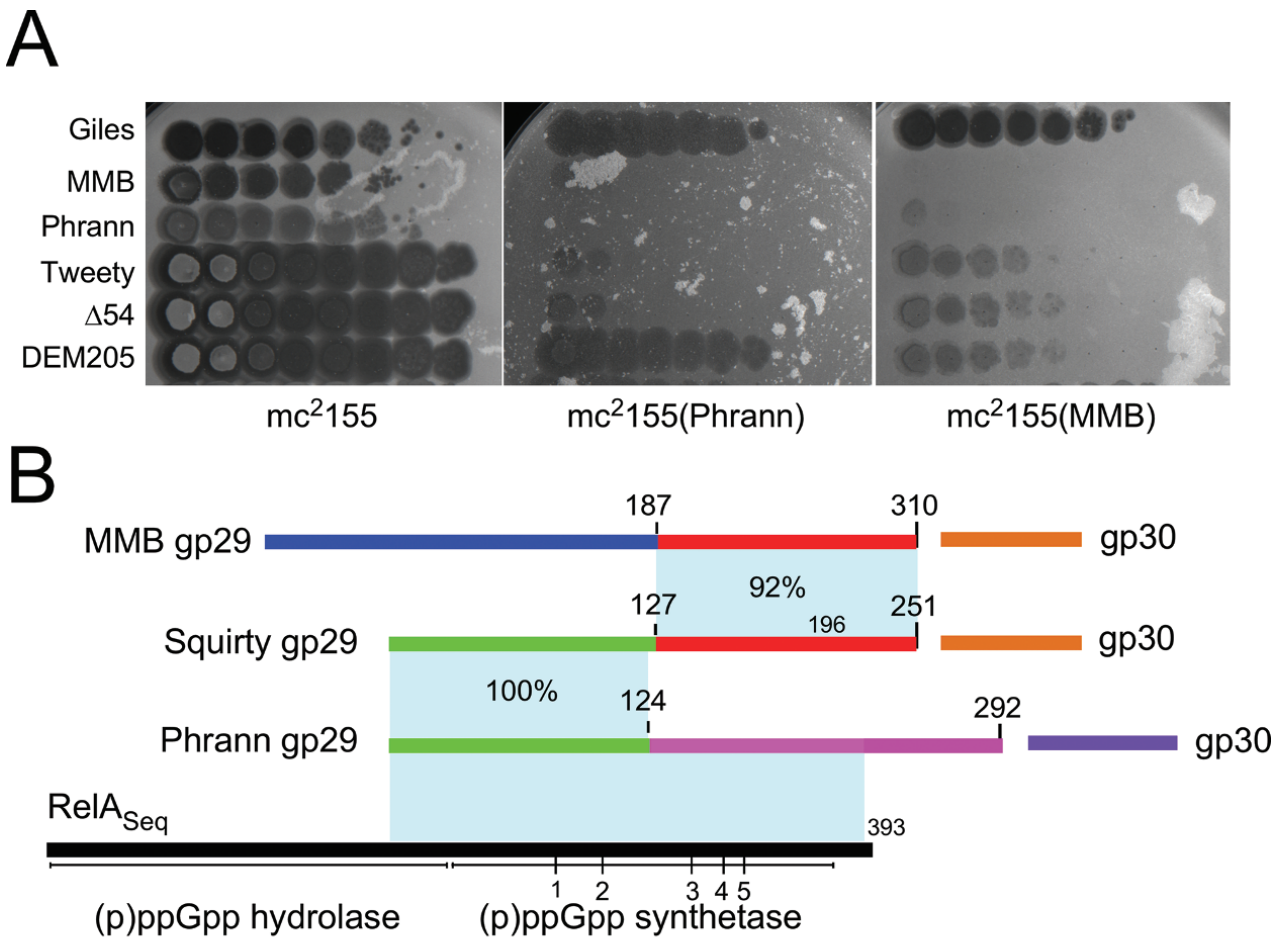
The presence of prophage-mediated defense systems is suggested from the expression patterns of lysogenic strains, as indicated by RNAseq analysis. The expression pattern of part of the Panchino genome is shown in Fig. 6, which clearly illustrates that the repressor is not the only phage gene being

expressed during lysogeny. Up to four additional genes are expressed (*28* to *31*), and the expression of gene *28* is several times greater than the repressor (Fig. 6). Bioinformatic analysis strongly predicts the gp28 is a multisubunit restriction system, containing hsdR-, hsdM-, and hsdS-like domains (63). Genes *30* and *31* are expressed at more modest levels and are of unknown function, although gp31 is a predicted membrane protein. Although prophage-expressed genes could mediate a multitude of physiological responses in the general category of lysogenic conversion, the restriction system is strongly implicated in viral defense.

The availability of the large collection of diverse phages that infect *M. smegmatis* mc^2155 facilitates the characterization of such defense systems. For example, determination of the plating efficiencies of about 100 phages shows that about one-third of them have a reduction of 10^{-5}-fold or greater plating efficiency on the Panchino lysogen relative to the parent strain. When Panchino *28* alone is expressed from a plasmid, the plating efficiencies of the Panchino lysogen are largely reproduced (63). The cluster N phages are homoimmune and show strong superinfection immunity to each other (Fig. 11A), and we note that Panchino gp28 does not alter infection of Panchino itself or other cluster N phages; thus, this defense system is heterotypic with regard to its specificity for the attacking phages. Presumably, genes *29*, *30*, and *31* could be involved in viral defense too, but if a phage(s) targeted by these is not present in the set that was tested, it could be readily overlooked.

The Panchino *28* to *31* genes are centrally located in the genome between the immunity cassette and the lysis genes (63). Even though the genomes in cluster N are closely related to each other, this central region is highly variable, and many of these genes are expressed from the prophages (63). Approximately 3 to 8 genes are expressed from each of 11 cluster N genomes, corresponding to over 25 phamilies, and the determination of plating efficiencies shows that all of the 11 prophages defend against at least one other phage (63). In the case of phage Charlie, the specificity is quite impressive, and the Charlie prophage defends against only one of the tested phages, Che9c. A Charlie derivative in which gene *32* has been deleted using Bacteriophage Recombineering of Electroporated DNA (BRED) engineering (98) loses its defense against Che9c, and a recombinant plasmid expressing gp32 recapitulates the defense (63). Charlie gp32 is a small (121-residue) protein that is predicted to be membrane localized and could plausibly act by exclusion, preventing Che9c DNA injection. Consistent with this is the observation that Charlie gp32 not only inhibits Che9c plaque formation, but also interferes with Che9c lysogenization. It is plausible that Charlie gp32 would defend against other phages that use similar host proteins for DNA entry, but these are rare in our collection.

Several of the cluster N prophages defend against phage Tweety (cluster F), including Phrann, and three closely related phages: Xerxes, Carcharodon, and MichelleMyBell (Fig. 11) (63). For this second group, a responsible gene was suggested from comparative genomic analysis, because Pipsqueaks is a closely related phage, but has a small deletion in the region corresponding to MichelleMyBell gene *29* (and its relatives), and Pipsqueaks does not defend against Tweety. Deletion of genes *29* and *30* from MichelleMyBell abrogates Tweety defense, and a plasmid carrying genes *29* and *30* reproduces the defense. When using extrachromosomal vectors, it was not possible to clone MichelleMyBell gene *29* without gene *30*, suggesting that high levels of gp29 are toxic and that gp30 alleviates the toxicity, akin to the behaviors of toxin-antitoxin systems. MichelleMyBell gp30 is predicted to be membrane localized, but the biochemical function of gp30 is unclear.



Genetic analysis of phage Phrann showed that Phrann *29* and *30* are required for defense against Tweety (note that the similarity of gene names is coincidental and does not indicate homology) (Fig. 11). These share some of the behaviors of the MichelleMyBell defense genes in that Phrann gp29 is toxic in the absence of Phrann gp30, but they are not related at the sequence level. Phrann gp29 is strongly predicted to be a (p)ppGpp synthetase with similarity to RelA family proteins (63). This poses a conundrum in that (p)ppGpp is used by bacteria as an alarmone to promote arrest of cell growth, and yet it is expressed well in a Phrann lysogen (63). However, the lysogen grows normally, and it is probable that gp30 interacts with gp29 and maintains it in an inactive state, consistent with its anti-toxic behavior. This model is attractive because the Phrann gp29/30 proteins would then be poised to be activated upon infection by an attacking phage (Fig. 11). Because the defense is specific to only a subset of the phages tested (including TM4 and Gaia, in addition to Tweety), these phages presumably code for a function that dissociates Phrann gp29 and gp30, resulting in activation of gp29, synthesis of (p)ppGpp, growth arrest, and inhibition of phage replication (63). Interestingly, Phrann gp29/30 defends against Tweety lytic growth but does not interfere with Tweety lysogenization, consistent with a post-DNA injection sensing mechanism. It is unclear what genes or sequences identify Tweety, TM4, and Gaia for targeting by this defense system, but early lytic genes are implicated (see below) (63).

MichelleMyBell gp29/30 likely acts similarly to Phrann, in spite of the lack of sequence similarity between the products (Fig. 11B). In an unusual set of relationships, the C-terminal half of MichelleMyBell gp29 is closely related (92% amino acid identity) to gp29 encoded by phage Squirty (cluster F). However, the N-terminal half of Squirty gp29 is 100% identical to Phrann gp29 (Fig. 11B). Thus, although Phrann gp29 and MichelleMyBell gp29 are not related to each other, it is plausible that MichelleMyBell is also involved in alarmone synthesis (63).

Mycobacteriophage Counterdefense

Phages often carry counterdefense systems such as anti-restriction and anti-CRISPR genes (99, 100), so it should not be surprising that mycobacteriophages have systems to counter prophage-mediated defenses. A particularly intriguing system is encoded by Tweety, which was revealed by isolating defense escape mutants (DEMs) that overcome either Phrann-mediated or MichelleMyBell-mediated defense (63). Many of these DEMs have genomic changes in gene *54*, a peculiar gene coding for a protein with multiple copies of a tetrapeptide repeat (Fig. 12). The DEMs typically have changes in the numbers of repeats, usually fewer but sometimes more (63). DEMs isolated for their escape of Phrann defense remain subject to MichelleMyBell defense, and vice versa (C. Gauthier and G.F. Hatfull, unpublished observations), suggesting that gp54 is being "tuned" to specifically counter the different defenses. The hypothesis that these mutants are gain-of-function derivatives rather than loss-of-activation mutants is illustrated by the observation that gene *54* can be deleted and Tweety is still subject to both Phrann and MichelleMyBell defenses (63).

Tweety gp54 plays no known role other than in its counterdefense capacity, but homologues are present in about 40 other cluster F phages, all with different numbers of tetrapeptide repeats. The repeats are composed of the

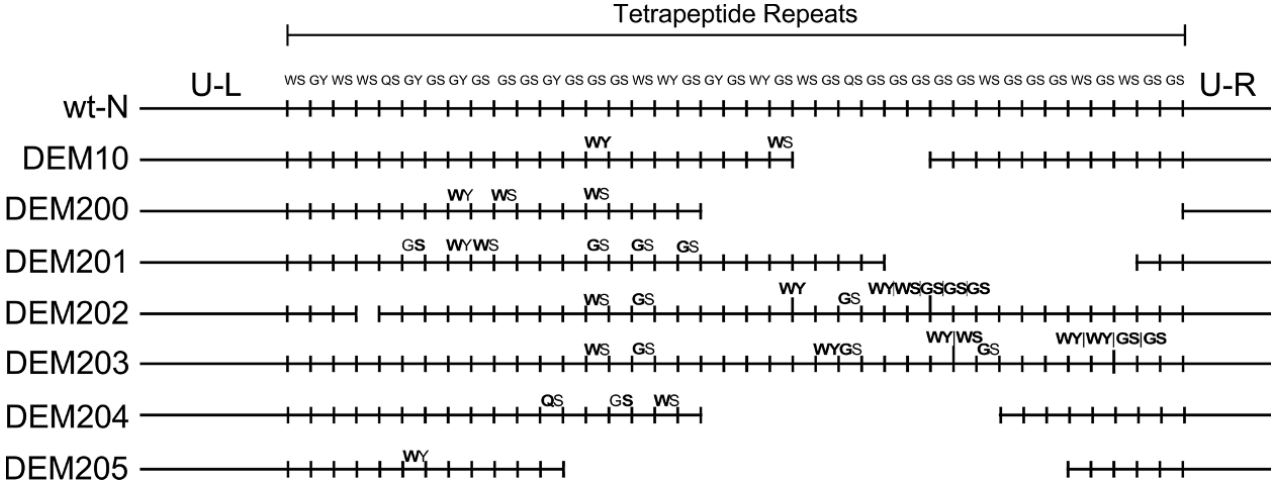

FIGURE 12 Variations in tetrapeptide repeats in Tweety gp54. Gene *54* of phage Tweety codes for a 374-residue protein in which a unique N-terminal (U-L) and C-terminal (U-R) flank a long series of tetrapeptide repeats. The number of repeats in the original sequenced genome is 48, although the derivative used for defense studies (wt-N) shown here only has 40. Each of the repeats has a sequence AAXX, where XX is either WS, GY, QS, GS, or WY, and the sequence at each repeat is shown. The organization of nine defense escape mutants (DEMs) are shown below, each of which efficiently overcomes defense mediated by the Phrann prophage. They all remain subject to defense mediated by the MichelleMyBell prophage. Six of the DEM mutants (DEM10, DEM200, DEM201, DEM202, DEM204, DEM205) have lost some of the repeats but also have altered repeat sequences, as indicated. DEM202 also has an insertion of five additional repeat copies. DEM203 has two insertions, one with two repeat units and the other with four repeat units.

sequence alanine-alanine-XX, where XX is either WS, GY, QS, GS, or WY (Fig. 12). The three-dimensional structure of this type of repeat is not known, but because the DEMs have variations in the numbers of repeats, it is plausible that it forms an extended structure, positioning the unique N- and C-terminal domains in configurations that can bind to gp29 and gp30 and prevent their dissociation. The mechanism by which expansion and contraction of the repeat number happens is also not known, but it is noteworthy that in addition to changes in repeat number, many of the mutants also have changes in the sequence of the repeat itself (Fig. 12). However, the changes in the repeat are always in the XX motif and always substituted by one of the tetrapeptide repeats found elsewhere. For example, DEM201, a mutant that overcomes Phrann defense, has lost 11 copies of the repeat, but 6 of the individual repeats are altered (Fig. 12). Not only are the 6 repeats not contiguous, but only 1 pair of the substituted sequences is present elsewhere, suggesting that 5 distinct mutational events created that derivative, in addition to the deletion of 11 copies. Because the repeated nature is also reflected as a 12-bp nucleotide sequence repeat, these variations could arise from replication errors and slippage, although it would appear to occur at a relatively high frequency. Whether the repeat substitutions play any functional role in counterdefense is unclear.

Finally, we note that although Tweety *54* homologues are predominantly found in cluster F phages, there is a related gene in the subcluster A1 phage, Nerujay (Nerujay gene *74*)

FIGURE 11 Prophage-mediated defense against phage attack. (A) Phage defense plaque assays. Ten-fold serial dilutions of phages Giles (control), MichelleMyBell (MMB), Phrann, and Tweety were plated onto lawns of a nonlysogen (mc^2155) and *M. smegmatis* lysogens of Phrann [mc^2155(Phrann)] and MichelleMyBell [mc^2155(MMB)]. The Phrann and MMB lysogens confer superinfection immunity to Phrann and MMB, because these are part of cluster N, and all of the cluster N phages are homoimmune, coding for closely related repressors. Tweety (cluster F) is unrelated to Phrann and MMB, and the Phrann and MMB lysogens defend against Tweety, and the efficiency of plating is greatly reduced relative to the wild-type strain. A defense escape mutant (DEM205) overcomes the Phrann defense and plates efficiently on the Phrann lysogen but remains subject to MMB-mediated defense. DEM205 contains a mutational change in gene *54*, but it is a gain offunction mutant, because a Tweety mutant in which gene 54 has been deleted (Δ54) is still targeted by the Phrann defense. (B) Relationships among phage-encoded (p)ppGpp synthetase-like proteins. Phrann gp29 is a homologue of RelA/SpoT proteins with similarity to the (p)ppGpp synthetase domain of *Streptococcus equisimilis* RelA, including five conserved motifs (1 to 5). The cluster F phage Squirty encodes a related protein (gp29) sharing the N-terminal 124 residues with Phrann gp29 but with divergent C-termini. MMB gp29 is not predicted to be related to Rel_{Seq} but shares its C-terminus with Squirty gp29. MMB gp30 and Squirty gp30 are closely related and are both predicted to be membrane localized. (C) Models for prophage-mediated viral defense. An integrated prophage (red line) confers defense against viral attack through numerous mechanisms, either homotypically (i.e., against the same or closely related viruses) or heterotypically (i.e., against unrelated phages). Homotypic defense includes repressor-mediated immunity (repressor, red circle) and superinfection exclusion (blue circle) against itself (red phage). Heterotypic defense includes an exclusion-like system illustrated by Charlie gp32 defense against Che9c (blue phage) and restriction against many viruses (illustrated by the green phage) by Panchino gp28. Defense is also mediated by a predicted (p)ppGpp synthetase (e.g., Phrann gp29; gold circle), which we propose is kept in an inactive form (gold circle with crossed lines) by an inhibitor (purple circle), which for Squirty gp30 is membrane localized. Lytic growth by specific phages activates the defense through early lytic protein, which is proposed to dissociate the (p)ppGpp synthetase from its inhibitor, enabling rapid accumulation of (p)ppGpp and growth arrest. Tweety encodes a counterdefense system (gp54) that may prevent activation of (p)ppGpp synthesis. Reproduced with permission from reference 63.

(Fig. 13). The unique N- and C-terminal regions are closely related to Tweety gp54 (90% and 80% amino acid identity, respectively), but Nerujay contains only 10 copies of the repeat, and only 2 tetrapeptide sequences are present, AAWS and AAGS. Nerujay is the only cluster A phage to carry such a gene, and it is notably absent from phage DD5, which is closely related in this region at the DNA sequence level (Fig. 13). A simple evolutionary explanation is that Nerujay acquired gene *74* relatively recently as insertion of a 796-bp fragment, perhaps derived from a cluster F phage similar to Ibhubesi, whose homologue (*54*) is identical in length to Nerujay *74* and shares 90% nucleotide sequence identity. Nerujay gp74 may also be active in counterdefense, but identifying which defense system it counters is a substantial challenge.

Exclusion during Lytic Growth

Many viruses have been reported to exclude superinfection of other viruses during either lytic or lysogenic growth. Some

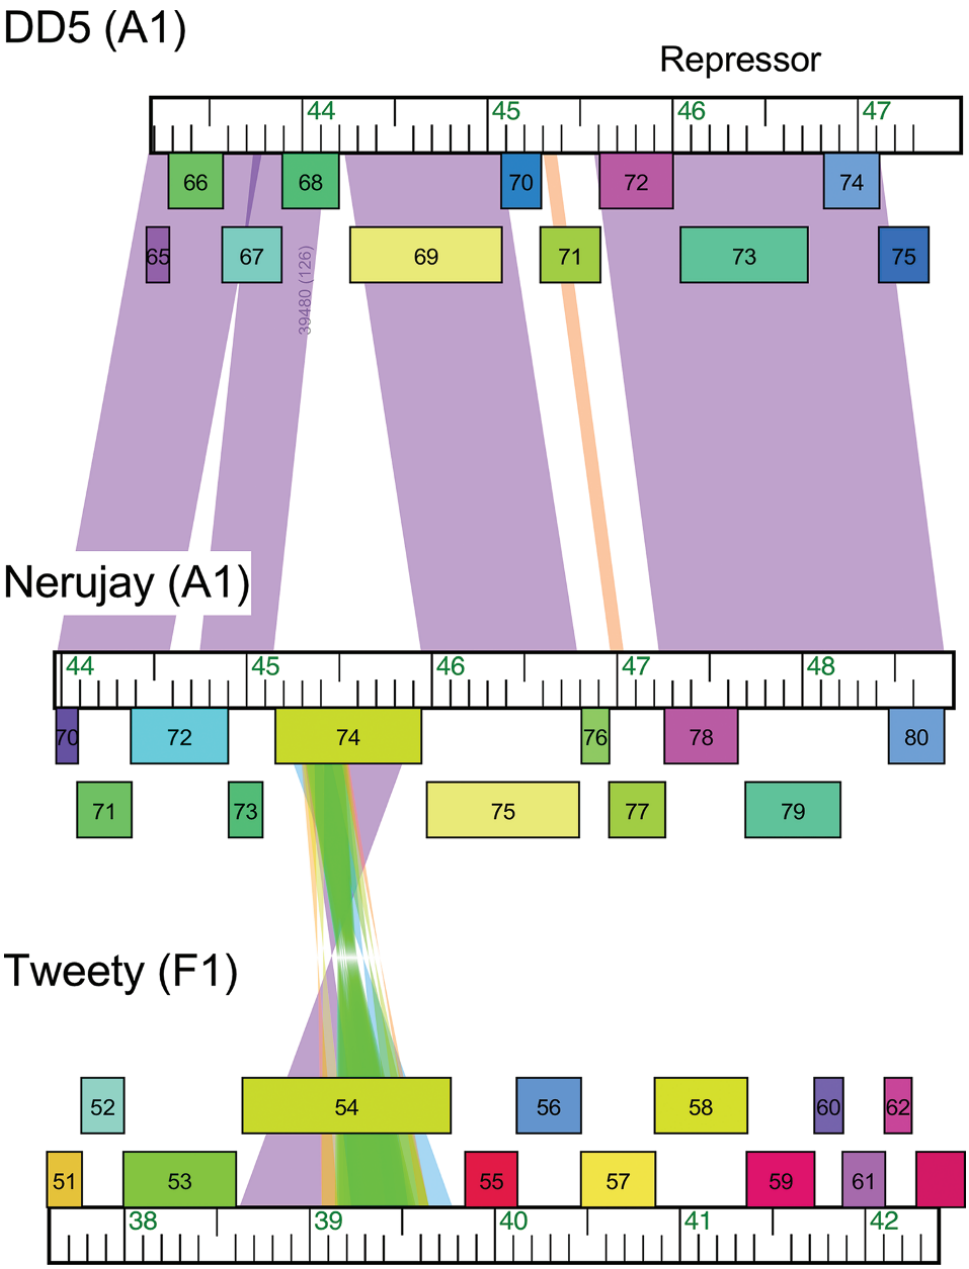

FIGURE 13 Genomes with potential counterdefense systems. Tweety gene *54* is active in counterdefense against Phrann (see Figs. 11, 12), and there are homologues in many other cluster F phages. The only phage outside of cluster F with a closely related homologue is the subcluster A1 phage, Nerujay. All other cluster A phages, including DD5, lack a Tweety *54* homologue. Segments of the genome maps are aligned with pairwise nucleotide sequence similarity shown as colored shading, as described for Fig. 7. In this region, all of the DD5 and Nerujay genes are transcribed leftward, and the Tweety genes are transcribed rightward.

well-studied examples include the T4 *imm* gene and P22 *sieA*, both of which are small membrane proteins that confer homotypic exclusion (101, 102). Coliphage HK97 also codes for a small membrane protein that is prophage expressed and prevents HK97 superinfection (103). It is not unusual for some of the small genes of unknown function in mycobacteriophages to be predicted membrane proteins that could perform such functions (e.g., there are eight predicted membrane proteins in the right arm of phage Nerujay), but a specific role for these in exclusion has not been shown. However, a WhiB-like regulator encoded in phage TM4 is implicated in homotypic exclusion, plausibly through regulation of host genes (104). In a recent example, superinfection exclusion was shown to be mediated by interference of a host protein used for efficient infection by some other phages (Fig. 14) (62).

This superinfection exclusion system was discovered through use of a screen for mycobacteriophage genes that are toxic to *M. smegmatis* when overexpressed (62). Approximately 5 to 10% of genes are expected to have this toxic property (105–108), and we identified gene *52* of phage Fruitloop (cluster F) as being highly toxic when overexpressed. Fruitloop gp52 interacts directly with the essential host protein Wag31 (DivIVA) and inactivates it, resulting in cell death (Fig. 14). Fruitloop *52* is expressed early in lytic growth and is not essential for plaque formation, and its toxicity is unlikely to be relevant for phage growth. Rather, it was reasoned that some mycobacteriophages depend on Wag31 for efficient infection, because it is polar localized and present both cytoplasmically and extracytoplasmically (109, 110). A search for phages inhibited by Fruitloop gp52 expression identified two subcluster B2 phages, Hedgerow and Rosebush, that are affected and presumably use Wag31 for efficient infection (62). Hedgerow and Rosebush are not related to Fruitloop at the nucleotide sequence level, and it is not evident that they have followed similar evolutionary paths as Fruitloop. It is plausible that mycobacteriophages code for many similar systems, targeting different aspects of mycobacteria that other phages exploit to gain entry.

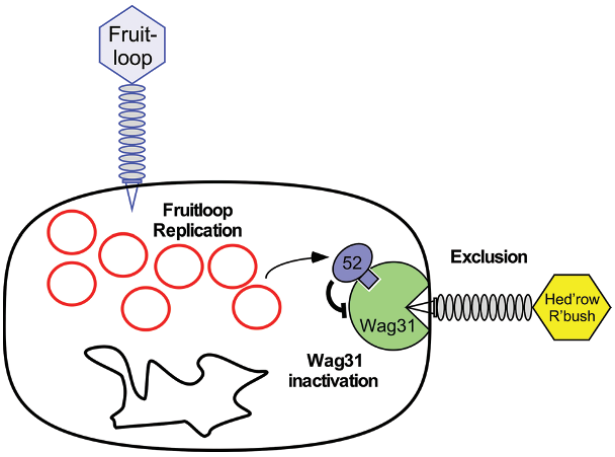

FIGURE 14 A model for Fruitloop gp52-mediated superinfection exclusion of Wag31-dependent phages. This model proposes a role for gp52 expressed by lytically growing phage Fruitloop in binding to and inactivating the host Wag31 (DivIVA) protein, which is essential and localizes to the growing pole of the cell. Some phages, such as subcluster B2 Hedgerow and Rosebush depend on Wag31 for efficient infection, such that gp52-mediated inactivation of Wag31 excludes them from superinfecting. Replicating Fruitloop genomes are shown as red circles alongside the bacterial chromosome (black circle), and Fruitloop gp52 is shown in blue, binding to Wag31, shown in green. Not drawn to scale. Reproduced with permission from reference 62.

Compatibility and Incompatibility

Most of the temperate mycobacteriophages can be grouped into homoimmune classes and have closely related repressors. The large majority of these carry integration systems, targeting a variety of *attB* sites. In general, if two phages are heteroimmune and use different *attB* sites for integration, they are fully compatible and there is no obvious impediment to the formation of double lysogens. This is not unexpected, and the sequences of large numbers of bacterial genomes show that they commonly carry two or more prophages. If phages are heteroimmune but use the same *attB* site, then they may compete with each other for stable lysogeny.

A subset of temperate mycobacteriophages do not have integration systems but instead encode *parABS* systems similar to those used by plasmids to promote segregation into daughter cells at division (57, 58). These phages, all of which group in cluster A but span 10 subclusters, replicate extrachromosomally at low copy number and, as such, are subject to incompatibility mediated potentially by both the prophage replication system and the partitioning systems themselves. None of the replication systems have yet to be described, but there is good evidence of incompatibility among phages with similar *parABS* systems (58). For example, a double lysogen of phages RedRock and Alma, both of which have *parABS* systems, can be constructed but not stably maintained without loss of one of the prophages (58). In contrast, a double lysogen of RedRock and Bxb1, which has a canonical integration system, stably maintains both prophages.

Repressor Theft

The immunity repressors have been well studied in the cluster A phages (107), although there is substantial sequence variation reflecting a variety of heteroimmune groups. Unexpectedly, a variety of other phages in other clusters carry closely related copies of some of these repressors (65). These related gene copies are found in lytic phages that do not form lysogens, including some cluster C phages, and also in temperate phages (e.g., cluster F and cluster J), where they are present in addition to their canonical repressors. For example, Fruitloop (cluster F1) has a canonical repressor (gene *44*), which confers immunity to itself and some other cluster F1 phages, and the stolen repressor (*37*), which shares 97% amino acid identity with the Bxb1 repressor. Fruitloop gene *37* is expressed in a lysogen, although at a somewhat lower level than the canonical repressor (62), but confers immunity to at least some cluster A1 phages such as SkiPole and Pinto (Deborah Jacobs-Sera and GFH, unpublished observations). Because the cluster C phages do not form lysogens, the repressor may block superinfection of cluster A1-like phages during lytic growth.

EXPLOITATION OF MYCOBACTERIOPHAGES

Using Recombinant Phages for Efficient Delivery

Bacteriophages have the inherent ability to efficiently inject their DNA into host bacterial cells. Mycobacteria do not undergo natural transformation at high frequency, and electroporation is effective, but only a subset of cells take up

DNA. In contrast, infection with mycobacteriophages at a multiplicity of infection greater than three generally results in DNA injection into every cell in the culture. This property was exploited early on in the development of mycobacterial genetic systems (12) and has been further developed for the delivery of transposons, reporter genes, and allelic exchange substrates (111–115). Phages are useful tools for the delivery of reporter genes such as luciferase or florescent proteins in rapid diagnostic assays for tuberculosis drug susceptibility in the clinic (116–119) but are also useful for understanding mycobacterial physiology. For example, dual reporter phages have been exploited to identify and analyze persister cells in *M. tuberculosis* (120).

Mycobacteriophage Tools for Mycobacterial Genetics

Mycobacteriophages also offer a rich reservoir of genes and cassettes for use in mycobacterial genetics. One application that has found widespread use is the development of integration-proficient vectors that transform mycobacteria by stable chromosomal integration using phage integrases. Integration vectors have been constructed from a variety of phages, including Adephagia, Brujita, L5, Bxb1, Tweety, Giles, Omega, and Ms6 (52, 68, 72–74, 83, 121, 122). These typically transform efficiently, and the transformants are quite stable, except if newly introduced genes are deleterious to growth and the integrase gene is retained in the recombinants. Most of these vectors work in both fast- and slow-growing strains, because the *attB* sites—especially those used by the tyrosine integrases—tend to be well conserved.

A second tool with broad applicability is a mycobacteria-specific recombineering system utilizing mycobacteriophage-encoded recombination systems (123). The most widely used system is that derived from mycobacteriophage Che9c, which has been used for both dsDNA and ssDNA recombineering (78, 79, 124). For dsDNA recombineering, both the exonuclease and DNA pairing genes (Che9c *60* and *61*, respectively) are required, but for ssDNA recombineering, only *61* is needed. The recombineering systems work in both *M. smegmatis* and *M. tuberculosis*, and recombination is sufficiently efficient that it can be used to introduce point mutations into the genome of *M. tuberculosis* (125). Many newly identified recombination systems are present in the multitude of mycobacteriophages sequenced since the Che9c system was developed, and some of these may be worth investigating for improved ease of use or efficiency.

The recombineering system has been especially useful for engineering the phages themselves (98, 123, 126). When phage DNA and a mutagenic DNA substrate are coelectroporated into recombineering-proficient cells, recombination is efficient, and following recovery, individual plaques can be screened by PCR for the presence of the mutant allele. Typically ~10% of progeny are mixed and contain both wild-type and mutant alleles, and a homogenous mutant derivative can be identified by PCR of plaques after replating. Point mutations can be introduced relatively easily, provided a PCR scheme is used that can distinguish between the mutant and wild-type alleles (68). The main limitation of the BRED approach is the question of whether plaques can be recovered following transfection in *M. smegmatis* (98). Many phages do this quite efficiently, and sufficient plaques can be readily recovered for screening. However, some phages transfect at very low efficiency or not at all, and these tend to be phages with larger genomes. Whether genome size *per se* is the principle factor or whether some of these phages use encapsidated phage proteins for infection is unclear.

Mycobacteriophages have also provided non-antibiotic-based selectable markers for mycobacteria, taking advantage of immunity repressor genes that confer immunity to superinfection, and lytic derivatives of the temperate phages that efficiently kill mycobacteria. The most well-developed system is based on the cluster K phage Adephagia, which infects both *M. smegmatis* and *M. tuberculosis* (127). Plasmids carrying the Adephagia repressor (gene *43*) can be introduced by electroporation and selected in the presence of an Adephagia derivative from which gene *43* has been deleted. The transformants carry an integrated copy of the Adephagia genome, with the additional advantage that the plasmid cannot be lost without lytic induction and death, thus ensuring plasmid stability. If the presence of the prophage is undesirable, a second phage derivative can be used in which both the repressor (*43*) and the integrase gene (*41*) have been deleted (127).

Mycobacterial plasmids based of the *oriM* origin of replication derived from plasmid pAL5000 (128–131) are somewhat unstable in the absence of selection (72), especially if recombinant genes they are carrying are not well tolerated. Addition of the phage-encoded *parABS* systems to these plasmids adds considerable stability to their maintenance (58).

Therapeutic Potential

The possibility of using mycobacteriophages for the treatment of mycobacterial infections has been postulated for some time, although little progress has been made (10). Although tuberculosis remains a major public health concern in many parts of the world, effective treatment could be achieved with current antibiotics, a robust health care infrastructure, and monitoring. However, the emergence of multiply and extensively drug-resistant tuberculosis infections demands new approaches, and phage applications may warrant attention. It would seem unlikely that mycobacteriophages could achieve sterilization from an *M. tuberculosis* infection and a long-term cure. But some gains might be achieved from combinations with antibiotics that could extend their effectiveness, lower required dosages, reduce the prevalence of resistance, provide relief in late stages of infection, or help prevent transmission. An alternative approach would be to use phages prophylactically, to protect coworkers or family members from infection when in close contact with an infected patient (10).

Therapeutic utility is likely to require a cocktail of phages to minimize the incidence of phage resistance, just as antibiotics must be used in combination for tuberculosis treatment. However, the key property of phages in such a cocktail is that resistance to one phage does not confer resistance to the other phages. Unfortunately, very little is known about either the specific receptors used for mycobacteriophage infection or the mechanisms of resistance (132), and this is an area that needs further investigation. Furthermore, relatively few of the phages isolated on *M. smegmatis* infect *M. tuberculosis*, and they generally group in a small number of clusters or subclusters (84). As such, they may use a rather limited set of receptors, and cross-resistance may limit the numbers that could be combined together into a suitable cocktail. Moreover, early phage typing studies suggested differences in phage sensitivities among clinical isolates of *M. tuberculosis*, and this needs to be revisited now that we have a deeper understanding of the genetic diversity of *M. tuberculosis* strains (133).

Infections of nontuberculosis mycobacteria may also represent possible targets for phage therapy. Attractive

targets are *Mycobacterium abscessus* infections associated with cystic fibrosis, which are often highly refractory to antibiotic therapies. Relatively little is known about the phage susceptibility profiles of *M. abscessus* clinical isolates, but a substantial proportion of sequenced *M. abscessus* strains carry one or more prophages (134, 135), which could code for viral defense systems. Suitable mycobacteriophage cocktails could conceivably be used to reduce the bacterial load in cystic fibrosis patients or to prevent infection following lung transplantation.

PERSPECTIVES

Mycobacteriophages have provided a wealth of insights into viral diversity and evolution and played indispensable roles in the development of mycobacterial genetics. We anticipate that the advances in mycobacteriophage genomics will slow somewhat, in large part because we are nearing saturation in the isolation of phages that infect *M. smegmatis*. However, as the emphasis shifts to phages that infect other mycobacterial strains and other *Actinobacteria*, new and different types of genomes are likely to be discovered. We anticipate that the coming years will see some progress toward defining the functions of more mycobacteriophage genes. The number of uncharacterized genes is vast, but the methods are available for their genetic, biochemical, and structural characterization, and the limiting factor may be the development of suitable assays. Surrogate approaches such as screening for toxicity (62, 106) and finding interacting partners (136, 137) should be useful strategies. Because many of the phage genes may play roles in microbial dynamics, the availability of such a large collection offers a very substantial resource.

Finally, the mycobacteriophages occupy a unique niche in how they have been isolated and characterized, mostly by early-career undergraduate students and faculty at institutions spread across the United States and the world (34). These students have not only made fantastic contributions to this field, but the fun, curious, and sometimes entertaining names of the phages they discovered will continue to amuse. The number of phages that infect actinobacterial hosts likely far exceeds the numbers of students who will isolate and characterize them over the coming years, and I can't wait to see the novelties, surprises, and potential utilities that emerge.

I thank Bekah Dedrick, Krista Freeman, Becky Garlena, Christian Gauthier, Carlos Guerrero, Debbie Jacobs-Sera, Ching-Chung Ko, Travis Mavrich, Welkin Pope, Dan Russell, and Katie Wetzel for comments on the manuscript and for other help and insights. The Mycobacteriophage_899 database is available at http://phamerator.webfactional.com/databases_Hatfull. I thank the National Institutes of Health and the Howard Hughes Medical Institute for support and all the student phage hunters and SEA-PHAGES faculty and staff for their amazing contributions to mycobacteriophageology.

Immunology of *Mycobacterium tuberculosis* Infections

JONATHAN KEVIN SIA AND JYOTHI RENGARAJAN

64

INTRODUCTION

Mycobacterium tuberculosis, the etiologic agent of tuberculosis (TB), remains a significant global public health burden (1). In 2016, there were 10.4 million new TB cases reported globally and nearly 1.7 million TB-related deaths (1). Understanding the host response to *M. tuberculosis* infection is a key aspect of efforts to eradicate TB through the development of effective vaccines and immune therapeutics. *M. tuberculosis* is an intracellular pathogen transmitted via inhalation of aerosolized, bacteria-containing droplets. Innate immune cells in the lungs, primarily macrophages, dendritic cells, monocytes, and neutrophils, readily phagocytose *M. tuberculosis* and are the earliest defenders against the pathogen. The transformation of bacteria-containing phagosomes into acidified, antimicrobial compartments is a central tenet of defense against *M. tuberculosis*. In this regard, the production of interferon-γ (IFN-γ), which can activate infected myeloid cells and inhibit bacterial replication, is a well-known antimycobacterial contribution by adaptive immune cells such as CD4 and CD8 T cells. Despite pressures from host immunity, *M. tuberculosis* is able to persist in the host. *M. tuberculosis* infection results in hallmark lesions called granulomas, which are initially aggregates of infected and uninfected myeloid cells circumscribed by a lymphocytic cuff. The granuloma is thought to prevent bacterial dissemination to extrapulmonary sites but can also become a niche for long-term bacterial persistence. *M. tuberculosis* has evolved myriad strategies to evade and subvert immune responses to persist within a host, and it is becoming increasingly clear that the immune response to *M. tuberculosis* infection involves contributions from a wide variety of innate and adaptive immune cells. A clearer understanding of the complex cross talk between *M. tuberculosis* and host immunity is essential for the development of efficacious TB vaccines. Despite being developed nearly a century ago, *Mycobacterium bovis* bacillus Calmette-Guérin (BCG), an attenuated strain of *M. bovis*, remains the only licensed vaccine against TB. Vaccination with BCG provides protection against severe forms of disseminated TB in children but has variable efficacy in preventing pulmonary disease in children and adults (2–4). However, the immunological basis for the poor efficacy of BCG remains unclear. Moreover, long-held concepts regarding the nature of desired immune responses in an ideal TB vaccine, namely, the induction of antigen-specific CD4 T cells producing IFN-γ, are being updated to reflect the expanding knowledge of host immunity to *M. tuberculosis* infection gathered from animal models and human cohort studies. Advances in imaging and single-cell technologies combined with high-throughput approaches and systems-based analyses are providing more information on the immune response to *M. tuberculosis* infection at increasingly higher resolutions. As our understanding of the host response to *M. tuberculosis* infection grows, opportunities to leverage knowledge of the immunology of *M. tuberculosis* infection toward improving therapeutics and vaccines for TB are increasing.

This article will cover integral features of the innate and adaptive immune response to *M. tuberculosis* infection. Additionally, it will highlight recent findings on the hallmark granuloma and novel cellular players contributing to the host response to *M. tuberculosis* infection. Finally, it will provide an overview of the state of TB vaccine research, including a summary of BCG-based vaccines and the TB vaccine pipeline.

IMMUNOPATHOGENESIS OF TB IN HUMANS AND ANIMAL MODELS

Overview of Human TB Disease and Comorbidities

Transmission of *M. tuberculosis* occurs after inhalation of aerosolized droplets containing live bacteria into the lungs. Successful transmission is influenced by a variety of conditions, including proximity and duration of contact with an individual with active TB (ATB) disease and the immunecompetency of the individual infected with *M. tuberculosis* (5–7). We now appreciate that in a clinical setting, *M. tuberculosis* infection presents as a continuum of diseased/infected states ranging from asymptomatic latent TB infection (LTBI) to ATB disease. This complexity, combined with remarkable heterogeneity in lesions within a single patient, has presented unique challenges to the eradication of TB (8). While the majority of individuals exposed to *M. tuberculosis* are able to control infection in the form of LTBI, an estimated 5 to 10% of people exposed to *M. tuberculosis* develop ATB, which is characterized by a persistent cough accompanied by sputum production, weight loss, weakness, and night sweats (9). Clinical diagnosis and treatment of *M. tuberculosis* infection is complicated by a variety of coinfections and comorbidities.

Comorbidities that modulate immune function can exacerbate TB disease or contribute to progression of individuals

doi:10.1128/microbiolspec.GPP3-0022-2018

with LTBI to ATB. HIV coinfection in latently infected individuals increases the risk of developing TB from a 5 to 10% lifetime risk to a 10% annual risk, and HIV infection is the single greatest risk factor for the development of TB (10–14). The relevance of HIV coinfection to global TB mortality is highlighted by the fact that more than a fifth of all TB-related deaths in 2016 were in HIV-positive individuals (1). Progressive depletion and dysfunction of CD4 T cells following HIV infection leads to immune suppression and negatively impacts immunity to *M. tuberculosis*. Specific depletion of *M. tuberculosis*-specific CD4 T cells has been reported in the peripheral blood (15, 16) and bronchoalveolar lavage (BAL) samples (17, 18) of HIV-infected individuals with LTBI. Several studies indicate that specific depletion may be a consequence of enhanced HIV coreceptor expression in CD4 T cells, particularly CCR5, in TB patients (15, 19–24). Alternative hypotheses to explain specific depletion of *M. tuberculosis*-specific CD4 T cells include differential functionality of specific T cells. In HIV coinfected LTBI, *M. tuberculosis*-specific CD4 T cells are reported to secrete interleukin 2 (IL-2) in contrast to MIP-1β (macrophage inflammatory protein 1 beta) secreted by cytomegalovirus-specific CD4 T cells (16). Analysis of viral loads in HIV coinfected LTBI showed an inverse correlation between viral load and the frequency of *M. tuberculosis*-specific CD4 T cells secreting IL-2 (25), suggesting that IL-2 producing *M. tuberculosis*-specific CD4 T cells may be specifically depleted in the context of HIV coinfection. Relatedly, HIV-coinfected individuals have lower frequencies of cytokine-producing *M. tuberculosis*-specific CD4 T cells with impaired proliferative capacity compared to HIV-uninfected individuals with LTBI (26–28), suggesting *M. tuberculosis*-specific CD4 T-cell dysfunction during HIV-infection. The relative contributions of depletion versus dysfunction of *M. tuberculosis*-specific CD4 T cells to enhanced TB risk following HIV infection remains unclear. Further, HIV infection may perturb protective immunity to *M. tuberculosis* in other immune compartments, such as CD8 T cells. For instance, *M. tuberculosis*-specific CD8 T cells from individuals with LTBI are reported to have impaired proliferation and degranulation in HIV-infected compared to HIV-uninfected individuals (29). Studies have also described associations between TB and many other conditions or activities, including smoking, malnutrition, diabetes, helminth infections, chronic lung diseases, and cancer (30, 31). Further investigations will be required to fully understand the basis of identified associations with other infections and morbidities.

Animal Models of Infection

Knowledge of the host response to *M. tuberculosis* infection has benefited greatly from the development of animal models of infection. The variable outcomes of *M. tuberculosis* infection in humans are challenging to model in a single animal model. Many experimental animals are susceptible to *M. tuberculosis* infection and can inform us about aspects of human disease. The mouse model for TB benefits from many advantages: ease of manipulation and housing, availability of well-characterized inbred strains, sophisticated techniques for the generation of mutant strains, availability of immunological and other reagents, and relatively low cost. Mice have been utilized to model host responses to *M. tuberculosis* infection, to evaluate drug and vaccine candidates, and to study the immune response to mutant strains of mycobacteria. Experimental infection can be delivered through multiple routes: intravenously, intraperitoneally, intratracheally, or via aerosolized particles. The latter method, especially low-dose aerosol infection, is the most physiologically relevant and has become the preferred method. Different mouse strains have well-characterized lung pathologies and levels of susceptibility (32–36). Typically, following bacterial deposition into the lungs, it takes approximately 2 weeks to begin priming adaptive immune responses in the lung-draining lymph nodes and a further 1 to 2 weeks for robust participation in the lungs by adaptive immune cells, but bacterial burdens continue to be maintained at a high level in the lungs of *M. tuberculosis*-infected mice. There are limitations to what can be gleaned from mouse models of *M. tuberculosis* infection due to the differences in lung pathology between mice and humans. Further, true latent infection and significant immune control of infection are difficult to establish in the mouse model, though chemotherapeutically induced models of paucibacillary disease in mice exist (37, 38). The development of humanized mice that can recapitulate the heterogeneity of human lung pathology may extend the advantages of the mouse model, but humanized mice are also reported to display aberrant T-cell responses and be unable to control bacterial burden (39, 40).

Other animal models of *M. tuberculosis* infection include guinea pigs, rabbits, fish, and non-human primates (NHP). Each has distinct advantages and disadvantages that make their use particularly suitable for different types of research questions. Following infection, guinea pigs exhibit pathological features, such as the organization and development of caseous necrotic granulomas, that more accurately recapitulate the human granulomatous response compared to mice (41). Further, guinea pigs are very susceptible to *M. tuberculosis* infection and, thus, are a good choice for testing candidate drugs and vaccines and studying dissemination dynamics. Similarly, rabbits develop a well-organized granuloma that can become necrotic following mycobacterial infection. However, rabbits are resistant to *M. tuberculosis*, and high numbers of bacteria during inoculation or use of more virulent strains are needed (42–45). Nevertheless, the rabbit model has been leveraged to study relatively rarer forms of TB, such as cutaneous and meningeal TB (46, 47). The usefulness of both the guinea pig and rabbit models is hampered by the scarcity of immunologic reagents relative to mice. The zebrafish model has provided novel insights into the establishment of the mycobacterial granuloma. Infection of transparent zebrafish larvae with the natural fish pathogen *Mycobacterium marinum* leads to the establishment of well-organized granulomas that become necrotic and can be visually monitored (48). The primary advantage of the zebrafish model is the transparency of the zebrafish larvae, which, alongside facile manipulation of host and bacterial genetics, has been leveraged for insight into early innate immune events leading to the formation of the granuloma as well as insights into human disease. Adaptive immunity is present in adult zebrafish, and different populations of CD4 T cells have recently been described (49, 50), but these animals are no longer transparent, and relevance of the adult zebrafish immune response to human TB have yet to be established.

The NHP model of *M. tuberculosis* infection reflects much of the heterogeneity observed in human TB. Infection of NHPs is typically performed by aerosol or direct bronchoscopic deposition into the lungs of rhesus or cynomolgus macaques and, depending on the dose of the inoculation and the strain of bacteria utilized, leads to symptomatic ATB disease or asymptomatic infection in which bacteria persist at low levels akin to LTBI. The NHP model accurately recapitulates many of the hallmark granulomas seen in humans, including the heterogeneity of granulomas that can be present in the same animal (51), and presents clinical

symptoms similar to those seen in humans (52–57). The NHP model is regarded as an important preclinical model for TB research and is an excellent model for studying immunity to *M. tuberculosis* and assessing candidate drug and vaccine efficacies (58–63). Further, the NHP model can be used to study reactivation in the setting of simian immunodeficiency virus coinfection or other types of immune modulation, such as anti-tumor necrosis-α (anti-TNF-α) treatment, CD4 depletion, or inhibition of indoleamine 2,3-dioxygenase (IDO) (64–71).

INNATE IMMUNITY TO *M. TUBERCULOSIS* INFECTION

The earliest encounter between host and pathogen in TB occurs at the interface between innate immune cells and *M. tuberculosis*. While innate immunity is critical for early antimycobacterial responses, it is also important for the progression of infection and long-term control of *M. tuberculosis* by continually priming and educating adaptive immune responses and by regulating inflammation. However, innate immune cells are often niches for bacterial replication, and *M. tuberculosis* utilizes a variety of strategies that subvert innate immune responses to establish a chronic infection. Here, we will detail key features of the innate immune response to *M. tuberculosis* infection, starting from recognition of the bacterium and phagosomal defenses within infected macrophages to priming of adaptive immune responses by professional antigen-presenting cells. In between, we will highlight how neutrophils and monocytes are mobilized after *M. tuberculosis* infection, the role that natural killer (NK) cells play during infection, how the balance of inflammation is regulated by the innate immune system, and how cell death affects the immune response. In each section, we will also highlight some of the myriad strategies that *M. tuberculosis* utilizes to subvert or evade the host innate immune response.

Recognition of *M. tuberculosis* by Pattern Recognition Receptors

Pathogen-associated molecular patterns on *M. tuberculosis* are recognized via a variety of receptors to mediate opsonic and nonopsonic bacterial uptake: C-type lectins (e.g., mannose receptors, DC-SIGN, Dectin-1, Dectin-2, Mincle), complement receptors (e.g., complement receptor 3), collectins (e.g., surfactant proteins A and D, mannose-binding lectin), scavenger receptors (e.g., MARCO, SR-A1, CD36, SR-B1), Fc receptors (e.g., FcgR), glycophosphatidylinositol-anchored membrane receptors (e.g., CD14), and Toll-like receptors (TLRs) (e.g., TLR-2, TLR-4, TLR-9) (72–74). Mannosylated lipoarabinomannan, phosphatidyl-inositol mannosides, phthiocerol dimycocerosates, phenolic glycolipids (PGLs), trehalose dimycolate, peptidoglycan, and other mycobacterial components are recognized by an array of cell surface and intracellular receptors that mediate phagocytosis and/or antimicrobial defenses. *M. tuberculosis* DNA (75, 76) or bacterial second messengers (77) can be recognized by cytosolic pattern recognition receptors (PRRs), such as cGAS and STING (78, 79), to induce downstream cytokine production and autophagy. Further, nucleotide oligomerization domain-like receptors (NLRs) are cytosolic PRRs that recognize *M. tuberculosis* pathogen-associated molecular patterns, such as muramyl dipeptide, to activate a multiprotein complex termed the inflammasome. Functional redundancies for many of the receptors are likely to exist due to promiscuous ligand binding by different receptors and the wide array of available ligands on *M. tuberculosis*. Indeed, single or double knockouts for canonical scavenger receptors and C-type lectin receptors did not modulate susceptibility or attenuate immune responses following *M. tuberculosis* infection (80). However, increased susceptibility to *M. tuberculosis* infection in a variety of knockout mice demonstrate that a number of PRRs and their associated signaling pathways also play important, nonredundant roles in host defense against *M. tuberculosis* infection.

M. tuberculosis expresses a variety of known or putative TLR ligands, and TLR-2, TLR-4, and TLR-9 have been implicated in host recognition of *M. tuberculosis* (reviewed in 73, 74). Polymorphisms in specific TLRs or TLR signaling proteins have also been strongly associated with pulmonary TB in humans and have been shown to influence immunity against *M. tuberculosis* (81–84). The contribution of individual TLRs to immunity against *M. tuberculosis* infection is variable, but the importance of the TLR signaling pathway to antimycobacterial immunity is evident in studies showing that mice lacking the common TLR adaptor protein, myeloid differentiation factor 88 (MyD88), quickly succumb to *M. tuberculosis* infection (85, 86). Susceptibility of *MyD88*$^{-/-}$ mice to *M. tuberculosis* infection has been attributed to deficient expression of NOS2 (86), impaired ability to activate the IL-1β or IL-1 receptor (IL1R) pathway (87, 88), impaired receptivity of macrophages to IFN-γ signaling (89), and impaired IL-12 and TNF-α responses in macrophages and dendritic cells (DCs) (85). Gene-deletion studies in single TLRs have revealed that innate immune responses to *M. tuberculosis* are likely the result of the complex activation of multiple signaling pathways. For instance, mice lacking both TLR-2 and TLR-9 are more susceptible to *M. tuberculosis* infection than mice lacking the ability to signal through either TLR by itself (90). The susceptibility of *MyD88*$^{-/-}$ mice to *M. tuberculosis* infection is an example of the importance of common adaptor molecules that integrate signals from multiple PRRs and other innate immune pathways for the induction of antimycobacterial immunity. Further evidence for this concept is demonstrated by the increased susceptibility of *M. tuberculosis*-infected mice lacking CARD9, an adapter molecule integrating signals from C-type lectin receptors, or PYCARD/ASC, an adapter molecule integrating signals from nucleotide oligomerization domain-like receptors for the induction of the inflammasome (91, 92).

MyD88 signaling in innate immunity integrates signaling from TLR and IL-1 receptor families by bridging ligand-receptor binding to IL-1-receptor-associated kinases and the activation of multiple downstream pathways, including NF-κB, mitogen-activated protein kinases, and activator protein 1. The IL-1 signaling pathway is clearly required for resistance to *M. tuberculosis* infection in mouse models and is supported by human immunogenetics studies (93–96). In mice, the absence of IL-1 signaling led to severe susceptibility to *M. tuberculosis* infection. Both IL-1α and IL-1β, as well as their common receptor, IL-1R1, have been implicated in immunity to *M. tuberculosis* (87, 88, 97–101). Secretion of the mature form of IL-1β requires cleavage by the terminal inflammasome effector, caspase-1, but *M. tuberculosis*-infected mice lacking MyD88, ASC, or caspase-1 signaling do not display impaired IL-1β levels (87). Further, mice deficient in IL-1β are considerably more susceptible to *M. tuberculosis* infection than mice lacking ASC or caspase-1 (87). These findings suggest that IL-1β is a key mediator of resistance to *M. tuberculosis* infection but also indicate that the basis for resistance conferred by MyD88, CARD9, and PYCARD/ASC likely depend on additional factors beyond IL-1β.

While host recognition of *M. tuberculosis* leads to the activation of innate immunity, *M. tuberculosis* has also evolved strategies that evade innate immune responses mediated by PRRs. Strain-specific expression of cell envelope components may be associated with differential immune responses. For example, the W-Beijing lineage strain, HN878, has been found to express polyketide synthase-derived phenolic glycolipids that are missing in lab-adapted H37Rv or other clinical isolates (i.e., CDC1551) (102). Expression of PGL by HN878 has been found to diminish production of multiple innate immune cytokines and chemokines (102, 103), though its role in the increased virulence of HN878 remains controversial. Modulation of innate immune responses by *M. tuberculosis* is also accomplished through the presence of immune-inhibitory lipid components that compete with immune-activating mycobacterial components for the same receptors. For example, expression of tetra-acylated sulfoglycolipids by the W-Beijing strain GC1237 can competitively bind TLR-2 to attenuate responses to canonical TLR-2 agonists, including mycobacterial lipomannans (104). Lastly, *M. tuberculosis* can also impair innate immune responses to cell-envelope components through enzymatic means. For instance, an *M. tuberculosis* serine-hydrolase, Hip1, was found to cleave multimeric, cell wall-associated GroEL2 to a secreted monomeric form to mediate attenuated macrophage and DC responses (105–109). Additionally, *M. tuberculosis* mutants lacking *hip1* or a putative mycobacterial metalloprotease, *zmp1*, display enhanced inflammasome activation (106, 110), suggesting that *M. tuberculosis* has multiple strategies for dampening activation of the inflammasome.

Thus, in addition to the array of host receptors that mediate recognition of *M. tuberculosis*, innate immune responses to infection likely depend on the strain of *M. tuberculosis*, the presence of cell wall components that can competitively inhibit the activation of PRRs, and the presence of *M. tuberculosis* enzymes that modify the immunogenicity of cell envelope components.

Phagosomal Defense in Macrophages

Macrophages are the first immune cells to encounter *M. tuberculosis* during infection and also represent the primary replicative niche for *M. tuberculosis*. Recognition of *M. tuberculosis* by macrophages leads to phagocytosis and sequestration of the bacterium in phagosomes, which typically eradicate pathogens via fusion with lysosomes and consequent acidification of the pathogen-containing phagolysosome. However, *M. tuberculosis* is able to survive and replicate in the phagosome by inhibiting phagosomal maturation and phagolysosomal generation through a variety of mechanisms (reviewed in 72, 111). Further, transcriptional profiling of intraphagosomal bacteria indicated that *M. tuberculosis* readily counters the nitrosative, oxidative, hypoxic, and nutrient-poor phagosomal environment through the expression of stress-adaptive genes (112), though a genome-wide transposon site hybridization screen for *M. tuberculosis* survival in macrophages suggested that *M. tuberculosis* constitutively expresses genes required for its survival (113). Nevertheless, it is clear that *M. tuberculosis* has adapted for a lifestyle inside the macrophage and employs many strategies to survive within these cells.

M. tuberculosis glycolipids can prevent accumulation of phosphatidylinositol 3-phosphate on phagosomal membranes and prevent phagolysosome biosynthesis (114). *M. tuberculosis* also secretes phosphatases (SapM and PtpA) and serine/threonine kinases (PknG) that are proposed to interfere with phagosomal maturation (115–121). There is also evidence that *M. tuberculosis* lipids, in particular, phthiocerol dimycocerosates, can mediate escape from the phagosome and host cell death (122). An *M. tuberculosis* secretion system, ESX-1, is also known for mediating disruptions in phagosomal integrity and preventing phagosome maturation. Promotion of aberrant phagosomal integrity and bacterial replication by *M. tuberculosis* ESX-1 is countered by IFN-γ-induced, Rab20-mediated phagosomal maturation (123). ESX-1-mediated phagosomal escape of bacteria is hypothesized to work through disruption of the phagosome by the 6-kDa early secretory antigenic target (ESAT-6) (124–127), though recent evidence proposes a contact-dependent, ESAT-6-independent mechanism for ESX-1-mediated phagosomal permeabilization (128). Nevertheless, ESX-1-mediated permeabilization of the phagosome exposes *M. tuberculosis* pathogen-associated molecular patterns, such as *N*-glycolyl-muramyl dipeptide, to cytoplasmic nucleotide oligomerization domain 2 receptors to induce type I IFNs (129, 130). ESX-1-mediated permeabilization of the phagosome also exposes extracellular bacterial DNA to the cytosolic DNA-sensing pathway, which leads to targeting of *M. tuberculosis* to autophagosomes for subsequent killing (75). *M. tuberculosis* ESX-3 has also been implicated in modulating intracellular trafficking of bacteria to avoid phagosomal maturation through inhibition of the host endosomal sorting complex required for transport (131–133). Thus, studies of the *M. tuberculosis* ESX secretion system have provided evidence for its role in both bacterial evasion of phagosomal pressures and host sensing of bacterial components. In addition to the ESX system, *M. tuberculosis* also expresses two SecA ATPase protein homologues (SecA1 and SecA2) involved in protein export (134). SecA2, in particular, has been implicated in virulence and intracellular growth (135, 136). Interestingly, both *M. tuberculosis* and BCG Δ*secA2* mutants are enriched in acidified phagosomes, indicating that mycobacterial SecA2 is required for arrest of phagosome maturation (137).

M. tuberculosis entry into macrophages through different receptors can lead to distinct activation of pathways that can inhibit or promote bacterial replication. The overall effect of multiple receptors engaging distinct or overlapping *M. tuberculosis* ligands is a complex and dynamic issue. For example, *M. tuberculosis* uptake by complement receptor 3 depended on host cholesterol, which mediated phagosomal association with coronin-1 and consequent inhibition of phagolysosome formation through activation of host calcineurin (138, 139). Alternatively, TLR-2 recognition of mycobacterial mannosylated lipoarabinomannan activates NF-κB and *NOS2* gene transcription that leads to antimycobacterial nitric oxide (NO) production (140). NO production is strongly associated with resistance to *M. tuberculosis*, though evidence for the antimycobacterial effects of NO is stronger in the mouse model. In mice, reactive nitrogen intermediates are toxic to mycobacteria *in vitro* (141–143), and infection can be exacerbated by the inhibition of NOS *in vitro* (144, 145) or *in vivo* (146–148). NO production following IFN-γ signaling has also been reported to limit overt inflammation by inhibiting processing of IL-1β by the inflammasome (149). Relatedly, mice with disrupted NOS2 alleles display exacerbated disease following *M. tuberculosis* infection (146, 150). Although *in vitro* studies using human alveolar macrophages and primary monocytes did not find an antimycobacterial role for NO (151–153), specific staining for NOS2 in the BAL of TB patients reveals upregulation in infected individuals compared to healthy controls (154). Nevertheless, *M. tuberculosis* has several strategies to cope

with otherwise damaging reactive nitrogen and oxygen intermediates: M. *tuberculosis* KatG, a catalase-peroxidase, can inactivate phagosomal reactive oxygen (155), and the M. *tuberculosis* proteasome can mediate resistance to nitrosative stresses (156). Promiscuous recognition of mycobacterial antigens by the same receptor may also have convergent outcomes as in the case for TLR-2-mediated recognition of M. *tuberculosis* cell wall fractions leading to TNF-α production in murine macrophages (157). TLR-mediated recognition of M. *tuberculosis* is also reported to synergize with the vitamin D pathway to induce the antimicrobial peptide (AMP), cathelicidin, in human macrophages (158, 159). The biologically active vitamin D metabolite, calcitriol, induces hCAP-18, a gene encoding the pro-form of cathelicidin, following TLR ligation of macrophages (158–160). In addition to direct antimicrobial activity, cathelicidin has been shown to exert antimicrobial functions by activating transcription of host autophagy genes *Beclin-1* and *Atg5* (161). The vitamin D pathway also synergizes with IFN-γ secreted by T cells to induce IL-15 autocrine signaling to promote autophagy and phagosomal maturation in M. *tuberculosis*-infected human macrophages (162).

Autophagy is the process whereby cytoplasmic constituents are degraded or recycled. A role for autophagy in antimycobacterial immunity in macrophages has been extensively characterized. Initial studies utilizing M. *bovis* suggested that autophagy plays a role in promoting phagosomal maturation to enhance bacterial killing (163). Moreover, LRG-47, an IFN-γ inducible p47 GTPase reported to be critical for phagosomal maturation and control of M. *tuberculosis* (164), is also involved in the induction of autophagy in M. *bovis*-infected macrophages (165). Autophagy-related genes were revealed to be involved in regulating the intracellular bacterial load of lab-adapted and clinical isolates of M. *tuberculosis* in a genome-wide small interfering RNA screen in infected human macrophage-like THP-1 cells (166). Accumulating evidence indicates that autophagy is integrated into the host response to M. *tuberculosis* infection by synergizing with pathogen sensing, phagosomal maturation, and IFN-γ inducible pathways to mediate antimycobacterial immunity: STING-dependent cytosolic sensing of M. *tuberculosis* DNA is required to deliver bacteria to autophagosomes and restrict bacterial replication (75); knockdown of cGAS in infected macrophages attenuated the induction of autophagy and survival during chronic M. *tuberculosis* infection (78); detection of cyclic-di-AMP secreted by M. *tuberculosis* in macrophages induced type I IFN production and autophagy to limit bacterial virulence (77); PARKIN, a conserved ubiquitin ligase, was shown to ubiquitinate M. *tuberculosis*-containing phagosomes to facilitate ubiquitin-mediated autophagy and restrict bacterial replication (167); IFN-γ-induced host ubiquilin-1 colocalizes with M. *tuberculosis* and mediates trafficking of bacteria to autophagosomes (168); IFN-γ receptor signaling mediated by the MyD88 adaptor-like (Mal) molecule induced autophagy and killing of intracellular M. *tuberculosis* in macrophages (169). Several studies have also delineated strategies employed by M. *tuberculosis* to evade autophagy. M. *tuberculosis* is reported to induce the expression of microRNA-33 to inhibit autophagy and regulate intracellular lipid metabolism to benefit bacterial replication (170). Further, a screen of M. *tuberculosis* cosmid clones in search of genes that inhibited bone marrow-derived DC antigen presentation revealed M. *tuberculosis* PE_PGRS47 (*Rv2741*) as an inhibitor of autophagy-mediated antigen presentation (171), suggesting that M. *tuberculosis*-mediated impairment of innate immunity can also negatively impact the generation of adaptive immunity. It is also becoming clear that autophagy-related proteins are likely to perform multiple functions, and care must be taken when interpreting specific knockouts or knockdowns of individual genes. For instance, myeloid cell-specific ablation of *Atg5*, but not other autophagy genes, compromised control of M. *tuberculosis* (172, 173). Deletion of the autophagy-related genes *Ulk1*, *Ulk2*, *Atg4B*, or *p62* compromised the ability to induce autophagy, but they were dispensable for the control of M. *tuberculosis* (173). Analysis of lung sections from M. *tuberculosis*-infected *Atg5* knockout mice indicated that Atg5 may be involved in regulation of neutrophil responses during infection, suggesting autophagy-independent roles for Atg5. Further, a recently described role for Atg5 in LC3-associated phagocytosis during M. *tuberculosis* infection supports the notion that specific components of autophagy can also overlap with other phagosomal pathways in immunity against mycobacteria (174).

Taken together, it is clear that macrophage recognition and phagocytosis of M. *tuberculosis* lead to a dynamic tug of war between antimycobacterial defenses and M. *tuberculosis* immune evasion. Macrophage defenses include AMPs, nitrosative stresses, phagolysosomal fusion, and autophagy and may operate independently of or subsequent to IFN-γ signaling. On the other hand, M. *tuberculosis* can subvert macrophage defenses at the level of the bacterial cell wall components that limit phagosomal maturation and the bacterial genes that combat or allow adaptation to intracellular immune pressure.

Recruitment and Function of Neutrophils and Monocytes Following *M. tuberculosis* Infection

Secretion of cytokines and chemokines early during infection recruits additional phagocytes to the site of infection. Early secretion of chemoattractants may be attributed to infected alveolar macrophages as well as lung epithelial cells (175–177). Moreover, a recent study suggests that cross talk between primary bronchial epithelial cells and infected macrophages may also promote secretion of chemokines (178). Trafficking of additional monocytes and granulocytes to the lung exerts immune pressure on M. *tuberculosis* and is crucial for the initiation of adaptive immune responses, but it may also promote M. *tuberculosis* cell-to-cell transmission and dissemination.

Recruitment of neutrophils serves as an early line of defense against M. *tuberculosis* infection via secretion of antimicrobial molecules and inflammatory mediators, but neutrophils also serve as niches for bacterial replication and can impede immunity against M. *tuberculosis*. In humans with active pulmonary TB, neutrophils have been found to be a significant population of M. *tuberculosis*-infected phagocytes in the BAL and sputum (179). Whole blood transcriptional profiling also identified a neutrophil signature in ATB patients that is associated with type I and type II IFN-inducible genes (180) and expression of the inhibitory molecule PD-L1 (181), suggesting that neutrophils may play an immunomodulatory role in human TB. In mice, the kinetics and magnitude of neutrophil recruitment following M. *tuberculosis* infection depends on the strain of mouse infected. Evidence for a pathogenic role for neutrophils is shown in studies comparing neutrophil recruitment in resistant versus susceptible mouse strains (182, 183). When comparing resistant C57BL/6 mice to susceptible DBA/2 mice after M. *tuberculosis* infection, a study found that neutrophils were rapidly recruited into the broncheoalveolar space at higher magnitudes in susceptible mice. Depletion of neutrophils at the onset of M. *tuberculosis* infection specifically extended the life spans of DBA/2 mice, suggesting that

early neutrophil involvement was pathogenic in genetically susceptible mice (183). Similarly, neutrophil depletion in susceptible I/St mice shortly after M. *tuberculosis* infection reduced lung pathology and bacterial growth and improved survival compared to C57BL/6 mice (184). In a separate study, depletion of neutrophils 5 weeks after aerosol M. *tuberculosis* infection of resistant BALB/c mice enhanced the levels of lung IL-6 and IL-17 without impacting IFN-γ and modestly enhanced control of bacterial burden (185). Neutrophil depletion in the first 4 days following intravenous M. *tuberculosis* infection of BALB/c mice, however, led to enhanced bacterial growth at extrapulmonary sites, suggesting that antimycobacterial immunity conferred by neutrophils may be dependent on the route of infection and the kinetics of neutrophil involvement (186). Utilizing fluorescently labeled bacteria, a recent study demonstrated that bacterial distribution in myeloid cells shifts from CD11b+ Ly6G– monocytes and macrophages to CD11b+Ly6G+ neutrophils in *Nos2*$^{-/-}$ animals infected with M. *tuberculosis*, suggesting that neutrophil influx can create a growth-permissive environment for M. *tuberculosis* under NO-deficient conditions (187). Evidence for beneficial roles that neutrophils play in antimycobacterial defense focus on neutrophil secretion of AMPs such as cathelicidin and lipocalin-2 to restrict bacterial replication (188) or via uptake of AMP-containing apoptotic neutrophils by M. *tuberculosis*-infected macrophages (189). Neutrophils can also release chromatin scaffolds that trap extracellular bacteria in an AMP-containing mesh. M. *tuberculosis* has been shown to induce the formation of neutrophil extracellular traps *in vitro* (190), and levels of neutrophil extracellular traps detected in the plasma of ATB patients were associated with disease severity and decreased with antibiotic therapy (191). Further, as discussed later in the chapter, dysregulation of neutrophil recruitment by unrestrained IL-17 responses during M. *tuberculosis* infection can incur pathological consequences by driving lung-damaging inflammation. Thus, the overall effect of neutrophil recruitment to the site of M. *tuberculosis* infection may be determined by host genetics, the context of infection (pulmonary versus extrapulmonary), or timing and duration of neutrophil activity.

In addition to neutrophils, monocytes are recruited to the site of M. *tuberculosis* infection. Similar to neutrophils, monocyte recruitment is important for innate immunity during M. *tuberculosis* infection but may also inadvertently promote M. *tuberculosis* dissemination. C-C chemokine receptor type 2 (CCR2) is a chemokine receptor expressed on monocytes and is responsible for CCL2-mediated recruitment of monocytes to sites of bacterial infection (192). CCR2 was found to mediate immunity against M. *tuberculosis* depending on the dose of infection. CCR2 knockout mice were more susceptible to high-dose intravenous M. *tuberculosis* infection (193), but not after low-dose infection (194). Monocytes have been shown to differentiate into macrophages and DCs following M. *tuberculosis* infection, and monocytes transferred into M. *tuberculosis*-infected mice were shown to be the predominant population of innate immune cells producing iNOS (195). Additionally, monocyte delivery of M. *tuberculosis* to pulmonary lymph nodes can coordinate with DCs to prime CD4 T cells after infection (196). Monocytes may therefore represent a recruited population of innate cells that combat M. *tuberculosis* infection through the production of reactive nitrogen intermediates and priming of adaptive immunity. However, monocyte recruitment following M. *tuberculosis* infection may also be detrimental to the host by providing an environment full of permissive cells. Treatment of M. *tuberculosis*-infected mice with polyinosinic-polycytidylic acid (polyIC) led to CCR2-dependent recruitment of a population of M. *tuberculosis*-permissive monocytes, severe susceptibility, and early mortality (197). Interestingly, susceptibility of polyIC-treated mice to M. *tuberculosis* infection was dependent on type I IFN signaling and was not due to any particular alteration to the T-cell response. The recruitment of neutrophils and monocytes to the site of M. *tuberculosis* infection represents a host strategy to contain bacterial replication that is co-opted by the bacterium to facilitate its growth and dissemination.

NK Cells in *M. tuberculosis* Infection

NK cells are innate lymphocytes with the capacity to secrete IFN-γ and perform cytolytic functions to mediate control of a variety of pathogens, including M. *tuberculosis*. Various components of the M. *tuberculosis* cell wall can bind directly to NKp44 found on NK cells (198), and NK cells can also recognize stress molecules upregulated on the surface of M. *tuberculosis*-infected cells (199). NK cells can mediate direct killing of M. *tuberculosis*-infected macrophages (199) but can also restrict intracellular bacterial replication via secretion of IL-22 (200) and IFN-γ (201) to increase phagolysosomal fusion of M. *tuberculosis*-containing phagosomes. Additionally, NK cells can enhance immunity against M. *tuberculosis* indirectly by enhancing CD8 T-cell production of IFN-γ (202) by promoting the expansion of γδ T cells (203) and by lysing M. *tuberculosis*-expanded regulatory T cells (204). The cytolytic capacity of NK cells is diminished in ATB patients relative to healthy controls and can be reconstituted following antibiotic therapy (205). Further, NK cell function in TB patients can be attenuated by monocyte-derived IL-10 (201). Interestingly, a population of IL-21-dependent NK cells that appears following BCG vaccination has been shown to expand following M. *tuberculosis* challenge (206), suggesting that NK cells may also display some hallmark characteristics of memory cells.

Inflammation and Cell Death During *M. tuberculosis* Infection

The regulation of inflammation is a critical factor that determines the outcome of M. *tuberculosis* infection. Overexuberant inflammation impairs cellular immunity, damages lung tissue, and can lead to lung cavitation and enhanced transmission. Inversely, too little inflammation can impair control of bacterial burden by delaying the induction of innate and adaptive immunity. While neutrophil recruitment and activity during M. *tuberculosis* infection can help contain bacterial replication, sustained neutrophilic inflammation can mediate damaging inflammation and promote disease. Importantly, whole blood transcriptomics identified a neutrophil-driven type I IFN-inducible signature in human TB that decreased upon treatment (180). Excessive type I IFN signaling has been shown to promote disease in mouse models and human samples. Mice lacking type I IFN signaling are more resistant to M. *tuberculosis* infection (207–210), though signaling through type I IFNs may play a protective role in the absence of IFN-γ (211, 212). Mechanisms underlying the pathogenic role of type I IFNs during M. *tuberculosis* infection include inhibition of IL-1β production (213, 214), induction of IL-10 to impair innate cytokine production (215), and loss of IFN-γ responsiveness in infected macrophages (215). In addition to induction of type I IFNs, neutrophils have also been reported to drive lung destruction through the secretion of matrix metalloproteinase 8 (216). The matrix metalloproteinase

family of enzymes has been implicated in lung tissue destruction during M. *tuberculosis* infection (217–220) but has also been shown to promote macrophage recruitment and bacterial dissemination during infection of zebrafish (221).

Eicosanoids are lipid mediators of inflammation derived from the oxidation of arachidonic acid. The balance between proinflammatory prostaglandin E2 (PGE2) and anti-inflammatory lipoxin A4 (LXA4), two members of the eicosanoid family of signaling molecules, can determine the outcome of M. *tuberculosis* infection (222–224). During M. *tuberculosis* infection, mice incapable of synthesizing PGE2 display increased susceptibility (223), and absence of the enzyme 5-lipoxygenase, which metabolizes arachidonic acid to LXA4, confers resistance (222). Importantly, therapeutic correction of low PGE2 levels can confer enhanced survival in highly susceptible mice infected with M. *tuberculosis* (100). Leukotriene A4 hydrolase is an enzyme that catalyzes the production of proinflammatory leukotriene B4 from leukotriene A4, which can also be converted to anti-inflammatory LXA4 as a counterbalance. In zebrafish, *LTA4H* mutants were found to be hypersusceptible to M. *marinum* infection due to dysregulation of the balance between leukotrienes and lipoxins; increased levels of LXA4 in *LTA4H* mutants impaired TNF-α responses and promoted susceptibility (225). The relevance of this finding to humans is highlighted in a TB meningitis cohort in Vietnam where heterozygosity for six *LTA4H* polymorphisms conferred a survival advantage over homozygosity (225). Indeed, anti-inflammatory glucocorticoid treatment efficacy in TB meningitis patients can be differentiated by a single nucleotide polymorphism in the *LTA4H* promoter controlling transcriptional activity, which suggests that the balance of inflammation is critical to disease progression and treatment outcomes in TB meningitis (226).

TNF-α is a critical proinflammatory cytokine in immunity against M. *tuberculosis* infection and can be secreted by a number of innate and adaptive immune cells. The importance of TNF-α in antimycobacterial immunity is clearly demonstrated by heightened susceptibility of TNF-α antibody-depleted animals or in animals lacking TNF receptor signaling following M. *tuberculosis* infection (227). TNF-α is also a critical mediator of immunity against TB in humans. This is demonstrated by increased rates of progression to ATB in LTBI patients receiving anti-TNF treatment for inflammatory disorders (228), which can be recapitulated in the NHP model of infection (70). The effects of anti-TNF treatment in humans and NHPs, as well as in mice (229–231), suggests that TNF-α is critical for maintaining sequestration of M. *tuberculosis* in the granuloma. Histopathological evidence from gene-disrupted or antibody-depleted mice infected with M. *tuberculosis* also suggests that TNF-α signaling may be playing a role in modulating apoptotic or necrotic cell death following infection (229, 231).

Cell death can be a means of restricting bacterial replication by the host or a way to disseminate to secondary loci of infection for M. *tuberculosis*. Apoptosis of M. *tuberculosis*-infected cells leads to fewer viable bacteria and effective cross-presentation of bacterial antigens (224, 232, 233), whereas necrosis of M. *tuberculosis*-infected cells allows viable bacteria to exit and disseminate (223, 234, 235). Proapoptotic M. *tuberculosis* mutants lacking *secA2* (236) and *nuo*G (237) were attenuated *in vivo*, and mice infected with these strains displayed enhanced priming of adaptive immunity compared to infection with wild-type M. *tuberculosis*, suggesting that prevention of host cell apoptosis is an M. *tuberculosis* virulence strategy. Relatedly, M. *tuberculosis*-infected murine neutrophils can aid in DC trafficking to the draining lymph nodes to initiate antigen-specific CD4 T-cell responses (238), but M. *tuberculosis* delays CD4 T-cell priming by inhibiting neutrophil apoptosis (239). Infection with the proapoptotic *nuo*G mutant M. *tuberculosis* resulted in earlier DC trafficking to lung-draining lymph nodes and earlier priming of antigen-specific CD4 T cells, but enhanced priming was abrogated upon neutrophil depletion (239). Additionally, uninfected macrophages performing a constitutive housekeeping function called efferocytosis can uptake M. *tuberculosis*-containing apoptotic bodies, which leads to delivery and killing of bacteria in lysosomes (240). This suggests that apoptosis may be a host strategy to limit bacterial replication by sequestering bacteria in vesicles that can be safely degraded by nearby innate immune cells. Inhibition of apoptosis by M. *tuberculosis* is driven by host intrinsic factors following infection with virulent strains. The proinflammatory eicosanoid PGE2 has been demonstrated to regulate synaptotagmin-7, a calcium sensor that maintains plasma membrane integrity (241). Human macrophages infected with virulent M. *tuberculosis* H37Rv, but not avirulent H37Ra, promote LXA4 production and inhibition of PGE2 biosynthesis, which impairs resealing of plasma membrane disruptions to preferentially induce host cell necrosis instead of apoptosis (241). Mice lacking PGE2 also suffered from increased lung bacterial burden following low-dose aerosol infection with virulent M. *tuberculosis* (223). Host cell necrosis following M. *tuberculosis* infection can be induced through activation of the cytosolic receptor interacting protein kinase 3 pathway, which inhibits apoptosis of infected macrophages through Bcl-xL and promotes necrosis through upregulation of ROS (242). Additionally, macrophages infected with virulent H37Rv, but not avirulent H37Ra, undergo proteolysis at the N-terminal of annexin-1, which prevents the completion of the apoptotic envelope and drives macrophage necrosis (235). Taken together, apoptosis represents a strategy by the host to limit infection through the combination of bacterial sequestration in apoptotic vesicles and the induction of adaptive immune responses, but M. *tuberculosis* may delay apoptosis or promote necrosis to facilitate replication and dissemination.

Initiation of Adaptive Immunity to *M. tuberculosis* by DCs

An important function of innate immunity during M. *tuberculosis* infection is the priming of adaptive immune responses. DCs are professional antigen-presenting cells that initiate adaptive immunity by presenting M. *tuberculosis* antigens in the context of major histocompatibility complex (MHC), costimulatory molecules, and cytokines. Depletion of cells expressing the pan-DC marker, CD11c, following M. *tuberculosis* infection impaired control of bacterial burden and delayed the initiation of adaptive immunity, illustrating the importance of DCs in mobilizing adaptive immune responses that can control bacterial replication (243). There is abundant evidence that M. *tuberculosis* is able to infect murine (244–246) and human DCs (247–249). In mice infected with green fluorescent protein GFP-expressing M. *tuberculosis*, DCs were found to be the major population of phagocytes infected by bacteria after 4 weeks (246). Upon M. *tuberculosis* infection, DCs mature and migrate to the lung-draining lymph nodes to initiate antigen-specific T-cell responses, which depended on the chemokine receptor CCR7 and its corresponding chemokines CCL19 and CCL21 (250–252). Further, IL-12, a cytokine secreted by myeloid cells and important for the induction of IFN-γ responses, is required for DC migration during M. *tuberculosis* infection (253). Priming of adaptive immune responses requires the transport of live

bacteria to the lung-draining lymph nodes (246, 250), but antigen-specific T cells can be primed by both the infected migratory DC and uninfected lymph node resident DC. A study demonstrated that infected DCs migrate to the lung-draining lymph nodes, where they secrete soluble, unprocessed *M. tuberculosis* antigens that are summarily phagocytosed by uninfected lymph node resident DCs (254). The exportation of *M. tuberculosis* antigens was initially proposed to benefit the host by circumventing inefficient antigen presentation by infected DCs. However, secretion of *M. tuberculosis* antigens by infected DCs may also benefit the pathogen by diverting antigen away from MHC class II antigen presentation (255).

Effective interaction between DCs and T cells is dependent on appropriate function of antigen presentation machinery, including expression of MHC, costimulatory molecules, and cytokines following *M. tuberculosis* infection. However, there is abundant evidence that *M. tuberculosis* infection impairs antigen presentation to evade antigen-specific T-cell responses. It is well recognized that *M. tuberculosis* infection leads to impaired MHC class II antigen presentation by macrophages (reviewed in 256). *M. tuberculosis*-mediated inhibition of phagosomal maturation has been implicated in attenuating processing of *M. tuberculosis* antigen 85 (Ag85) and the MHC class II-associated invariant chain (257). Multiple studies have also reported that *M. tuberculosis* infection impairs MHC class II expression in macrophages through inhibition of class II transactivator, a master transcriptional regulator controlling expression of MHC class II molecules (258–261), although there is little evidence of similar inhibition of MHC class II in DCs. Nevertheless, *M. tuberculosis* infection of DCs leads to functional impairment of antigen presentation. *M. tuberculosis* infection has been shown to impair DC maturation of human (reviewed in 262) and murine DC functions (reviewed in 263, 264). Studies examining proliferation of T-cell receptor transgenic CD4 T cells specific for *M. tuberculosis* Ag85 as a proxy for functional antigen presentation have demonstrated that *M. tuberculosis* EsxH can impair antigen processing through inhibition of the host endosomal sorting complex required for transport (ESCRT) (265). Additionally, *M. tuberculosis* promotes suboptimal antigen presentation *in vitro* and *in vivo* without detectable differences in the expression levels of costimulatory molecules when compared to BCG-infected DCs (266). Interestingly, studies using a mutant *M. tuberculosis* strain lacking *hip1* (discussed above) indicate that *M. tuberculosis* readily impairs DC costimulation and cytokine production to evade antigen-specific CD4 T-cell responses (107, 109), and a recent study demonstrated that BCG *hip1* retains similar immune evasion functions (267). Taken together, the initiation of the adaptive immune response requires the participation of DCs, which themselves are readily infected and subverted by *M. tuberculosis* infection. *M. tuberculosis* subversion of DC functions can interfere with antigen presentation and delay or impair the initiation of the adaptive immune response. Improving DC functions during *M. tuberculosis* infection may improve innate and adaptive immunity and enhance immune control of bacterial burden. A study that exogenously engaged the CD40 costimulation pathway in *M. tuberculosis*-infected DCs improved DC functions and promoted antigen-specific CD4 T-cell responses that augmented control of lung bacterial burden (268). Further, mucosal transfer of Ag85B-loaded DCs following challenge with *M. tuberculosis* augmented the efficacy of BCG vaccination (269), suggesting that early antigen presentation by DCs is an important component that determines the efficacy of vaccine-induced immunity. DCs are critical players that initiate adaptive immune responses to *M. tuberculosis* and determine the outcome of infection. Interventions or therapies that improve DC functions may provide benefits by augmenting cross talk between DCs and antigen-specific T cells.

ADAPTIVE IMMUNITY AGAINST *M. TUBERCULOSIS*

Protective immunity to *M. tuberculosis* and control of bacterial replication requires adaptive immune responses. This is best exemplified by the extreme susceptibility to mycobacterial infections of lymphopenic HIV patients and gene-deleted mice lacking MHC class II or T cells in general. Cytokine secretion and direct antimicrobial actions of antigen-specific T cells are key features of the adaptive immune response against *M. tuberculosis* infection. Further, the long-lived nature of antigen-specific memory T cells provides the basis for developing vaccines that induce antimycobacterial immunity. There are also expanding roles for B cells, γδ T cells, and CD1-restricted T cells that provide specific responses to a diverse set of *M. tuberculosis* antigens that complement antigens classically presented through MHC class I and II. However, adaptive immune responses can also become malignant by promoting excessive inflammation or be rendered ineffective from chronic antigen exposure. Here, we cover the importance of timing, location, and quality of CD4 T-cell responses during *M. tuberculosis* infection, how CD8 T cells contribute to immunity against *M. tuberculosis*, the roles that inhibitory receptors play during infection, the phenotypes and functions of memory T cells, and the roles that B cells, γδ T cells, CD1-restricted lymphocytes, and mucosal associated invariant T (MAIT) cells play in immunity against *M. tuberculosis*.

Kinetics and Homing of CD4 T Cells after *M. tuberculosis* Infection

In the mouse model of infection, CD4 T-cell responses are absolutely required to control bacterial replication, and animals lacking such responses succumb rapidly (270, 271). MHC class II knockout mice or CD4 depletion led to abrupt mortality following *M. tuberculosis* infection (270, 271). CD8 T cells play a key role in immunity against *M. tuberculosis* but cannot compensate for CD4 deficiency (270). Similarly, antibody depletion of CD4 in cynomolgus macaques severely compromised control of *M. tuberculosis* and led to reactivation in latently infected animals (69). Thus, the initiation of the CD4 T-cell response is a key feature defining the outcome of *M. tuberculosis* infection. There is a widely recognized delay in the initiation of antigen-specific CD4 T-cell responses following low-dose aerosol infection of mice (250, 272–275) and NHPs (276). *M. tuberculosis*-infected cynomolgus macaques had detectable antigen-specific responses 4 weeks postinfection (276). In mouse models of infection, antigen-specific CD4 T-cell responses are first detected in the lung-draining lymph nodes 2 weeks after infection. Significant antigen-specific lung CD4 T-cell responses are subsequently detected in the lungs 3 weeks after infection. This is in stark contrast to antigen-specific responses to other bacterial (277) or viral (278) pathogens, which are detected swiftly after infection. Adoptive transfer of ESAT-6-specific CD4 T cells prior to aerosol *M. tuberculosis* infection have demonstrated an apparent kinetic bottleneck whereby lung antigen-specific activation occurs only 7 days after infection despite the presence of antigen-specific T cells (279), suggesting that antigen-specific responses are delayed by

mechanisms other than trafficking of CD4 T cells from the mediastinal lymph nodes to the lungs. Delay in the initiation of adaptive immune responses to M. *tuberculosis* infection may be due to a variety of factors, including slow growth of the bacterium, inhibited apoptosis of infected macrophages and neutrophils, and delayed activation and migration of DCs, which cumulatively allow M. *tuberculosis* to establish a persistent infection in the lung.

CD4 T cells interact with infected macrophages to restrict intracellular M. *tuberculosis* replication. Thus, the effectiveness of the CD4 T-cell response depends on proper homing of antigen-specific CD4 T cells from lymphoid tissues to M. *tuberculosis*-infected cells in the lung. In M. *tuberculosis*-infected mice, antigen-specific CD4 T cells expressing CXCR3 localized to the lung parenchyma and were more efficient at controlling bacteria following M. *tuberculosis* infection when compared to vasculature-restricted CD4 T cells that expressed CX3CR1 (280). Interestingly, cells retained in the lung vasculature secreted the highest amount of IFN-γ during infection (280). Adoptive transfer studies demonstrated that IFN-γ accounted for greater control of bacterial burden in the spleen over the lung and drove immunopathology when overexpressed (281), suggesting that the function of IFN-γ may be to mediate control of bacterial dissemination to extrapulmonary sites and that IFN-γ may be detrimental when unrestrained. The distinction between vasculature-restricted and parenchyma-localizing CD4 T cells seems less important in rhesus macaques (282), where the majority of antigen-specific CD4 T cells can be found in the lung parenchyma but are restricted to the outer lymphocytic cuff of granulomas. Notably, studies have demonstrated that expression of IDO by cells in the granulomas of M. *tuberculosis*-infected rhesus macaques can mediate inhibition of T cell entrance into granuloma, and biochemical inhibition of IDO led to reorganization of the granuloma to include T cells localizing into the macrophage core (66, 283). Taken together, there is strong evidence that localization of antigen-specific CD4 T cells into the lung tissues where M. *tuberculosis*-infected myeloid cells reside is an important feature of protective immunity to M. *tuberculosis*.

Quality and Specificity of the CD4 T-Cell Response to *M. tuberculosis*

The quality of the T-cell response is an important feature determining the outcome of M. *tuberculosis* infection. Canonically, the production of IFN-γ by Th1 cells, CD8 T cells, and other lymphocytes is considered essential for protection against mycobacterial infections. In human immunogenetics studies, Mendelian susceptibility to mycobacterial disease (MSMD) is a spectrum of genetic mutations in five autosomal genes (*IFNGR1*, *IFNGR2*, *STAT1*, *IL12B*, *IL12RB*) and an X-linked gene that confer susceptibility to avirulent environmental mycobacteria and BCG (284). Deficiencies related to IFN-γ signaling in young patients with mutations in *IFNGR1* and *IFNGR2* confer fatal susceptibility to mycobacterial infections (285–288). STAT1 is an intracellular molecule important for IFN-γ signaling, and individuals with heterozygous germline *STAT1* mutations lose gamma-interferon activating factor (GAF) expression (289). GAF is an important transcription factor that facilitates IFN-γ-induced gene expression. Individuals with heterozygous *STAT1* mutations have impaired nuclear accumulation of GAF and suffer from recurrent mycobacterial infections (289). Additionally, mutations affecting IL-12 expression levels and signaling also confer susceptibility to mycobacterial infections. Two mutations in the leucine zipper domain of NEMO, an intracellular protein involved in NF-κB activation, impairs CD40-mediated IL-12 production in monocytes and DCs (290) and leads to recurrent mycobacterial infections. Similarly, defects that impair IL-12p40 lead to decreased IFN-γ levels and confer susceptibility to mycobacterial infections (291–294). Mutations in *IL12RB* are the most frequent genetic factors associated with Mendelian susceptibility to mycobacterial disease, but recurrent mycobacterial susceptibility in individuals with *IL12RB* mutations can be mitigated with BCG vaccination or primary BCG disease (291, 292, 295–298), suggesting that IL-12/IL-23 signaling may not be completely required for secondary immunity. IFN-γ is readily detected in human BAL in patients with TB disease and decreases following therapy (299), which is likely a consequence of decreasing bacterial loads. In contrast, studies of human peripheral blood mononuclear cells show a decrease in IFN-γ responses in ATB patients compared to controls (300–305). Lower frequencies of M. *tuberculosis*-specific IFN-γ responses in ATB patients may reflect trafficking of these cells to the lungs, resulting in specific depletion from the periphery. IFN-γ secretion is also an important tool leveraged for the detection of M. *tuberculosis*-specific CD4 T-cell responses in humans and in animal models. Genome-wide analysis of M. *tuberculosis*-specific CD4 T-cell epitopes in LTBI individuals revealed three broadly immunodominant antigenic islands related to bacterial secretion systems recognized by IFN-γ secreting CD4 T cells (306). Animal models of TB also demonstrate a key role for IFN-γ in immunity against M. *tuberculosis* infection. Mice deficient in IFN-γ succumb to low-dose M. *tuberculosis* infection (307, 308). Correspondingly, mice lacking IL-12 are also unable to control M. *tuberculosis* infection (253, 309, 310). The antimycobacterial effects of IFN-γ in mouse models are broadly related to the induction of AMPs, iNOS, and cytokines that activate infected macrophages to restrict intracellular bacterial replication, though other mechanisms underlying IFN-γ-mediated immunity to M. *tuberculosis* infection are still being elucidated. IL-10-deficient mice are less susceptible to M. *tuberculosis* infection due to an enhanced Th1 response (311), suggesting that IL-10 limits Th1 immunity during M. *tuberculosis* infection. However, Th1 cells secreting IL-10 can also impair host control of M. *tuberculosis* infection (312), and CD4 T cells producing both IFN-γ and IL-10 are detected in the BAL of ATB patients (313). Given that IL-10 secretion by Th1 cells has been shown to be a result of high antigen dose (314), it is possible that adaptive immunity at stages of infection when bacterial burden is high may be compromised by T cell-derived IL-10. T-bet is a member of the T-box family of transcription factors that is encoded by *Tbx21* and is the master transcriptional regulator for lineage commitment to the Th1 subset (315). Interestingly, adoptive transfer of T-bet knockout ESAT-6-specific T-cell receptor-transgenic CD4 T cells skewed toward Th1 *in vitro* retains the capacity for early protection against M. *tuberculosis* infection (316), suggesting that protection conferred by Th1 cells may be independent of T-bet or IFN-γ production. Taken together, these studies demonstrate a clear requirement for the IL-12/IFN-γ axis in immunity against M. *tuberculosis* infection in humans and animal models. Further studies delineating the mechanisms underlying IFN-γ- and Th1-mediated immunity against M. *tuberculosis* are warranted.

Although Th1 responses are important for immunity against TB, studies have also demonstrated that CD4 T-cell subsets secreting IL-17 (Th17) and FoxP3+ regulatory CD4 T cells contribute to the response against M. *tuberculosis* infection. There are context-dependent beneficial or

detrimental roles for Th17s during infection with *M. tuberculosis*. Infection with a W-Beijing lineage strain of *M. tuberculosis*, HN878, induce Th17 responses, and mice deficient in IL-17 display increased bacterial burden following infection (317). IL-17 receptor A subunit knockout mice (318) and IL-17A knockout mice (319) also displayed impaired long-term control of high-dose infection with H37Rv. Transfer of BCG-specific, IFN-γ knockout Th17 cells into *M. tuberculosis* infected, T cell-deficient mice conferred enhanced protection and prolonged survival compared to transfer of naive IFN-γ knockout CD4 T cells (320), suggesting that Th17 cells can mediate protection independently of IFN-γ. In humans, significant frequencies of IL-17-producing CD4 T cells were found in the peripheral blood mononuclear cells and BAL of BCG-vaccinated healthy individuals and declined in patients with active disease (321). Further, individuals with bi-allelic *RORC* loss-of-function mutations displayed impaired IL-17 and IFN-γ responses and were susceptible to mycobacterial disease and candidiasis (322). The generation of Th17 responses to *M. tuberculosis in vitro* requires costimulation through the CD40-CD40L pathway since the absence of CD40 on DCs or CD40L on CD4 T cells attenuates antigen-specific IL-17 responses (268). Activation of *M. tuberculosis*-infected DCs through CD40 promoted enhanced antigen-specific Th1 and Th17 responses that contributed to better control of bacterial burden *in vivo* (268), suggesting that a balanced Th1 and Th17 response is desirable for immunity against *M. tuberculosis*. The precise role of Th17 cells in protective immunity to *M. tuberculosis* remains unclear but may be related to their role in the development of less hypoxic granulomas (323), in the recruitment of Th1 cells (324), or in the induction of CXC-chemokines and B-cell follicles (325). However, unrestrained IL-17 responses have also been shown to promote detrimental immunopathology, typically through pathological neutrophilia. IFN-γR1 knockout animals (326) or IFN-γR1 bone marrow chimeric mice selectively lacking the receptor in nonhematopoietic cells (327) display amplified Th17 responses following *M. tuberculosis* infection that lead to a pathogenic accumulation of neutrophils detrimental to the host, suggesting that IFN-γ signaling serves a regulatory role by limiting excessive IL-17-mediated neutrophilia.

FoxP3+ CD4 T cells, or T-regulatory cells (T-regs), can impair antimycobacterial T-cell responses and contribute to disease but can also limit overt inflammation. FoxP3+ T-regs can be found in the peripheral blood and airways of *M. tuberculosis*-infected macaques (328) and humans (329–334). In mice, T-regs accumulate in the lung-draining lymph nodes and the lungs following low-dose aerosol *M. tuberculosis* infection (335). Importantly, FoxP3+ T-regs localized to pulmonary areas adjacent to effector CD4 T cells and depletion of T-regs before and early after infection-enhanced control of bacterial burden (335). Further, *M. tuberculosis*-specific T-regs delay the expansion of antimycobacterial CD4 and CD8 T cells and, consequently, transfer of *M. tuberculosis*-specific T-regs confers increased susceptibility to infection (336). Regulation of T-regs during *M. tuberculosis* infection may be mediated by Th1 responses since *M. tuberculosis*-specific T-regs are selectively eliminated following IL-12 driven T-bet expression (337). The functional properties of T-regs responsible for limiting antimycobacterial CD4 and CD8 responses remains unclear. IL-10 was not found to be secreted by T-regs in mice infected with H37Rv (335). In contrast, T-regs from mice infected with the W-Beijing strain, HN878, were found to secrete IL-10, express inhibitory receptors, and expand to greater degrees compared to infection with H37Rv (209), suggesting that IL-10 secretion by T-regs may be dependent on bacterial strain. Notably, the expansion of T-regs in the lungs of mice and outbred guinea pigs infected with W-Beijing strains occurred concurrently with a loss of Th1 responses and is associated with severe pulmonary pathology (209, 338). However, progressive loss of T-regs in chronically infected TLR-2 knockout mice was associated with increased pulmonary inflammation (339), highlighting a role for TLR-2-mediated recruitment of T-regs in limiting tissue pathology at chronic stages of disease. Taken together, these results suggest that the functional contribution of T-regs to immunity against *M. tuberculosis* infection and outcome of disease may be dependent on multiple factors, including strain of bacteria and stage of infection.

In humans and animal models, *M. tuberculosis* establishes a persistent infection despite the induction of adaptive immune responses. Persistent inflammation and chronic antigen exposure precedes functional exhaustion due to chronic antigenic stimulation. In contrast to the expression of Ag85B, which decreases early following infection, ESAT-6 is expressed by *M. tuberculosis* throughout infection (340, 341). Multiple studies examining CD4 T-cell responses to ESAT-6 and Ag85B have suggested that antigen-specific responses are dictated by bacterial expression of those antigens throughout infection. CD4 T cells specific for ESAT-6 display a terminally differentiated phenotype with evidence for functional exhaustion, which runs in contrast to Ag85B-specific CD4 T cells that appear functional but are quickly diminished (272, 342–347). Indeed, a vaccine that contains ESAT-6, Ag85B, and Rv2660c, which is expressed at late stages of infection, demonstrated enhanced efficacy compared to BCG or to a vaccine containing ESAT-6 and Ag85B (348), suggesting that rational incorporation of antigens present at different stages of infection may improve vaccine efficacy. A clearer understanding of protective CD4 T-cell immunity will require further studies of the spectrum of antigens recognized by CD4 T cells following infection with *M. tuberculosis* in animal models and in humans.

Role of CD8 T Cells in *M. tuberculosis* Infection

Mice with gene deletion of β2 microglobulin, which abrogates MHC class I antigen presentation, or mice depleted of CD8 T cells live longer than corresponding disruptions to the MHC class II pathway or CD4 T-cell responses following *M. tuberculosis* infection (270). Regardless, CD8 T cells contribute significantly to immunity against *M. tuberculosis* infection. Mice lacking TAP-1 (transporter associated with antigen processing 1) antigen presentation molecules have deficient CD8 T-cell responses and succumb more rapidly following *M. tuberculosis* infection compared to wild-type controls (349, 350). Depletion of CD8 T cells in rhesus macaques compromises protective immunity from BCG vaccination or chemotherapeutic interventions (57), suggesting that CD8 T cells are important components of recall responses to *M. tuberculosis* infection. Similarly, in a mouse model of latency induced by antibiotic treatment, CD8 T-cell responses were found to be important in preventing reactivation (351). The importance of CD8 T cells during *M. tuberculosis* infection is related to their secretion of cytokines and cytolytic effector molecules that can limit bacterial replication. In addition to IFN-γ and TNF-α, CD8 T cells secrete perforin to lyse *M. tuberculosis*-infected macrophages (352). CD8 T cells can also release granulysin in cytotoxic granules to directly kill intracellular *M. tuberculosis* (353, 354). The use of anti-TNF-α therapy in patients with rheumatoid arthritis depletes a subset of effector memory

CD8 T cells that secrete granulysin and express cell surface TNF (355), which may partially explain the increased progression from LTBI to ATB in patients undergoing anti-TNF-α therapy. Human CD8 T cells respond to epitopes in CFP10 (356), ESAT-6 (357, 358), and the Ag85 complex (359, 360). A variety of human CD8 T-cell clones tested against a panel of synthetic peptides derived from immunodominant *M. tuberculosis* antigens revealed that CD8 T-cell responses are concentrated toward a limited set of epitopes and are generally restricted by the HLA-B allele (361, 362). *M. tuberculosis* escape from the phagosome and induction of apoptosis by *M. tuberculosis*-infected macrophages can promote cross-presentation of *M. tuberculosis* antigens to CD8 T cells. However, as previously discussed, virulent *M. tuberculosis* has been shown to inhibit host apoptosis and favor necrosis to circumvent efficient induction of CD8 T-cell responses. All considered, CD8 T cells are a critical component of adaptive immunity to *M. tuberculosis* infection and play an important role in different disease contexts by limiting reactivation during latency and by directly participating in antimicrobial functions during active infections.

Inhibitory Receptors During *M. tuberculosis* Infection

Chronic viral infections, such as HIV, induce the expression of coinhibitory receptors on the surface of T cells that can dampen T-cell functionality. Abrogation of coinhibitory receptor ligation has been shown to be a viable strategy to revitalize functionally exhausted virus-specific T-cell responses. The evidence for the importance of coinhibitory receptors during *M. tuberculosis* infection in animal models and in human samples varies between human and small animal models and between the specific inhibitory receptor studied. PD-1, CD160, and 2B4 are inhibitory receptors associated with CD8 T-cell dysfunction in chronic viral infections (363, 364) but are expressed at low levels on *M. tuberculosis*-specific CD8 T cells (365). Expression of inhibitory molecules, including PD-1 and CTLA-4, among *M. tuberculosis*-specific CD4 T cells has been shown to decrease following treatment (366, 367). Importantly, expression of PD-1 on antigen-specific CD4 T cells from LTBI was not associated with decreased effector functions, and these cells proved to be polyfunctional with respect to cytokine production upon antigen restimulation (368), suggesting that PD-1 may be an indicator of bacterial burden and CD4 T-cell activation rather than functional exhaustion. However, there is some *in vitro* evidence from human samples suggesting that blockade of PD-1/PD-L1 interaction can prevent *M. tuberculosis*-specific CD4 T-cell apoptosis (369) and enhance CD8 T-cell degranulation and antigen-specific IFN-γ responses from the peripheral blood mononuclear cells of a subset of high-responding ATB patients (370). There is evidence that T-cell responses during ATB disease are less polyfunctional and have limited proliferative capacity compared to LTBI individuals (371, 372), but whether this functional impairment is mediated by inhibitory receptors such as PD-1 remains unclear. PD-1-deficient mice infected with *M. tuberculosis* have increased bacterial burden, neutrophilic infiltration, overt inflammation, tissue necrosis, and diminished lifespan compared to wild-type mice (373), suggesting that PD-1 is required to prevent aberrant inflammation during *M. tuberculosis* infection. Further, adoptive transfer studies demonstrated that PD-1-expressing CD4 T cells are highly proliferative (342, 346), and CD4 T cells lacking PD-1 can drive pathology and mortality following *M. tuberculosis* infection (374), together suggesting that PD-1 may mark functional CD4 T cells with intrinsic capacity for immunoregulation. T-cell immunoglobulin and mucin domain-containing 3 (Tim-3) is another inhibitory receptor shown to play a role in mediating antimicrobial responses by binding to one of its ligands, galectin-9 (375), and inducing the production of IL-1β by human and murine macrophages infected with *M. tuberculosis* (375, 376). In contrast to PD-1, Tim-3-deficient mice were less susceptible to *M. tuberculosis* infection, and Tim-3 blockade was shown to improve antigen-specific CD4 and CD8 T-cell cytokine expression (377), suggesting that Tim-3 may play a role in limiting T-cell responses by promoting functional exhaustion. However, Tim-3-expressing, *M. tuberculosis*-specific T cells from ATB patients were functionally superior to T cells expressing low levels of Tim-3. Further, small interfering RNA- or antibody-mediated disruption of Tim-3 signaling on the T cells from ATB patients led to attenuated IFN-γ and TNF-α production by Tim-3-expressing T cells, while Tim-3 ligation augmented IFN-γ production (378). The mechanisms underlying the roles of receptors such as PD-1 and Tim-3 require further study and may deviate from their role in viral immunity. The evidence accumulated thus far suggests that these molecules mark functional T cells that play important roles in antimicrobial activity and prevention of uncontrolled inflammation following *M. tuberculosis* infection.

Memory T-Cell Responses

In humans, antigen-specific memory T-cell responses have been detected in individuals with LTBI and in TB patients following successful treatment and cure. Memory T-cell subsets can be identified according to their cell surface phenotype and functional properties, and distinct populations of antigen-specific memory T cells can be categorized based on their expression of a panel of cell surface activation markers and chemokine receptors (379). Characterization of *M. tuberculosis*-specific memory CD4 T cells in LTBI indicated that these cells did not express activation markers and were largely of a CD45RA-CCR7 phenotype descriptive of T effector memory cells (368, 380). In contrast, analysis of LTBI individuals using MHC class II tetramers revealed a population of tetramer+CD45RA-CCR7+ central memory CD4 T cells that further expressed CXCR3+CCR6+ (306), highlighting the heterogeneity of memory CD4 T-cell phenotypes that can vary based on antigen specificity, disease status, and manner in which specific responses are identified. Human memory CD8 T cells are predominantly terminally differentiated effector memory T cells in individuals with LTBI (365, 381). Memory T-cell responses have also been studied in the context of "memory-immune" mice, which are *M. tuberculosis*-infected mice that subsequently receive antibiotic treatment. In this context, both memory CD4 (382, 383) and CD8 (384, 385) T cells play a role in immunity against *M. tuberculosis* infection. T cells from memory-immune mice expanded rapidly, secreted IFN-γ, and conferred a significant level of protection at early timepoints after infection (383, 386–388) but are ultimately unable to confer long-term protection (389), suggesting that memory T cells generated after primary *M. tuberculosis* infection have limited capacity to protect from reinfection.

B-Cell and Antibody Responses During *M. tuberculosis* Infection

There is a body of evidence suggesting that humoral immunity plays a role in defense against *M. tuberculosis* infection (reviewed in 390). B cells can be found alongside T cells in

the lymphocytic cuff in human granulomas (391–393), and whole blood gene expression analysis revealed significant changes in B-cell-associated genes in TB patients after initiation of TB treatment (394). Notably, antibodies to *M. tuberculosis* proteins have been reported in the sera of TB patients (395), and antibodies identified in a subset of health care workers exposed to *M. tuberculosis* provide modest protection *in vitro* and in a mouse model of infection (396). Utilization of a high-throughput approach to identifying antibody targets in the *M. tuberculosis* proteome revealed a set of extracellular antigens recognized by antibodies in the plasma of patients with ATB (397), suggesting that B cells are active participants in immunity to *M. tuberculosis* infection. B-cell-deficient mice have elevated neutrophilic recruitment and exacerbated lung immunopathology following *M. tuberculosis* infection (398), which is mediated through enhanced IL-17 responses in *M. tuberculosis*-infected B-cell-deficient or B-cell-depleted animals (399). These studies suggest that B cells can influence the outcome of *M. tuberculosis* infection by moderating inflammatory responses. Antibody production by B cells can promote divergent outcomes (400). Binding of antibody to the inhibitory Fc gamma receptor II B attenuates macrophage IL-12 production and negatively impacts Th1 responses (401), while passive transfer of monoclonal antibodies specific for *M. tuberculosis* cell wall components can improve the outcome of infection in mice (390). B-cell secretion of cytokines can also influence *M. tuberculosis*-infected macrophages. Type I IFN expression by murine B cells and B cells from pleural effusion of TB patients altered macrophage polarization toward an anti-inflammatory phenotype (402). Taken together, these studies highlight a role for B cells, which constitute a significant population of lymphocytes around lung granulomas in the adaptive immune response to *M. tuberculosis* infection by modulating inflammation through the secretion of antibodies and cytokines.

γδ, CD1-Restricted T Cells, and MAIT Cells in Immunity against *M. tuberculosis*

γδ T cells are a population of T cells that express a restricted repertoire of T-cell receptor genes, recognize nonpeptide antigens such as microbial metabolites and phosphoantigens (403), and can be found at mucosal surfaces including the lung (404). γδ T cells proliferate when exposed to *M. tuberculosis*-infected monocytes (405). Multiple *M. tuberculosis* metabolites, including pyrophosphate, prenyl pyrophosphate derivatives (406, 407), and triphosphorylated thymidine-containing compounds (408), are recognized by human γδ T cells. Human γδ T cells can also respond to mycobacterial heat shock proteins (409), though this response may be dependent on BCG immunization (410). Vγ9Vδ2-expressing γδ T cells represent a significant proportion of *M. tuberculosis*-reactive T cells in peripheral blood (411–413) and can restrict intracellular *M. tuberculosis* replication in macrophages (414). Interestingly, Vγ9Vδ2 T cells can function as antigen presentation cells via provision of CD40 costimulation to promote the expansion of αβ T cells with enhanced capacity to restrict intracellular BCG replication (415). Additionally, human Vγ2Vδ2 T cells recognize *M. tuberculosis* (416), and in NHPs, Vγ2Vδ2 T cells are expanded by phosphoantigen and IL-2 administration (417). Adoptively transferred Vγ2Vδ2 T cells into naive animals confer protection against *M. tuberculosis* infection (418). γδ T cells have been shown to mediate direct killing of *M. tuberculosis* via secretion of granulysin and perforin (419) or through the induction of TNF-α by monocytes (420). There is also evidence that γδ T cells can influence DC cross talk with T cells by promoting DC maturation and expression of costimulatory molecules (421). In mice, γδ T cells accumulate in the lung-draining lymph nodes, are responsive to *M. tuberculosis* antigen independent of MHC class II (422), and are significant sources of early IL-17 production following *M. tuberculosis* infection (423).

Due to the large repertoire of glycolipids present on the mycobacterial cell wall, a significant T-cell response is directed at glycolipid antigens presented by the CD1 family of molecules. CD1 molecules are a family of MHC class I-like antigen presentation molecules that present glycolipid antigens to T cells. There are five CD1 family members in humans, split into two groups based on sequence homology. Group 1 molecules include CD1a, CD1b, CD1c, and CD1e. CD1d is the sole inclusion in group 2 (424). Mycobacterial lipids are readily presented by CD1 molecules in human cells, but mechanistic studies of this family of molecules is limited because mice only express two orthologs of CD1d and do not express group 1 molecules. Nevertheless, studies in human cells revealed that mycobacterial lipids presented by group 1 CD1 molecules promote T-cell proliferation and cytokine production (425–432). Mycobacterial glycerol monomycolate, glucose monomycolate, sulphoglycolipids, and mycolic acid can be presented through CD1b (426–428, 433). CD1b-restricted T cells expand and secrete IFN-γ and IL-2 upon interaction with cognate antigen and contract following anti-TB therapy (430). Interestingly, use of CD1b tetramers loaded with glucose monomycolate revealed that CD1b-restricted T cells are antigen-specific and also express CD4 (429, 434). *M. tuberculosis* lipids presented through CD1a and CD1c have also been identified. A family of *M. tuberculosis* lipopeptides called didehydroxymycobactins are presented by CD1a (435), and a variety of phospholipid antigens are presented by CD1c (425). The precise role of CD1-restricted T cells in immunity during *M. tuberculosis* infection remains unclear, and further studies of their function in the periphery and especially in BAL would inform their potential as targets for TB vaccines.

MAIT cells are a subset of T cells with innate-like qualities enriched in mucosal tissues, including the intestinal mucosa, lung, and liver (436–438). These cells recognize antigen through a nonpolymorphic MHC class I-related molecule 1 (439) presenting pterin-containing byproducts of riboflavin synthesis in bacteria and fungi (440). In humans, MAIT cells express a semi-invariant Vα7.2 and CD161 and can either be double negative for CD4 and CD8 or CD4-CD8+ (436, 441). MAIT cells have been described in the peripheral blood of healthy individuals and are depleted in ATB patients (442), possibly reflecting migration into the lung. These cells produce IFN-γ and TNF-α upon activation (442, 443), but their contribution to the immune response to *M. tuberculosis* infection requires further study.

INITIATION AND HETEROGENEITY OF THE GRANULOMA

The granuloma is a hallmark histopathological structure in TB. It represents host sequestration of bacteria to limit dissemination as well as a niche for long-term persistence of *M. tuberculosis*. Further, the selectively drug-permeable nature of the TB granuloma can diminish the efficacy of drugs meant to treat persistent bacteria (444). The granuloma is composed of an aggregate of *M. tuberculosis*-infected and -uninfected macrophages in varying stages of maturation and differentiation (445–447). Macrophages in the granuloma can undergo an epithelioid transformation, become

lipid-filled foamy macrophages, or merge into multinucleated giant cells. This central core of macrophages is accompanied by neutrophils, DCs, and fibroblasts circumscribed by T and B lymphocytes and progressively becomes a hypoxic environment where many cells undergo necrotic death to form an acellular core termed the caseum (448). The granuloma is a hallmark structure in human TB that is modeled variably among available animal models. C57BL/6 and BALB/C mice do not naturally recapitulate the human granuloma in that lung lesions are rarely necrotic and caseating. The animal models that most closely recapitulate the heterogeneity of human granulomas include certain susceptible inbred mouse strains that present with necrotizing granulomas (C3HeB/FeJ, DBA/2, CBA/J, I/St), guinea pigs, rabbits, and the NHP model. Additionally, the zebrafish model has also yielded fundamental insights into the initiation and dynamics of the tuberculous granuloma.

The transparency of zebrafish larvae has made direct visualization of the initiation of the granuloma possible following infection with *M. marinum* (48). Studies based on this model have revealed that the innate immune response is sufficient to initiate the granuloma following infection. Recruitment of additional macrophages mediated, in part, by mycobacterial ESX-1 proteins initiates a cascade of events that leads to the establishment of the mycobacterial granuloma (221, 449). Importantly, recruited macrophages can traffic through the initial granuloma to phagocytose apoptotic infected macrophages and egress to form distal secondary granulomas (450). Mycobacterial lipids play a key role in establishing the granuloma by limiting macrophage effector functions and promoting the recruitment of additional macrophages to facilitate dissemination. In particular, mycobacterial phthiocerol dimycocerosate can mask TLR-signaling and prevent induction of nitrosative stresses (451), and mycobacterial PGL can induce macrophage production of CCL2 to recruit CCR2+ monocytes that permit bacterial dissemination (452). These studies collectively indicate that the initiation of the mycobacterial granuloma is dependent on recruitment of bacteria-permissive macrophages and monocytes following initial infection and can be mediated by mycobacterial secreted factors and membrane lipids.

TB granulomas can vary in their cellular composition, oxygenation levels, inflammatory milieu, and bacterial burden. This heterogeneity can exist between and within infected hosts. Infection of cynomolgus macaques with a panel of *M. tuberculosis* isolates that differed by a single nucleotide polymorphism revealed that individual granulomas can be founded by a single bacterium and can vary in their bacterial burden compared to other granulomas within the same host (51). Analysis of T-cell functionality between sterile and nonsterile granulomas revealed a modest association between IL-10 and IL-17 responses and clearance of *M. tuberculosis* in sterile granulomas (453). However, in the context of TNF-α neutralization in latently infected macaques, IL-10 and IL-17 responses were associated with animals at higher risk of reactivation (71). Proteome analysis of laser-capture microdissected human and rabbit lung lesions suggests that inflammatory responses typical of the center of the TB granuloma are physically segregated from anti-inflammatory responses in adjacent lung tissue (454). T-cell functionality in the granuloma may therefore be a function of disease status and proximity to the bacteria-containing, hypoxic, and necrotic core of the TB granuloma. Additionally, T cells near the granuloma can be negatively impacted by the depletion of key amino acids required for proper function. As mentioned previously, IDO, an enzyme that functions in the catabolism of tryptophan, is expressed by cells in the core of the granulomas of rhesus macaques infected with *M. tuberculosis* (283), and inhibition of IDO promoted granuloma reorganization and attenuated disease (66). The functionality of T cells within granulomas may also be regulated by direct cross talk with infected myeloid cells, including macrophages and DCs. Intravital imaging of mycobacteria-induced liver granulomas revealed limited antigen-specific T-cell migration arrest in response to infected myeloid cells (345), suggesting that T cells do not interact meaningfully with infected cells in granulomas. Taken together, these studies highlight the vast complexity and heterogeneity of the TB granuloma.

IMMUNOLOGY OF TB DIAGNOSTICS

TB diagnosis relies on evaluation of clinical symptoms and patient history combined with radiographic examination and detection of bacteria in sputum (9). The presence of acid-fast bacilli in sputum smears by microscopy does not specifically indicate infection with *M. tuberculosis*; microbiological culture and nucleic acid amplification-based tests are required to confirm the presence of *M. tuberculosis* infection. Xpert MTB/RIF, a cartridge-based near-patient diagnostic assay utilizing real-time nucleic acid amplification of *M. tuberculosis* DNA, which also detects drug resistance to the first-line drug rifampicin, is recommended by the World Health Organization for TB diagnosis (455, 456). IFN-γ release assays (IGRAs), which leverage the specificity of the immune response to *M. tuberculosis*, are the basis of the QuantiFERON-TB Gold In-Tube and T-SPOT.TB diagnostic assays. IGRAs measure IFN-γ produced by antigen-specific T cells in blood that recognize *M. tuberculosis* antigens (ESAT-6, CFP-10, TB7.7) (457). IGRAs provide increased specificity over traditional Mantoux skin tests that depend on delayed-type hypersensitivity reactions to purified protein derivative, which is not specific to *M. tuberculosis* infection, and positive results may be due to BCG vaccination or exposure to environmental mycobacteria. However, IGRAs do not differentiate between active and latent TB and cannot be used to diagnose TB disease. While sputum-based smear and culture techniques are established worldwide for clinical indication of *M. tuberculosis* infection, collection of sputum, especially from children, can be challenging and is not completely reliable. Therefore, there is interest in developing non-sputum-based diagnostic approaches for TB. Detection of urinary lipoarabinomannan in suspected TB cases is being investigated in HIV-infected (458) and -uninfected (459) individuals. Blood-based biomarkers discriminating between LTBI and ATB are being investigated for potential application to TB diagnostics and treatment response (460–462). HLA-DR, CD38, and Ki67 expression on *M. tuberculosis*-specific CD4 T cells from peripheral blood is reported to be a highly specific and sensitive method to discriminate LTBI and ATB and evaluate treatment response (460). A recent study suggests that HLA-DR could function as a robust marker distinguishing LTBI and ATB in HIV-infected populations (461). Further understanding of the spectrum of antigen-specific responses to *M. tuberculosis* infection can be leveraged to develop diagnostics that can monitor infection and treatment response.

TB VACCINES

The only currently licensed vaccine against TB is bacillus Calmette-Guérin (BCG), an attenuated strain of *M. bovis* (463, 464). BCG confers protection against severe forms of TB, including miliary TB and TB meningitis (465), but does

not reliably protect against pulmonary TB in children or adults (3, 4, 466). The lack of validated correlates of protection against TB is a severe limitation to TB vaccine development. Despite the importance of IFN-γ responses in resistance against *M. tuberculosis* infection in humans and animal models, accumulating evidence suggests that induction of enhanced IFN-γ responses is not sufficient to obtain a more efficacious TB vaccine. Indeed, the frequency and functional profile of BCG-specific CD4, CD8, and γδ T cells from whole blood, including IFN-γ-producing T cells, did not correlate with protection against TB in newborns (467). As of 2017, there are 14 TB vaccine candidates in varying phases of clinical development representing three broad strategies: subunit vaccines pairing *M. tuberculosis* antigens with adjuvants, viral-vectored vaccines utilizing an attenuated virus for antigen delivery, and whole-cell vaccines utilizing attenuated *M. tuberculosis* or related mycobacterial species. Protein subunit vaccines currently under clinical development include M72/AS01E (468), H4:IC31 (469), H56:IC31 (470), and ID93/GLA-SE (471). Among viral-vectored vaccines, results from the MVA85A phase IIb clinical trial have prompted reevaluation of immune correlates to aim for in a TB vaccine. MVA85A is a modified vaccinia Ankara virus expressing Ag85A from *M. tuberculosis* that was utilized as a booster vaccine in infants previously vaccinated with BCG (472). Notably, vaccination with MVA85A enhanced frequencies of antigen-specific, polyfunctional CD4 T cells co-expressing IFN-γ, IL-2, and TNF-α (472). Although MVA85A vaccination enhanced antigen-specific CD4 T-cell responses, it did not provide added protection against TB disease in infants (472). Other viral-vectored vaccines in various stages of development include Ad5Ag85A (473), ChAdOx1.85A + MVA85A (474), MVA85A-IMX313 (475), and TB/FLU-04L. Additionally, a recent study utilizing a recombinant cytomegalovirus demonstrated protection in rhesus macaques (476). While viral vectors do not require the use of adjuvants, previous exposure to the vector may attenuate vaccine-induced responses and represents a potential complication to the use of viral vectors. Whole-cell vaccines currently under development include killed *Mycobacterium vaccae*, DAR-901 (477), VPM1002, MTBVAC, and RUTI. VPM1002 is an approach to improve BCG immunogenicity and vaccine potential by engineering BCG to express lysteriolysin from *Listeria monocytogenes* to escape the phagosome and carry a urease deletion mutation that facilitates phagosomal acidification, thereby enhancing MHC class I antigen presentation to CD8 T cells (478). MTBVAC is a genetically attenuated *M. tuberculosis* strain lacking *phoP* and *fadD26* that abrogates synthesis of various surface lipids (479). Lastly, the therapeutic vaccine candidate RUTI was developed by growing *M. tuberculosis* under stress prior to fragmentation, detoxification, and delivery in liposomes to individuals with LTBI to prevent progression to ATB (480–482).

There have been substantial advances in our understanding of immunity against *M. tuberculosis* from the days of Drs. Calmette and Guérin. Nevertheless, the absence of suitable alternatives to BCG highlights the challenges before us. *M. tuberculosis* is adept at subverting the cross talk between innate and adaptive immunity, and it will be important to understand that cross talk for the rational development of better vaccines. Even in the absence of protective correlates and in the face of disappointing preliminary results for MVA85A, the state of TB vaccine development is resurgent now more than ever and provides cause for optimism for the development of more efficacious vaccines and therapeutics against TB.

Unraveling the Structure of the Mycobacterial Envelope

MAMADOU DAFFÉ AND HEDIA MARRAKCHI

65

INTRODUCTION

The bacterial cell envelope, defined as the structure that surrounds the cytosol, is critical for bacterial physiology, because many crucial processes take place in this compartment. The cell wall contributes to the bacterial shape, mechanical resistance of the cells, and their protection against hostile environments. In addition, the envelope constituents are involved in cell division, transport of molecules (solutes and ions) and macromolecules (proteins), cell motility, adhesion, and protection, being in direct contact with the environment etc. The genus *Mycobacterium* belongs to the *Corynebacteriales* order, which also includes corynebacteria, nocardia, rhodococci, and other related microorganisms. Mycobacteria are probably the most successful microorganisms to parasitize animals and humans. Among the more than 200 valid species described to date in the genus *Mycobacterium*, only three are strict pathogens for humans: *Mycobacterium tuberculosis* (the Koch's bacillus), *M. leprae*, and *M. lepromatosis*. Tuberculosis still represents a major public health problem worldwide, remaining one of the leading causes of death from an infectious agent; about one-quarter of the world's population is infected by the Koch's bacillus and thus susceptible to develop the disease. In addition, two-thirds of mycobacteria species are opportunistic pathogens for humans, and all mycobacteria produce granulomatous lesions in experimental animals with large enough inoculum (1). Most mycobacterial pathogenic species grow very slowly (e.g., generation times of 24 hours and 13 days for the tubercle and leprosy bacilli, respectively), whereas saprophytes are relatively rapid growers (e.g., doubling time of 6 hours for the widely used genetically tractable *M. smegmatis*).

Mycobacteria and related genera are classified among the *Actinobacteria*, a division of Gram-positive bacteria, although they do not reliably retain the stain, a clear indication of the uniqueness of their cell envelope composition (2). Dissection of their fascinating coat reveals an atypical architecture of their envelope, different from those of both Gram-positive and Gram-negative bacteria (Fig. 1B). Unlike those of the former group of bacteria, with a reputed lipid-poor cell envelope (less than 10%), mycobacterial cell envelopes are extremely rich in lipids, representing up to 40% of their cell dry mass, more than the recorded 20% in Gram-negative bacteria (3). This high lipid content is in agreement with the huge number of genes devoted to the synthesis and regulation of this class of compounds (4). This hallmark would explain the tendency of mycobacteria to grow in clumps and their distinctive property of acid-fastness, but also their impermeability to nutrients and small molecules and their resistance to alkali, dilute acid, and infected mammalian cells (3).

Reviews have been recently published on the biogenesis (5), structures (6), and transport (2, 7, 8) of mycobacterial cell envelope constituents. This chapter highlights major advances in deciphering key biological and structural features of this unique and fascinating mycobacterial coat.

THE MICROSCOPIC APPEARANCE OF THE MYCOBACTERIAL CELL ENVELOPE

When studied by transmission electron microscopy (TEM), the mycobacterial cell envelope recurrently displays a multilayered structure (Fig. 1A). In TEM, the specimen is fixed prior to being embedded in a hydrophobic resin, followed by ultrathin sectioning and staining with heavy-metal salts. Consequently, fixation protocols and the use of different solvents can lead to extraction and shrinkage of its different constituents. Lipids noncovalently attached to cell wall polymers may be extracted by solvents during the dehydration step, and water-rich structures may collapse (9, 10). In ultrathin conventional sections (11), the cell envelope of mycobacteria looks more like that of Gram-positive bacteria (Fig. 1). It consists of a plasma membrane (PM), a thick electron-dense layer, an electron-transparent layer, and an outer layer of variable density and thickness (Fig. 1). The PM appears asymmetrical in images of some conventionally prepared cells, with the accumulation of material in its outer leaflet (12–14). This asymmetry, however, is dependent upon conditions of fixation (15). To circumvent these disadvantages, freeze-substitution techniques have been used (16, 17), but with little success, because the resulting images were diffuse and not resolved as expected (Fig. 1A).

More recently, cryo-electron microscopy of vitreous sections (CEMOVIS) and cryo-electron microscopy (cryoEM) of whole-mount cells have been applied to mycobacteria (Fig. 1B). In these techniques, the specimens are observed at liquid nitrogen temperature, which allows them to be imaged in their fully hydrated and unstained state. As expected, images observed for the mycobacterial cell envelope look significantly different from those seen by TEM (11, 18, 19). They revealed a symmetrical PM, a periplasm containing a granular layer presumably consisting of proteins, and for the first time, the presence of a long-predicted outer membrane (Fig. 1B). The existence of an outer membrane was supported

doi:10.1128/microbiolspec.GPP3-0027-2018

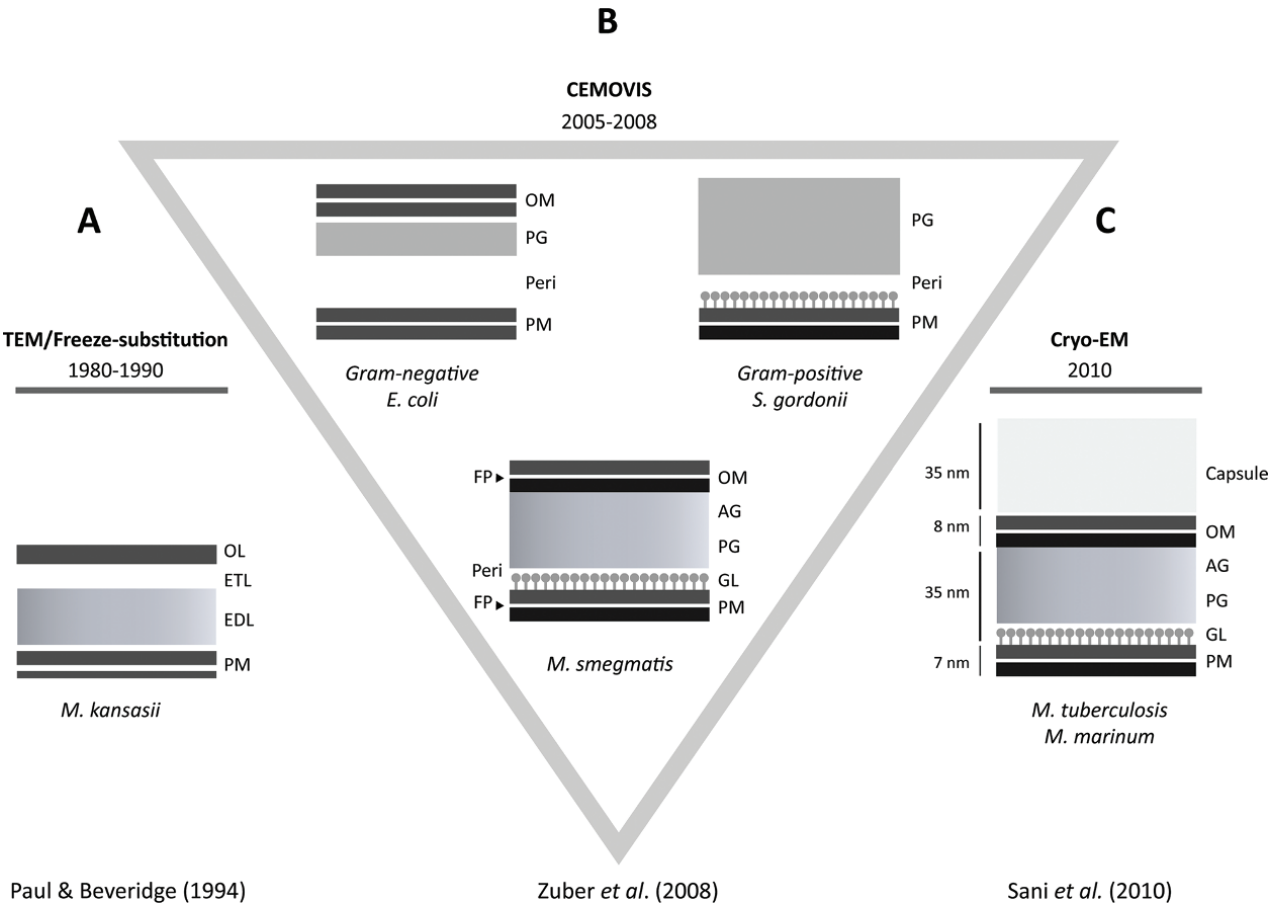

FIGURE 1 Diagrams (adapted from references 11 and 17–19) of the cell envelopes extracted from images obtained by (A) TEM, (B) CEMOVIS of various bacterial cells, and (C) cryoEM of whole-mount mycobacteria. AG, arabinogalactan; CEMOVIS, cryo-electron microscopy of vitreous sections; cryo-EM, cryo-electron microscopy; EDL, electron-dense layer; ETL, electron-transparent layer; FP, fracture plane; GL, granular layer; OL, outer layer; OM, outer membrane; PG, peptidoglycan; PM, plasma membrane; peri, periplasm; TEM, transmission electron microscopy.

by data from freeze-fracture electron microscopy, which clearly showed the occurrence of a major fracture plane in the outer part of the envelope, in addition to the expected plane that typifies the PM (Fig. 1B). However, no direct observations of the hypothetical outer membrane were available using TEM. The demonstration of the existence of an outer membrane fits nicely with the very low permeability of mycobacteria to nutrients and antibacterial drugs, 10- to 100-fold lower than that of the notably impermeable bacillus *Pseudomonas aeruginosa* (20). Consistently, mycobacteria and other members of the *Corynebacteriales* order contain pore-forming proteins (porins) in their cell walls (21).

During eukaryotic cell infection, a space between the wall of *M. lepraemurium* and the phagosomal membrane was observed in electron microscopic pictures, called the "capsular space" (22). Almost concomitantly, when studying the permeability of mycobacteria to dyes using light microscopic techniques, a tentative correlation was made between the capsule space and an unstainable halo observed only around some pathogenic mycobacteria (23–25). According to Hanks (26), this halo would also correspond to the "electron-transparent zone" that is seen in several published electron micrographs surrounding intracellular mycobacterial pathogens but not around nonpathogenic mycobacteria or pathogenic mycobacteria grown *in vitro* under standard conditions (27, 28). Consistently, a capsule-like structure was observed around *in vitro*-grown pathogenic mycobacteria that were first either coated with specific antibodies or preembedded in gelatin prior to the different drastic treatments involved in conventional electron microscopy studies (29, 30). Under these conditions, the capsule-like structure was not seen around the nonpathogenic *M. smegmatis* and *M. aurum* (30). Definitive proof of the existence of a capsule in pathogenic mycobacteria came from whole-mount plunge-frozen mycobacteria imaged by cryoEM (Fig. 1C), which does not require the use of a cryo-protectant and under conditions where they were grown without detergent or shaking (19). The layer was not observed in CEMOVIS pictures (Fig. 1B) (11, 18), probably because the density of the capsule matches that of the cryo-protectant-containing freezing solution. Likewise, the capsule was not observed in pictures of mycobacteria grown in detergent-containing culture media, which is routinely used to prevent mycobacterial cell clumping (19). When the same bacteria are instead processed by conventional methods commonly used to observe mycobacteria by TEM, the outer layer probably collapses by dehydration to give a dark layer (outer layer, Fig. 1A).

From the combination of chemical and microscopic data, it is now well established that the mycobacterial envelope consists of a PM surrounded by a complex cell wall composed

of peptidoglycan (PG) covalently linked to arabinogalactan (AG) esterified by mycolic acids (MAs), which form the inner leaflet of an outer membrane bilayer. MAs are very-long-chain, up to 100 carbons, 2-alkyl 3-hydroxylated fatty acids. An outermost layer, called "capsule" in the case of pathogenic species (9), in turn surrounds the cell wall (Fig. 1C). A periplasmic space, defined as the region located between the PM and the cell wall PG exists in mycobacteria, as revealed by CEMOVIS (Fig. 1B).

THE PLASMA MEMBRANE

The bilayer structure of the mycobacterial PM is similar to that of other Gram-positive and -negative microorganisms (Fig. 1), consistent with the published chemical composition, comprising phospholipids and proteins, with specific metabolic functions (9). Its asymmetrical appearance in images of some conventionally prepared cells (12, 15) has been attributed to the presence of excess glycoconjugates, e.g., phosphatidylinositol mannosides (PIMs), lipoarabinomannan (LAM), and lipomannan, in the thicker outer leaflet. Although glycoconjugates were identified in the PM (see below), their distribution between the two leaflets is not known. Alternatively, the observed apparent thicker outer leaflet in some conventional preparations may be due to the collapse of the granular layer, presumably composed of proteins, by a few nanometers beyond the outer leaflet of the PM (11), as shown by CEMOVIS (see Fig. 1).

The native PM is typically and easily obtained by breaking the cells by mechanical stress, e.g., sonication or shearing in the French pressure cell, followed by fractionation using differential centrifugation or density gradients (31, 32). The determination of specific enzyme activities, e.g., NADH oxidase (31), generally follows the purification process. Further chemical and biochemical analyses of the fractions are necessary to check their purity (31, 32). As far as lipid composition of the purified PM is concerned, no significant difference between those of fast- and slow-growing *Mycobacterium* species examined have been observed. Polar lipids, mainly phospholipids, assemble in association with proteins into a lipid bilayer (see 33). The polar lipids of the mycobacterial PM are composed of hydrophilic head groups and fatty acid chains that usually consist of mixtures of straight chain, unsaturated and mono-methyl branched fatty acid residues fewer than 20 carbons. Palmitic ($C_{16:0}$), oleic (cis $\Delta 9$ $C_{18:1}$), and 10-methyloctadecanoic (called tuberculostearic) acids are the major fatty acid constituents of the isolated PMs. The main phospholipids of the PM are PIM, phosphatidyl glycerol, cardiolipid, and phosphatidyl ethanolamine, while phosphatidyl inositol occurs in small amounts. Incidentally, PIM and phosphatidyl ethanolamine have also been identified among the lipids extracted from the mycobacterial cell surface by means of gentle mechanical treatment of cells with glass beads (34), yet the function of phospholipids in those layers is still unknown. Besides phospholipids, other lipids, such as menaquinones, may be present in the PM (see 33). The mycobacterial lipopolysaccharides LAM and lipomannan are partly located in the PM, and the relative contents of both lipopolysaccharides are growth-phase dependent (31, 35). The lipid composition of the PM of *M. smegmatis* also has been determined using detergent extraction, namely, with dioctyl sulfosuccinate sodium (36). The composition of the PM of *M. smegmatis* isolated by the latter method differs significantly from that obtained by breaking the cells by mechanical stress followed by fractionation using differential centrifugation or density gradients (31, 32). Notably, trehalose monomycolate (TMM), a lipid never reported in isolated mycobacterial PMs (9), was found in the PM using the detergent extraction method (36). Rather, TMM has been isolated from the cell surface of several mycobacterial species by mechanical treatment (34).

Bottom-up quantitative proteomics analysis allowed the identification of more than 2,000 membrane proteins in the purified PM of *M. smegmatis* (31). These include the canonical membrane ATP synthase, cytochrome P450, and ABC transporter YjfF, as well as enzymes involved in the biosynthesis of PIM, e.g., the mannosyltransferase PimB (37) and galactofuranosyltransferase GlfT2 (38). To assemble their cell wall components, which include PG, AG, lipids, and lipoproteins, as well as surface and outer membrane proteins (OMPs) (see below), mycobacteria must transport them or their precursors. Although little is known about the transport of these constituents from the cytosolic compartment to the exterior of the cell, mechanisms similar to those functioning in Gram-negative bacteria have been postulated (2, 7). Consistently, several transmembrane proteins such as MmpL (mycobacterial membrane protein large), involved in the transport of various lipids (2, 7), have been located, at least partly, in the PM (Fig. 2). Among the MmpLs of *M. tuberculosis*, MmpL3 is involved in the transport of TMM, and MmpL7 mediates the transport of phthiocerol dimycocerosate, whereas MmpL10 was reported to participate in the translocation of acylated trehaloses. All these lipids contribute to the integrity of the cell envelope, regulate membrane permeability, and have important physiological functions. The PM also contains the sophisticated secretion systems, named 6-kDa early secretory antigenic target (ESAT6) protein family secretion systems (also known as type VII secretion systems), used to export a set of effector proteins that help the pathogen resist or evade the host immune response (8).

THE CELL WALL

The cell wall of mycobacteria and related genera differs in composition from those of both Gram-positive and Gram-negative bacteria. It is a giant complex constituted of the outer membrane bilayer, AG, and PG. The mycobacterial outer membrane, also known as mycomembrane (MM), exhibits a 7- to 8-nm thickness (Fig. 1B), similar to that of the PM, and contains MAs. MAs form the inner leaflet of the MM, covalently linked to AG, which in turn is covalently attached to PG, a complex polymer classified as A1γ, as in *Escherichia coli* and *Bacillus* spp. This represents the so-called mAGP (mycoloyl-arabinogalactan-peptidoglycan), formerly known as the cell wall skeleton, defined as the material remaining after removal of all non-covalently bound wall-associated substances (39). The outer leaflet of the MM is presumably composed of various lipids (31).

Mycobacterial walls are readily isolated and purified from fragments of PM and cytosolic material by breaking the cells with mechanical stress, followed by purification using differential centrifugation or density gradients to remove unbroken cells (see 31, 32). The mycobacterial cell wall appears in conventional TEM (40) as an electron-dense layer surrounded by an electron-transparent layer (Fig. 1A). The occurrence of the latter in sections of *Corynebacteriales* devoid of MAs, e.g., *Corynebacterium amycolatum* (41), calls into question the long-assumed interpretation that the low density of the electron-transparent layer is attributed to lipids, notably MA.

The cell wall can be dissected into its constituent parts by relatively gentle methods so that each part may be studied separately (see 42–44). The PG is composed of repeating

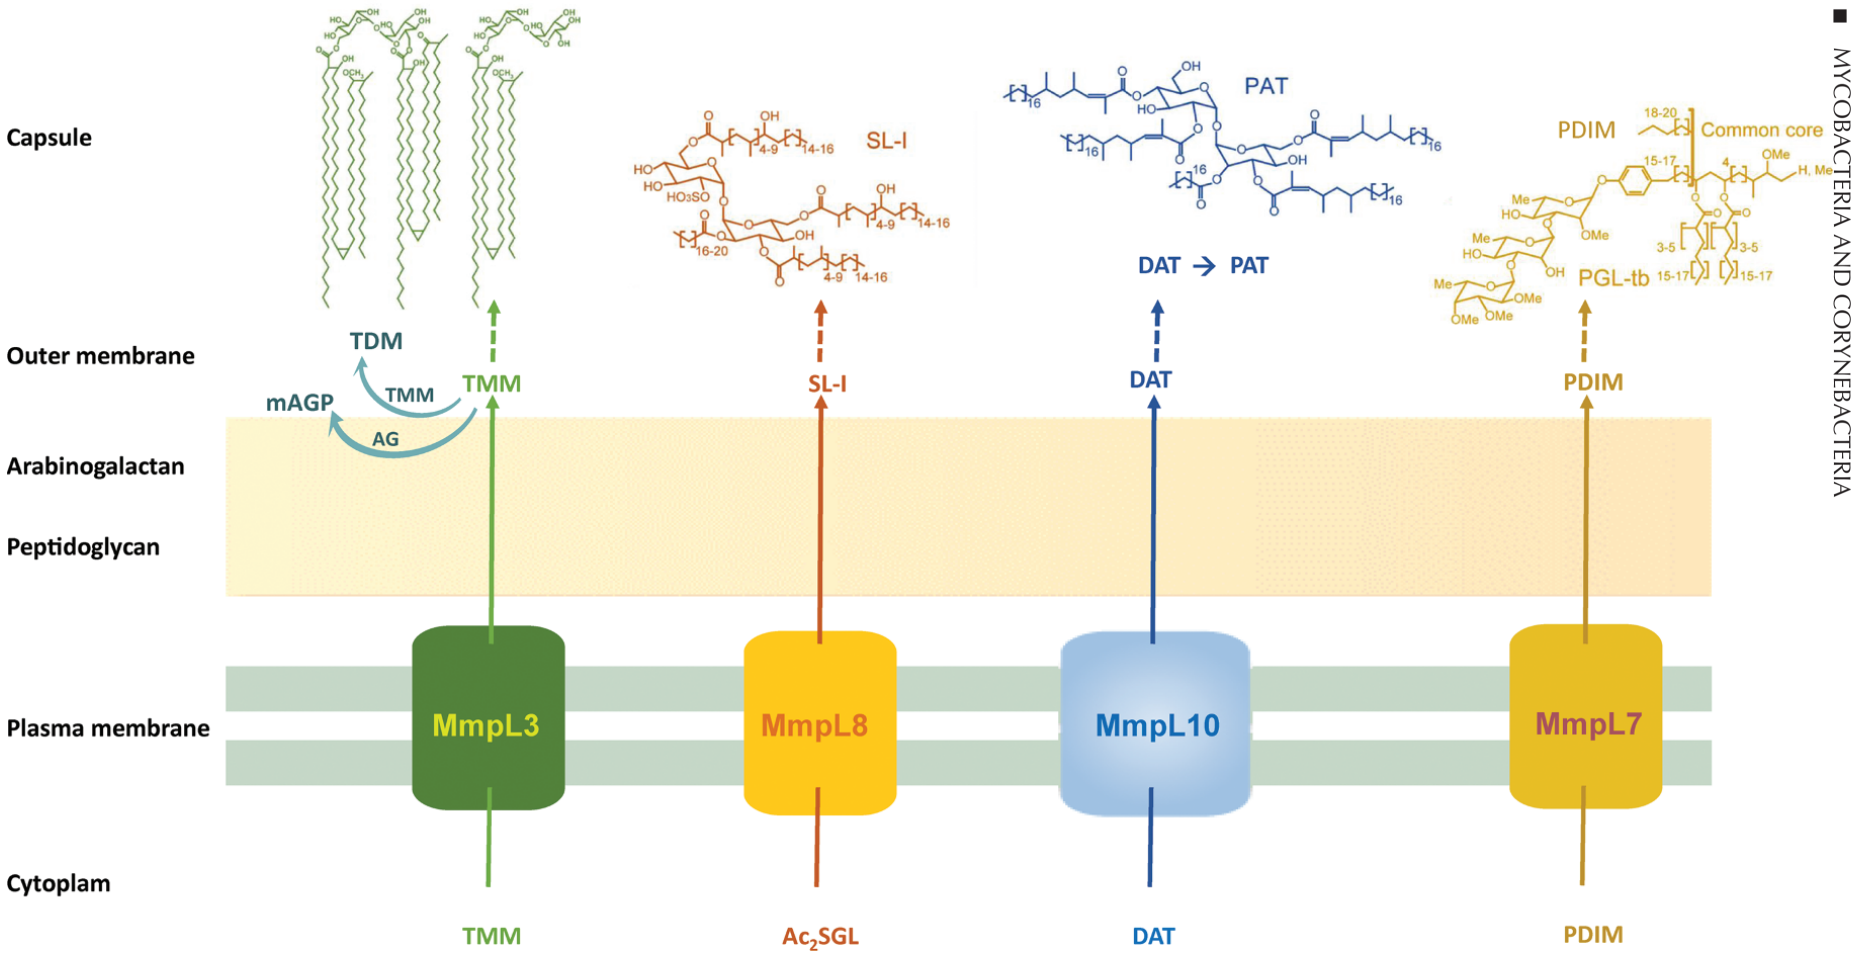

FIGURE 2 Chemical structures of representative mycobacterial lipids and their export systems through the plasma membrane to reach their final locations in the outer membrane (mycomembrane) or/and capsular compartment of the cell envelope. Some of the lipids are ubiquitous (e.g., TMM and trehalose dimycolate), whereas other are species- or type species-specific (e.g., PAT, phthiocerol dimycocerosate, PGL-tb), found in selective mycobacterial species or strains. TMM is used to transfer its mycoloyl residue onto both the arabinan termini of AG and TMM to yield the cell wall skeleton mAGP and trehalose dimycolate, respectively. Ac_2SGL, diacylated sulfoglycolipid; AG, arabinogalactan; DAT, diacyl trehalose; mAGP, mycoloyl-AG-peptidoglycan; mAGP, mycoloyl-AG-peptidoglycan; MmpL, mycobacterial membrane protein large; PAT, polyacyltrehalose; PDIM, phthiocerol dimycocerosate; PGL-tb, phenol glycolipid of *M. tuberculosis*; SL-I, sulfolipid I, the major sulfolipid of *M. tuberculosis*; TDM, trehalose dimycolate; TMM, trehalose monomycolate.

units of *N*-acetylglucosamine and *N*-acetyl/glycolylmuramic acid cross-linked with a peptide side chain that may be cross-linked to that of other glycan strands. The tetrapeptide side chains of PG consist of L-alanyl-D-isoglutaminyl-*meso*-diaminopimelyl-D-alanine. These peptide chains are heavily cross-linked, with up to 80% cross-linking, compared with 50% in *E. coli* (3). Interestingly, the PG of *M. leprae* has a glycine residue substituted for the L-alanine residue found in the PG of *Mycobacterium* spp. examined to date.

The AG is a branched heteropolysaccharide that contains a galactan chain composed of alternating 5- and 6-linked D-galactofuranosyl residues; three D-arabinan chains substituted the D-galactan chain in *M. tuberculosis*, of which MAs (45) esterify two-thirds of the nonreducing termini of the penta-arabinosyl motifs. In fact, MAs (Fig. 2) esterify the four-hydroxyl groups at position 5 of both terminal and 2-linked D-arabinofuranosyl of the penta-arabinosyl motifs of AG. The cell wall of the *in vivo*-grown leprosy bacillus (a yet *in vitro* noncultivable bacterium) was found to contain significantly more AG-MA attached to PG than that of *in vitro*-grown *M. tuberculosis*, and only half of these are occupied by mycoloyl residues (46).

In 1982, Minnikin proposed an original model of an outer membrane analogous to that found in Gram-negative bacteria. In this model, the very-long-chain MAs that esterified the AG arranged themselves to form the inner leaflet of an asymmetric outer membrane, the outer leaflet being constituted of free polar mycolate trehaloses (33). This suggested the existence of a second hydrophobic layer in addition to the PM and could explain the very low permeability to polar molecules. It could also provide a good explanation for the additional and main fracture plane observed in freeze fractures of mycobacteria (47–51): the fracture would occur between the two leaflets of the outer membrane (Fig. 1B). This model was later supported by experimental data (see 52), notably the work of Nikaido and his colleagues, who showed that an aqueous suspension of purified walls of *M. chelonae* produced an X-ray diffraction pattern with reflections characteristic of close-packed hydrocarbon chains in a semicrystalline monolayer (53). However, the complete lack of observation of this outer membrane bilayer in transmission electron micrographs of sectioned mycobacterial cells seriously called into question the validity of this model.

Using CEMOVIS, three research groups have independently clearly visualized a symmetrical 7- to 8-nm-thick bilayer whose thickness was comparable to that of PM in the mycobacterial species analyzed (11, 18, 19). The thickness of the outer membrane MM was even less in corynebacteria, around 4 to 5 nm (11, 18). The fact that the outer membrane contains MA was proved by the absence of this structure in a mycolate-less *Corynebacterium* mutant. LAM and lipomannan located in the MM would presumably be associated with its outer leaflet (Fig. 3), comparable to the location of LPS in Gram-negative organisms (31, 35). Among the lipids proposed to compose the outer leaflet of the MM in various models, TMM, trehalose dimycolate (Fig. 2), and phospholipids (cardiolipid/phosphatidyl glycerol, phosphatidyl ethanolamine, and phosphatidyl inositol, plus a few PIMs) have been clearly identified in the MM-containing fractions of *M. smegmatis* (31). The 7- to 8-nm thickness of the outer membrane layer contradicts the arrangement of MA, whose long alkyl chains would be organized parallel to one another to yield a >40-nm-thick asymmetrical bilayer (33). In view of the 7- to 8-nm thickness of the MM in the observed micrographs (Fig. 1B), the alkyl chains of MA have to be arranged in a folded manner (as shown for TMM and trehalose dimycolate in Fig. 2). Consistent with the published chemical structures and fold of mycobacterial MAs (54, 55), a model was proposed in which mycoloyl chains are intercalated in a zipper-like manner and the long mycoloyl chains are folded in an ω-shape (11).

Like Gram-negative bacteria, mycobacteria need to transport and assemble their outer membrane and to import small polar molecules across their outer membrane, notably those needed for nutrition. In Gram-negative bacteria, the transport of lipids, lipoproteins, and outer membrane proteins (OMPs) involves a combination of ATP-dependent transporters in the PM, chaperones in the periplasm, and β-barrel proteins that facilitate the insertion and translocation/folding into the outer membrane (2). The nutrition issue is solved by producing specialized proteins called porins, which form hydrophilic pores through the structure (Fig. 3). These pore-forming proteins have been identified in the walls of both fast-growing mycobacterial species, such as *M. chelonae* and *M. smegmatis* (21, 56, 57), and *M. tuberculosis* (58, 59). However, as Rv0899 (OmpA-Tb) adopts a mixed alpha/beta-structure and does not form a transmembrane beta-barrel (60), its status as a porin is a matter of debate (21). As expected, the crystal structure of the major OMP of *M. smegmatis*, MspA, reveals a β-barrel transmembrane channel (61). MspA forms an octameric composite β-barrel where each monomer comprises two β-strands. In Gram-negative bacteria, such as *E. coli*, there are about 60 OMPs. Using *in silico* analysis, two independent studies have proposed a list of putative OMPs in *M. tuberculosis* based essentially on β-barrel computational predictions (21). Out of 100 putative mycobacterial OMPs, only a few have been identified and characterized. These include mycoloyl transferases (originally called Fbp for fibronectin-binding proteins or antigen85) (63), some glycosylated proteins (Rpf proteins) (62), the outer membrane channel protein CpnT (63), and sphingomyelinase Rv0888 SpmT protein (64). Proteomic analysis confirmed the presence of Fbps and porins (MspA in the case of *M. smegmatis*) in the cell wall fraction, but also putative transporters, e.g., the mycobacterial cell entry protein family (31).

THE CAPSULE

The first mycobacterial capsules defined, namely, those of *M. leprae* and *M. lepraemurium*, were composed of lipids, but this turns out to be the exception. The fibrillar substance that surrounds *M. lepraemurium* inside the phagocytic vacuoles of the host cell (50) was composed of glycopeptidolipids (GPLs) (9), and massive amounts of phenolic glycolipids (PGLs) (Fig. 2) were isolated from cells infected with *M. leprae* (65, 66). However, both GPL-positive and GPL-negative strains of the *M. avium-M. intracellulare* complex elaborate capsules (67), indicating that the capsule is not always composed of lipids. Moreover, most strains of *M. tuberculosis* are devoid of PGL (68).

Knowing that *in vitro*-grown pathogenic mycobacterial species secrete abundant amounts of polysaccharides and proteins (69, 70), we postulated that the material shed into the culture medium of *in vitro*-grown mycobacteria is retained by the phagosomal membrane to form the electron-transparent zone seen around pathogenic species in phagocytic cells (9). Consistently, more extracellular material was recovered from the culture filtrates of the pathogenic species, e.g. *M. tuberculosis* (71) and *M. kansasii* (69), than from those of saprophytic and nonpathogenic strains such as *M. smegmatis* and *M. aurum* (69). Accordingly, the nature of the capsular constituents of various mycobacterial species were determined by analyzing the composition of their extracellular materials and those extracted by gentle shaking

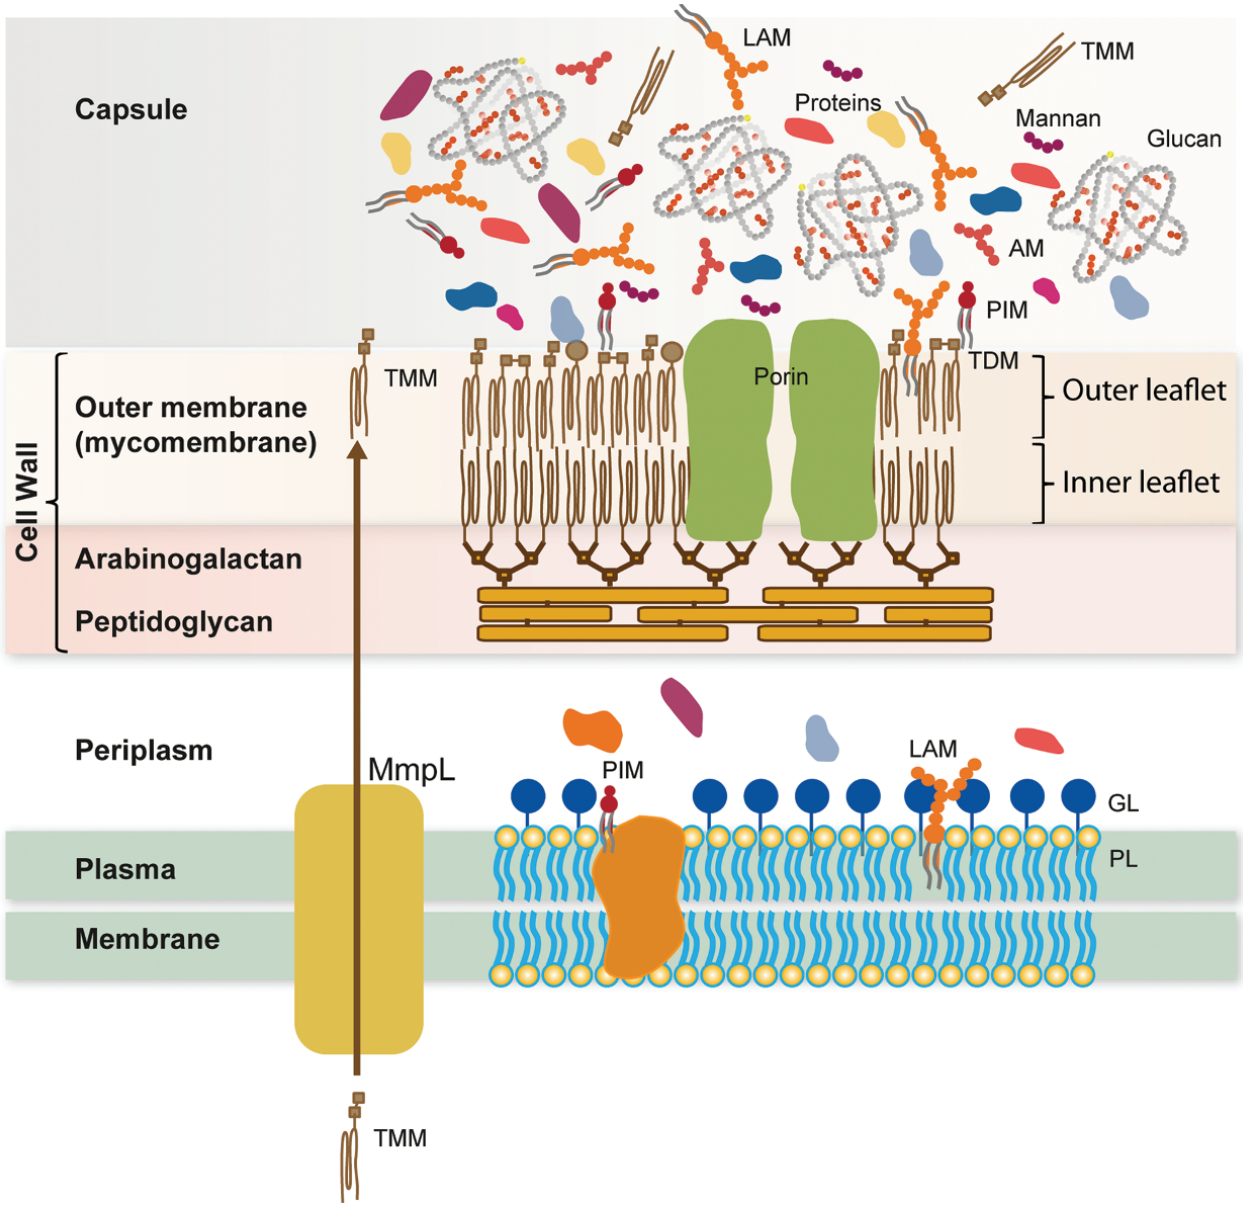

FIGURE 3 Model of the mycobacterial cell envelope. The cell envelope consists of a plasma membrane, a periplasm, the cell wall skeleton, and the outermost layer, called capsule in the case of pathogenic species. The plasma membrane is composed of phospholipids (e.g., PIM), lipopolysaccharides (e.g., LAM), and proteins, which include MmpL involved in the transport of lipids. The periplasmic space contains the GL and, presumably other proteins. The cell wall skeleton is made of peptidoglycan, arabinogalactan and mycolic acid residues that form the inner leaflet of the outer membrane (mycomembrane). The outer leaflet of the latter membrane is composed of various lipids, notably, trehalose mycolates. The capsular layer is a matrix of glucan that contains proteins, (lipo)polysaccharides, and small amounts of lipids. AM, arabinomannan; LAM, lipoAM; GL, granular layer; MmpL, mycobacterial membrane protein large; PIM, phosphatidyl inositol mannosides; PL, phospholipids; TDM, trehalose dimycolate; TMM, trehalose monomycolate.

of bacterial pellicles with glass beads and/or by detergent extraction for short periods of time (34, 69, 72). Importantly, these treatments, aiming at de-clumping the cells, do not affect their viability, as judged by scanning electron microscopy (34, 70).

The main components of the outermost capsular layer of slow-growing mycobacterial species, most of which are pathogens (e.g., *M. tuberculosis* and *M. kansasii*), are polysaccharides (69, 70), whereas the major components of the outer layer of rapid growers (e.g., *M. phlei* and *M. smegmatis*) are proteins (69). The major extracellular and capsular component of slow-growing mycobacterial species is a glucan (Fig. 3) that is composed of repeating units of five or six α-(1→4) linked D-glucosyl residues substituted at position 6 with mono- or oligoglucosyl residues (69, 70, 71, 73). The surface-exposed and extracellular materials also contain a D-arabino-D-mannan, a heteropolysaccharide that exhibits an apparent molecular mass of 13 kDa, and a mannan chain composed of an α–(1→6)-D-mannosyl core, with some units substituted with α-D-mannose at position 2. Importantly, glucan was identified in the capsule of *M. tuberculosis* inside the phagocytic vacuoles of the host cell (74).

The outermost part of the mycobacterial cell envelope contains only a tiny amount of lipid (2 to 3% of the surface-exposed material). Some of the species- and type-specific lipids and glycolipids, e.g., phthiocerol dimycocerosate, PGL, and GPL, can be found on the surface of the capsule, in agreement with serological and ultrastructural findings (see 9). Progressive extraction of the capsular material with glass beads and short-time treatment with Tween 80 detergent shows that most of the lipids are in the inner rather than in the outer part of the capsule (34).

The outermost capsular proteins of *in vitro*-grown *M. tuberculosis* are a complex mixture of polypeptides (70). Some proteins seem to correspond to secreted polypeptides found in short-term culture filtrates, whereas others appear to be cell wall associated (29). In fact, most of the hundreds of proteins identified in the short-term culture filtrate of *M. tuberculosis* by two-dimensional SDS-PAGE (75) are also found in significant amounts in the surface-exposed material extracted by mild mechanical treatment of cells. This observation supports the concept that the compounds found in culture filtrates of *in vitro*-grown cells are probably shed from the surface of the bacilli and, in an *in vivo* context, would be confined around the cells in the capsular layer (9). Components of the early secretory antigen transport system were recently localized to the capsule by immuno-electron microscopy of cryosectioned mycobacteria (19).

CONCLUDING REMARKS

The chemical structure of most of the core components of the mycobacterial cell envelope was determined a long time ago, establishing its extreme richness in lipid. However, it is only recently that a combination of CEMOVIS and whole-cell cryoEM has revealed the true structure of the mycobacterial cell envelope, i.e., the existence of a Gram-negative-like (diderm) outer membrane in these Gram-positive bacteria and an outermost capsular layer of protein and carbohydrate (Fig. 3). Determining the composition, localization, and supramolecular organization of the capsular and cell wall constituents and understanding how these factors make the envelope essential to *M. tuberculosis* survival, virulence, and pathogenesis remain major challenges. This will require synergistic expertise in analytical and structural biochemistry and biophysics to fill the gap in understanding the MM compartment by isolating and defining the full lipid and protein compositions of the capsule and cell wall. Deciphering the supramolecular organization of the capsule and MM-containing cell wall represent an additional exciting goal. The discovery of how mycobacteria select and organize their envelope constituents to resist killing should help decode the mechanisms involved in the mycobacterial pathogenicity and provide new potential targets for antituberculosis chemotherapy. In this respect, the biogenesis of MM constitutes a highly relevant and validated pharmaceutical target for antituberculosis drug discovery.

The Dream of a Mycobacterium

CATHERINE BARANOWSKI, E. HESPER REGO AND ERIC J. RUBIN

66

> A toutes ces activités, il faut une cohésion rigoureuse pour que puisse se réaliser le rêve de la bactérie: produire deux bactéries. [To all these activities, it takes a rigorous cohesion to realize the dream of the bacterium: produce two bacteria.]
>
> FRANÇOIS JACOB, 1965 (1)

Bacterial psychology is a challenging field. Like many psychologists, Jacob impressed the bacterium with our own value system. And part of that is defining what it is to be alive. As microbiologists, we generally define bacterial life as the ability to form progeny, to become two bacteria through cell division. Like all reproductive processes, bacterial division uses a combination of mechanics and mystery. Here, we will focus on the mechanics (and mystery) of cell division in acid-fast mycobacteria, a genus that includes the major human pathogens *Mycobacterium tuberculosis* and *Mycobacterium leprae*.

From the 1968 study in which Hirota, Ryter, and Jacob classified temperature-sensitive mutants blocked for various steps of cell division in *Escherichia coli* (2) to the discovery of the FtsZ ring (Z-ring) in 1991 by Bi and Lutkenhaus, microbiologists have launched into an era of genetic, microscopic, biochemical, and structural work to understand bacterial cell growth and division (3). (For a review on the history of cell division research see reference 4). This topic has been studied most in the model rod-shaped bacteria, the Gram-negative *E. coli* and the Gram-positive *Bacillus subtilis*. Work on cell growth and division in mycobacteria is not as extensive as in *E. coli* or *B. subtilis*. However, mycobacteria face the same challenge as these other organisms: organizing, both spatially and temporally, the factors that are responsible for making two cells from one. This process requires the concerted effort of many molecules to elongate the cell, replicate and separate the chromosome, build the septal cell wall that separates the two daughter cells, and separate the now distinct daughter cells. As you will see in this article, one common theme in the nascent field of mycobacterial cell division is that mycobacteria have often solved these challenges differently, sometimes vastly so, than either *E.coli* or *B. subtilis*.

We will take a comparative approach. Throughout this article, we will describe distinct stages of cell division in *B. subtilis* and follow with the current knowledge of this process in mycobacteria. Mycobacteria are quite different than *B. subtilis*, and for many described proteins in *B. subtilis*, mycobacteria either lack homologs or use unique factors and protein interactions to fill these voids.

Cell elongation and division are intimately associated processes that require both synthesis and remodeling of the complex mycobacterial cell wall. The mycobacterial cell wall consists of covalently linked layers of fatty acids (mycolic acid), a carbohydrate polymer known as arabinogalactan, and an innermost layer of peptidoglycan (PG) (5). The envelope of most other bacteria, like *B. subtilis*, is comprised of PG, but these other polymers are unique to mycobacteria and related bacteria. We favor a model whereby the synthesis and remodeling of the distinct layers is coordinated, but there is currently little direct evidence to support this model.

MYCOBACTERIAL GROWTH: A DIFFERENT BALLGAME

The first obvious difference between *B. subtilis* and mycobacteria is in the geometry of cell division. To increase in size, mycobacteria insert new material at or near their poles, rather than along their side walls (Fig. 1) like *B. subtilis* and *E. coli*. However, where exactly cell wall synthesis occurs is still unclear. Many cell wall synthetic enzymes localize to the peripolar region (6), but pulse chase experiments with dyes that covalently bind the cell wall suggest that new cell wall material is inserted at the very distal end of the cell (Fig. 2, bottom panel) (7). Supporting this last observation are labeling experiments with dyes that incorporate into different layers of the cell wall via enzymatic processes. These dyes brightly label the cell poles (8–10) (Fig. 2, top panel), as does a fluorescent analog of vancomycin (11, 12) which labels unprocessed, un-crosslinked PG. Thus, it seems most likely that mycobacteria insert a new cell wall at the distal ends of the poles. But how that is coordinated by enzymes that are most abundant at adjacent cellular regions will need to be reconciled in future research.

In general, polar growth leads to a different set of challenges not encountered by side-wall growers. First, the site of division in pole growers becomes the site of elongation. This means that division and elongation might need to be more tightly controlled temporally in mycobacteria than in *B. subtilis*, so that growth from the new poles does not occur before the cells completely divide. This raises a question: Are the components of the mycobacterial division complex (divisome) distinct from those of the elongation machinery (elongasome)? Throughout this review, you will see that mycobacterial cells blocked in certain points of division are elongated and form ectopic poles, suggesting that division and elongation can be uncoupled. This does not necessarily mean that the divisome and elongasome contain mutually

doi:10.1128/microbiolspec.GPP3-0008-2018

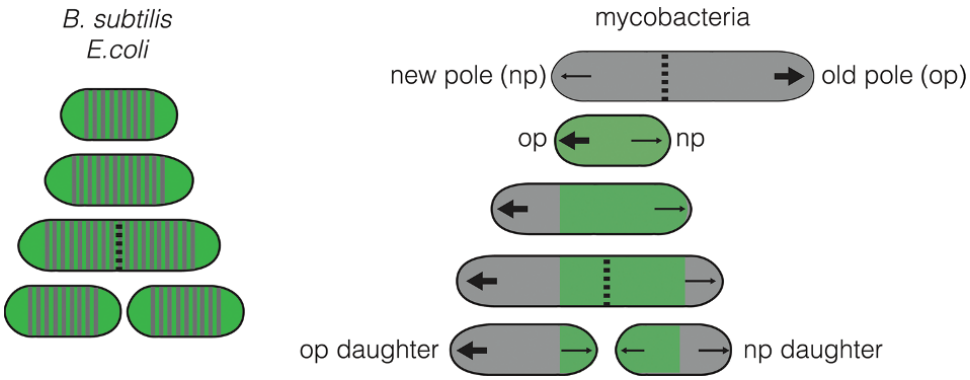

FIGURE 1 Characteristics of growth and division in *B. subtilis* and mycobacteria. *B. subtilis* and *E. coli* grow by adding new cell wall (gray) along the lateral cell body. Mycobacteria grow only at the polar regions, and do so at unequal amounts depending on the identity of the pole. This is observed by using a cell wall dye (green) to stain the existing cell wall and observe outgrowth of the newly synthesized, unstained cell wall (7). Arrows, polar location of new cell wall synthesis (a large arrow indicates more growth); dotted line, septum; green portion, old cell wall; gray portion, new cell wall.

exclusive proteins; however, it does support a model where division and elongation are temporally, and potentially spatially, separate. For example, there are localization, phenotypic, and protein-protein interaction data that place PonA1, a cell wall synthase, in both the elongasome and divisome. However, we lack a precise understanding of when the divisome becomes the elongasome at the new growth pole. Therefore, assigning proteins to either the divisome or elongasome based on localization at a single time point could be misleading, because factors involved in elongation also localize to the site of division/new pole and may belong to both machineries.

Second, polar growth leads to the spatial segregation of the cell wall with different ages, while lateral cell growth leads to the mixing of new and old material (7, 10, 13) (Fig. 2). In *Mycobacterium smegmatis*, it has been shown that the daughter cell inheriting the pole created at the most recent division, the so-called new pole, inherits the oldest cell wall (7) (Fig. 2, bottom panel). The functional consequence of this remains unknown, but it may contribute to the distinct characteristics of the daughter cells.

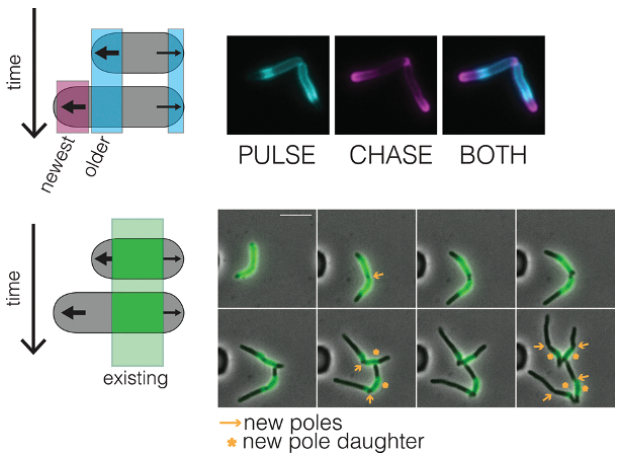

FIGURE 2 Polar growth segregates the cell wall based on age. (Top) Fluorescent D-amino acids are thought to incorporate into nascent PG. Pulse chase with these shows how the new and old cell walls are spatially segregated in *M. smegmatis* (Baranowski C, Rego EH, and Rubin EJ, unpublished images). (Bottom) Alexa-488 NHS ester stains the existing cell wall (green). New cell wall is unstained and can be monitored using time-lapse microscopy. After two divisions, the oldest cell wall is inherited by the new pole daughter cells (*) in *M. smegmatis*. (Baranowski, Rego, and Rubin. unpublished images; 7).

Lastly, the manner by which mycobacteria maintain their rod shape in the face of turgor pressure must be completely different than in the model rod-shaped organisms *B. subtilis* and *E. coli*. In *B. subtilis*, MreB, a homolog of eukaryotic actin, dictates the location of new cell wall synthesis along the side wall, incorporating new material at sites of negative curvature to aid in rod shape maintenance as the cell grows (14). This rod shape propagates in an MreB-dependent manner along the greatest membrane curvature (circumferentially around the cell) (15). Not only do mycobacteria lack an obvious homolog of MreB, but they grow from a much smaller portion of the cell (11). It remains a mystery how cell shape can be maintained across the entire cell. However, we do have a few clues. Mycobacteria encode a homolog of *B. subtilis* DivIVA called Wag31. In *B. subtilis*, depletion of DivIVA results in elongated cells that cannot divide, indicating a role in division (16). In contrast, depletion of Wag31 in mycobacteria leads to cells that lose their rod shape first at the pole, and eventually throughout the entire cell, resulting in a spherical cell. Further, dysregulation of Wag31 results in polar growth from incorrect sites (6). Thus, it appears that Wag31 in mycobacteria works to establish the site of polar growth, unlike its counterpart in *B. subtilis*, which has a role in dictating septum placement. Additionally, depletion of enzymes responsible for synthesizing or remodeling PG results in loss of rod shape either at the cell poles (17, 18) or along the mid-cell (6). Thus, it may be that Wag31 is responsible for directing formation of the poles and that the structure and rigidity of the cell wall itself, established at the time of cell wall synthesis at the pole, aids in shape maintenance as the cell grows.

THE MYSTERY AND MECHANICS OF DIVISION

Once a cell grows, it must divide to make two cells. The factors involved in cell division are referred to collectively as

the divisome, and they work in concert at the mid-cell. The purpose of the divisome is to (i) identify the mid-cell for Z-ring placement; (ii) recruit Z-ring anchors, stabilizers, and regulators; (iii) build the septal cell wall; and (iv) split the two halves of the partitioned cell. The bacterial chromosome must be replicated and segregated in concert with cell division; however, this process will not be covered in this review.

Identify the Mid-Cell for Z-Ring Placement

FtsZ, a tubulin homolog, polymerizes into a ring (Z-ring) at the mid-cell to begin cell division (3; reviewed in 19). The mid-cell placement and stabilization of the Z-ring are the critical first stages of bacterial cell division. Recent work using metabolic labeling of PG, the crucial innermost cell wall layer, as well as fluorescent fusions to FtsZ and other well-characterized septal proteins in *B. subtilis* shows that FtsZ treadmilling directs septal synthesis in an inward-spiral fashion (you can also imagine a bullseye) (20). Thus, the Z-ring is the figurative and literal ringleader of bacterial cell division. Once placed, the Z-ring recruits a cascade of factors, both structural and enzymatic, required for synthesizing and splitting the septum (which becomes the new cell poles) to create two daughter cells (for review of FtsZ see references 19 and 21).

An (a)side on (a)symmetry

B. subtilis grows along the lateral cell body and divides at the mid-cell with striking precision (22), resulting in two nearly identical daughter cells. However, many observers (though not all) have observed that, on average, mycobacteria grow asymmetrically, with growth occurring in unequal amounts from the two poles (5). Multiple reports show that the old pole continues to grow during and after septation but that the new pole—the pole established at septation—takes some time before it grows. Thus, the overall amount of elongation from the poles in one cell cycle is different. This can easily be visualized by staining the existing cell wall with a dye and following the outgrowth of a new, unstained cell wall (6, 7, 23, 24). Likewise, the amount of incorporated PG-specific fluorescent D-amino acids supports this finding (10) (Fig. 2). While the total amount of growth appears different between the poles, the rate of cell wall addition may be the same between the poles at the end of division (10, 25, 26).

Besides potential differences in growth from the distinct poles, divisome placement may also be asymmetric. Fluorescent fusions to FtsZ show that septal placement in mycobacteria occurs over a range of the mid-cell, skewed toward the new pole (26–28). As a result of asymmetry in growth and Z-ring placement, mycobacterial daughter cells are phenotypically distinct—cells inheriting the new pole are smaller, while old-pole daughters are larger (5). The consequences and molecular details of this heterogeneity are poorly understood. Recently, however, a mycobacteria-specific protein, LamA (loss of asymmetry mutant A), was found to actively promote asymmetry by inhibiting growth at the new pole (23). Loss of LamA leads to a population of cells that can be more uniformly killed by certain antibiotics, suggesting that heterogeneity generated through cell growth and division confers a survival advantage in some conditions.

Identify the Mid-Cell for Z-Ring Placement (continued)

FtsZ is highly conserved in nearly all bacteria, including mycobacteria. One unique feature of mycobacterial FtsZ is that its polymerization can be inhibited, at least *in vitro*, via phosphorylation by the serine/threonine protein kinase, PknA (29, 30). In general, phosphorylation by PknA and PknB, both of which are essential for growth, plays a key role in regulating many mycobacterial divisome components. Depletion of either of these kinases results in elongated cells, implying a defect in division (31). Throughout this review, we will highlight specific ways in which division is regulated via phosphorylation by these kinases.

Where not to put the Z-ring: over the chromosome and at the poles (see also 32). Division occurring over the chromosome is lethal, and creation of a daughter cell without DNA is not useful. Therefore, mechanisms exist to prevent Z-ring formation over the chromosome and at the poles. *B. subtilis* has two systems that prevent Z-ring formation from occurring at these nonoptimal locations—Noc and Min. The Noc protein (nucleoid occlusion) binds along the chromosome, avoiding the replication terminus (which ends up orienting at mid-cell) (32). It then spreads from primary sites and associates with the membrane to inhibit Z-ring formation over the nucleoid (32). The Min system prevents the Z-ring from forming at the poles. The *B. subtilis* Min system comprises MinC,D,J and DivIVA. MinC is recruited and activated by membrane-bound MinD to interact with and inhibit FtsZ. This MinCD complex is recruited to the poles by the DivIVA interacting partner, MinJ (33). DivIVA is believed to localize to the septum/new pole late during division, at sites of negative membrane curvature, where it begins the recruitment of the Min system (34). To date, the mycobacterial DivIVA homolog, Wag31, has no described function in septal placement and, instead, functions in late septation/early pole establishment through interactions with non-Min-related septal and polar machinery.

Mycobacteria do not have a known Noc homolog, and there has been only one report of a single Min protein distantly related to MinD (Ssd). Cells overexpressing ssd are longer, and transcriptional profiling shows numerous genes involved in growth and division to be repressed (35). However, we do not yet know whether this protein acts in a system akin to *B. subtilis* Min.

While the exact molecular mechanism of septal placement in mycobacteria remains unknown, it appears that the mycobacterial cell wall again plays a role. A recent study utilizing atomic force microscopy identified troughs on the mycobacterial cell surface that formed at the poles and, eventually, became the sites of division one or two generations later. This suggests that potential Z-ring placement sites are created and inherited well before division has begun, the earliest described marker of Z-ring placement in bacteria to date. The nature of the troughs and the mechanism of their formation are not yet known, but this might represent a novel Z-ring placement strategy in bacteria (28).

Recruitment of Z-Ring Anchors, Stabilizers, and Regulators

FtsZ resides in the cytoplasm yet must trigger events occurring outside of the plasma membrane. Accordingly, is must be anchored to the membrane, an action achieved through various "early" interacting proteins. Once the Z-ring is anchored, the septal wall must be synthesized and daughter cells must then be split. Thus, the "late" divisome is comprised of structural proteins that recruit PG synthesis enzymes and these enzymes themselves. While in *B. subtilis*, there is clear distinction between the early and late divisome (~20% of the cell cycle passes between recruitment of these portions of the complex), this distinction is less well defined in mycobacteria but only perhaps due to a lack of data (36).

Early divisome

The goal in the early steps of divisome assembly is to help the Z-ring polymerize and to anchor it to the membrane. The FtsZ ring is dynamic and requires both stabilizing and destabilizing proteins to function properly (21). Division in *B. subtilis* begins with Z-ring formation at the mid-cell, which recruits FtsA (37), SepF, ZapA, and EzrA (21). FtsA, an actin homolog, and SepF help anchor the Z-ring to the membrane (21). ZapA interacts with FtsZ and promotes its polymerization and stability (21, 32). A mutant of the transmembrane protein EzrA produces extra Z-rings (hence the name). The resultant mutant cells are longer, suggesting that negative regulation of the Z-ring by EzrA is necessary for successful division. This protein has been shown to inhibit Z-ring polymerization *in vitro* (21, 34). EzrA also works to recruit PBP1, a PG synthase, to the divisome (38).

Thus far, only SepF from *B. subtilis*'s early, FtsZ-interacting divisome has been identified in mycobacteria. *B. subtilis* SepF localizes to the septum in an FtsZ-dependent fashion and anchors and stabilizes the Z-ring (21, 39). In addition, in *B. subtilis*, *sepF* is synthetically lethal with *ftsA* and *ezrA*, perhaps due to overlapping functions (21). Likewise, mycobacterial SepF localizes to the septum in an FtsZ-dependent manner. Depletion and overexpression of *sepF* leads to filaments and branching—canonical phenotypes of cell division inhibition in mycobacteria (39).

In *B. subtilis*, ClpX, the ATPase chaperone/substrate recognition portion of the ClpXP protease, inhibits FtsZ assembly. Intriguingly, this appears to be independent of its ATPase function (40, 41). Similarly, mycobacterial ClpX interacts directly (*in vivo*) and inhibits FtsZ polymerization (*in vitro*). Overexpression of ClpX leads to multinucleate, elongated cells, suggesting a defect in septal assembly and division (42).

Connecting the cytoplasmic steps to the periplasmic steps

After the early *B. subtilis* divisome is assembled (the Z-ring anchored and stabilized), "late" divisome proteins are recruited (43). These proteins connect the cytoplasmic steps of division to the periplasmic steps required to build the septal cell wall (reviewed in 21). To summarize decades of work briefly, a complex of structural proteins—FtsQ (DivIB), FtsL, and FtsB (DivIC), transmembrane proteins that are critical in connecting Z-ring formation to septal synthesis—and FtsW, a PG transglycosylase, localize to the septum to recruit other PG synthases. The timing and dependency of septal protein localization in *B. subtilis* reveals interdependency between members of the FtsQLB complex, FtsW and Pbp2B (a monofunctional PG transpeptidase) (36). This is in contrast to the more linear dependency of localization in *E. coli*: FtsK→FtsQLB→FtsW→PBP3 (34).

Mycobacterial homologs of the essential *ftsL* and *ftsB* have been identified and experimentally validated through localization, depletion, and *in silico* structural predictions (44). Intriguingly, these homologs have substantial N- and C-terminal expansions compared to their *B. subtilis* counterparts, presumably for mycobacteria-specific interaction partners. In mycobacteria, depletion of either *ftsL* or *ftsB* causes cells to filament and branch, a phenocopy of known septal protein depletions (*ftsZ*, *pbpB*). FtsL and B, along with FtsQ and FtsK (a DNA translocase), localize to the septum. Depletion studies allow inferred localization dependencies of these structural divisome components in mycobacteria. Localization of FtsK, FtsQ, FtsL, or FtsB depend upon FtsZ. FtsK localization does not require FtsQ, L, or B. FtsQ can partially localize in the depletion of FtsL or FtsB, supporting a preliminary dependency hierarchy: FtsZ→FtsK→FtsQ→FtsLB (44). Thus, finding counterparts to known *B. subtilis* divisome members provides a handle to identify and study previously uncharacterized mycobacteria-specific divisome proteins (Fig. 3, brown dashed lines).

One potential mycobacterial "work-around" in the absence of canonical Z-ring anchors like FtsA is the unique interaction between mycobacterial FtsZ and FtsW. FtsW is the divisome-specific homolog of the SEDS (shape, elongation, division, sporulation) family protein RodA, whose function is to polymerize glycan strands of PG through its transglycosylase function (45). Mycobacterial FtsW and FtsZ have non-canonical C-terminal extensions that are proposed to facilitate their interaction (46). They localize at the septum in a manner suggesting that FtsZ localizes before FtsW (47). FtsW also interacts with and appears to recruit PbpB, a monofunctional PG transpeptidase, to the septum (48). In cells depleted of FtsW, FtsZ localizes between nucleoids, but these cells are not proficient at division (48). By interacting with early divisome-founding FtsZ and late divisome septal PG synthase PbpB, FtsW appears to link beginning cytoplasmic steps with late periplasmic wall synthesis steps in mycobacteria.

In actinomycetes, the cascade of interactions is facilitated by the small transmembrane protein, CrgA. CrgA is involved in nearly all steps of cell division: from the start of division, to septal wall synthesis, to establishment of the new growth poles. CrgA interacts with FtsZ and two PG transpeptidases, PbpA and PbpB. It localizes to the septum after the Z-ring and may be required for proper recruitment of PbpB, similarly to FtsW (49). CrgA also interacts with the mycobacteria-specific CwsA, a transmembrane protein that interacts with Wag31 (50). Expression of *cwsA* is directly linked to Wag31 abundance at the poles, suggesting that it is an important factor in either recruiting or maintaining Wag31 at the poles (50). Since Wag31 is associated with new polar growth, the information flow from CrgA through CwsA to Wag31 may coordinate establishing the new pole at the site of division.

Another transmembrane protein, FhaB (also called FipA), interacts with FtsZ. This relationship depends on phosphorylation of FhaB by PknA. FhaB is required for interactions between FtsZ and FtsQ during oxidative stress, a condition that pathogenic mycobacteria experience in the

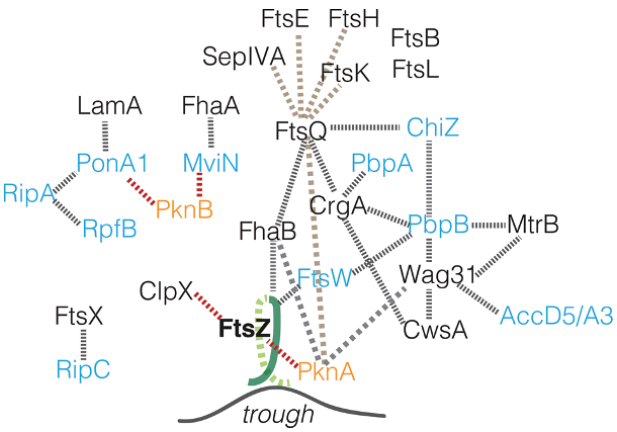

FIGURE 3 Mycobacterial divisome interactions. A schematic of mycobacterial divisome protein interactions. Note that interactions are not necessarily direct given the available data. Gray dotted lines, physical interactions; red dotted lines, negative regulation; brown lines, FtsQ pulldown proteins (44); blue text, cell wall enzymes; orange text, kinases.

host, suggesting that it may be a signal transducing interaction between the Z-ring and the structural divisome protein FtsQ during intracellular division (5, 30).

While these examples are understood in some detail, several other proteins produce morphologic changes when disrupted. Loss of proteins such as the *whiB2* homolog *whmD* and the MinD like protein Ssd result in branching and chaining morphologies, phenotypes associated with disrupted cell division (35, 51). The functions of these proteins remain unknown.

Call to Arms: Septal Cell Wall Synthetic Machinery To Build a Wall

Constructing the septal wall

Division requires synthesis of a wall between two halves of the cell and physical separation of the two halves into independent daughter cells. The cell wall of mycobacteria is multifaceted, consisting of linked layers of PG, arabinogalactan, and mycolic acids (5). The coordination between layers seems likely, but evidence of this is currently slim. This discussion of septal cell wall synthesis will focus on the PG layer.

PG, a netlike structure comprising disaccharide chains cross-linked by peptide bridges, is located outside of the plasma membrane. PG synthesis begins in the cytoplasm, where the disaccharide backbone and pentapeptide side chain are linked to a lipid and flipped across the membrane by the lipidII flippase, MurJ (MviN in mycobacteria) (52) (Fig. 4). This unit is added to the existing glycan strand by the transglycosylase function of bifunctional penicillin-binding proteins (class A PBPs or aPBPs) and by SEDS proteins such as RodA (45, 53). To covalently close the PG network into a cage-like molecule, the peptide bridges are cross-linked between either the fourth and third (4-3) or the third and

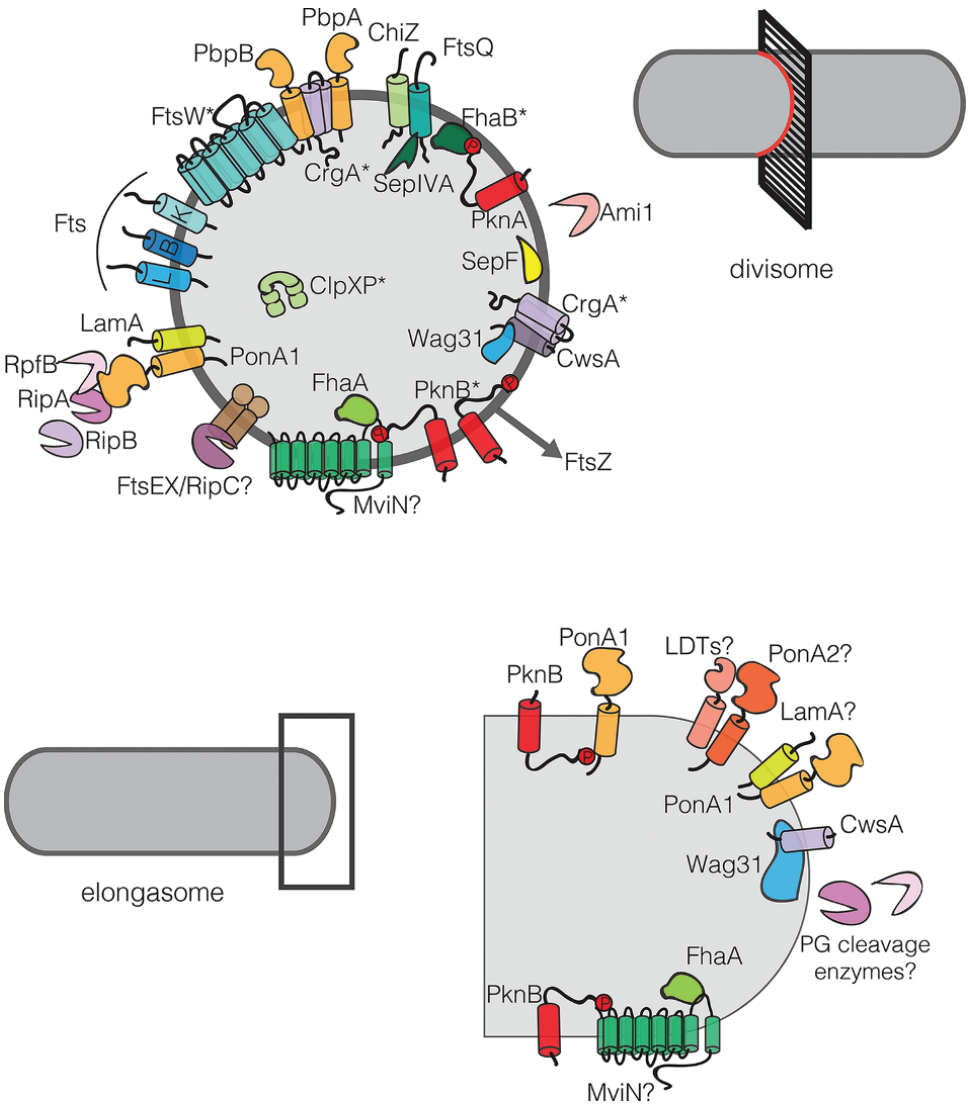

FIGURE 4 Mycobacterial divisome and elongasome members. (Top) Schematic of proteins involved in mycobacterial cell division. Proteins marked with an asterisk (*) have been shown to interact with FtsZ. The FtsZ ring is illustrated as a dark gray circle upon which the divisome members are arranged. (Bottom) Schematic of proteins involved in mycobacterial elongation. Interacting proteins are depicted touching, and proteins with a question mark (?) may belong in these complexes, but data are limited.

third (3-3) residues of opposite PG strands. The 4-3 cross-links, those commonly found in most well-studied PG, are catalyzed by the transpeptidation function of aPBPs and/or by mono-functional class B PBPs (bPBPs), which possess only transpeptidase activity (53). The 3-3 cross-links, a variety of connection that is rare in the PG of other model rods but highly enriched in mycobacteria, are made by L,D-transpeptidases (5, 54, 55) (Fig. 4).

Mycobacteria encode homologs of the *B. subtilis* proteins that perform the essential cytoplasmic steps of PG synthesis, but there are important differences in their regulation. For example, the first committed step of PG synthesis, performed in the cytoplasm by MurA, is regulated by a CwlM, a degenerate PG amidase homolog (56). Phosphorylation of CwlM by PknB results in binding and activation of MurA to initiate PG synthesis. This regulatory cascade functions in times of starvation when CwlM is dephosphorylated, resulting in a halt of PG synthesis and reductive cell division.

Another difference is MviN, which is also regulated via phosphorylation in mycobacteria. MviN's phosphorylation by PknB recruits FhaA to a pseudokinase domain of MviN. Depletion of MviN causes cells to arrest PG synthesis as measured by precursor abundance in the cytoplasm. FhaA depletion leads to an accumulation of PG illustrated with a fluorescent derivative of vancomycin. FhaA localizes to the poles and septum. Together, these data suggest that FhaA may work to inhibit PG synthesis at the MviN step. Alternatively, FhaA may be required for a PG processing event required to remove the substrate for fluorescent vancomycin binding (57).

After lipid II is flipped across the plasma membrane, it must be incorporated into the existing PG network by both transglyosylases and transpeptidases. In *B. subtilis*, it is possible to delete all of the aPBPs, suggesting the presence of another glycosyltransferase (58). In *B. subtilis*, this was recently identified to be RodA in the elongation complex (45) and is likely FtsW, a homolog of RodA, in the division complex. In mycobacteria, the story again appears slightly different. PonA1, an aPBP, is an essential member of the *M. smegmatis* elongation complex and is synthetically lethal with PonA2, another aPBP, in *M. tuberculosis* (59). PonA1 is essential because of its transglycosylase activity (24). RodA is not annotated essential in either organism. On the other hand, FtsW is essential and localizes to the site of division. Thus, these data suggest that, in contrast to *B. subtilis*, the bifunctional PBPs are the major transglycosylases involved in elongation in mycobacteria. During division, the story may be more similar to *B. subtilis*, with FtsW fulfilling the major transglycosylase role.

Working in concert with the PG transglycosylases are transpeptidases. Again, this role can be filled by either aPBPs or bPBPs. There are two main divisome-associated bPBPs in *B. subtilis*, Pbp1 and Pbp2B. Pbp2B (also known as FtsI or PbpB in mycobacteria) localizes to the septum in an FtsQLB-dependent manner (60) and works in partnership with FtsW (21, 36). Pbp1 is thought to shuttle in a cell cycle dependent between old septa (poles), to the sidewall, and then to the division complex via interactions with GspB and EzrA. (38, 61).

In mycobacteria, there is evidence for both an aPBP (PonA1) and bPBPs (PbpB, PbpA) being involved in division. PbpB interacts with divisome members FtsW, MtrB, and CrgA (see above; Fig. 3). Depletion of *pbpB* leads to branching, filamenting cells, clearly blocked in cell division (44, 62). Cells lacking *pbpA* are longer than the wild type, and PbpA may localize to the septum (63). While PonA1 plays a critical role in elongation, it may also have a role during division. The best evidence for this is that PonA1 localizes to both the septum and poles and interacts with RipA, a PG hydrolase important for daughter cell separation (64). However, given the difficulty of assigning proteins to the division or elongation complex based on protein localization at a single time point (see "Mycobacterial Growth: a Different Ballgame"), it could be that PonA1's appearance at the septum reflects recruitment to the site of the nascent poles. Indeed, genetic modulation of PonA1's function results in elongation defects rather than canonical cell division defects (24). Further, its overexpression results in the appearance of atopic poles, suggesting an early role in the establishment of polar elongation.

Breaking the cell wall

Once the wall is made between the two halves of the cell,it must be split to create two independent daughter cells. This is achieved in *B. subtilis* through hydrolysis of PG by LytC, D, E, and F (65–67). Localization studies found LytE and LytF of *B. subtilis* at the septum and poles (68).

Currently, three PG hydrolases have been implicated in mycobacterial cell division: RipA/B, ChiZ, and Ami1. RipA and B are operonic D,L-endopeptidases that cleave within PG peptide side chains (69). These proteins have been shown to be synthetically lethal with one another (70). RipA interacts with resuscitation promoting factor B (RpfB), a lytic transglycosylase, as well as with PonA1. It is cleaved and activated by the MarP protease, specifically in acidic conditions like those found in host phagosomes (10). RipA localizes to the poles and the septum (64, 71). Cells depleted of the *ripAB* operon chain and branch (septa are made but not cleaved), suggesting that this operon is required for daughter cell separation. RipA PG cleavage is synergistic with RpfB (72). Intriguingly, RipA and PonA1 interact in the same domain as RipA/RpfB. Adding PonA1 to a mixture of RipA and RpfB reduces the rate PG hydrolysis by the RipA/RpfB complex but does not inhibit RipA activity alone, suggesting a that the interaction of RipA with PonA1 and RpfB helps coordinate the synthesis and breakdown of the septal wall (5, 17).

ChiZ, like many PG hydrolases, contains a LysM domain known to bind PG (73). ChiZ shares some similarities with *B. subtilis* YneA, a protein whose expression is induced by DNA damage, which curbs division by inhibiting the Z-ring and cell separation (74, 75). Overexpression of *yneA* leads to filaments, but intriguingly, these filaments can be bypassed by a *divIB* (*ftsQ*) mutation further linking YneA with cell division (75). Similarly, overexpression of *chiZ* leads to filamentation, and Z-ring assembly appears partially defective; some normal Z-rings appear to form, but much of FtsZ appears distributed throughout the cell. ChiZ does not appear to inhibit FtsZ polymerization *in vitro* (74). It interacts with PbpB and FtsQ but does not appear to affect their localization (76). The mechanism by which ChiZ and YneA act in division remains unclear.

Ami1, a putative PG amidase, was recently found to be involved in mycobacterial division. In *Δami1* cells, division is blocked, leading to filamentation and lateral/polar branching. Stability of Z-rings appears compromised in these cells, and lysis at the site of attempted septation is observed (77).

Notably, PG hydrolysis is a dangerous game for a bacterial cell, so hydrolase enzymes must be carefully regulated. FtsEX, an ABC transporter complex, is required for proper cell division in *E. coli* through recruitment of EnvC, a regulator of PG amidases at the septum and also through interaction with early divisome anchor FtsA (78, 79). However, FtsEX appears to regulate the CwlO hydrolase during cell

elongation and not division in *B. subtilis* (80). In mycobacteria it has been shown that FtsX interacts with a RipA homolog, RipC, but the role of these proteins in division is yet to be explored (81).

Physical separation of daughter cells in *B. subtilis* occurs slowly. In contrast, mycobacterial cell separation has been described as "V-snapping," where daughter cells literally snap away from each other at the septum but often retain a point of contact (like the quick opening of a door) (82). High-speed imaging has recently revealed that actinobacteria, like mycobacteria, split rapidly, in approximately 10 milliseconds (83). While some mycobacterial cells V-snap, some cells quickly push away from each other at the septum but fail to V-snap; rather, they "straight" snap. This is likely due to the complexity of the mycobacterial cell wall, which must be quickly sheared for full V-snapping (83). In fact, all layers of the cell wall, including PG, arabinogalactan, and mycolic acids, are present at the site of the septum by metabolic labeling (8, 10).

THE CIRCLE OF LIFE: CREATING A NEW GROWTH POLE

In *B. subtilis*, the late septum, post-separation, becomes a synthesis-inert pole. In stark contrast, the pole created at division in mycobacteria becomes the location of cell wall synthesis, the hub of growth for these bacteria.

As previously mentioned, *B. subtilis* DivIVA is a cooperative partner of the Min system to prevent septation over the nucleoid. This can be classified as an early division inhibitor at the stage of Z-ring placement. Conversely, the mycobacterial DivIVA homologue, known as Wag31 or Antigen84, plays a critical role in late stage septation/new pole establishment. It is essential for survival, and its misregulation results in distinct division and elongation impairment phenotypes—branching cells in *wag31* overexpression (84) and polar bulges when depleted (6, 12). Like *B. subtilis* DivIVA, the N-terminus appears to direct Wag31 to polar curvature that may help it localize to the poles (6). Wag31 is phosphorylated by PknA/B (31, 85), but it is unclear how phosphorylation regulates its function (62, 85).

Wag31 localizes primarily to the old pole (i.e., the pole that existed before the most recent division [Fig. 1]) and is observed at the very late septum after the membrane has come down and separated daughter cells (12, 26). This postmembrane septal localization may indicate a role for Wag31 in the transition from a septum to a pole (26). In line with this, Wag31 interacts with members of both division (septal PG synthase PbpB (62, 86), MtrB-discussed below) and elongation (CwsA) machinery. The interaction of Wag31 and PbpB prevents protease cleavage of PbpB in oxidative stress conditions such as growth in macrophages. This highlights a critical link between *in vivo* stresses and cell division (86).

In addition, Wag31 has been shown to interact with the mycolic acid synthesis enzymes AccA3 and AccD5 (6), supporting the notion of coordination between the mycobacterial layers. Interestingly, these enzymes localize in a manner like Wag31, primarily at the old pole but also at the transitioning septum (6), again suggesting that Wag31 may be involved in the creation of new poles at the site of division.

Wag31 is not an enzyme, and yet, it must somehow coordinate cell wall synthases to the pole. How this is accomplished is unknown. We do know that one major PG synthase involved in elongating the cells, PonA1, is also regulated by phosphorylation in mycobacteria. PonA1 is phosphorylated by PknB, an essential Ser/Thr eukaryotic-like kinase (24). A phosphoablative mutation in PonA1 increases the rate of cell elongation. Thus, PonA1's activity is negatively regulated by phosphorylation (24). PonA1 further interacts, either directly or indirectly, with LamA, a mycobacteria-specific protein that actively inhibits growth from the new pole to create asymmetry in polar growth, at the late divisome (23) (see "An (a) side on (a)symmetry" above). Like FtsZ ring assembly, there may be both stimulatory and repressive forces at play to maintain balance in cell wall synthesis.

MYCOBACTERIAL GROWTH RATE: DOES SLOW AND STEADY WIN THE RACE?

Many laboratory bacteria are famous for their ability to rapidly multiply. Mycobacteria, however, grow and divide relatively slowly or, in some cases, not at all under laboratory conditions. There is diversity even among the mycobacterial genus. For example, soil-dwelling *M. smegmatis* are "fast growers," dividing once every ~2.5 hours. On the other side of the spectrum are the human pathogens *M. tuberculosis* and *M. leprae*, which grow extremely slowly during infection (between 20 hours to a few days for *M. tuberculosis* and ~2 weeks for *M. leprae* (87)). Cultured *M. tuberculosis* grows at a similar rate (~20 hours) (88), suggesting that slow growth is not simply a matter of host restriction. Why do mycobacteria grow slowly? The short answer is that we do not know, but that will not stop us from speculating.

One possibility is that polar growth leads to a different set of rules governing bacterial growth. At what point does a bacterium divide? Is it based on time, on size, or on amount of growth? These three hypotheses are known as the sizer, the timer, and the adder models, respectively. Recent work supports the idea that bacteria such as *E. coli*, *Caulobacter crescentus*, and *B. subtilis* may adhere to the adder model, whereby cells add a constant amount of volume during a cell cycle, independent of cell size (89, 90).

The adder model relies on exponential growth. In lateral growers such as *B. subtilis* this is an easy feat to accomplish: as new cell wall is inserted along the entirety of the cell body, the area of new addition also grows. Polar growth, however, does not so simply allow for exponential addition because expansion is restrained to a specific, and proportionally small, geographic area of the cell. Indeed, at first it seemed that mycobacteria might be governed by a different principle. Early work suggested that mycobacteria employ a timer mechanism, dividing after a certain amount of time independent of cell size (7). However, two recent studies strongly suggest that mycobacteria are governed by the same adder principle as other bacteria, albeit with modifications (91, 92). One surprising conclusion from these studies is that single mycobacterial cells appear to grow exponentially (26, 92).

Another possible factor in slow growth is the formidable nutrient barrier provided by the mycobacterial cell wall. And, of course, there is a strong causal relationship between nutrient availability and growth rate: in nutrient-rich environments, bacteria grow faster and, to an extent, become larger. Is the availability of nutrients rate-limiting in mycobacteria? *M. smegmatis*, the most well-studied fast-growing mycobacteria, encodes a porin, MspA, which aids in the uptake of nutrients across the myco-membrane. Notably, MspA is absent in *M. tuberculosis* (93). Expressing *mspA* in BCG, a slow-growing mycobacteria naturally lacking *mspA*, caused the cells to slightly but reproducibly increase their doubling rate, supporting a link between nutrient uptake and growth rate in mycobacteria (93–95). Likewise, porin knockdowns in the fast-growing mycobacteria *Mycobacterium fortuitum*, lead to a decrease in colony size, suggesting

that nutrient uptake plays some role in growth rate (96). However, this must only be part of the story, because expression of MspA only marginally increased the growth rate of BCG.

An additional putative factor in the slow growth of mycobacteria is the rate of DNA replication. In many other species, the demands of fast growth necessitate mutlifork DNA replication because DNA replication is slower than the process of growth and division in nutrient-rich conditions (97). Until recently, it was thought that mycobacteria were not capable of multifork DNA replication, thus decreasing the potential to increase the growth rate beyond this rate-limiting step. However, a recent study challenges this idea, showing multifork replication using time-lapse microscopy and fluorescent reporters of replication-related proteins (98). Intriguingly, the authors found that multifork replication occurred in nutrient-rich and nutrient-poor conditions. Thus, it remains unclear what role multifork replication plays in mycobacteria. Perhaps mycobacterial DNA polymerization is inherently slow. *M. smegmatis* has an estimated DNA synthesis rate of 400 bases/second. This is quite rapid compared to *M. tuberculosis* with a proposed rate of 50 bases/second (98, 99). However, these rates are sluggish in relation to the 600 to 1,000 bases/second that *E. coli* and *B. subtilis* can accomplish (100). DNA replication, the so-called "C" period of the cell cycle, takes up ~75% of the *M. smegmatis* cell cycle (26, 98). Oddly, the *in vitro* rate of nucleotide incorporation by mycobacterial DNA polymerase DnaE1 is faster than that of *E. coli* PolIIIα (101). This suggests that conditions within the cell, for example, limited nucleotide pools, restrict the rate of new chromosomal synthesis (100).

Yet another possibility is that the construction of the intricate cell wall itself limits the growth rate of mycobacteria. Supporting this idea is the recent *E. coli* study by Vadia et al. (102). They proposed an "outside-in" model, in which *E. coli* cell size is limited by fatty-acid synthesis so that cell volume does not increase at a rate faster than can be accommodated by the cell envelope. Certainly, cell wall fatty acid synthesis could be a contributing factor to mycobacterial slow growth since mycobacteria must synthesize their complex and long mycolic acids, and there are substantial cell wall differences between fast- and slow-growing mycobacteria (93).

MORE DEEP THOUGHTS ON MYCOBACTERIAL DIVISION

While bacteria dream of dividing, pathogens dream of dividing within the host. And mycobacteria seem to be exquisitely tuned for doing so: *M. tuberculosis* is an obligate pathogen with essentially no environmental niche. And it is highly successful. In 2016 there were over 10 million new cases of *M. tuberculosis* infection estimated and nearly 2 million deaths (103). Thus, an important part of thinking about the growth of this organism is to consider its adaptations to the host. The slow growth rate is likely optimized for surviving in humans, though why this should be remains unclear. And the ability to survive for decades as an asymptomatic infection, perhaps growing slowly or not at all, permits a reservoir of infection that ensures the long-term survival of the species. The cell wall is appropriately adapted to interface with the host (5). And while the pattern of growth has been inherited from the soil-dwelling organisms from which it has likely evolved, *M. tuberculosis* takes full advantage of it to avoid clearance during infection.

The outcome of these adaptations is crucial when we consider therapy for tuberculosis. The thick cell wall and its multiple embedded efflux pumps present a formidable barrier for many drugs that are effective against other bacteria (104). At the same time, it creates new opportunities to target structures and processes that are absent in model organisms. For example, antibiotics such as ethambutol and isoniazid that inhibit the formation of arabinogalactan and mycolic acid synthesis, respectively, are absolute mainstays of tuberculosis therapy. With a better understanding of the underlying molecular mechanisms, other unique aspects of mycobacterial cell division could provide effective and specific targets for tuberculosis therapy.

Those of us who study mycobacteria are indebted to the groundbreaking research conducted in *B. subtilis* and *E. coli*—work that has created a template on which to base our thinking about our own organisms. But mycobacteria create their own, unique paradigms. Model bacteria might dream alike, but each unusual bacterium dreams in its own way. C'est la vie!

Mycobacterium tuberculosis Metabolism

GABRIEL T. MASHABELA*, TIMOTHY J. DE WET AND DIGBY F. WARNER

67

INTRODUCTION

The notion that metabolic capacity might correlate with lifestyle has largely been confirmed by comparative genomics analyses of different bacterial species: free-living bacteria tend to have larger, more complex genomes than pathogens and symbionts (1), with obligate intracellular organisms often representing the extreme limit of small genome size (2). This correlation exists also in *Mycobacterium*, a genus which includes environmental organisms as well as a select group of animal and human pathogens—primarily of the *Mycobacterium tuberculosis* complex (MTBC) (3)—whose genome sizes and compositions relate broadly to habitat and host range (4, 5). Most notable among these from a public health perspective is *M. tuberculosis*, the causative agent of tuberculosis (TB), an airborne infectious disease which continues to result in over 10 million new cases and more than 1.5 million deaths globally each year (6). This is despite the widespread use of a neonatal anti-TB vaccine (7) and the existence of an effective combination chemotherapy (8), the insufficiency of which points to systemic failures in TB diagnosis and treatment (9, 10), as well as the complexities encountered in eliminating an organism that has coevolved with its human host (11) and, throughout modern history, has proven adept at exploiting urbanization (12), economic disparity (13, 14), societal upheaval (15), and incarceration (16–18) in maintaining a global prevalence characterized by high-burden endemic regions (6).

M. tuberculosis is an obligate human pathogen; the bacillus can infect other animals, but evidence for zoonotic transmission (back) to humans from these "spillover" hosts (11) is scarce (19). Consistent with its near exclusive association with a single "maintenance host" (11), the *M. tuberculosis* genome has undergone significant downsizing during its evolution from a generalist ancestor. Nevertheless, *M. tuberculosis* retains a large metabolic repertoire, much of which is shared with other mycobacteria with very different lifestyles (20–22); moreover, horizontal gene transfer during the early evolution of the MTBC has enabled the acquisition of additional functions that are critical for pathogenicity (23–25). In other words, the organism has harnessed, adapted, and even augmented the metabolic pathways of its environmental ancestor in evolving the capacity to persist and propagate within its obligate human host (21, 22, 26).

The development of specialist *M. tuberculosis* sublineages from more generalist precursors (11, 27)—in some cases through the inactivation of certain genes (28)—appears, therefore, to signal natural evolution driven by key structural changes in human population demographics and geographies. These include the shift to urbanization, the introduction and widespread use of anti-TB drugs and, possibly, BCG vaccination (29). Greater host population density and the emergence of comorbidities such as diabetes and HIV might additionally have favored the selection of more virulent strains (30, 31), though this inference is not always clear-cut (32). A common theme, however, is that gain or loss of different metabolic functions appears to be a major factor in the modern evolution of the *M. tuberculosis* bacillus (21, 22, 28, 33–36).

We noted previously (37) that the topic "*M. tuberculosis* metabolism" is very broad, encompassing all the dynamic processes and chemical transformations which enable bacillary cellular function and physiology, including those involved in maintaining structural integrity, energy production, generation of biomass, and elimination of waste. It is not possible, therefore, to cover these in any detail in a single review. Instead, this article will attempt to situate *M. tuberculosis* metabolism within the framework of an intimate host-pathogen coevolution while providing some insights into the special challenges faced in elucidating metabolic function (as distinct from metabolic capacity) in a pathogen with no known reservoir outside its obligate human host. Where relevant, we will highlight recent advances in our understanding of different aspects of the metabolism of *M. tuberculosis*, focusing primarily on those which represent unusual adaptations or departures from the model intracellular pathogens; that is, the key observations implicating specific metabolic functions in mycobacterial pathogenicity and the host-pathogen interaction. In addition, given the strong interest in the development of new (shorter) combination regimens for both drug-susceptible and drug-resistant TB, we will consider the impact of metabolism on the susceptibility of *M. tuberculosis* to existing and experimental anti-TB drugs. As with other summaries of this subject, the reader is advised not to consider this a standalone piece. Rather, any of a number of specialist reviews should be consulted for further

PE/PPE proteins	77

details on those aspects covered only superficially here, as well as for different perspectives on the key gaps in current knowledge of fundamental mycobacterial metabolism and the implications thereof for TB prevention and new TB drug development (for a list of suggested readings, please see Table 1).

MYCOBACTERIAL METABOLISM AND HUMAN TB DISEASE

Although the precise duration of the *M. tuberculosis*-human coevolution remains subject to contention (11)—estimates range from fewer than 6,000 years (38) to around 70,000 years (39)—there is general acceptance that the interaction extends across millennia. It was striking, therefore, when the first whole-genome sequence of *M. tuberculosis* revealed the genetic potential for synthesis of all essential amino acids, vitamins, and cofactors, with a disproportionate number of pathways dedicated to lipid and fatty acid metabolism (40). This large metabolic capacity (often conflated with "metabolic flexibility" [41–43]) represents a key departure from many other obligate pathogens which tend to rely on the host to complement their limited (and often diminishing) metabolic repertoires (44) and is critical to understanding the defining characteristics of this organism and the disease it causes (26, 45–48). Such characteristics include (i) long-term coevolution of *M. tuberculosis* with humans (38, 39), leading to sympatric associations of specific lineages with geographically distinct human populations (11, 49), (ii) the ability to persist for months to decades in a subclinical state (in some cases characterized by undetected disease [50]) which might develop later to cause active TB (26, 47, 51–53), (iii) the inertness to clearance by the host immune response or eradication by antibiotics (54, 55), (iv) the requirement for extended-duration combination therapy to effect symptom-free cure (8, 56) and, linked to that, (v) the difficulties inherent in developing new drugs and combination regimens to accelerate therapy (57, 58), and (vi) the capacity to acquire—and adapt to—drug resistance mutations that might otherwise be expected to incur a crippling fitness cost, particularly where sequential mutations confer multidrug resistance (59–61). Each of these characteristics reinforces the durability of *M. tuberculosis* in preserving its special niche within humans and, by implication, the challenges inherent in disrupting this association, whether by vaccines, chemotherapy, or other interventions (Fig. 1).

Pathogenicity and Metabolism

That physiology and pathogenicity cannot be separated in an obligate pathogen such as *M. tuberculosis* seems axiomatic (26, 62). However, the relevance of this precept to efforts to counter TB might be less evident and so bears restating: an understanding of mycobacterial metabolic capacity supports the inference that *M. tuberculosis* is a "survival machine," able to exploit its human host as both a source of nutrients for increased biomass and a reservoir for long-term persistence (26, 37, 63). Reinforcing this premise is the observation that the infecting population does not necessarily drive a metabolic program aimed at maximizing growth rate (64, 65) or biomass (26, 37, 63, 66). Instead, as observed by others (66), the frequent requirement for bacilli to exit the standard bacterial cell cycle owing to the pressures imposed by the host immune response and, in the modern history of *M. tuberculosis*, antimycobacterial chemotherapy, demands the capacity to maintain viability in a state of rapidly reactive and reversible metabolic quiescence for extended periods.

While evidence exists for decades-long survival of bacilli in an asymptomatic host (67, 68), most cases of clinical disease are thought to arise within 1 to 2 years of infection (53, 69). During this period, those bacilli which survive the attempts at clearance by the host's innate immunity generally maintain a state of paucibacillary, asymptomatic infection in which host lipids and mycobacterial antigens are accumulated within alveoli in the lung apices. There is a spread of bacilli which, depending on the preferred model, is thought to occur via bronchi (69) or via the lymphatics (70). And, although most new lesions regress spontaneously, necrosis can result in caseous pneumonia, a heterogenous outcome which can be paucibacillary or multibacillary, with or without significant neutrophil involvement. Importantly, this manifestation—known as post-primary TB disease—depends on the acquisition of systemic immunity by the infected host. Its sequelae are considered the key determinant of disease outcome: softening and fragmentation of the caseous pneumonia triggers its expulsion by coughing, in turn leaving a hole which can become the site of active bacillary growth and the primary source of organisms for transmission; in contrast, those sites which are not removed by coughing are sources of ongoing inflammation, ultimately leading to fibrocaseous disease (69). Though central to disease pathogenesis, these events in post-primary TB, in particular, the development during latent infection of an asymptomatic obstructive lobular pneumonia, have not been adequately studied, owing to the unavailability of suitable clinical specimens and the failure of animal models to recapitulate many of the key features. Inevitably, mycobacterial metabolism under these conditions, too, remains very poorly understood.

The quiescent state adopted by *M. tuberculosis* is distinct from "true dormancy," a very specific physiological and morphological condition often involving sporulation, for which the bacillus appears to lack the necessary genetic machinery (71). Physiologically, though, it is interesting to note that a deficiency in α-crystallin—a major TB antigen (72), bacterial protectant, and chaperone protein which has been implicated in long-term bacillary survival (55)—is associated with hypervirulence *in vivo* (73). This seems to imply a disturbance of the natural host-pathogen interaction where a genetic lesion has deprived the bacillus of its natural capacity for persistence. The observation, noted previously (37), that mutations in regulatory genes are often associated with hypervirulence (74–76) appears to buttress this conclusion. So, too, does recent evidence (28) implicating disrupted secretion of the large class of *Mycobacterium*-specific

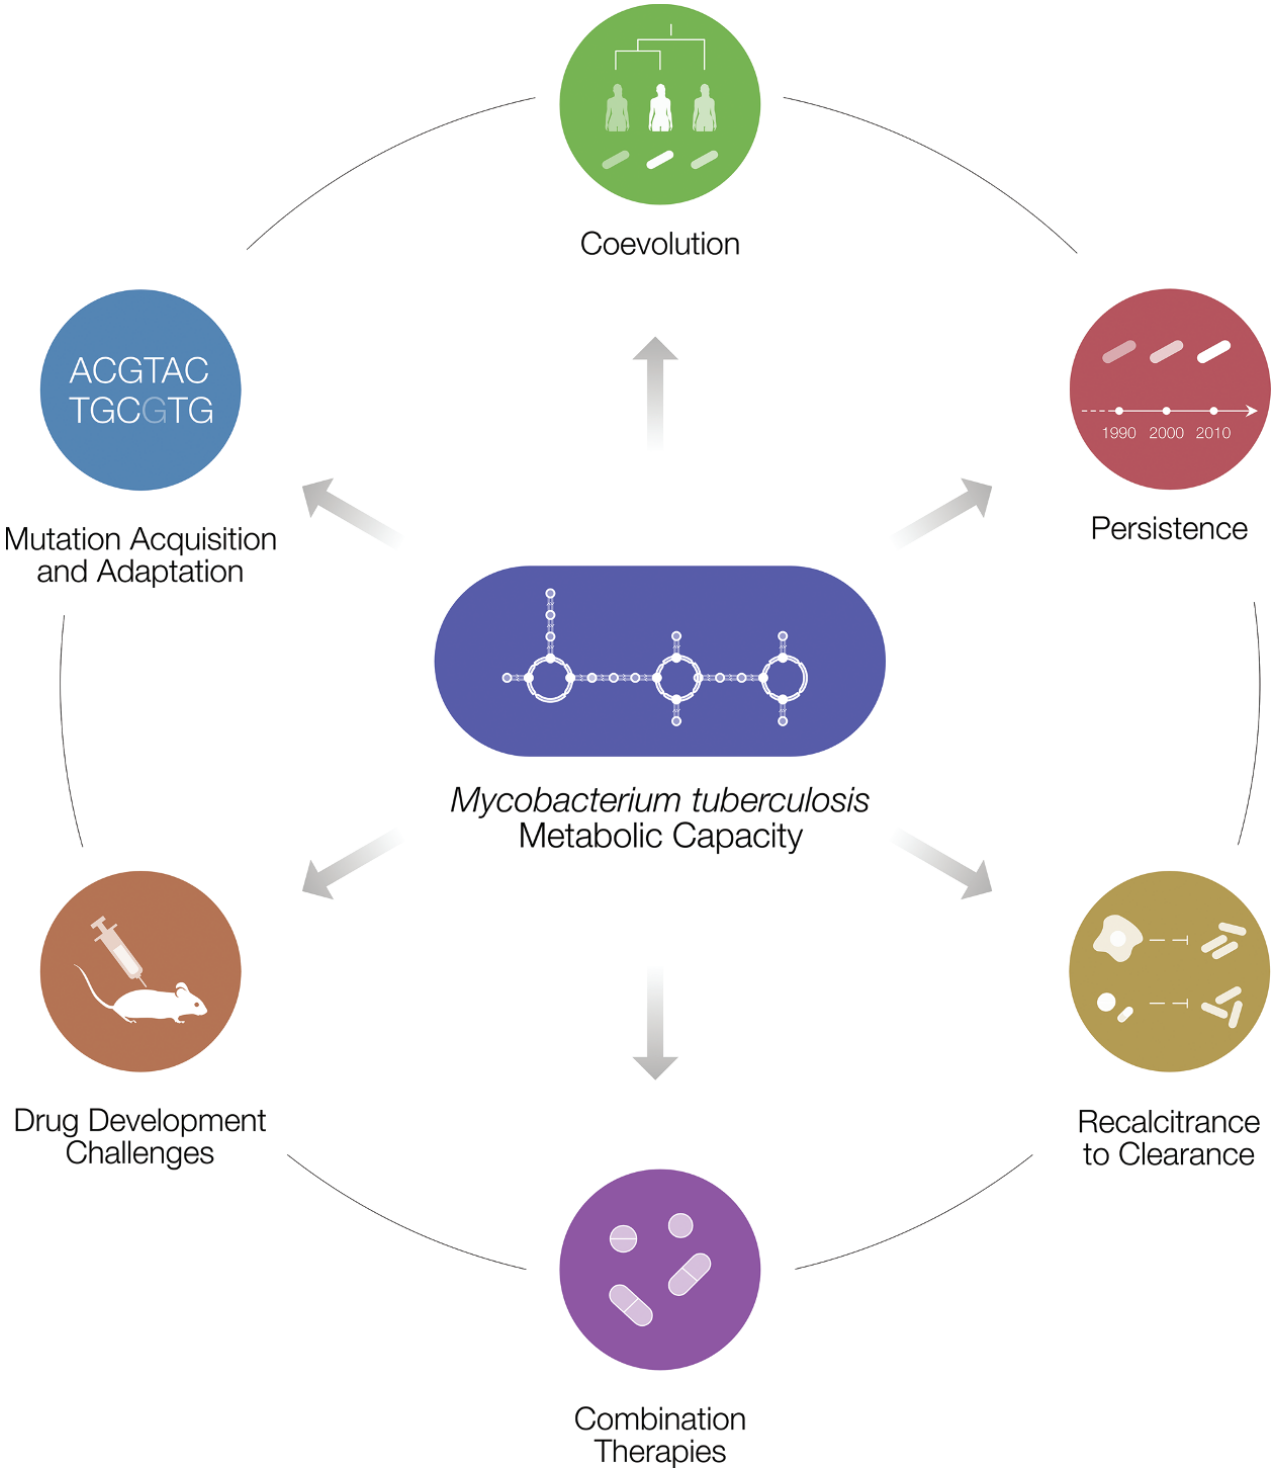

FIGURE 1 The metabolic capacity of *M. tuberculosis* is critical to understanding key features of mycobacterial pathogenicity, which include (i) long-term coevolution with humans, (ii) the ability to persist for months to decades in a subclinical state, (iii) inertness to clearance by the host immune response or eradication by antibiotics, (iv) the requirement for extended duration combination therapy to effect symptom-free cure and, linked to that, (v) the difficulties inherent in developing new drugs and combination regimens to accelerate therapy, as well as (vi) the capacity to acquire—and adapt to—multiple drug resistance mutations without incurring a crippling fitness cost.

PPE-MPTR and PE_PGRS proteins (whose functions remain largely unknown [77]) in enhanced growth and virulence of modern Beijing lineage strains *in vivo*. The inferred centrality of a conserved host-pathogen interaction in TB pathogenesis is reinforced in the "hyper conservation" of T cell epitopes (39, 78), a feature which might be integral to the development of post-primary TB (69, 79).

At an epidemiological level, the inference that *M. tuberculosis* is hard-wired for persistence is supported by the fact that the number of active TB cases globally (~10 million) (6) is dwarfed by the estimated annual incidence (thought to exceed tens of millions [53]) and global prevalence of infections (estimated at ~25% of the world's population [80] but subject to contention [53]). As Rhee and colleagues have cogently argued, this entails that the bacillus must occupy a range of physiological states book-ended by "unrestrained replication" and "perpetual quiescence" (26), extremes which are incompatible with the natural history of the species (11, 49). In turn, the notion that *M. tuberculosis* cellular function defaults to persistence immediately suggests the corollary: host status, whether genetic (81), immunological (82), nutritional (83, 84), environmental (85, 86), or a combination of some or all of these, is critical in determining who develops, and succumbs to, TB disease (a seemingly obvious conclusion, perhaps, but one which reinforces the potential pitfalls in attempting to define—and quantify—mycobacterial "virulence" as a solely bacterial property).

The intimate, dynamic, and durable interaction between *M. tuberculosis* and humans defines the framework within which any new anti-TB interventions must be considered. That is, tackling any single aspect—for example, drug regimens to treat active cases, novel preventative chemotherapies or vaccines to forestall new disease, or strategies to block transmission—is unlikely to prove sufficient on its own (87). Importantly, it also underscores an acknowledged limitation of many studies which aim to elucidate fundamental aspects of *M. tuberculosis* metabolism: namely, that the potential disconnect separating bacillary metabolic functions active during host infection (whether in the presence or absence of manifest TB disease) versus those actuated—and therefore described—*in vitro* and/or *in vivo* in the various disease models risks a growing phenomenology of metabolic capacity distinct from direct evidence of metabolic function in the context of the complete biological system which defines TB (37, 88).

Investigating Metabolism *in Vitro*

While the majority of genome-wide mutagenesis studies recognize the importance of, and even exploit, the applied *in vitro* conditions (or infection model) in inferring conditional essentiality (89–93), the impact of growth conditions on experimental observations has often been ignored in fundamental mycobacteriology. This is despite an increasing number of reports of the profound impact of the growth medium and various additives on the described phenotypes (94–97, 344). Aside from auxotrophy (92, 98, 99), perhaps the most illustrative example of how even apparently absolute concepts such as essentiality (100) can be condition-dependent is provided by the paradoxical tolerance of cell wall-targeting antibiotics in cell wall-deficient L-form bacteria (101), a phenotype which demonstrates the potential for wholesale loss of a fundamental macromolecular structure under the appropriate conditions—in that case, *in vivo* residence in a suitably osmoprotective intracellular environment.

Similarly, practical considerations tend to favor the use of culture conditions that enable optimal (that is, the most rapid) growth. For *M. tuberculosis*, this generally means aerobic incubation in standard medium (usually Middlebrook 7H9 base or equivalent) comprising glycerol and glucose as the primary carbon sources (102). The disconnect between *in vitro* and *in vivo* models used in experimental investigations of mycobacterial metabolism and those environments which are likely to prevail in the natural human host is not unique to *M. tuberculosis* (103). Therefore, in addition to appreciating that logarithmic aerobic growth represents just another condition and that mycobacterial physiology in this state will necessarily influence assessments of gene essentiality or metabolic pathway vulnerability, there is a pressing need to develop experimental systems that target slow-growing and nongrowing states, perhaps in the context of more advanced cellular scaffolds (104). Though often performed in the context of TB drug discovery, the application of advanced analytical technologies to determine the precise molecular content (proteins, lipids, metabolites) of a number of environments, including macrophage organelles (105), lipid droplets (106), and tissue samples from animal models and patients (107, 108), represents an exciting area of development and might be complemented by recent advances in generating more complex tissue culture models (109).

Many researchers have made pioneering efforts to develop other complex models of *M. tuberculosis* growth and survival, and the strategies adopted to model environments that are far less favorable for unchecked generation of biomass have yielded important insights into metabolic function under the applied conditions, as well as revealing condition-selective antimycobacterial compounds. These include manipulating the pH of growth media, the inclusion of peroxide and/or nitric oxide stresses, oxygen and nutrient deprivation, and combinations thereof (110–115), many of which have been applied in screening programs aimed at identifying compounds with condition-specific activities or those able to inhibit survival of nonreplicating bacilli (116, 117). Again, while each is intuitively attractive, the difficulties inherent in translating inferences derived from these *in vitro* systems to human TB disease remain daunting; the field urgently requires a proof-of-concept demonstration of enhanced therapeutic efficacy achieved using a novel small molecule whose development has been prioritized owing to its condition-selective activity in one of more *in vitro* models.

Moving to More Complex Models

Like for many other pathogens, investigations of cellular functions in the context of the host-pathogen interface of *M. tuberculosis* have tended to focus primarily on the effectors of immunity (host) or virulence (bacillus), with the metabolic consequences of infection often ignored (44). Systems biology and its tools, including the analysis of labeled metabolites (118–122) and other mass spectrometry-based technologies (123–127), have eroded this bias, enabling key insights into the biochemical compositions and metabolic fluxes which characterize *M. tuberculosis* bacilli under different conditions and in different infection models (128). These and related approaches have also been used to elucidate the regulators of metabolic adaptation and function (129–131), the mechanisms of action of existing and experimental anti-TB drugs (43, 131–134), in assigning functions to proteins of unknown or predicted function (133) and in functional genomics of clinical *M. tuberculosis* isolates (36). Except for sputum bacilli, though, the number of studies directly investigating *M. tuberculosis* metabolic function and physiological state(s) *in situ* during host infection remains very small (135–137).

In some cases, results from experimental systems *in vitro* and *in vivo* have been combined with analyses of human TB pathology to construct sophisticated models of mycobacterial metabolism (138, 139). Though compelling, the *in vivo* relevance of these is largely untested; for this reason, determining the metabolic and physiological states adopted by the tubercle bacillus in the infected human host represents the ultimate, though daunting, scientific goal. Knowledge that the functions of approximately 40% of the *M. tuberculosis* proteome remains predicted or obscure (140, 141)—so, too, the speculative reasons the bacillus possesses numerous examples of apparently redundant or duplicate pathways (142–149)—exacerbates the size of the task. Moreover, growing evidence indicating key functional differences between (and even among different laboratory stocks of) the laboratory strain, *M. tuberculosis* H37Rv, clinical *M. tuberculosis* isolates, and other species of the MTBC (33–35, 150, 151), implies that diverse phenotypes will inevitably be recorded when different species, and even strains (152), are tested in the same assay. That is, while prevailing approaches might enable some generalizable insights into core *M. tuberculosis* metabolism, the next phase demands innovative approaches to study bacilli of different genotypes in the context of natural host infection (153). Here, understanding the features which differentiate infection outcomes in sympatric versus allopatric hosts (154) might provide some important insights (151).

Of course, the fact that the diversity which characterizes *M. tuberculosis* lineages and strains is matched by the genetic and phenotypic variety of host immune cells further complicates these analyses. For example, different macrophages and macrophage-like cell lines are commonly explored to understand mycobacterial function in the intracellular environment (155); for TB, these are usually immortalized human and mouse cell lines (e.g., THP-1s, J774s), mouse bone marrow-derived macrophages, and human peripheral blood mononuclear cells (156), with some recent reports proposing alternative, more complex, systems (109, 157). Macrophages themselves are functionally diverse, however, and follow different developmental trajectories and respond to a variety of activation signals (158). Consequently, there are significant risks inherent in a rigid dependence on standard models, a pitfall underscored by recent observations that alveolar macrophages might offer a more favorable intracellular environment for *M. tuberculosis* survival and dissemination than interstitial macrophages (159, 160). Moreover, evidence that a shift to aerobic glycolysis in infected cells can enable proliferation of intracellular bacilli (161, 162) requires that caution should be exercised in drawing conclusions about mycobacterial metabolic function from experiments utilizing the different macrophage lines. To enable rapid anabolism, proliferating cells (as is the case for the various cell lines) naturally drive a strong Warburg metabolism which is independent of intracellular infection but must inevitably impact the metabolic response of the infecting bacillus (161). A further complication is that this effect can be species-specific, with recent evidence highlighting differential metabolic responses in human versus mouse macrophages (163). In this light, the proposal that intracellular pathogens might have evolved to take advantage of specific immune cell subsets locked into promicrobial metabolic programs (44) seems apposite. Therefore, special emphasis must be placed on the need for much greater functional and ontogenic information about the host cells in which bacilli preferentially reside during infection. And this should be coupled with a better understanding of the extent to which immunometabolic responses of host cells to *M. tuberculosis* are cell-type specific, host species specific, and/or strain specific (45, 161).

M. tuberculosis Metabolism and the TB Disease Life Cycle

Other than during transient periods of transmission, when bacilli are released into the environment in droplet aerosols, the entire *M. tuberculosis* life cycle occurs within the infected host (26, 164). This concept—encapsulated in the notion of humans as the "maintenance host" (11)—is critical to understanding *M. tuberculosis* pathogenicity: the ability to infect, persist, cause disease, and trigger production of infectious aerosols demands the capacity for survival and propagation in different environments and under a variety of stresses. Current knowledge of *M. tuberculosis* infection reinforces this notion. Most experimental models, ranging from intramacrophage systems *in vitro* (165, 166) through small animals (159, 167, 168) to nonhuman primates (NHPs) (169, 170), indicate that bacilli are able to replicate rapidly immediately after infection, with evidence of early dissemination in NHPs (170) until host-mediated killing results in a decline in replication rates and total bacillary load. Even then, it appears from the mouse model (167) that replication might continue in discrete microenvironments throughout infection (68), a possibility recapitulated in genomic data from bacilli isolated from NHPs which revealed the acquisition of chromosomal mutations during subclinical disease (171). Moreover, although its relevance to *in vivo* infection remains to be established, the observation that *M. tuberculosis* replicates rapidly inside dead macrophages (172) further argues that the transient growth rates (and fates) of infecting bacilli in different lesions in the same host are likely to be dynamic and unlinked.

The heterogeneity which characterizes host infection supports a model in which infecting bacilli must establish an early foothold within the new host before seeding a number of discrete lesions, the fate of which appears to be determined for each lesion at a local level, independent of events in other microenvironments (173). For *M. tuberculosis* as a species, each new infection represents a potential dead-end if transmission is prevented. Therefore, long-term survival within a host—and by any mechanism—appears to represent the best hedge against this risk. Loss of immune control at any stage during the host's lifetime might then allow for stimulation of the destructive pathology that could enable (or enhance) infectious aerosol release, renewing the infection cycle.

This is the lens through which mycobacterial metabolism must be viewed. Transient opportunity for generation of biomass means that preservation of viability under varied and multiple stresses represents the driving metabolic imperative. While contrary to popular views which conflate bacterial virulence with rapid growth, the enforced (and sustained) quiescence which likely characterizes human *M. tuberculosis* infections is a feature of most bacteria in their preferred niches, whether pathogens or not (103). The apparently "surprising" retention of a multifunctional metabolism in a successful obligate pathogen appears then to be just the opposite: metabolic flexibility is, instead, precisely the attribute which enables *M. tuberculosis* to occupy its preferred environment—the human host—without recourse to a separate (environmental) reservoir. For *M. tuberculosis*, the absence of any competing microorganisms within its "ultranarrow ecologic niche" (66) additionally ensures a privileged, albeit transiently hostile, space in which replication can occur subject to prevailing conditions, largely determined by the host immune response. Again, this highlights the need for

greater understanding of the metabolic functions which ensure prolonged viability under nonreplicating persistence. Here, it is interesting to consider recent work with other bacteria which has demonstrated the conditional essentiality of many genes, including a large number of proteins of unknown function, in long-term fitness under growth arrest (174, 175), as well as the potential for selective targeting of pathogens under these conditions (176).

The example of *pat* mutants, engineered strains of *M. tuberculosis* which achieve population numbers similar to wild-type bacilli *in vivo* but do not cause the same degree of pathology (177), has been cited as evidence of the fact that disease outcome is not necessarily linked to the bacillary population size (37). Rather, it is the interplay between the host response and the infecting *M. tuberculosis* population—and the antigens it produces (69)—which determines infection outcomes (178). This tenet is perhaps best captured in the aphorism that *M. tuberculosis* is necessary, but not sufficient, for TB disease (82, 179).

Again, evidence from pioneering studies in NHPs reinforces this conclusion. For both diseased and clinically latent monkeys, the population of culturable organisms commonly numbers around 2×10^5 bacilli per lesion prior to the onset of the adaptive immune response and stabilizes at a median of $\sim 10^2$ bacilli per lesion during active disease (169). That is, the total numbers of bacilli present in active versus latent disease can overlap. Moreover, while there can be microenvironments in which the mycobacterial population achieves large numbers during active disease, the total bacillary burden generally seems much lower than might be expected given the extent of pathology (180). This observation is reiterated in human studies (69, 82) and contrasts with recent conclusions from an unrelated infectious disease model which demonstrated that infection outcome was directly attributable to bacterial load (181).

It is important, though, to differentiate TB disease in HIV-infected versus HIV-uninfected individuals. The enhanced propensity for extrapulmonary disease and TB bacteremia in HIV-TB cases argues that infection outcomes in the context of HIV-mediated immunodeficiency might correlate much more closely with the mycobacterial burden (182). Moreover, while the precise cause of death in disseminated TB disease in HIV-infected individuals remains speculative (183, 345), for pulmonary TB in individuals who are not immune-suppressed, it is clear that most patients ultimately succumb to advanced pathology (signaling a systemic failure in TB diagnosis and treatment [184]), a distinction which reinforces the intimate interplay between host and pathogen in the context of a functional immune response (185). Therefore, to consider TB disease as a single entity and, by extension, to categorize *M. tuberculosis* metabolic states (and, by implication, metabolic vulnerabilities) according to a single framework that assumes a handful of possible infection outcomes (51, 52) imposes a conceptual constraint that, albeit practically appealing, is potentially crippling in its failure to accommodate the complexity inherent in an infectious organism adapted to persistence, not virulence.

TB as Polymicrobial Infection of Humans

The continual acquisition of new sequence data from different mycobacterial species and strains has enabled comparative genomics analyses to determine the evolutionary histories of the different members of the MTBC with greater resolution (3). Importantly, when key genetic differences are considered against the backdrop of the very specific host tropisms of the different MTBC members, it becomes increasingly evident that laboratory-determined virulence is not only insufficient to understand pathogenicity, but likely inappropriate. As noted elsewhere (186), each species has diverged from a common ancestor through coevolution with its own cognate host, resulting in genetically related but phenotypically distinct pathogens specifically suited to hosts with disparate social and biological features.

M. tuberculosis causes TB, a disease which manifests primarily as damage of the lungs, yet extrapulmonary forms are also known which affect other organs and sites, including the pleura, abdomen, genitourinary tract, meninges, skin, joints, and bones (187). Lymph nodes, too, are often cited among lists of "extrapulmonary" sites, but this modifier is likely inaccurate given significant evidence that infection of lymph nodes constitutes a critical event in TB pathogenesis (70, 188, 189). Also distinct from extrapulmonary TB is the observation that *M. tuberculosis* can occupy diverse anatomical and cellular niches during latent host infection (190). Even in "simple" cases of pulmonary TB, infecting *M. tuberculosis* bacilli are not restricted to specific environments but can be found in multiple different host compartments, including cellular and necrotic granulomas and the inner surfaces of open cavities (58, 191–193). In each of these, bacilli can be sequestered within host cells or located in extracellular niches (194), reinforcing the suggestion that TB disease might usefully be considered a polymicrobial infection (195).

The occupation of diverse host microenvironments—in many cases, by paucibacillary populations—with independent disease trajectories constitutes a major obstacle to elucidating the metabolic adaptations demanded of bacilli located within (or transitioning between) the different niches (26). From a pharmacological perspective, this uncertainty presents a clear challenge to developing approaches that will ensure optimal drug delivery to bacilli in dynamic and disparate physical loci and metabolic states (57, 58, 196) and to understanding which (sub)populations must be controlled (or eliminated) for favorable therapeutic outcomes (55, 189, 197–199). For drug discovery, such uncertainty undermines efforts to identify unequivocally the pathways and functions which are critical to mycobacterial survival and so might represent viable antibiotic targets, that is, the organism's "metabolic vulnerabilities." In addition, it renders ambiguous the potential utility of compounds known to be selectively active against either proliferating or quiescent organisms, growing or subsisting on different nutrient sources (conversely, such molecules are of unquestionable utility as probes of the distinct metabolic states adopted by *M. tuberculosis* in those environments). Therefore, for those wanting (simply) to understand the link between bacillary metabolism and host disease, the lack of granularity informing available descriptions of *in situ* metabolism poses unresolved challenges regarding the assays and approaches—available and required—that might best elucidate mycobacterial metabolic function *in vitro*, in infection models, and in clinical disease.

Immunometabolism and Pathometabolism at the Host-Pathogen Interface

Like all intracellular pathogens, the bacillus must adapt its metabolism to the host cell, whose own metabolic status might correspondingly be altered as a consequence of infection (200). Though poorly understood, this interplay between immunometabolism (201) and pathometabolism (202) is critical to infection outcomes (45). There is increasing evidence that successful intracellular pathogens such as *M. tuberculosis* have evolved to exploit the reciprocal

determinism linking host cellular function and metabolic status (161). Ergo, this interplay might offer a solution to the apparent paradox that the very immune cells designed to eliminate the invading pathogen can function as a preferred niche (44). Consistent with their role as early responders, innate immune cells appear much more vulnerable to infection than adaptive immune cells, reinforcing the inference that organisms such as *M. tuberculosis* have adapted to the tightly regulated responses of innate immune cells to enable long-term intracellular survival. The observation that a core transcriptional profile unites species and lineages across the MTBC in response to intracellular infection (151) strengthens this conclusion and is supported by the presence of metabolic enzymes among the hyperconserved T-cell epitopes in *M. tuberculosis* (203). That is, through millennia of coevolution, the bacillus is likely to have adapted to the complex network of metabolic and immune alterations and signals triggered in its host.

The corollary also appears to hold true: in response to *M. tuberculosis* infection, some host macrophages shift to a "Warburg-like" (161) program of aerobic glycolysis (162, 204–207) in which oxidative phosphorylation is reduced and cytosolic glycolysis and the mitochondrial tricarboxylic acid cycle are redirected primarily to the biosynthesis of fatty acids. In an example of "bipartite metabolism" (44), these are utilized as energy sources by the intracellular bacillus (120) without imposing excessive metabolic stress on the host macrophage, which is able to drive an anabolic program utilizing the available glucose. Notably, a metabolic shift in the infected macrophage has been implicated in the accumulation of intracellular lipid bodies characteristic of foamy macrophages. In turn, this phenotype has been closely linked with mycobacterial persistence and disease progression (208–211), though recent observations suggest that it might be more nuanced (212). There is also evidence that altered metabolism at the site of *M. tuberculosis* infection influences cytokine production (213), reinforcing the connection between cellular metabolic state and immune function. Here, it is useful to consider the key observation that, at a metabolic level, the host-pathogen interaction is likely to possess emergent properties: specifically, the metabolic responses of host cells to living bacteria are likely to be more subtle and complex than the sum of metabolic responses to individual bacterial components (161).

Given the major recent impact of positron emission tomography and computed tomography imaging in providing unprecedented insights into TB disease pathogenesis and heterogeneity, both within and between individuals in different disease models and human TB patients (50, 169, 180, 189), it is worth noting here that the technique utilizes a [^{18}F]fluoro-2-deoxy-2-D-glucose ([^{18}F]-FDG) probe which exploits the enhanced glucose utilization of inflammatory cells. Recent work investigating the potential for alternative probes to provide cell-specific information ([^{18}F]-FDG is taken up by all glycolytically active cells and does not distinguish subsets) has revealed the dynamic nature of granuloma composition and metabolism over the course of infection (214), again reinforcing the critical concept that lesional progression with an individual does not follow a fixed temporal program (173).

M. TUBERCULOSIS METABOLISM

As noted at the outset, it is not possible to cover all aspects of mycobacterial metabolism within a single review. Instead, this and subsequent sections will provide a very brief update on research supporting four key concepts which are critical to understanding *M. tuberculosis* metabolic function and regulation, namely, (i) metabolic and respiratory flexibility, (ii) the capacity for cocatabolism of different nutrient sources, (iii) the potential for metabolic anticipation, and (iv) the heavy investment in cell wall metabolism.

Central Metabolism

"Not a picky eater, at least not for carbon and nitrogen sources" (Luiz Pedro De Carvalho, Twitter, 1 March 2019). Despite its levity, this declaration, made recently in promotion of research demonstrating the utilization by *M. tuberculosis* of amino acids as nitrogen sources (215), perhaps best summarizes a sizeable literature on (mostly *in vitro*) mycobacterial metabolic function (see Table 1 for selected references). Unsurprisingly, the predominant focus over the past 2 decades has been on carbon utilization, and consistent with this bias, this aspect of mycobacterial metabolism has been extensively reviewed (26, 45). Among the central tenets emerging from this work are that *M. tuberculosis* can cocatabolize different carbon sources (216), an observation which signals a key departure from classic bacterial metabolism in which diauxic growth regulated via carbon catabolite repression constitutes the dominant model.

A number of subsequent studies have reinforced carbon cocatabolism as critical to *M. tuberculosis* cellular function and pathogenicity, identifying specific roles for fructose-1,6-bisphosphate aldolase (217) and pyruvate kinase (218) in enabling this capacity. Moreover, the persistence defect observed in an *M. tuberculosis* mutant lacking both glucokinase homologues—in other words, functionally depleted of glycolytic potential—supports the conclusion that both carbohydrates and fatty acids are required for long-term survival *in vivo* (219). More recent research has extended the capacity for cocatabolism to nitrogen sources *in vitro* (215) and in an intracellular model (220), strongly suggesting the generalizability of this principle to mycobacterial metabolism. In this context, recent evidence of the power of techniques such as cryo-electron microscopy in revealing cytoplasmic organization and the presence of microcompartments in different prokaryotes (221, 222) suggests the intriguing possibility of investigating the potential that cocatabolism is spatially regulated.

At least one codicil to the inferred absence of catabolite repression in *M. tuberculosis* might exist in the observation that cholesterol-dependent growth inhibition cannot be alleviated by the provision of glucose as an alternative carbon source (223). This implies that preferential utilization of cholesterol—predicted to be a feature of *M. tuberculosis* pathogenicity (224)—might represent a critical constraint to mycobacterial metabolic flexibility (223). In some ways, this phenomenon is reminiscent of the very well-described differential (often poor) growth of clinical *M. tuberculosis* isolates in specialist laboratory medium following isolation from patient samples, including sputum (54, 225). In turn, it highlights the fact that, while *M. tuberculosis* H37Rv is the workhorse of experimental mycobacteriology, this strain has become adapted to growth in laboratory media through decades of serial passage *in vitro* (152).

The concept that growth arrest represents a key stress response in *M. tuberculosis* and, importantly, might be triggered even when the organism retains the metabolic capacity to grow (65) is also central to understanding mycobacterial pathogenicity. This preservation strategy appears to be enabled, at least partially, by the capacity for "anticipation" of future events, an example of which was provided by the observation that *M. tuberculosis* exposed to hypoxia remodels

its own cell envelope to generate building blocks for later reentry into the cell cycle (226). Notably, this capacity is enabled by the catabolism of trehalose mycolates, from which the bacillus generates pentose phosphate intermediates that are incorporated into peptidoglycan biosynthesis much later, when environmental conditions improve, that is, contingent on re-aeration at an indeterminate future time. This illustrates an inherent capacity for preservation that might be hard-wired through long-term adaptation to predictable host environments and stimuli (227). Reinforcing this idea, very recent work has demonstrated that multiple stresses induce expression of the small regulatory RNA, MrsI, which functions to preserve intrabacillary iron reserves, perhaps in anticipation of iron deprivation in the infected macrophage (228). Although not involving metabolic anticipation *per se*, the observation that utilization of nitrate as the sole nitrogen source requires a functional proteasome (229) is analogous in demonstrating the very tight connection between metabolic pathway utilization and regulation of cellular macromolecular synthesis and recycling, perhaps offering insights into the organism's intrinsic responses to *in vivo* nutrient availabilities.

Respiration

Like all mycobacteria, *M. tuberculosis* is an obligate aerobe. Therefore, survival in growth-inhibitory hypoxic environments demands sufficient energy generation for maintenance functions, while aerobic conditions enable full metabolic activity for bacillary replication (230). From comparative genomics of different mycobacteria, it is apparent that, whereas major biosynthetic pathways are reasonably conserved, occurring within core orthologous clusters, the respective complements of genes involved in energy metabolism are more diverse. This observation is consistent with the adaptation of individual species to specific environmental and host niches and, perhaps, replication rates (21, 22).

M. tuberculosis possesses multiple branched pathways for electron transfer from a variety of low-potential reductants to oxygen during aerobic growth (230) and to alternative electron acceptors under hypoxic conditions (231). The potential flexibility suggested by the expanded complement of primary dehydrogenases and oxidoreductases (232)—the function and regulation of which remain poorly understood (230)—is, however, tempered by the observation that aerobic respiration in *M. tuberculosis* appears to depend on a single lipoquinone, menaquinone, and two terminal respiratory oxidases, the aa_3-type cytochrome *c* oxidase and the cytochrome *bd* menaquinol oxidase (231). Moreover, evidence suggests the obligatory coupling of ATP generation to the electron transport chain and the membrane-bound F_1F_0-ATP synthase, irrespective of the oxygen concentration or the proton motive force (230). And, whereas some bacteria are able to utilize ATP to energize the cytomembrane via coupling of ATP hydrolysis to proton pumping, the *M. tuberculosis* F_1F_0 ATP synthase lacks ATP hydrolysis activity (233). These limitations are unusual for mycobacteria and have been exploited in the development of the diarylquinoline bedaquiline (Sirturo), the first new FDA-approved anti-TB drug in over 40 years, whose initial use has been restricted to multidrug-resistant TB pending the results of ongoing phase 2 and phase 3 trials (234, 235).

As noted elsewhere (230), the *M. tuberculosis* genome encodes expanded complements of both electron donors and electron acceptors whose roles in pathogenicity are largely unexplored. It is perhaps no exaggeration to suggest that, of all the core metabolic functions, respiration and energy metabolism are those which have been most prone to very selective investigation given the practical difficulties associated with manipulating the bacillus under variable conditions of hypoxia and anoxia, the default reliance on standard, glucose-based growth media *in vitro*, and the general use of mouse models which recapitulate only certain aspects of TB pathology (236). A salient example is provided by the likely contribution of the assimilatory/respiratory nitrate reductase to bacillary survival under various stresses, a notion supported by strong functional and comparative genomics evidence that the acquisition of molybdopterin biosynthetic and salvage genes (molybdenum cofactor is essential for multiple enzymes in carbon, sulfur, and nitrogen metabolism, including nitrate reductase [145, 237]) differentiates the pathogenic *M. tuberculosis* from precursor (nonpathogenic) mycobacteria (22).

The predicted capacity of infecting bacilli to subsist under different conditions and in various microenvironments offering very different substrates for energy generation argues for further research into the consequences of disrupted mycobacterial bioenergetics for host infection outcomes (238, 239). Certainly, early clinical reports of the benefits of bedaquiline for multidrug-resistant and extensively drug-resistant TB are very encouraging (234, 235). Moreover, in addition to highlighting the possible benefits of targeting components of the oxidative phosphorylation machinery for new TB drug development, knowledge about the precise mechanism of action of this compound has proved very instructive. By binding the *atpE*-encoded F_1F_0 oligomeric c-ring subunits, bedaquiline effectively functions as a nonclassic uncoupler: exposure of bacilli to the drug stimulates respiration owing to the electroneutral uncoupling of proton transport and ATP synthesis (240, 241). This is important because it suggests the potential to target the proton motive force, a property that appears to be shared by known antimycobacterial compounds (242), as well as verapamil (243). However, caution is required given recent observations that inhibition of energy metabolism might have unintended consequences in some combinations (244).

Cell Wall Homeostasis

Consistent with its dominant role in the biology of *M. tuberculosis*, the cell wall has been the subject of intensive study for decades (Table 1): as a primary site of the host-pathogen interface (245–247), as a target of—and impermeability barrier to—many current and experimental antimycobacterial drugs (248–251), and as a major determinant of the robustness and durability of the bacillus throughout its life cycle (252). The molecular composition and arrangement of the mycobacterial cell envelope, classified as Gram positive but comprising an outer membrane and a periplasmic space, is quite well understood and broadly comprises three distinct layers (251, 253, 254). Exterior to the plasma membrane, a peptidoglycan layer links covalently to a mycolyl-arabinogalactan layer which is decorated with noncovalently linked lipids and lipoglycans such as the phosphatidylinositol mannosides, phthiocerol dimycocerosates, phenolic glycolipids, and lipoarabinomannan, which have been investigated for their roles in mycobacterial pathogenicity (255) and as diagnostic markers (256, 257). This outer membrane or "mycomembrane" is, in turn, surrounded by a loosely attached capsular layer predominantly comprising polysaccharides and proteins (95, 253).

Less well understood is how the construction, maintenance, and remodeling of the cell envelope are regulated and accomplished in concert with the mycobacterial cell cycle,

particularly *in vivo* in different host microenvironments (258, 259). Here, an emerging theme is the application of advanced, live-cell and time-lapse imaging in combination with elegant fluorescent bioreporters, in most cases fluorophore-linked analogs of natural cell wall precursors which are incorporated into the cell wall without significant impairment of mycobacterial growth (260–265). Moreover, advances in mass spectrometry have enabled the cataloguing of cell wall lipids, fatty acids, and proteins with ever greater resolution (266), including under different growth conditions (267), in response to drug treatment (268), and in drug resistance and drug tolerance (94, 269).

Accessing Nutrients from the Host

The number of M. *tuberculosis* organisms required to initiate successful host infection remains unknown. Though deep sequencing suggests the possibility for transmission of multiple genotypes (270), most historical estimates are that a single bacillus might be adequate (271). This prediction has been reinforced most convincingly in NHP models in which the elegant use of genetic "barcodes" has shown that individual lesions can arise from a single seeding M. *tuberculosis* genotype (169, 170). Whatever the number, proliferation depends on the ability of the invading pathogen to assimilate host nutrients for energy consumption and macromolecular synthesis. Precisely which host-derived nutrients M. *tuberculosis* accesses, where this occurs, and how are subjects of ongoing investigations (41, 272–277). A core paradox in M. *tuberculosis* research is that, whereas the promiscuity in the nutrients and cofactors potentially assimilated from the host seems to complement M. *tuberculosis*'s autarkic metabolism (41), the same promiscuity is difficult to reconcile with the inferred impermeability of the mycobacterial cell wall. This apparent incongruity has driven the search for potential transport and porin proteins in the mycobacterial outer membrane (278, 279).

An intriguing mechanism for nutrient acquisition was proposed in a series of studies characterizing the tuberculosis necrotizing toxin (TNT), an enzyme which intracellular M. *tuberculosis* utilizes to kill the host macrophage and gain access to cytoplasmic nutrients (280–283). Synthesizing multiple lines of experimental evidence, the prevailing model holds that bacilli contained within the macrophage phagolysosome deploy CpnT, a bifunctional protein comprising an N-terminal pore-forming domain and C-terminal NAD^+ glycohydrolase (TNT), via the mycobacterial ESX-1 type VII secretion system (284) to effect macrophage death. Notably, release of TNT into the macrophage cytoplasm (the glycohydrolase is pH sensitive, and so, inactive in the acidified phagolysosome) is dependent on the ability of the other ESX-1 substrate, EsxB (also known as ESAT-6/CFP-10), to puncture the phagolysosomal membrane, therefore requiring the neat coordination of mycobacterial effectors to ensure that intraphagosomal bacilli (which, from the inserted CpnT N-terminal domain, now possess the membrane pores necessary for maximal nutrient uptake) are poised to take advantage of the inactivated host cell. In an intriguing twist, parallel work has suggested that, contrary to the connotations of its explosive moniker, the mycobacterial toxin might deliver a "blast without power" (285), resulting in necrotic cell death that might deliberately limit immunogenicity. Given the implied importance of this mechanism to the ability of M. *tuberculosis* to exploit the host macrophage, perhaps while minimizing host immune detection, it would be interesting to know whether the enhanced growth in dead macrophages described recently (172) also depends on functional TNT and, moreover, whether loss of TNT impacts pathogenicity *in vivo*.

MYCOBACTERIAL METABOLISM AND NEW TB DRUG DISCOVERY

We noted previously (286) that investigations of core metabolic processes in M. *tuberculosis* are generally framed within the context of drug discovery—whether looking specifically for new active molecules or vulnerable targets or attempting to elucidate mechanisms of action or to reveal reasons for compound failure or bypass. Examining the current TB drug pipeline, it is evident that significant progress has been made in expanding not only the number of different mechanistic classes represented in the most promising drug-target pairs, but also in validating new high-value targets for future discovery programs (134, 287). Nevertheless, the challenges for new TB drug discovery remain significant. Compound permeation (288), xenobiotic metabolism (289), and efflux (290–292) are three major innate mechanisms of drug resistance, all of which are poorly understood and correspondingly difficult to demonstrate or quantify. Impermeability of the complex mycobacterial cell envelope is often cited as a major confounder to new TB drug development. Though intuitively attractive, the evidence to support this conclusion remains scarce. In contrast, the formidable capacity of M. *tuberculosis* for biotransformation of xenobiotics is much better established (289) and, with the mostly theoretical contribution of efflux (293), might represent the major innate barrier to antibiotic activity (294).

The increasing appreciation of the organism's capacity for biotransformation has exposed the lack of rapid, medium-throughput strategies to measure metabolism of xenobiotics (289). Similarly, despite the frequency with which the inactivity of many compounds against M. *tuberculosis* is assumed to be a function of poor or failed permeation, proving so remains enormously difficult. The inability to determine quickly and reliably whether a compound—and its analogs in a structure-activity relationship analysis—has lost activity owing to differential (lost) target engagement, inactivation via metabolic transformation, extrusion by efflux, or failure to penetrate severely undermines medicinal chemistry efforts. Without complete information about the fate of the applied molecule, efforts to optimize physicochemical properties toward a drug-like lead are based almost entirely on experience, intuition, and empiricism (i.e., that which works is clearly evident in the inhibition of bacillary growth in a specific assay, usually an MIC determination *in vitro* [295]). The scarcity of techniques to enable rapid determination of the intrabacillary accumulation and metabolism of compounds, perhaps even independent of inhibitory activity, therefore presents a significant obstacle to rational drug development and suggests that strategies employed in other model systems (296, 297) might be usefully adapted to this end.

Recent work elucidating the impact of cell wall antibiotics on membrane fluidity and biogenesis (298, 299), as well as the observation that many compounds with antimycobacterial activity function as protonophores (242, 243)—in some cases, in addition to interacting directly with their cellular target activity (300)—and so operate at the cytoplasmic membrane (the site of many so-called promiscuous targets, including DprE1, QcrB, and MmpL3 [250, 301]), reinforces the sense that outer membrane impermeability might not present the major obstacle to drug efficacy. This impression will, however, require confirmation via the use of advanced metabolomics approaches to elucidate the

(differential) penetration of different compounds into the mycobacterial cytoplasm (302).

Efflux, too, presents a potentially sizeable but largely undefined obstacle. The M. *tuberculosis* genome encodes more than 40 predicted efflux pumps, only a handful of which have been implicated in innate drug resistance (232, 292, 303, 304). Recent evidence that the antihypertensive verapamil does not function as an efflux pump inhibitor but instead disrupts membrane energetics in M. *tuberculosis* (243) reinforces the perils inherent in making inferences from phenotypic observations in the absence of compelling mechanistic insight. Even ostensibly clear-cut drug-target interactions can have surprising locations (305), while the mechanism of resistance does not always correlate with the mechanism of action (306, 307).

From a metabolic perspective, incomplete understanding of M. *tuberculosis* metabolism in its human host can have very practical implications for TB drug discovery. For example, two separate studies elucidating the *guaB2*-encoded mycobacterial inosine monophosphate dehydrogenase (IMPDH) as the target of related compound series took very different views of the potential of their respective molecules for advancement as candidate drugs and, by implication, the attractiveness of *de novo* purine biosynthesis as an anti-TB target. The first (149) propounded IMPDH as "vulnerable" and, consequently, worth pursuing. In contrast, challenging pharmacokinetics, coupled with the observation that concentrations of guanine in resected lung tissue from TB patients achieve levels in excess of those required to allow bypass of IMPDH through salvage, prompted the authors of the second study to conclude the opposite. They argued that IMPDH might be "essential" but is "not vulnerable" (107), thus consigning GuaB2 and its chemical inhibitors to red flag status for new TB drug development, at least in their estimation (270). These conflicting views reinforce the fact that, even where a molecular catalogue of individual tissues, lesions, or microcompartments is available, it might not necessarily enable an unequivocal prediction of what the bacillus is able to access and assimilate from its surroundings. That is, the *availability* of any nutrient must be distinguished from its *accessibility* to the infecting M. *tuberculosis* population. Of course, when prioritizing resources for new drug candidates, it is prudent to assume that all nutrients, if present, are (potentially) accessible. The risk that salvage might overcome antibiotic-mediated nutrient starvation therefore ensures that the bar is set very high for new TB drug development (308).

Harnessing Metabolism to Potentiate Drug Activity

Earlier sections highlighted some of the ways in which different intrinsic metabolic functions contribute to the innate resistance of M. *tuberculosis* to antibiotics, reinforcing a theme which has been discussed extensively elsewhere (65, 309, 310). Increasingly, however, knowledge of metabolic function is being exploited not only to circumvent innate resistance mechanisms, but also to understand the metabolic functions which might subvert antibiotic efficacy so as to identify novel countermeasures (64, 311, 312). Recent work highlighting the contribution of altered propionate metabolism to the emergence of drug resistance in M. *tuberculosis* (313) provides a very important example of the potential for metabolic deficiency to confer a tolerant phenotype that enables the acquisition and fixation of genetic drug resistance. Moreover, the growing number of studies demonstrating altered metabolic function in drug-resistant organisms, including M. *tuberculosis* (269, 314), suggests that this phenomenon might even be more widespread.

A corollary to the above is that metabolism might also be harnessed to improve drug action. For example, the inferred mechanism of action of the repurposed agent, clofazimine, which triggers a redox cycling mechanism that generates toxic reactive oxygen species (315), reinforces the notion that bacilli might be trapped in a futile and ultimately destructive metabolism. Notably, by combining clofazimine with other compounds targeting components of the mycobacterial electron transport chain, Steyn and colleagues demonstrated the potential to enhance killing of M. *tuberculosis* in an intracellular model (43). In an analogous example of this approach, inactivation of the essential maltosyltransferase, GlgE, was shown to trigger an amplification loop which resulted in rapid mycobacterial death owing to self-poisoning by maltose 1-phosphate accumulation (316). Though the precise mechanism differs in each case, these observations suggest the potential for combination regimens based on drug targets and/or mechanisms of action which incorporate inhibition of growth (target/drug A) and prevention of ordered metabolic shutdown (target/drug B); that is, combinations designed to prevent metabolic escape. This strategy is distinct from both metabolic bypass (in which an alternative, perhaps less efficient or autonomous, mechanism exists to enable generation of the same essential metabolite, e.g., via scavenging from the host) and metabolic buffering (in which partially redundant mechanisms enable the organism to maintain homeostasis). Instead, it entails eliminating the organism's inherent capacity for surviving through replicative and metabolic quiescence and so might add a further element to the three models for antimycobacterial drug synergy proposed previously (65). A recent report describing the identification of chemical inhibitors of the stringent response enzyme, Rel_{Mtb}, a (p)ppGpp synthetase, provides a cogent demonstration of the potential of this therapeutic approach (317).

To some extent, this strategy overlaps with the idea, summarized in a recent review, of developing "metabolism-targeted adjuvant therapies" to prevent antibiotic tolerance (311). In support of that proposal, the authors cite the targeted disruption of regulatory mechanisms, for example, through the identification of artemisinin analogs as inhibitors of the mycobacterial DosRST system (318), an ~50-gene regulon that has been implicated in antibiotic tolerance in infection models *in vitro* and *in vivo* (319). In addition, they provide several illustrations of the potential to achieve or enhance antimycobacterial activity by interfering with bacillary metabolism. These include the direct inhibition of specific "tolerance/persistence" effectors such as isocitrate lyase (320) or nicotinamide adenine dinucleotide synthetase, NadE (321). Of particular interest, though, is the proposition that stimulating bacillary respiration and energy metabolism, for example, by providing a glycolytic substrate together with an alternative terminal electron acceptor such as fumarate (322), can increase efficacy of known antibacterial agents against apparently recalcitrant subpopulations. This concept not only reinforces the impact of metabolic state on antibiotic efficacy (an obvious conclusion), but it also suggests the potential to manipulate bacillary metabolism artificially through the deliberate provision of nutrients which might drive a defined metabolic program that ensures susceptibility to the applied agent. That is, it opens the door for a combination comprising an (inhibitory) antibiotic and a (stimulatory) metabolite.

FUTURE PERSPECTIVES

This review has highlighted the complications inherent in working with an infectious pathogen whose preferred

anatomical target (i.e., the human lung) is difficult to access. The result is that most studies, rather than revealing mycobacterial metabolic function in the context of TB disease, have tended to elucidate the metabolic capacity of the bacillus, either *in vitro* in different growth media and under various stresses thought to mimic the intrahost environment or *in vivo* in experimental models of infection (37). Those attempts, much fewer in number, to investigate M. *tuberculosis* pathogenicity (including metabolism) *in situ* or closer to the site of disease have predominantly relied on bacilli captured in sputum or bronchoalveolar lavage fluid, lymph node or other biopsies, or lung resections of treated patients. One consequence is that the potential distinction between primary and post-primary TB as separate disease entities (and therefore likely invoking different mycobacterial metabolic functions) has been obscured (69, 79).

As noted above, determining the metabolic and physiological states adopted by the tubercle bacillus in the infected human host represents the ultimate goal and, though still a significant challenge, seems increasingly attainable with the development of new technologies. Recent advances such as the ability to obtain transcriptional data from very-low-abundance RNA (258, 323) and at the single-cell level (324) promise to provide much greater insight into the exchange of stimuli and responses that occurs between M. *tuberculosis* and its host cell during intracellular infection and which shapes the metabolic adaptation of the invading bacilli to the available nutrients in this and other microenvironments. Exciting advances in other bacterial models, including the combined application of RNA profiling with stable isotope labelling (325, 326), reinforce the sense that elucidating the growth rates—and metabolic states—of even slow-growing pathogens such as M. *tuberculosis* will become feasible (327).

A recent systems pharmacology study (198) suggests another approach to this problem, namely, the potential to combine empirical data derived from *in vitro* and *in vivo* experiments—ideally including clinical samples (197, 328)—to generate a complex mathematical model that simulates disease progression within a single locus. In that case, a shift was made from the M. *tuberculosis*-infected macrophage as the "unit of infection" (155) to the granuloma in modeling the efficacies of different fluoroquinolone antibiotics as anti-TB agents. Their approach enabled a compelling demonstration of the capacity to incorporate both host and bacillary factors in building the model and, at the same time, raised the possibility that this strategy could be adapted to (or informed by) metabolomic, proteomic, and lipidomic data. Notably, the study also highlighted the emergent properties of a complex system comprising infecting bacilli and different types of host immune cells (the variety was necessarily limited to a handful of T cell subsets and macrophage phenotypes owing to the demands of computational modeling). Again, this suggests the potential to enable key insights into the dominant metabolic pathways active in different lesions, how these might influence infection trajectories and pathological outcomes, and how they might be exploited for improved chemotherapy.

We thank Valerie Mizrahi and Richard Haynes for critical review of the manuscript and members of the MMRU for many discussions of key ideas. We apologize to those authors whose work was not cited here owing to space limitations.

Research on different aspects of mycobacterial metabolism in the Molecular Mycobacteriology Research Unit is enabled by financial support from the Department of Science and Technology (DST) and National Research Foundation (NRF) of South Africa, the South African Medical Research Council, the University of Cape Town, the U.S. National Institute of Child Health and Human Development (NICHD) U01HD085531-02, and the U.S. National Institute of Allergy and Infectious Diseases (NIAID) R21AI115993. We also gratefully acknowledge the support of the Research Council of Norway (INTPART, AMR-PART) for work on antimicrobial resistance in M. tuberculosis.

Protein Export into and across the Atypical Diderm Cell Envelope of Mycobacteria

VINCENT J. C. VAN WINDEN, EDITH N. G. HOUBEN AND MIRIAM BRAUNSTEIN

68

INTRODUCTION

Mycobacteria are *Actinobacteria*, which is a phylum of high-GC Gram-positive bacteria. Among the wide range of *Mycobacterium* spp. are several important pathogens. Most notable of these is *Mycobacterium tuberculosis*, the causative agent of tuberculosis (TB). Although the number of TB cases and deaths show a declining trend in the past decade, the World Health Organization recently warned that "current actions and investments in research are falling far short" (http://www.who.int/mediacentre/news/releases/2016/tuberculosis-investments-short/en/). Over 1.3 million deaths and up to 10.0 million new infections were attributed to *M. tuberculosis* in 2017, which makes *M. tuberculosis* the most deadly infectious agent in the world, surpassing HIV and the malaria parasite (1). One issue facing efforts to control TB is that the live attenuated bacillus Calmette-Guérin (BCG) vaccine strain is not able to provide lifelong protection against *M. tuberculosis* (2). Another problem is the increased incidence of infections caused by multidrug-resistant *M. tuberculosis* strains. Consequently, major research efforts focus on understanding *M. tuberculosis* pathogenesis and physiology to advance the development of new anti-TB vaccines and antibiotics.

M. tuberculosis is a member of the order *Corynebacteriales*, which is an order that is characterized by its resistance to many classic antibiotics and its ability to withstand highly stressful environments, such as oxidative stress, desiccants, and common disinfectants (3, 4). These features can be explained by the presence of a unique cell envelope, which differs from that of both typical Gram-positive (low-GC), bacteria also called *Firmicutes*, and Gram-negative bacteria. While members of the *Corynebacteriales* have a traditional inner membrane, their peptidoglycan layer is connected to an additional polymer of arabinose and galactose (i.e., an arabinogalactan layer), which in turn is linked to mycolic acids, unusually long fatty acids that can contain up to 90 carbon atoms (Fig. 1) (5–8). It is now widely accepted that these mycolic acids are the main constituents of a second (outer) membrane, which also contains noncovalently linked (free) lipids such as phthiocerol dimycocerosates and phenolic glycolipids. Finally, mycobacteria have a more loosely attached capsular layer, which mainly consists of polysaccharides and proteins (9). Although the presence of an outer membrane in mycobacteria was initially proposed in 1982 (10), its existence was not confirmed until 2008 by electron microscopy (EM) imaging (7, 11). Thus, although the order *Corynebacteriales* belongs to the group of high-GC Gram-positive bacteria, their double-membrane, or diderm, cell envelope is physically more similar to the inner and outer membrane-containing cell envelope of Gram-negative bacteria, because EM images of the two reveal a resemblance. However, despite the resemblance, the mycolic acid outer membrane of *Corynebacteriales* differs dramatically from the Gram-negative outer membrane, the latter being composed of phospholipids and lipopolysaccharides.

The firm bond of the long mycolic acids to the underlying arabinogalactan and peptidoglycan structures results in very low fluidity of the outer membrane, which contributes to the high impermeability of the *Corynebacteriales* cell envelope (5). Although this characteristic provides excellent protection from extreme environmental conditions, it also requires *Corynebacteriales* species to have pathways to import and export molecules. In line with the notion that the mycolic acid-containing membrane is functionally comparable to the outer membrane of Gram-negative bacteria, both mycobacteria and corynebacteria possess outer membrane porins for importing hydrophilic nutrients through the outer membrane (12–14). At the same time, the unique cell envelope of *Corynebacteriales* necessitates the existence of special pathways for secreting proteins into the environment.

In this article, we will review the different pathways mycobacteria use to export proteins from the cytoplasm into the cell envelope or beyond into the extracellular environment (i.e., to secrete them across the outer membrane) (Fig. 1). Four types of protein export pathways are currently known in mycobacteria: two highly conserved systems that exist across Gram-positive and Gram-negative bacteria (the Sec and Tat pathways) and two specialized systems that exist in mycobacteria, corynebacteria, and a subset of low-GC Gram-positive bacteria (the SecA2 and type VII secretion [T7S] pathways). The Sec, Tat, and SecA2 pathways serve to transport proteins across the inner membrane, and whether an exported protein remains in the putative periplasmic space between the two membranes or reaches the capsule or extracellular environment is determined by currently unknown secondary mechanisms. T7S pathways differ in that, so far, periplasmic localization of substrates has not been observed, suggesting that this pathway may secrete proteins beyond the outer membrane. However, here too,

doi:10.1128/microbiolspec.GPP3-0043-2018

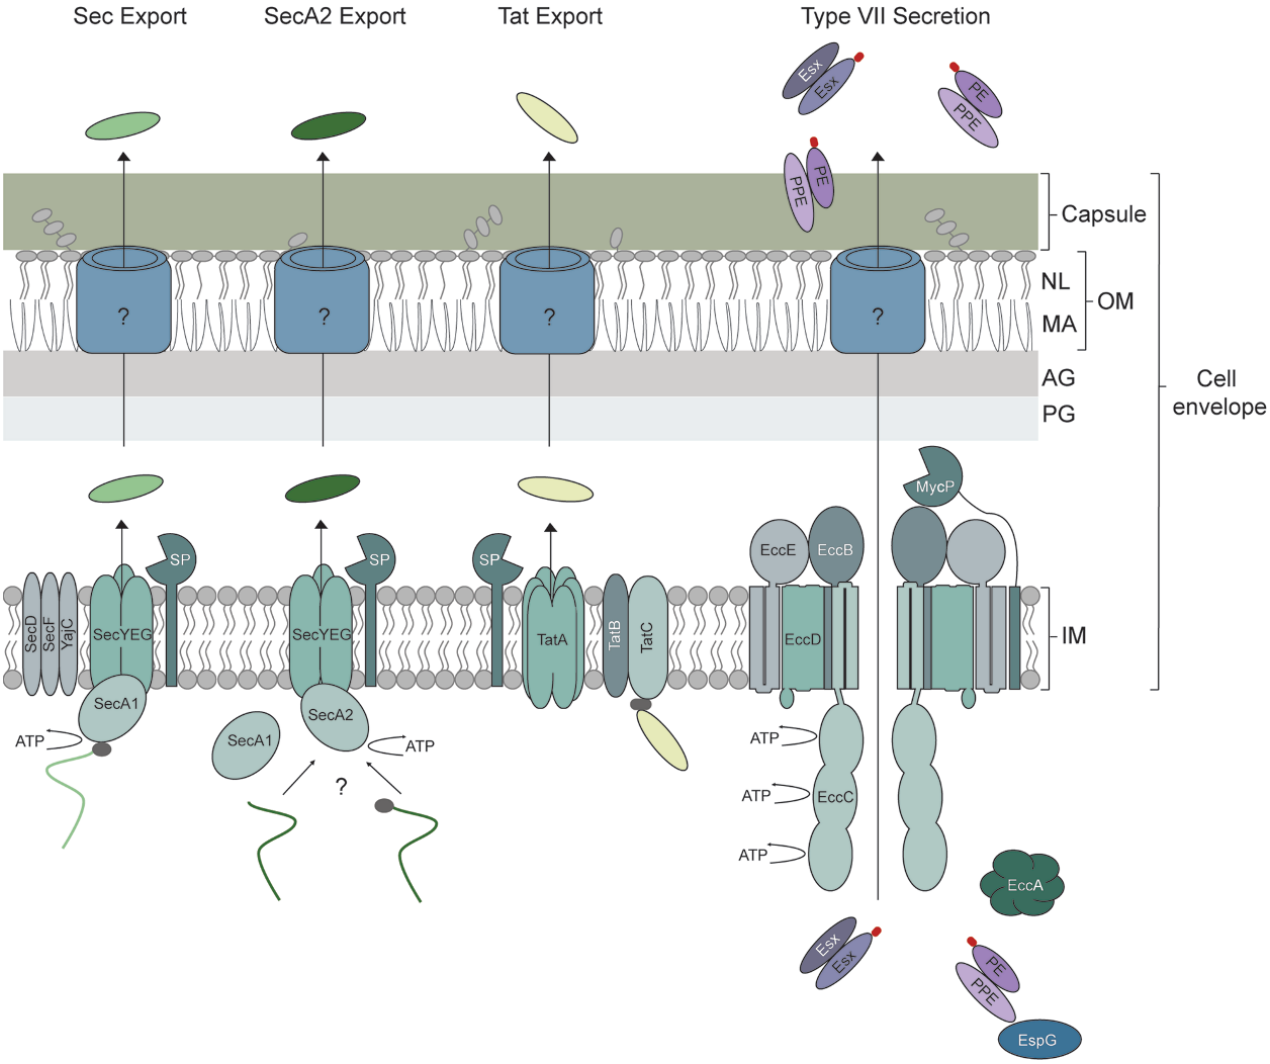

FIGURE 1 Model of the mycobacterial cell envelope and export systems. Although the mycobacterial cell envelope contains a traditional cytosolic (inner) membrane, the peptidoglycan layer is covalently linked to an arabinogalactan layer consisting of arabinose and galactose, which in turn is covalently linked to mycolic acids. These unusually long fatty acids (up to 90 carbon atoms) are one of the main components of the outer membrane, which also contains noncovalently bound (free) lipids. The final layer of the cell envelope is the capsule, mainly consisting of polysaccharides and proteins. The cell envelope is highly impermeable and unique to other Gram-positive bacteria. To export proteins into and across the cell envelope, mycobacteria have four systems, Sec, SecA2, Tat, and type VII secretion (T7S). The Sec pathway exports unfolded proteins across the inner membrane, and the substrates bind to an ATPase, SecA1, which targets the substrates to the translocation channel consisting of SecYEG and provides energy for translocation. The additional membrane components SecD, SecF, and YajC increase the efficiency of export. Upon translocation across the inner membrane, the N-terminal signal peptide (depicted in gray) is removed by a signal peptidase (SP). Less is known about the SecA2 pathway. Substrates are dependent on the ATPase SecA2; however, studies show that they also utilize the SecYEG channel and possibly SecA1, as well. The list of SecA2-dependent exported proteins includes examples with and without a signal peptide. The third export system, the Tat pathway, exports folded proteins. The Tat substrates, containing an N-terminal signal peptide, with a pair of arginine residues, is targeted to the membrane components TatBC, which then recruit homo-oligomers of TatA for subsequent transportation across the membrane. Similar to Sec, the signal peptide is removed by a signal peptidase. The T7S system consists of five conserved membrane components, of which EccBCDE form the secretion complex. EccC is the ATPase, providing the required energy for the secretion process. Although the mycosin protease (MycP) is not an integral component of the secretion complex, it associates with the complex and is essential for successful secretion. The substrates (Esx and PE-PPE) are secreted as heterodimers and are targeted to the secretion complex by a conserved secretion signal that includes a YxxxD/E motif (depicted in red), whereas the cytosolic chaperone EspG is required for directing the PE-PPE pairs to their specific T7S. The role of the second conserved cytosolic component, EccA, remains uncertain. It is currently unknown how Sec, SecA2, Tat, and T7S substrates are secreted across the outer membrane into the capsular layer or culture supernatant. IM, inner membrane; PG, peptidoglycan layer; AG, arabinogalactan layer; MA, mycolic acids; NL, noncovalently bound lipids; OM, outer membrane.

the mechanism for crossing the outer membrane remains a mystery.

THE MYCOBACTERIAL SEC PATHWAY

Bacteria export a large proportion of their proteome to the cell envelope or extracellular environment (~20 to 35%) (15, 16). In all bacteria, the majority of this protein export is carried out by the general Sec pathway (16). Mycobacteria have ~1,000 predicted Sec-exported proteins (this number includes proteins exported across as well as into the inner membrane), many of which have been experimentally demonstrated to be exported (17, 18). Among the many proteins exported by the Sec pathway are proteins with essential functions in the cell envelope (i.e., nutrient acquisition, cell wall biogenesis); consequently, in all bacteria the Sec pathway is essential for viability (19). Further, there are Sec-exported proteins with critical roles in host-pathogen interactions, making the Sec pathway critical for bacterial pathogenesis as well (17, 18, 20). The Sec pathway is highly conserved in bacteria, and most of our understanding of this pathway comes from studies of the *Escherichia coli* system (for recent reviews of the Sec system see references 21 and 22). Mycobacteria possess conserved orthologues of all the critical Sec pathway components, and as expected, these Sec orthologues are either proven or predicted by saturating mutagenesis transposon-site hybridization or transposon insertion sequencing studies to be essential (23). While only a few mycobacterial Sec proteins have been directly studied, the results so far indicate that the Sec pathway of mycobacteria functions similarly to the Sec pathways of other bacteria.

The Sec pathway transports proteins across the inner membrane. Sec-exported proteins can remain in the cell envelope or through subsequent mechanisms transit across the additional cell envelope layers and be fully secreted. Sec-exported proteins travel across the inner membrane through a channel composed of the integral membrane proteins SecY, SecE, and SecG (Fig. 1), in which SecY forms the central core (24). Sec-exported proteins are in an unfolded state during their translocation through the channel (25). SecY and SecE are sufficient to achieve translocation, while SecG improves the efficiency of export (26–28). There are also additional membrane components that improve Sec export efficiency: SecD, SecF, and YajC (29). The SecA ATPase provides energy for protein translocation (30, 31). SecA binds to Sec-exported proteins in the cytoplasm, targets them to SecYEG in the membrane, and harnesses energy from repeated rounds of ATP binding and hydrolysis to drive stepwise export of unfolded proteins through the SecYEG channel in the inner membrane (32). For mycobacteria, the second step a Sec-exported protein may take to cross the outer membrane remains completely unknown.

While the majority of bacteria have a single essential SecA, mycobacteria and a subset of other Gram-positive bacteria have two SecA proteins (named SecA1 and SecA2) (33–35). As demonstrated in mycobacteria, the two SecAs have unique functions. SecA1 functions in the general Sec pathway, as described above. SecA2 is a specialized SecA and is discussed later in the article. Consistent with SecA1 being the SecA of the essential general Sec pathway, SecA1 of *Mycobacterium smegmatis* and *M. tuberculosis* is essential for viability (33, 36; L. Rank and M. Braunstein, unpublished). SecA1 exports proteins with Sec signal peptides (introduced below) (36) and has ATPase activity, as expected for it being the canonical SecA (37).

Sec export is a posttranslational process. Following protein synthesis, Sec-exported proteins exist in the cytoplasm as unfolded preproteins with N-terminal signal peptides that are ~25 to 30 amino acids long (38). The Sec signal peptide is composed of a positively charged N-terminus, a hydrophobic central domain, and an uncharged polar C-terminus containing a signal peptidase cleavage site (39). For lipoproteins exported by the Sec pathway, there is also a lipobox motif at the C-terminus of the signal peptide with an invariant cysteine that serves as the site of lipid attachment and anchoring of the protein to the cell envelope postexport (40). In association with export, the signal peptide is removed from the preprotein by one of two signal peptidases (LepB for the majority of Sec preproteins and LspA for lipoprotein preproteins specifically), which serves to produce the cleaved, mature protein species on the extracytoplasmic side of the membrane (39). As is the case in all other bacteria studied to date, LepB of *M. tuberculosis* is essential (41). On the other hand, LspA of *M. tuberculosis* is not essential, although it is important for pathogenesis (42, 43). The dispensability of LspA is also the case for Gram-positive *Firmicutes*, while in Gram-negative bacteria, LspA is essential (44).

The general principles of signal peptides established for other bacteria also apply to mycobacterial proteins exported by the Sec pathway, as shown by *in silico* prediction programs for Sec signal peptides being good predictors of *M. tuberculosis*-exported proteins (18) and by comparing *in silico* predictions to experimentally determined N-terminal signal peptides of *M. tuberculosis* (45).

In addition to possessing a signal peptide, another required feature of Sec-exported proteins is that they must be unfolded to be exported (25, 46, 47). Cytosolic chaperones can help preproteins maintain an unfolded and translocation-competent state, and the SecA-SecYEG translocase may also play a role (48, 49). Gram-negative bacteria have a SecB chaperone that maintains a subset of preproteins in an unfolded state compatible with transport through SecYEG (49, 50). SecB also has a role in delivering preproteins to SecA (51). However, SecB is not present in Gram-positive bacteria. In *M. tuberculosis*, there is a SecB-like protein (Rv1957); however, Rv1957 is not conserved across mycobacteria, and the available data indicate that Rv1957 is a chaperone for the HigBA toxin-antitoxin system and not a protein export chaperone (52).

In addition to the above described posttranslational export of proteins across the inner membrane, the Sec pathway also participates in cotranslational export of transmembrane domain (TMD)-containing integral membrane proteins into the membrane (53). With membrane proteins, once the TMD emerges from the ribosome, the nascent polypeptide is recognized by the signal recognition particle (SRP), (comprising the Ffh protein and the 4.5S RNA), which then delivers the ribosome-mRNA-nascent protein complex to the SRP receptor FtsY (54). The SRP receptor in turn delivers the nascent protein to the SecYEG channel for translocation. For integral membrane proteins, there is a lateral gate in SecY that allows TMDs to transfer out of the channel and integrate into the inner membrane through a process that is facilitated by the integral membrane YidC protein (55). Specifically, for membrane proteins with large periplasmic domains, SecA may assist in exporting these domains across the membrane (56). Both Ffh and FtsY are GTPases, and GTP hydrolysis is required for membrane protein delivery (57). Using purified proteins, *M. tuberculosis* Ffh and FtsY are shown to possess functions of their *E. coli* counterparts; they possess GTPase activity and interact with one another and with the 4.5S RNA of *M. tuberculosis* (58, 59). Working with a conditional *yidC* depletion strain of *M. tuberculosis*, YidC was demonstrated to be required for

growth and membrane protein localization, as expected for a YidC ortholog (60). However, in the fast-growing *M. smegmatis*, *yidC* depletion has no effect on growth (60).

THE MYCOBACTERIAL Tat PATHWAY

The twin-arginine translocase (Tat) pathway is another conserved export system of bacteria. Again, our understanding of the Tat pathway comes largely from studies of the *E. coli* system (for a recent review see reference 61). Similar to the Sec pathway, after transport from the cytoplasm, Tat-exported proteins can either remain in the cell envelope or be fully secreted via a subsequent mechanism. Here too, the pathway for crossing the outer membrane remains a mystery. Proteins exported by the Tat pathway are synthesized as preproteins with cleavable N-terminal signal peptides. However, as the name of the pathway reflects, Tat signal peptides are distinguished from Sec signal peptides by a Tat motif containing a pair of twin arginine residues (see below) (62). Compared to the Sec pathway, fewer total proteins are exported by the Tat pathway. Some *Streptomyces* strains are estimated to have ~150 proteins exported by the Tat pathway, and *M. tuberculosis* may have as many as 95 proteins (63), whereas other bacteria have far fewer or lack a Tat pathway completely (64, 65). Most notably, the Tat pathway is fundamentally different from the Sec pathway in that folded, rather than unfolded, proteins are exported (66). The studies conducted so far of the mechanism of Tat export in mycobacteria indicate that the Tat system of mycobacteria functions similarly to the Tat pathways of other bacteria.

Like in *E. coli*, in high-GC Gram-positive actinobacteria, including mycobacteria, the Tat pathway is made up of three integral membrane proteins: TatA, TatB, and TatC (Fig. 1) (67–69). TatA and TatB are small homologous membrane proteins, each containing a single TMD. TatC is a larger integral membrane protein (70). In Firmicutes, however, the Tat pathway is a streamlined system with only TatA and TatC (65).

Tat preproteins are recognized by a complex of TatB and TatC, with TatC recognizing the twin arginine signal peptide (71, 72). Once a preprotein is bound to TatBC, homo-oligomers of TatA are recruited to the complex (71) and the Tat preprotein is transported across the membrane. Tat export is a posttranslational process, and the energy required to drive Tat transport comes from the proton motive force (73, 74). The mechanism of transit across the membrane remains a significant unknown. Some models propose that TatA oligomers form a substrate-fitted protein-conducting channel (75) that accommodates folded proteins of different sizes and shapes. An alternative model proposes that TatA multimers lead to destabilization of the membrane in the vicinity of the TatBC-substrate complex and thereby allow TatC-driven translocation of the substrate without the need of a channel (76). Following export, Tat preproteins undergo signal peptide cleavage by the same signal peptidases that work with the Sec pathway: LepB or LspA (77, 78).

Tat signal peptides resemble Sec signal peptides in having a positively charged N-terminus, a hydrophobic central domain, and an uncharged polar C-terminus containing a cleavage site. However, Tat signal peptides are distinguished from Sec signal peptides by the presence of a Tat motif with twin arginines (R-R-X-Φ-Φ [Φ = hydrophobic]) (62). Substitution of the twin arginines with other residues prevents export of most Tat-dependent proteins, but there are a few examples of Tat-exported proteins with only one arginine (79–81). In mycobacteria, Tat signal peptides appear to follow the same rules established in other bacteria. So far, 18 *M. tuberculosis* proteins are confirmed as having functional Tat signal peptides (for a list see reference 23). Working with the endogenous β-lactamase of *M. tuberculosis* (BlaC), which is a Tat-exported protein, the requirement of the twin RR pair for mycobacterial Tat export was confirmed (63, 67). Since β-lactamases must be exported to protect bacteria against β-lactam antibiotics, the requirement of the Tat pathway for BlaC export contributes to the natural resistance of *M. tuberculosis* to β-lactams.

In addition to a Tat signal peptide, the second required feature of Tat-dependent proteins is that they are folded prior to export. Unfolded or misfolded proteins are generally unacceptable for export, suggesting that the Tat export system has a "proofreading" ability that restricts export to properly folded proteins (66, 82).

In addition to fully exporting proteins across the membrane, the Tat pathway plays a role in the delivery of a small subset of integral membrane proteins into the inner membrane. These cases either involve a protein with a Tat signal peptide and a C-terminal TMD, with the latter becoming integrated into the membrane during translocation, or a protein with a noncleavable N-terminal Tat signal peptide that remains anchored in the membrane (65, 83, 84). Most recently, examples of integral membrane proteins that require both the Sec and Tat pathways to deliver and transport across the membrane multiple periplasmic domains were identified. The role of the Tat pathway in this interesting subset of proteins is to translocate periplasmic domains that, similar to many soluble Tat substrates, must bind a cofactor in the cytoplasm and, therefore, fold prior to export. An internal Tat motif is present in such Tat-dependent periplasmic domains. The first example of a dual Sec- and Tat-dependent membrane protein was the *Streptomyces* Rieske iron-sulfur binding protein, which is a subunit of the cytochrome bc_1 complex (85).

In general, the Tat pathway is not essential for bacterial viability, and *tat* mutants are viable, at least in standard laboratory media (65). This is not the case, however, for *M. tuberculosis*, which provides one of the few examples of a bacterium with an essential Tat pathway (69). In fact, even in the fast-growing and nonpathogenic mycobacterium *M. smegmatis*, the Tat system is not essential, although *tatA*, *tatB*, and *tatC* deletion mutants have *in vitro* growth defects (67, 68). A possible explanation for the essentiality of the *M. tuberculosis* Tat pathway is that, like the case in *Streptomyces*, the mycobacterial Tat pathway may be required for export of the iron-sulfur-bound periplasmic domain of the Rieske membrane protein (i.e., QcrA) subunit of cytochrome bc_1 since in *M. tuberculosis* the cytochrome bc_1 complex is essential (86). In support of this possibility, the iron-sulfur binding domain of *M. tuberculosis* QcrA has an internal Tat motif (RRKLI).

THE MYCOBACTERIAL SECA2 PATHWAY

Mycobacteria are unusual in having two SecA homologues, but they are not the only bacteria with two SecAs. Along with other *Actinobacteria* (e.g., corynebacteria) (87), there is a subset of *Firmicutes*, including *Listeria* (88), *Clostridioides* (89), *Staphylococcus* (90), some *Streptococci* (91–93), and some *Bacilli* (94) with two SecAs. In all these cases, SecA1 is the name given to the canonical and essential SecA ATPase of the general Sec pathway, and SecA2 refers to a specialized SecA that promotes export of a relatively small set of proteins. It is important to note that not all SecA2 systems are similar or evolutionarily conserved (35, 95). SecA2 systems can be divided into at least two groups: mycobacteria,

Listeria monocytogenes, and *Clostridioides difficile* provide examples of SecA2 systems in which SecA2 appears to work with the canonical SecYEG channel of the general Sec pathway to export a small but diverse set of proteins (89, 96, 97). These systems are called multisubstrate SecA2 systems or SecA2-only systems, the latter name referring to their lack of a second SecY (SecY2) in the system. *Staphylococcus* and *Streptococci* are examples of bacteria with SecA2 systems that include an accessory SecY (SecY2) and additional accessory Sec proteins (98). These latter systems export a single large glycosylated substrate, and they are called accessory Sec (aSec) or SecA2-SecY2 systems and will not be discussed further here.

Composition of the Mycobacterial SecA2 Pathway

The SecA2 pathway exists in all mycobacteria. In contrast to SecA1 of the general Sec pathway, the role of SecA2 in mycobacterial protein export is limited to a smaller set of proteins, and SecA2 is not essential for mycobacterial growth *in vitro* (99–102). In pathogenic mycobacteria, SecA2 is required for pathogenesis (99–101). Early studies of the SecAs of mycobacteria demonstrated that SecA2 and SecA1 are functionally distinct proteins. Even if SecA2 is overexpressed, it cannot replace the requirement for SecA1, and if SecA1 is overexpressed, it cannot carry out the function of SecA2 (33). The functional differences between SecA1 and SecA2 remain a big unknown. Both SecAs have ATPase activity (37), and the crystal structures of *M. tuberculosis* SecA1 and SecA2 reveal a surprisingly high level of structural similarity, with both SecAs possessing the functional domains of canonical SecAs (103).

As shown with SecA2 variants harboring amino acid substitutions in the ATP binding site of *M. smegmatis* SecA2 (K129R) or *M. tuberculosis* SecA2 (K115R), ATP binding is required for SecA2 to carry out its function in protein export and pathogenesis (37, 104). Interestingly, *secA2 K129R* in *M. smegmatis* is dominant negative and associated with more severe phenotypes than a *secA2* null mutant. Moreover, SecA2 K129R is associated with reduced levels of the sole SecY of mycobacteria, and suppressors of the severe *secA2 K129R* phenotypes map to *secY* (96). These results support a model whereby the severe phenotypes of SecA2 K129R result from a detrimental interaction with the canonical SecYEG channel of the general Sec pathway. By extension, these effects of SecA2 K129R argue for SecA2 exporting proteins through the same SecYEG channel that is used by SecA1 (Fig. 1). Data from *L. monocytogenes* and *C. difficile* are consistent with SecA2 working with the canonical SecYEG channel in these other multisubstrate SecA2-only systems as well (89, 97).

Along with SecY, SecA1 may also be important for mycobacterial SecA2-dependent export. SecA proteins are known to dimerize, and a recent study demonstrated heterodimer (as well as homodimer) formation *in vitro* with *M. tuberculosis* SecA1 and SecA2 proteins purified from *E. coli* (105). While it remains to be demonstrated if SecA1-SecA2 heterodimers are biologically relevant, another finding in support of a role of SecA1 in the SecA2 pathway is that export of SecA2-dependent substrates in *M. smegmatis* is compromised when SecA1 is depleted. However, it is also possible that this latter result reflects a role for SecA1 in delivering components of the SecYEG channel to their membrane location (104).

The convergence of SecA1 and SecA2 on the same translocation channel raises the question of what distinguishes the SecA2 pathway from the general Sec pathway. We expect there are distinctive features of SecA2 substrates and additional components of the SecA2 pathway that distinguish it from the general Sec pathway.

The Multisubstrates of the Mycobacterial SecA2 Pathway

Through a combination of discovery proteomics and direct testing of candidates, proteins that are exported by the SecA2 pathway have been identified in *M. tuberculosis*, *Mycobacterium marinum*, and *M. smegmatis* (99, 101, 102, 106). Across these species, there are currently 15 validated examples of proteins that are exported in a SecA2-dependent manner (Table 1). Some of these proteins localize to the cell envelope, and others are fully secreted. From proteomics experiments, there are additional candidates for SecA2-dependent proteins that remain to be validated. The current list of SecA2-dependent proteins includes examples of proteins with or without predicted N-terminal signal peptides or TMDs. In the SecA2-only system of *L. monocytogenes*, the list of proteins identified as SecA2 dependent also includes examples with or without signal peptides (107). The list of proteins exported by the mycobacterial SecA2 pathway reveals functional themes.

Solute binding proteins (SBPs), a category of transporter proteins, are exported by the SecA2 pathways of *M. tuberculosis*, *M. marinum*, and *M. smegmatis* (99, 101, 102, 106). SBPs are exported into the cell envelope to carry out functions in delivering solutes to membrane-localized ABC (ATP-binding cassette) transporters for import into the cell. The first SBPs identified as exported by the SecA2 pathway are the *M. smegmatis* Msmeg1704 and Msmeg1712 proteins (106), which are predicted to function in sugar import. SBPs are also identified as being exported by the SecA2 pathways of *M. tuberculosis* and *M. marinum* (101, 102). Of 15 SBPs identified by quantitative proteomics of *M. tuberculosis*, 13 are detected as being exported in a SecA2-dependent manner (102). SBPs are also on the list of SecA2-exported proteins for the *L. monocytogenes* SecA2-only system (107). It is worth noting that SBPs exist across bacteria (i.e., they are not always exported by SecA2 systems). The SecA2-dependent SBPs of mycobacteria possess recognizable N-terminal signal peptides containing a lipobox motif, with the majority having predicted Sec signal peptides. However, 4 of the 13 SecA2-dependent SBPs of *M. tuberculosis* are predicted to have Tat signal peptides (102).

Mce proteins, another category of transporter proteins, are also exported in a SecA2-dependent manner in mycobacteria (101, 102). Comparative proteomics of cell envelope fractions of wild-type versus *secA2* mutant *M. tuberculosis* and *M. marinum* strains identified numerous components of cell envelope-localized Mce transporters as SecA2-dependent; Mce components are also SecA2-dependent in *M. smegmatis* (L. Rank and M. Braunstein, unpublished). These exported Mce components possess either a signal peptide or transmembrane domain. Mce transporters are thought to function similarly to ABC transporters in that they recognize an extracytoplasmic solute (in this case, a lipid) and deliver it to a membrane complex that imports it across the membrane using ATP hydrolysis (108). In an interesting similarity to SecA2-dependent SBPs, each Mce transporter (*M. tuberculosis* has four Mce transporters) includes six exported Mce proteins that are thought to function like SBPs. It remains to be resolved if SecA2 is required for export of numerous individual components of Mce transporter complexes or if the role of SecA2 is to export one or a small number of Mce proteins that are required to stabilize the entire Mce complex

TABLE 1 Validated examples of SecA2-dependent exported proteins of mycobacteria

Protein	Signal peptide/ transmembrane[a]	Species	Function	Reference
Ms1704	SP	*M. smegmatis*	SBP	106
Ms1712	SP	*M. smegmatis*	SBP	106
PhoS1 (Rv0928)	SP	*M. tuberculosis*	SBP	102
DppA (Mmar_5154)	SP	*M. marinum*	SBP	101
Mce1A (Rv0169)	TM	*M. tuberculosis*	Mce transporter component	102
Mce1C (Rv0171)	SP	*M. tuberculosis*	Mce transporter component	102
Mce1E (Rv0173)	SP	*M. tuberculosis*	Mce transporter component	102
Mce1F (Rv0174)	TM	*M. tuberculosis*	Mce transporter component	102
SapM (Rv3310)	SP	*M. tuberculosis*	Phosphatase effector	111
PknG (Rv0410c)	None	*M. tuberculosis* *M. marinum*	Kinase effector	101, 102
LipO (Rv1426c)	SP	*M. tuberculosis*	Predicted esterase (possible effector)	102
SodA (Rv3846)	None	*M. tuberculosis*	Superoxide dismutase	99, 293, 294
KatG (Rv1908c)	None	*M. tuberculosis*	Catalase-peroxidase	99
LipA (Mmar_2284)	SP	*M. marinum*	Cell wall hydrolase	99
MMAR_3060	SP	*M. marinum*	Conserved hypothetical	101

[a]SP, Signal peptide; TM, transmembrane.

in the cell envelope. In the latter scenario, a defect in the export of a single Mce protein may account for the observed reduction in abundance of numerous Mce components in a *secA2* mutant.

Effectors of phagosome maturation arrest are another category of protein exported by the SecA2 pathway. A hallmark of pathogenic mycobacteria that survive in macrophages, such as *M. tuberculosis* and *M. marinum*, is their ability to arrest the phagosomes in which they reside from maturing and fusing with degradative lysosomes (109). As a result, pathogenic mycobacteria are in a phagosomal environment that is permissive for replication and sequestered from antigen-presenting compartments that drive immune responses. Phagosome maturation arrest is a complex process involving numerous *M. tuberculosis* proteins (i.e., effectors) that must be exported to reach their site of action at the host-pathogen interface. In *M. tuberculosis* and *M. marinum*, the SecA2 pathway is required for phagosome maturation arrest (101, 110), and SapM and PknG are two SecA2-dependent effectors of this process (101, 111). SapM is a secreted phosphatase that dephosphorylates phosphatidyl inositol-3-phosphate and thereby limits phagosomal recruitment of host factors that drive downstream phagosome fusion and maturation events (112). PknG is a eukaryotic-like serine threonine kinase that is found in both the cytoplasm and cell envelope of pathogenic mycobacteria (113). From its exported location, PknG has a poorly defined role in phagosome maturation arrest (114), and from its cytoplasmic location it has better-characterized roles in metabolism and redox homeostasis (113, 115, 116). Through experiments in which wild-type levels of exported SapM and/or PknG were restored to the *secA2* mutant of *M. tuberculosis* or *M. marinum*, the role of the SecA2 pathway in exporting these proteins was proven to be required for phagosome maturation arrest (101, 111). However, since the combined effect of restored SapM and PknG export is not sufficient to fully restore phagosome maturation arrest to the *secA2* mutant, additional SecA2-dependent effectors must exist. A candidate for an additional factor is the *M. tuberculosis* lipoprotein LipO, which was identified in a screen for phagosome maturation arrest effectors of *M. tuberculosis* (117). LipO, which was initially detected as being SecA2 dependent by comparative proteomics (102), was recently validated as being exported in a SecA2-dependent manner (K. Zulauf and M. Braunstein, unpublished). Although there is a clear role for the SecA2 pathway in exporting effectors of phagosome maturation arrest, it is important to note that not all effectors of this process are exported by the SecA2 pathway.

Proteins lacking signal peptides are another category of SecA2-dependent protein. PknG, SodA (superoxide dismutase), and KatG (catalase-peroxidase) make up this subset of SecA2-dependent proteins (99, 101, 102). Although there are multiple reports of all three of these proteins being exported by mycobacteria (i.e., localized to the cell envelope or secreted fractions), they lack any obvious signal peptide or TMD, which makes them unconventional exported proteins (113, 114, 118–120). At the same time, these proteins are also known to reside in the mycobacterial cytoplasm, where they have physiological functions (113, 115, 116, 118, 121). Interestingly, the SecA2-only pathway of *L. monocytogenes* is also reported to export a SodA protein lacking a signal peptide (122). However, nothing is known about the recognition of proteins lacking signal peptides by the SecA2 pathway, and it remains possible that the effect of SecA2 on their export is indirect. For example, there may be signal peptide-containing proteins exported by SecA2 that are themselves responsible for export of these unconventional proteins.

The Defining Features of SecA2 Substrates

While there are exceptions, the majority of SecA2-exported proteins possess N-terminal signal peptides. The role of the signal peptide in export of SecA2 substrates was evaluated with Msmeg1704, Msmeg1712 (123), and SapM (K. Zulauf and M. Braunstein, unpublished). As is the case for proteins exported by the general Sec pathway, the signal peptide on

these SecA2 substrates is necessary for protein export to occur, and the signal peptide is cleaved in association with export to release the mature protein (106). Experiments in which the signal peptide of a SecA2-dependent and SecA1-dependent substrate are swapped demonstrate that the signal peptide does not determine whether a protein is exported by the SecA2 pathway (123). Rather, the mature domains of SecA2-exported proteins impart the requirement for SecA2 in their export.

The defining feature of the mature domain that dictates the need for SecA2 in export may be a propensity to fold in the cytoplasm prior to export. In support of this idea, when the Sec signal peptide of Msmeg1704 is exchanged for a signal peptide that directs preproteins for export through the Tat pathway, Msmeg1704 is exported by the Tat pathway (123). Since the Tat pathway requires preproteins to be folded prior to export, this suggests that the mature domain of a SecA2 substrate can fold in the cytoplasm prior to export.

Since there is no SecB protein export chaperone in mycobacteria, one possibility is that the SecA2 pathway is adapted to facilitate export through the SecYEG channel of problematic substrates that can fold in the cytoplasm. Along these lines, a mycobacterial protein export chaperone named SatS was recently identified as playing a role in the SecA2 pathway (124). SatS stabilizes and prevents aggregation of a subset of SecA2 substrates. Thus, SatS may serve to keep SecA2 substrates in an unfolded state compatible with transport through SecYEG and thereby help the SecA2 pathway export proteins that have the potential for folding in the cytoplasm.

MYCOBACTERIAL T7S PATHWAYS

Substrates of the T7S pathway are among the most abundantly secreted proteins, indicating their ability to efficiently cross the mycobacterial outer membrane (125). Although conserved throughout the phylum *Actinobacteria* (see below), this secretion pathway was first described in mycobacteria, and in earlier literature T7S was referred to by multiple names, such as ESAT-6 secretion system (Ess), WXG100 secretion system (Wss), and Snm (secretion in mycobacteria) system (126, 127). However, with the visualization of the diderm cell envelope and the observation that T7S substrates are efficiently secreted into the extracellular environment and therefore need to pass two membranes, the term T7S, in line with the specialized secretion systems found in Gram-negative bacteria, became the accepted standard name (128, 129). Mycobacteria can contain up to five T7S systems, named ESX-1 through ESX-5 (125, 130). Of these five systems, the ESX-1 system was the first one to be discovered, being responsible for the secretion of the EsxA and EsxB proteins, also known as ESAT-6 and CFP-10, respectively, in *M. tuberculosis* (131, 132). The importance of the ESX-1 system for the virulence of *M. tuberculosis* is clearly demonstrated by the observation that deletion of a large portion of the *esx-1* gene cluster, resulting in a nonfunctional system, is the decisive determinant for attenuation of the vaccine strain *Mycobacterium bovis* BCG (133–135). Further studies, in both *M. tuberculosis* and the closely related fish pathogen *M. marinum*, showed that the ESX-1 system is crucial for intracellular survival in macrophages by mediating lysis of the phagosomal membrane (136). This membrane permeabilization has been linked to phagosomal escape (137, 138). Additionally, phagosome permeabilization by the ESX-1 system is likely required for the delivery of secreted effectors from the phagosomal lumen to the host cell cytosol, including effectors secreted from mycobacteria by other ESX systems, SecA, SecA2, or Tat. Although this permeabilization has been mainly attributed to the ESX-1-secreted protein EsxA, different studies provide conflicting results (138–142). Further research is therefore required to pinpoint the ESX-1 substrate that is responsible for the phagosomal membrane rupture (138–142). Besides its pivotal role in the virulence of pathogenic mycobacteria, ESX-1 is also present and functional in nonpathogenic mycobacteria such as the fast-growing *M. smegmatis*. Intriguingly, the ESX-1 system of *M. smegmatis* seems to have a very different role, of promoting DNA conjugation, which will be discussed later (143). The diverse roles of ESX-1 are probably caused by a difference in the ESX-1 substrates that are secreted by different species. Indeed, *M. smegmatis* lacks several ESX-1 substrates that are present in *M. tuberculosis* and *M. marinum* and have been linked to virulence (136).

The role of the ESX-1 system in virulence and pathogenicity has been a major focus of TB-related research for more than a decade. The function and importance of several of the other ESX systems have only been described in the past few years. Strikingly, while the ESX-1 system is dispensable for growth in culture, both the ESX-3 and ESX-5 systems are necessary for bacterial viability in *M. tuberculosis*. The essentiality of the ESX-3 system is due to its role in iron and zinc uptake (144, 145). Possibly linked to its role in iron acquisition, ESX-3 is one of the most conserved ESX systems, being present in all mycobacterial species, of which genome sequences are available. In addition to this, the ESX-3 substrates EsxH, PE15, and PPE20 also play a role in immune modulation, e.g., EsxH is required for inhibition of phagosome maturation (146, 147). The ESX-5 system, on the other hand, is only present in the subgroup of so-called slow-growing mycobacteria, which contains most pathogenic species, such as *M. tuberculosis*, *Mycobacterium leprae*, and *M. marinum* (148). Although it is still unknown what the exact role of the ESX-5 system is, its essentiality for growth has been linked to outer membrane permeability and nutrient uptake in *M. marinum* (149). Furthermore, the ESX-5 system has been shown to be involved in immune modulation of the host as well (150–154). The characterization of the exact roles of the ESX-5 system is complicated by the large number (>100) of substrates that it secretes.

The roles of the ESX-2 and ESX-4 systems and the substrates they secrete remain unknown. Several studies have shown that these systems are not essential for virulence or *in vitro* growth of *M. tuberculosis* (155, 156), although a transposon insertion sequencing study found that mutations in the ESX-2 and ESX-4 systems resulted in a reduced fitness in dendritic cells (157). In contrast to this, a recent study by Laencina et al. showed that the ESX-4 system of the opportunistic pathogen *Mycobacterium abscessus* is not only functional but even plays a critical role in virulence (158), because ESX-4 transposon and deletion mutants showed reduced survival both in amoeba and murine cells. This phenotype was suggested to be the result of impaired phagosomal rupture, a feature generally attributed to the ESX-1 system in *M. tuberculosis* and *M. marinum*. Because *M. abscessus* lacks the ESX-1 system, ESX-4 may carry out its role in this species. Finally, in *M. smegmatis*, ESX-4 seems to be, together with ESX-1, involved in DNA conjugation as well (see below) (159, 160).

In addition to these five ESX systems that are genomically encoded, many other *esx* loci have been identified that are located on plasmids (161–163). In addition, homologous *esx* gene clusters are present throughout the phylum *Actinobacteria*, not only in species with a diderm cell envelope similar to that in mycobacteria, such as in corynebacteria and

nocardia, but also in species that lack a mycolic acid-containing outer membrane (130, 164, 165). Lastly, more distantly related systems are present and functional in a subset of *Firmicutes*, such as *Staphylococcus aureus*, *Streptococcus intermedius*, and *Bacillus subtilis*. Because most T7S components present in *Actinobacteria* are not conserved in the *Firmicutes* systems, *Firmicutes* systems are referred to as type VIIb secretion systems, opposed to the type VIIa systems of *Actinobacteria* (130, 166, 167).

Composition and Mechanism of Mycobacterial ESX Systems

The ESX systems of mycobacteria contain a set of conserved components. During the early years of T7S-related research, genome annotation numbers were often used to refer to these components. To avoid confusion, researchers in the T7S field proposed a systematic nomenclature based on the genetic composition of the systems, which is now the accepted standard (128). Based on this nomenclature, genes that are conserved in at least four of the mycobacterial ESX systems are defined as *ecc*, for *esx* conserved component. The system-specific genes, in most cases encoding secreted substrates, are designated *esp*, for *esx*-specific protein. There are two exceptions to this rule, *mycP* and *esp*G. Although the mycosin proteases (MycP) are conserved in all ESX-systems, the term "mycosin" was already an established name and was therefore not altered. For the second exception, EspG was originally not identified as a conserved component due to low homology between the different *esp*G genes. However, the EspG proteins, present in four of the ESX systems, have now been shown to be functional homologues (168, 169). For the major substrate groups, the previously defined terms were kept. The first of these groups are called the Esx proteins, because "EsxA" (ESAT-6) and "EsxB" (CFP-10) were already frequently used terms for two members of this group. The second, larger group contains the so-called PE and PPE proteins, referring to the presence of a proline-glutamic acid (PE) or proline-proline-glutamic acid (PPE) N-terminal amino acid motif (128, 130, 154, 170).

ESX substrates

All mycobacterial ESX systems are encoded by genes that are clustered in distinctive genomic loci. In the middle of these gene clusters is always a pair of *esx* genes. These *esx* genes, which are cotranscribed, encode small proteins of the WXG100 family, named after the conservation of a tryptophan and glycine residue separated by a random amino acid and their length of roughly 100 amino acids (166, 171). The *esx* genes are not limited to the ESX loci; additional *esx* gene pairs can be found throughout the genome sequence (130, 148). The two Esx proteins that are encoded from the bicistronic transcript form heterodimers in the cytosol and are codependent on each other for secretion (Fig. 1) (172). For example, the ESX-1 system contains the well-described protein pair EsxA-EsxB, which are believed to be secreted as a dimer (173, 174). However, whereas EsxA has been shown to play a major role in virulence, this has not been shown for EsxB (138, 175). From this observation, it is postulated that EsxB is the chaperone for EsxA and that their interaction is required for successful secretion. Because their interaction is required for successful secretion, an *esxB* mutant shows a similar phenotype as an *esx*A mutant (139, 176). The heterodimer EsxA-EsxB is the first Esx pair for which a high-resolution structure has been solved (174). The structure shows the presence of a helix-turn-helix motif in both proteins, where the turn contains the WXG motif and the double helices interact in an antiparallel orientation with the double helices of the partner. Furthermore, it shows that the N- and C-terminal tails are flexible. Predicted structural similarities suggest that the EsxA-EsxB structure can serve as a model for the other Esx proteins, which was confirmed by the crystal structures of the ESX-3-associated heterodimeric substrates EsxG-EsxH and EsxR-EsxS (177, 178).

Genes encoding the second substrate group, the PE and PPE proteins, are also present in four of the *esx* loci; only the ESX-4 gene cluster does not contain any *pe* or *ppe* genes. However, most *pe* and *ppe* genes are not associated with these loci (130, 148, 154, 179). In fact, pathogenic mycobacteria contain up to 99 *pe* and 69 *ppe* genes and, e.g., in *M. tuberculosis* approximately 10% of the encoding genome belongs to *pe* and *ppe* genes. While the ESX-1 and ESX-3 systems are responsible for the secretion of some PE and PPE proteins (147, 154, 180), the majority of the PE and PPE proteins are secreted through the ESX-5 system (150). Similar to the Esx proteins, several *pe* and *ppe* genes are clustered in a bicistronic operon, consisting of one *pe* and one *ppe* gene, and at least some of the corresponding proteins form heterodimers (169, 181). These heterodimers are often dependent on each other for stability and solubility (Fig. 1) (169, 181, 182).

Substrates belonging to the PE/PPE protein group are often bound to the cell surface, which is in contrast to the Esx proteins that are mainly secreted into the culture medium (183, 184). These substrates consist of a distinctive N- and C-terminal domain: whereas the N-terminal PE and PPE domains, with a length of ~110 and 180 amino acids, respectively, are highly conserved and are involved in the secretion process, the C-terminal domains are less conserved and are thought to be involved in protein-specific functions. The resolved crystal structures of PE25-PPE41 and PE18-PPE15 reveal structural similarities between Esx and PE-PPE heterodimers (182, 185). While the PE domain only consists of two alpha helices, the PPE domain contains five alpha-helices, of which helices $\alpha 2$ and $\alpha 3$ mediate dimerization with the PE partner, forming a four-helix bundle similar to Esx pairs. Unlike Esx dimers, only the PPE protein contains a WXG motif in the turn between these two helices. The fourth and fifth alpha helices of the PPE domain form an extending hydrophobic tip that is recognized by the EspG component, which will be discussed below (169, 180, 181, 185). The size of the more variable C-terminal domains of PE and PPE proteins can be large; for example, the subgroup of PE_PGRS (polymorphic GC-rich repetitive sequence) proteins can have C-terminal domains of over 1,400 amino acids (148). Only a minority of these C-termini contain predicted functional domains, e.g., executing predicted lipase activity. Consequently, a function has been described for only a few PE-PPE proteins (186, 187).

The final group of substrates, the Esp proteins, are specific for the ESX-1 system (188–191). Although less is currently known about the secretion of these substrates, EspA and EspC are cotranscribed and have been shown to be codependent on each other for secretion and interact to form a heterodimer (188, 192), similar to what is likely the case for EspE and EspF (184, 188, 193). In contrast to this, another ESX-1 substrate, EspB, has a PE-PPE dimer-like fold, forming a double helix-turn-helix by itself, suggesting that it is secreted as a monomer (194, 195). Whether the final Esp substrates, EspK and EspJ, are secreted as monomers or heterodimers remains unknown (190, 191).

An intriguing feature of ESX-1 substrates is that there are some cases of unpaired substrates being codependent on each other for secretion; i.e., the secretion of EspA-EspC is affected by mutations in *esxA-esxB*, and vice versa (176, 188, 196).

This codependence of ESX-1 substrates complicates the understanding of the mechanism of secretion by the ESX-1 system, because a mutation in, e.g., specific chaperones, will also affect the secretion of ESX-1 substrates that do not interact with this chaperone. Furthermore, it makes it difficult to pinpoint specific functions for individual ESX-1 substrates (132, 176, 197). Some level of codependence of substrates for secretion has also been reported for ESX-3 and ESX-5 substrates. For ESX-3, deletion of *esxH* has been shown to abolish secretion of ESX-3-dependent PE-PPE proteins, although this does not happen the other way around (147). The ESX-5 substrate, PPE38, is required for secretion of the two largest ESX-5 substrate groups, PPE_MPTR and PE_PGRS (198). Although the mechanism for this dependency on PPE38 is currently unknown, PPE38 appears to be of great importance because the emerging *M. tuberculosis* Beijing isolates share a polymorphism in the *ppe38* locus (198). In addition, the ESX-5 substrate PPE10 affects the integrity of the capsular layer of mycobacteria (see below) (199), indirectly affecting the proper localization of other substrates, not only of ESX-5 but also of the ESX-1 system (199).

ESX secretion signal and the cytosolic chaperone EspG

Unlike Sec or Tat substrates, the ESX substrates do not contain an N-terminal signal peptide; instead, the Esx, PE, and Esp substrates have a C-terminal secretion signal directly downstream of a helix-turn-helix. In the case of the Esx and PE-PPE heterodimers, only one of the proteins has this secretion signal: EsxB of the EsxA-EsxB pair (172) and the PE protein in the case of the PE-PPE pairs (195). Two elements of the secretion signal have been identified. One is a conserved motif, consisting of a tyrosine residue and a residue with a negative charge separated by three random amino acids (YxxxD/E). This motif is required for secretion of T7S substrates (195). The other element is downstream of the YxxxD/E motif at the extreme C-terminus of the protein. These approximately seven amino acids, which include additional hydrophobic residues, are also required for secretion (172). In addition, these C-terminal seven amino acids interact with the C-terminal domain of the ESX-1 component EccCb1 of *M. tuberculosis*, as demonstrated by yeast two-hybrid analysis and immunoprecipitation (172). Structural studies demonstrate a similar interaction between a peptide containing the last 23 residues of EsxB and EccC of the T7S system of *Thermomonospora curvata* (200). It is noteworthy that only the last seven amino acids of this peptide were visible in the structure. The YxxxD/E motif was disordered in the structure, suggesting that the motif is not involved in the binding of this peptide to EccC (200). However, it remains unclear how the entire signal interacts with EccC in the context of the full substrate and the complete secretion system. Sequence alignments across the wider array of WXG100 subfamilies also identify a C-terminal consensus sequence, aligned to the side of alpha helix 2, consisting of a conserved HxxxD/E motif (like that of YxxxD/E) and hydrophobic residues downstream of this motif (201). Swapping the C-terminal 15 amino acids, including the YxxxD/E secretion motif of two PE substrates, secreted by ESX-1 or ESX-5 did not affect their secretion or by which system they were transported (195). This shows that, although the C-terminal secretion signal is essential for secretion, it is not involved in system specificity. Instead, a recent study by Phan et al. showed that the fourth and fifth helix of the PPE domain, recognized by the EspG chaperone, contains the signal for system-specific recognition (180).

Although EspG was at first considered an ESX-1-specific protein, it has now been established to be a conserved component; in fact, only the ESX-4 system does not contain an *esp*G gene. Although the EspG proteins share a low amino acid conservation, the solved tertiary structures of $EspG_1$, $EspG_3$, and $EspG_5$ are very similar (169, 181, 202). Previous studies illustrated the importance of $EspG_5$ in the general secretion process, because it is required for the secretion of several ESX-5 substrates in *M. marinum* (151). More information about its role in the secretion process was obtained by the observation that the deletion of $espG_1$ decreases the stability of PPE68 in *M. tuberculosis* (203), which indicated that the EspG proteins might function as a chaperone. Importantly, the chaperone of the ESX-5 system, $EspG_5$, only interacts with PE-PPE pairs secreted by the ESX-5 system in *M. marinum* (169). Similar to this, $EspG_1$ was shown to only bind to an ESX-1 dependent PE-PPE heterodimer and not to PE-PPE pairs secreted by the ESX-5 system (168). This is in line with the observation that $EspG_1$ and $EspG_5$ increase the solubility of their cognate PE-PPE substrates *in vitro* (181). Because EspG is strictly cytoplasmic, it was hypothesized that EspG is required for the recruitment of the PE-PPE pairs to the membrane-embedded secretion complex, after which it dissociates from these substrates (Fig. 1) (168).

The regions involved in the interaction of EspG and PE-PPE dimers were shown by the crystal structure of $EspG_5$ in complex with the PE25-PPE41 dimer (169, 181). The structure showed that $EspG_5$ only binds to the hydrophobic tip of helices $\alpha4$ and $\alpha5$ of the PPE domain of PPE41 and does not interact with the PE protein, including the general secretion signal. This corresponds with an earlier study showing that the YxxxD/E motif of the PE protein is not required for binding of the PE-PPE pair to EspG (195). The observation that binding of $EspG_5$ does not introduce conformational changes to the PE-PPE dimer, but increases the solubility of the protein pair (181), suggests that EspG prevents self-aggregation via the hydrophobic tip of the PPE protein (169, 181).

Because EspG proteins specifically interact with PE-PPE pairs of their respective system, it was already postulated that EspG might direct system specificity of these substrates (169). To confirm this, Phan et al. investigated the role of the region involved in $EspG_1$ binding, hereafter called the $EspG_1$ binding domain, of the ESX-1 substrate PE35-PPE68_1 in *M. marinum* (180). Indeed, PE35-PPE68_1 could be rerouted to the ESX-5 system by replacing the $EspG_1$ binding domain of PPE68_1 with the equivalent $EspG_5$ binding domain of the ESX-5 substrate PPE18. This domain replacement makes the PE35-PPE68_1 protein pair independent of both $EspG_1$ and the ESX-1 membrane complex but, instead, dependent on $EspG_5$ and the ESX-5 complex for secretion. These findings show not only that EspG is required for the solubility of PE-PPE complexes, but also that it specifically directs these protein pairs to their respective ESX system. The additional observation in several studies that $EspG_1$ is also required for the secretion of Esx and Esp proteins in *M. marinum* is probably an indirect effect of the substrate codependence, because Esx pairs lack an EspG binding domain (180, 204). Finally, recent findings show that the ESX-1 substrate EspE interacts with EspH, a small ESX-1-associated protein that is not secreted, in the cytosol of *M. marinum*, which is required for the stable expression and secretion of EspE-EspF (204). Interestingly, several ESX-1-associated proteins show homology and conserved predicted structural features to EspH (i.e., EspD and EspL), indicating that these Esp proteins might serve as specific chaperones for specific Esp substrates.

EccA

The second ESX conserved cytosolic component is EccA, belonging to the family of AAA+ (ATPases associated with diverse cellular activities) proteins. AAA+ ATPases have been linked to a wide range of mechanisms, such as protein homeostasis, signaling pathways, and the assembly and disassembly of protein complexes (205, 206). A distinctive feature of AAA+ proteins is that they usually form hexameric rings with an opening in the center. Although not a common feature of prokaryotic secretion systems, the type VI secretion system also contains an AAA+ ATPase, which is involved in the disassembly of the secretion apparatus (205). EccA is absent in the ESX-4 system, similar to the cytosolic chaperone EspG. All EccA homologs have an identical composition, consisting of distinctive N- and C-terminal domains separated by a linker region. The C-terminal domain contains the typical AAA+ ATPase characteristics, such as the walker and oligomerization motifs, whereas the N-terminal domain contains 12 antiparallel α helices arranged into 6 tandem tetratricopeptide repeat motifs, known for their involvement in protein-protein interactions (207–209). Full-length $EccA_1$ indeed has been shown to form hexamers, although it has (relatively low) ATPase activity *in vitro* (207). Furthermore, it was confirmed that oligomerization and ATPase activity are mediated by the C-terminal domain. Because expression of only the C-terminal domain results in higher ATPase activity than full-length $EccA_1$, it is thought that the N-terminal domain plays a regulatory role in this activity (207).

The role of EccA in secretion remains unclear. Early studies, showing that $EccA_1$ is essential for secretion of EsxA and EsxB in *M. tuberculosis* and *M. marinum*, suggested that EccA proteins might play a role as a chaperone in the ESX secretion process (140, 210). Similarly, $EccA_5$ was also found to be required for the secretion of ESX-5 substrates in *M. marinum* (153, 211). However, other studies of *M. tuberculosis*, *M. marinum*, and *M. smegmatis* showed that $EccA_1$ and $EccA_5$ are dispensable for ESX-1- and ESX-5-mediated secretion, respectively, suggesting that the involvement of this component varies between different strains and/or growth conditions (127, 212). The latter notion is supported by the recent finding that the importance of $EccA_1$ for secretion of EsxA in *M. marinum* is dependent on the growth condition (204). Although yeast two- hybrid experiments indicated that a peptide corresponding to the C-terminus of EsxB interacts with $EccA_1$ (213), this interaction could not be observed with full-length EsxB, nor does $EccA_1$ affect the conformation or solubility of EsxB (207). On the other hand, both yeast two-hybrid assays and *in vivo* protein pull-downs in *M. marinum* showed that $EccA_1$ is able to interact with EspC (188). This interaction can be blocked by the removal of the C-terminus of EspC, which also blocks the secretion of EspC. However, $EccA_1$ could not be shown to interact with EsxA or EsxB in this same study. Although this could mean that $EccA_1$ exclusively interacts with the Esp proteins and targets them to the membrane-embedded secretion machinery, the role of the EccA component in the other ESX systems that do not secrete Esp substrates remains unknown.

ESX membrane components, complex formation, and structure

The ESX systems of mycobacteria contain five conserved membrane components, EccB, EccC, EccD, EccE, and MycP, which are expected to be involved in the transport of ESX substrates across the cell envelope. All these components have been shown to be essential for secretion for ESX-1 (132, 214, 215), ESX-3 (216), and ESX-5 (149, 153, 212, 217). EccD is the most hydrophobic of these five components, predicted to have up to 11 TMDs, whereas the other components have only one or two TMDs and contain relatively large N- or C-terminal hydrophilic domains. EccD is postulated to be the core membrane pore of the secretion machinery due to its hydrophobicity. The structure of the ~110-amino acid N-terminal soluble domain of $EccD_1$ has been solved and shows a ubiquitin-like fold with a negatively charged groove, suggesting a role in the recruitment of other components of the secretion complex or possibly as a gating element of the secretion channel (218). The structure of the C-terminal soluble domain of $EccB_1$ shows an elongated shape with a hydrophobic core, suggesting a more structural role of this protein that likely forms a hexamer (218, 219). In addition to this, the C-terminal domain of $EccB_1$ was shown to have ATPase activity *in vitro*, although it is uncertain whether this has functional relevance because this domain is predicted to be located in the periplasm, where ATP is absent (219). There is no crystal structure available for EccE; however, it is predicted to have two TMDs and a C-terminal soluble domain of unclear localization.

EccC is the most conserved of all T7S components, because it is the only component that is also found in the type VIIb secretion systems in *Firmicutes* (see below) (220). EccC contains three predicted functional domains, which all show homology to the family of FtsK-SpoIIIE ATPases (221), named after the two best-studied members, FtsK and SpoIIIE (222), both mediating DNA transport. Another notable protein of this family is the type IV coupling protein, involved in the recognition of substrates and protein transport in type IV secretion systems (223). Just like the AAA+ ATPases, a major part of the FtsK-SpoIIIE ATPases also forms ring-like hexamers. However, because EccC contains three nucleotide binding domains (NBDs), opposed to one, it might have different structural features.

Although EccC has been proposed to be the motor of the secretion complex, energizing the translocation of substrates across the cell envelope, its function remains unclear. Of the different EccC proteins, $EccC_1$ has been most extensively investigated. In contrast to other EccC proteins, which are encoded by a single gene, $EccC_1$ has the unusual feature that it is encoded by two genes, *eccCa*$_1$ and *eccCb*$_1$. However, both yeast two-hybrid experiments and protein pull-downs showed that it most likely functions as a single unit (132, 212, 224). $EccCb_1$ has been shown by the Cox lab to interact with the C-terminus of EsxB that contains the general secretion motif (188). This suggests that it could play a similar role as the type IV coupling protein in mediating substrate recognition and subsequent transport. The same group subsequently solved the crystal structure of the cytoplasmic domain of EccC from the actinobacterium *T. curvata* (200). The structure revealed that NBD2 and NBD3 were both bound to ATP, while NBD1 was in a nucleotide-free state, indicating a low ATPase activity of NBD2 and NBD3. They additionally produced a cocrystal of a truncated version of EccC with a peptide representing the last 23 amino acids of the C-terminus of EsxB bound to NBD3. The ATPase activity of EccC, shown to be held in an auto-inhibited state of NBD1 by interactions with NBD2, could not be induced by binding of the C-terminus of EsxB, suggesting that other substrates or components are required for this (200). Interestingly, they did find that EsxB binding resulted in the multimerization of EccC in both dimers and higher-order oligomers. From these findings the authors proposed a working model in which binding of multiple substrates induces EccC multimerization and subsequent activation of NBD1. The suggestion that NBD1 is the main domain

responsible for energizing protein translocation is supported by another study that found that ATP binding to NBD1 of $EccC_5$ of *M. marinum* is essential for secretion, while mutations in the ATP pocket of NBD2 and NBD3 only reduced secretion efficiency (149).

Evidence that the conserved membrane components form a large membrane-embedded secretion complex was first provided for the ESX-5 system of both *M. marinum* and *M. bovis* BCG (212). First, the five components with predicted TMDs were indeed shown to be localized to the cell envelope, of which four, $EccB_5$, $EccC_5$, $EccD_5$, and $EccE_5$, were shown to be part of a 1.5-MDa membrane-embedded complex, postulated to form the ESX-5 membrane channel (Fig. 1). Subsequent antibody pull-downs on $EccB_5$ confirmed that these four proteins are the main constituents of this complex, with a notable absence of the fifth membrane component, $MycP_5$. Finally, limited proteolytic digests indicated that the N-terminal part of $EccE_5$ and the middle and C-terminal part of $EccC_5$ are the most exposed domains of the complex. Additional studies using protein pull-downs of Strep-tagged $EccCb_1$ and $EccC_5$ of *M. marinum* showed that the composition of the ESX-1 complex is comparable to that of the ESX-5 complex, also forming a complex of approximately 1.5 MDa (224). Mass spectrometry analysis confirmed the presence of the four Ecc components in both ESX complexes. Although $MycP_1$ and $MycP_5$ were present in the ESX-1 and ESX-5 complexes, respectively, they were both below the set threshold levels, indicating that the MycP proteins are not integral components of these assemblies.

More recently, the first image of a mycobacterial T7S system was published, determined by negative-stain single-particle analysis (225). For this, the ESX-5 system of the slightly thermophilic and slow-growing *Mycobacterium xenopi* was overproduced in and purified from *M. smegmatis*, which does not naturally contain an ESX-5 system. The overproduction in *M. smegmatis* resulted in a relatively stable and functional system with a similar composition and size as the complexes that were previously isolated for *M. bovis* BCG and *M. marinum* (212, 224). Furthermore, the reconstituted system in *M. smegmatis* allowed the investigation of the minimal requirements for complex formation. This showed that the ESX-5 complex assembles independently of the presence of ESX-5 substrates, opposed to the previously proposed mechanism of EsxB-dependent multimerization of EccC (200).

The EM images of negatively stained purified complexes and subsequent three-dimensional reconstruction resulted in a 13-Å structure, revealing a 6-fold symmetry and a size of 28 (width) × 16 (height) nm, with a 5-nm-wide central pore. Interestingly, based on previously solved crystal structures of Esx and PE-PPE heterodimers, the central pore is wide enough to allow the secretion of folded, dimeric ESX-substrates (201). The combination of the observed symmetry with mass spectrometry-based stoichiometry determination suggests that the four individual components are each present in 6 copies, resulting in a 24-subunit complex with a mass of 1.8 MDa, opposed to the previously estimated 1.5 MDa (212, 224).

The raw EM images of single particles showed "beads-on-a-string-like" densities extending from the main body of the complex. These extrusions have a similar shape as that previously shown for the cytosolic portion of EccC of *T. curvata* (200), and specific gold labeling confirmed them to be the EccC subunits. The seemingly random orientation of these EccC extrusions suggests that they are flexible, which was also observed by small-angle X-ray analysis, resulting in their absence in averaged complexes. Segmentation analysis in combination with the available crystal structure of the soluble domain of $EccB_1$ allowed for the fitting of $EccB_5$ at the periplasmic side of the complex, while gold-labeling showed that the C-terminal domain of $EccE_5$ is also periplasmic and located at the periphery of the complex (218, 225).

A distinct and interesting feature is that the dimensions of the ESX-5 complex dictate that it can only span the inner membrane of mycobacteria, because it is not tall enough to span both the inner and mycobacterial outer membrane (184). This is in contrast to the complexes of type I, II, III, IV, and VI secretion systems in Gram-negative bacteria, which span both the inner and outer membrane. It therefore remains unknown how T7S substrates can cross the outer membrane of mycobacteria. However, several possibilities have been proposed, which will be discussed below.

The fifth membrane component, the mycosin protease, or MycP, is not an integral part of the core ESX secretion complex, as shown by protein pull-down analysis (212, 224, 225). However, it is highly conserved in T7S systems throughout the phylum *Actinobacteria* (4), indicating that it does play an important role within T7S. Mycosins are subtilisin-like serine proteases, which had been identified and indicated to be cell envelope associated for *M. tuberculosis* before T7S was discovered (226, 227). Because mycosins have a predicted N-terminal signal sequence and a C-terminal TMD, the protease domain is most likely located in the periplasm.

Crystal structures of $MycP_1$ from *Mycobacterium thermoresistible* and *M. smegmatis* and a structure of $MycP_3$ from *M. smegmatis* all show a similar subtilisin-like alpha/beta structure, consisting of a seven-stranded beta sheet surrounded by eight alpha helices (228, 229). The active site, consisting of an aspartic acid, histidine, and serine residue, is in the active conformation in all mycosin structures (228). One interesting feature is the presence of an atypical N-terminal extension. Subtilisins usually contain an N-terminal propeptide that blocks the active site of the protease and is cleaved and degraded upon protein maturation (230). In contrast, the "propeptide" of mycosins does not block the active site of the protease, but it is instead tightly wrapped around the protease domain. *In vivo* data furthermore showed that the N-terminal domain remains attached to the protease without blocking protease activity (228), while *in vitro* analysis showed that the N-terminal extension is most likely involved in protein stability (231, 232). Additional unique features of mycosins are the presence of three extended loops in the protease domain, surrounding the active site and extending the active site pocket (228, 229). Finally, the substrate binding grooves of $MycP_1$ and $MycP_3$ show significant differences to each other, in both the surface hydrophobicity and the depth of interacting sites, which is also influenced by differences in the three extended loops of the protease domain (228). These differences are probably the basis for substrate specificity of the mycosins.

Although the catalytic site is conserved in mycosins, as is their predicted active conformation, only one mycosin substrate has so far been identified: $MycP_1$ has been shown to process the ESX-1 substrate EspB near its C-terminus, both *in vitro* and *in vivo*, in *M. marinum* and *M. tuberculosis* (214, 224, 228). Interestingly, the proteolytic inactive mutant showed an increased secretion of ESX-1 substrates, indicating that although $MycP_1$ is required for secretion, its proteolytic activity is not (214, 224). In line with this observation, while $MycP_1$ is crucial for intracellular growth and virulence, a proteolytic inactive mutant of $MycP_1$ resulted in only a slight attenuated phenotype in a mouse infection model (214). This disparity suggests that mycosins have an additional role in ESX systems, besides being involved in the processing of

substrates. This second role has been identified to be in the stabilization of the core membrane-embedded ESX-secretion complex, because in the absence of MycP, its respective ESX complex is highly unstable (224). Furthermore, it was shown that although mycosins are not a stable component of the ESX complex, they do loosely associate with it (Fig. 1). It is currently unknown whether this decreased stability is the only way that mycosins directly affect secretion; hopefully, additional interaction studies between the ESX complex and MycP can shed more light on this. Although proteolytic activity is not required for secretion, the decreased virulence of an active site mutant of $MycP_1$ could potentially be of interest for the development of novel drugs that block protease activity (233).

Outer membrane translocation of substrates

Because the EM structure of the isolated ESX-5 membrane complex indicates that this core secretion channel only spans the inner membrane (225), the outer membrane channel in T7S remains unknown. While these findings suggest that T7S is a two-step process in mycobacteria, i.e., mediated by two separate membrane channels, one in the cytoplasmic membrane and one in the mycobacterial outer membrane, a one-step mechanism for T7S, i.e., a single membrane channel that mediates protein export across the complete cell envelope, is still possible, because outer membrane components could be lost during the complex purifications. However, the five conserved membrane components EccB, EccC, EccD, EccE, and MycP are most likely not involved in outer membrane translocation, because all these components can also be widely found in T7S systems of *Actinobacteria* that lack mycolic acids, the major constituent of the mycobacterial outer membrane. Therefore, in both scenarios, a one-step and a two-step mechanism, the proteins mediating outer membrane translocation remain unknown. Notably, there is no conserved component within the different *esx* clusters that could be involved in this second translocation step, with the exception of the PE and PPE proteins, which are present in most ESX systems and have only been found in *Corynebacteriales*.

The identification of outer membrane proteins involved in T7S secretion is complicated by the fact that very little is known about mycobacterial outer membrane proteins in general (234). In fact, for mycobacteria, only the outer membrane porin MspA of *M. smegmatis*, which is not present in slow-growing species, has been properly characterized and its crystal structure solved (12, 235). The 96-Å-tall MspA porin is an octamer, showing an 8-fold rotational symmetry with a central pore (12). The individual subunits contain a 134-amino acid domain forming the bulk of the porin. This globular domain consists of two 4-stranded antiparallel beta sheets connected by a 50-residue loop at the base of the structure, forming two 16-stranded beta-barrels. While four highly homologous Msp porins, MspA, B, C, and D, are critical for the sufficient uptake of nutrients such as glucose and phosphate in *M. smegmatis*, no such porins are present in *M. tuberculosis*. In *M. tuberculosis*, CpnT and SpmT are the best candidates for outer membrane proteins, because they have been shown to be involved in nutrient and metabolite uptake (236–240) and possibly form a channel or porin (241, 242). However, thus far, the structures of these channels remain unknown. Most attention has been given to the identification of mycobacterial outer membrane proteins that form a beta-barrel, analogous to the Gram-negative bacteria. However, research on PorB, one of the porins present in *Corynebacterium glutamicum* (243–245), shows a very different structure for an outer membrane porin (14). The core of this protein consists of 70 residues forming 4 alpha helices connected by disulfide bridges, showing that mycolic acid-embedded proteins do not necessarily need to form beta-barrel-like structures.

None of the mycobacterial outer membrane proteins identified so far have been linked to protein export; however, there are indications that specific ESX substrates may be involved in the outer membrane translocation step. For ESX-1, there are currently two substrates suggested to be involved in this second secretion step: EspB and EspC. Both EspB and EspC have been shown to be required for secretion of EsxA/EsxB in pathogenic mycobacteria (246, 247), whereas EspB is still secreted in the absence of EspA-EspC or when EsxA-EsxB is not secreted (188, 246).

As already mentioned, EspB has the specific feature that it forms a PE-PPE-like fold by itself and is therefore probably secreted as a monomer (194, 248). Interestingly, this substrate has been shown to multimerize upon secretion and to form heptameric tubular-shaped particles after overexpression in *E. coli*, as visualized by negative-stain EM (248). Modeling the solved crystal structure of monomeric EspB without the C-terminal portion that is cleaved off by $MycP_1$ results in an arrangement where the hydrophobic helical tips of EspB are tightly packed, possibly allowing membrane-embedding activity. This has led to the hypothesis that EspB might be within the (outer) membrane and involved in the secretion of ESX substrates. The cleaved off C-terminal fragment of EspB was shown to be dispensable for the formation of these ring-shaped oligomers. By direct comparison of structures with and without this region, the C-terminus was visualized as an appendage protruding from the top of the ring (248). A model was subsequently proposed in which the C-terminal cleavage of EspB by $MycP_1$ has a regulatory function for passage through this potential channel, which could help to explain the increased secretion of ESX-1 substrates in an active site mutant of *mycP*$_1$ (214, 224).

EspC is the second ESX-1 substrate proposed to be involved in the outer membrane translocation. EspC, which is secreted as a heterodimer together with EspA, has been shown to localize to the cell surface of *M. tuberculosis* and forms filamentous structures when overproduced in *E. coli* (192). Based on these findings, EspC was postulated to form filaments that have a role analogous to the type III injectisome needle proteins, mediating contact-dependent phagosomal lysis (142, 249). However, while EspC is required for the secretion of EsxA and EsxB in *M. tuberculosis* (188), EspC is absent in *M. smegmatis*, while this species does secrete EsxA-EsxB. Possibly another unknown protein could replace the function of EspC in *M. smegmatis*.

It still needs to be seen whether EspB and/or EspC are involved in the outer membrane translocation step within T7S. In any case, this would only provide a model for the secretion of ESX-1 proteins, because EspB is not required for secretion of ESX-5 substrates (250). This would suggest that each ESX system has its own specific outer membrane components. The only current hypothesis for the outer membrane channels of ESX-3 and ESX-5 is that this role is performed by members of the PE/PPE families. This hypothesis is supported by their localization to the cell envelope and the notion that they are not widely found outside mycolic acid-containing species.

Role of Mycobacterial ESX Systems in Conjugation and Cell Physiology

While the mycobacterial ESX systems are known to play critical roles in virulence, e.g., in immune modulation

(ESX-3 and ESX-5) and phagosomal escape (ESX-1), more recently, several crucial roles in cell physiology and nutrient uptake have been additionally found and described. Here, we will discuss several of those roles and the involved ESX systems (Fig. 2).

One of the first nonvirulent roles attributed to an ESX-system was the role of the ESX-1 system in horizontal gene transfer in *M. smegmatis* (143). The DNA transfer is unidirectional, chromosomally encoded, and allows for the transfer of large genomic fragments. This form of conjugation is called distributive conjugal transfer and has so far not been described for other mycobacteria, including *M. tuberculosis* (159). An interesting observation is that, while recipient strains are dependent on the ESX-1 system for DNA uptake (143), *esx-1* mutants in the donor strains are hyper-conjugative (251). In addition to the ESX-1 system, the ESX-4 system is also required for receiving DNA by the recipient, because a deletion of $eccC_4$ or $eccD_4$ blocked conjugation (159). The presence of ESX-4 was only required for the recipient strain, because the same genes could be deleted in the donor strain without affecting DNA transfer. A more recent study showed that SigM, the regulator of ESX-4, is highly upregulated in the recipient when in contact with a donor cell, suggesting that ESX-4 is specifically induced upon cell-cell contact (160). The exact role of ESX-1 and ESX-4 in conjugation by *M. smegmatis* remains unclear. The fact that conjugation takes place in a contact-dependent manner (159) might indicate that putative surface-localized ESX-1 and ESX-4 substrates might be required for initial donor-acceptor engagement and/or communication.

More recently, a conjugative plasmid has been described for *M. marinum*, the pRAW plasmid (161). This plasmid

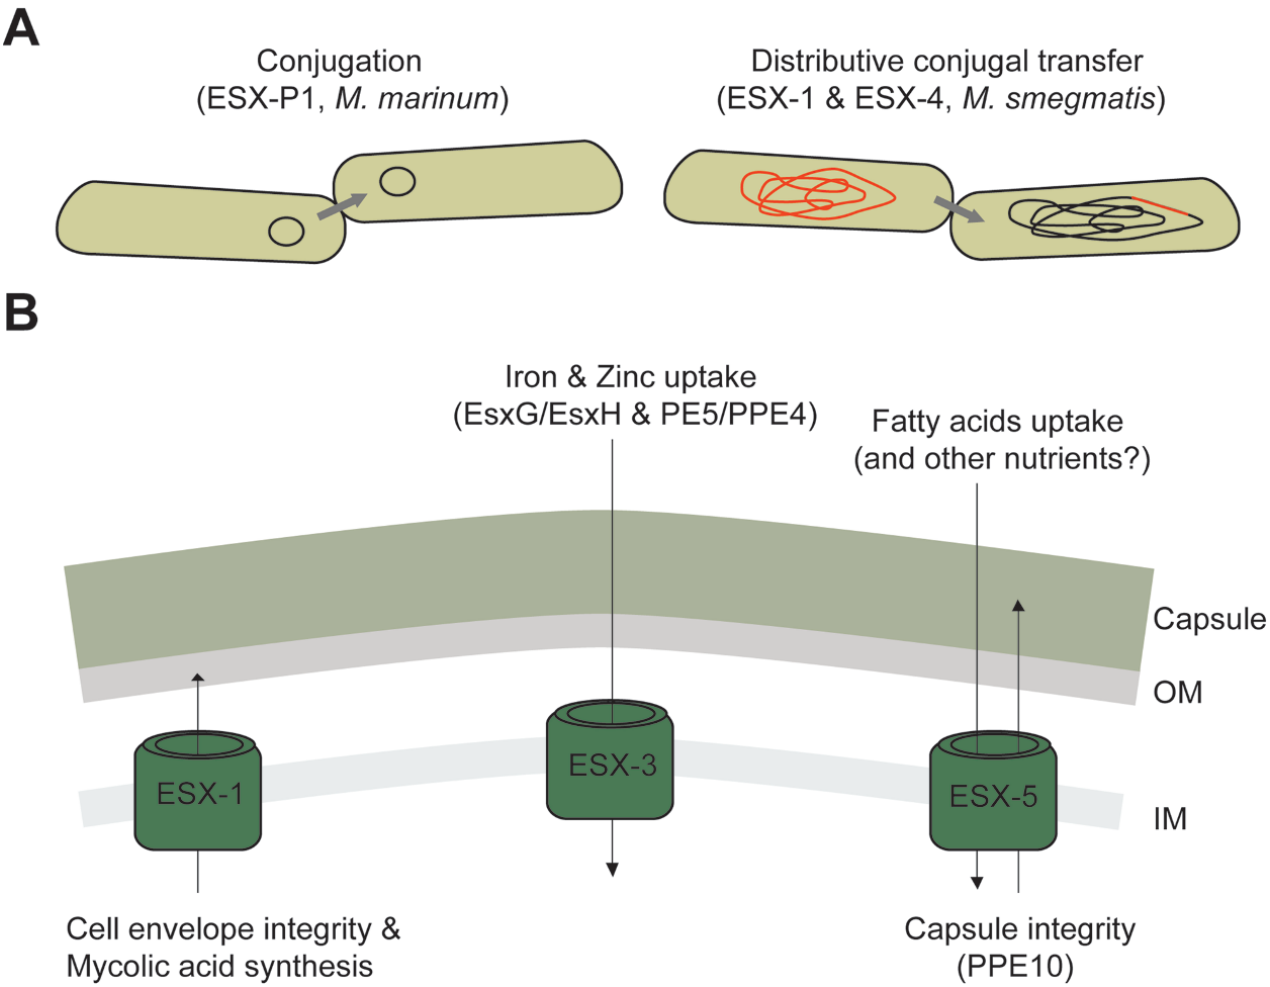

FIGURE 2 Roles of ESX systems in DNA transfer, and cell physiology and nutrient uptake. (A) The pRAW plasmid-encoded ESX-P1 system, present in certain strains of *M. marinum*, is involved in DNA conjugation, allowing the transfer of the plasmid to other slow-growing mycobacteria (161). Similar plasmids are found in other mycobacteria, and they have been linked to the evolution and distribution of *esx* gene clusters within mycobacteria (162, 256). In addition, the ESX-1 and ESX-4 systems of *M. smegmatis* are involved in distributive conjugal transfer, allowing the horizontal gene transfer of random large genomic fragments (143, 159). (B) A second major role of the ESX-systems is in cell physiology. While the ESX-1 system has been linked to the integrity of the cell envelope and the biosynthesis of mycolic acids (196, 210, 264), the ESX-3 and ESX-5 systems are involved in the uptake of metabolites and nutrients, respectively. The ESX-3 system and two of its substrate pairs (EsxG-EsxH and PE5-PPE4) have been specifically linked to the uptake of iron and zinc (144, 145, 147), while the ESX-5 system has been linked to the utilization of fatty acids and possibly other nutrients (149) Finally, the ESX-5 system secretes a substrate (PPE10) that is required for the integrity of the capsular layer (199). IM, inner membrane; OM, outer membrane.

contains not only an *esx* gene cluster, designated *esx-P1*, but also genes predicted to encode type IV secretion-like proteins, known to be involved in DNA conjugation in Gram-negative and Gram-positive bacteria (161, 252, 253). The pRAW plasmid could be transferred very efficiently, but only between different slow-growing species, whereas no transfer was observed to fast-growing mycobacteria, such as *M. smegmatis* (161). Conjugation of the pRAW plasmid was shown to depend on the presence of an intact *esx-P1* cluster and on the type IV-like genes (161). Interestingly, since then, similar *esx* gene cluster-containing plasmids have been found in various nontuberculous mycobacteria, both pathogenic and nonpathogenic (161, 254, 255). The wide distribution of these *esx*-containing plasmids has been linked to a possible role of plasmids in the evolution and distribution of *esx* gene clusters within mycobacteria (162, 256). Because ESX-P1 is most closely related to the ESX-5 system, pRAW-like plasmids might have been involved in acquiring the ESX-5 system in slow-growing mycobacteria.

DNA exchange and/or cell-to-cell contact is not the only function assigned to ESX systems. Another critical role of these systems is in the uptake of nutrients. In fact, both the ESX-3 and ESX-5 systems are involved in this, explaining why these systems are required for bacterial viability in slow-growing species (149, 155, 217, 257). The ESX-3 system is transcriptionally controlled by the iron-dependent transcriptional repressor (IdeR), and in *M. tuberculosis*, additionally by the zinc uptake repressor (Zur), indicating that the ESX-3 system is linked to the uptake of metal ions (258, 259). Indeed, the ESX-3 system is upregulated at low iron levels (145, 257, 260), and more recent work confirmed that the ESX-3 system is actively involved in the uptake of iron and, in the case of *M. tuberculosis*, also of zinc (144). The ESX-3 system was additionally shown to be essential for growth of *M. tuberculosis*, not only in low-iron or -zinc conditions, but also for optimal growth in high-iron and -zinc concentrations (144). For *M. tuberculosis*, six substrates of the ESX-3 system have been identified: EsxG-EsxH, PE5-PPE4, and PE15-PPE20. Interestingly, only EsxG-EsxH and PE5-PPE4 appear to be involved in iron uptake, while PE15-PPE20 is involved in immune modulation (147). In contrast to *M. tuberculosis*, the deletion of the ESX-3 system of *M. smegmatis* only affected bacterial growth when *fxbA* was also deleted. FxbA is an enzyme required for the biosynthesis of the high-affinity iron chelator or siderophore exochelin, which is not produced by *M. tuberculosis* (144, 145, 216). Importantly, the production of a second siderophore, mycobactin, only affected growth in this *fxbA* mutant, linking the function of ESX-3 to iron uptake through mycobactin (147). Later, it was shown that the addition of hemin rescues the growth of an *esx-3* mutant in *M. tuberculosis* (144), supporting the hypothesis that ESX-3 is involved in iron uptake (145).

Both directed knockout experiments and transposon insertion sequencing experiments have shown that the central components of the ESX-5 system are required for growth of *M. marinum* and *M. tuberculosis* (149, 217). Using a modified screen, transposon mutants could be identified that allowed the deletion of ESX-5 (149). These mutants contained a transposon in either the *mas* or *ppsD* gene, both involved in the synthesis of the phthiocerol dimycocerosates and phenolic glycolipids. The absence of these outer membrane lipids results in a more permeable cell envelope (149). To test whether a more permeable outer membrane was responsible for the observed difference in *esx-5* essentiality, an independent mechanism was devised. Indeed, heterologous expression of the outer membrane porin MspA from *M. smegmatis* in *M. marinum* also allowed the generation of *esx-5* mutants (149). Because the ESX-5 system is only present in slow-growing mycobacteria, while MspA-like outer membrane porins are only present in fast-growing species, it was proposed that the ESX-5 system is able to substitute the function of these porins in nutrient uptake (149). Growth assays utilizing different carbon sources showed a difference in the growth rate of wild-type *M. marinum* compared to an *esx-5* mutant for Tween-80, suggesting that the ESX-5 system is involved in the utilization of fatty acids (149). ESX-5 mutants were subsequently shown to be unable to internalize fluorescently labeled fatty acids (149). In addition to its role in uptake, the ESX-5 system could additionally be involved in the processing of Tween-80, releasing the oleic acid, as one of its substrates, LipY, degrades long-chain triacylglycerols (261). The role of the ESX-5 system in nutrient uptake is further substantiated by its upregulation under phosphate-limiting conditions by the Pst-SenX3-RegX3 system (262). This would also mean that specific ESX-3 and ESX-5 substrates might form the outer membrane channels that mediate the uptake of specific nutrients.

The ESX-5 system has a second physiological role, because it is required for the integrity of the capsule of *M. marinum* via its substrate PPE10 (199). Mutations in the *esx-5* system components or in *ppe10* resulted in a reduced capsular layer and, subsequently, reduced amounts of glycolipids and surface-localized proteins, such as EspE and PE_PGRS proteins (199). As a result of these morphological differences, a *ppe10* mutant showed a reduced hemolytic activity and reduced ubiquitin binding during infection of host cells, indicative of phagosomal rupture and cytosolic translocation, respectively, as read-outs for ESX-1 functionality (199). A study also found a link between the ESX-1 system and cell envelope integrity, because *esx-1* mutants in *M. tuberculosis* have been shown to have an increased susceptibility to detergents (196), although another study showed that ESX-1 mutations did not impact cell envelope integrity (263). Finally, studies of *M. marinum* have suggested a link between the ESX-1 system and mycolic acid biosynthesis (210, 264). In addition to these physiological roles, substrates of ESX-5, mainly the PE_PGRS proteins, have been implicated in host-pathogen interactions by various groups, although some of these results are still ambiguous (265).

T7S in Other Species

As already mentioned, T7S is also found outside of the mycobacterial family, not only throughout the phylum of *Actinobacteria*, including corynebacteria, nocardia, and *Streptomyces* species, but also in more distantly related systems that can be found in the *Firmicutes*. The T7S systems found in *Actinobacteria* are highly similar to the ESX systems of mycobacteria, all containing an Esx protein pair and four of the five conserved membrane components, EccB, EccC, EccD, and MycP; the membrane component EccE is only present in some T7S systems. In many cases *pe/ppe* gene pairs can also be identified (4). Interestingly, although EccE has been shown to be an integral component of both the ESX-1 and ESX-5 membrane complexes, the structure of the ESX-5 complex of *M. xenopi* showed that $EccE_5$ is present at the periphery of this complex, and in the absence of $EccE_5$, complexes could still successfully be purified (225). This makes it reasonable that secretion complexes can be functional without the EccE component in some T7S systems of *Actinobacteria*. The strong conservation of MycP is also rather unexpected, because MycP is not an integral component of the core secretion complex in mycobacterial ESX systems of

(212, 224, 225). However, because MycP is required for a stable ESX complex and successful secretion in mycobacteria (214, 224), it is possible that this is a conserved feature in all *Actinobacteria*. In addition to this, the association of MycP to the core complex might be stronger in the T7S systems of other *Actinobacteria*. This hypothesis is supported by the T7S gene cluster found in *Bifidobacterium dentium*, where there are two *mycP* copies, one of which is part of a chimeric gene together with a complete homologue of *eccB*. This gene potentially produces a chimeric protein, in which the periplasmic domain of EccB is fused to the protease domain of MycP (4).

Within the *Actinobacteria*, T7S is not limited to species containing mycolic acids, i.e., to species with a diderm cell envelope, because it is also present, for instance, in *Streptomyces* species such as *S. coelicolor*. These mycolic acid-lacking bacteria can also contain the five conserved membrane components (164), supporting the model of the ESX membrane complex mediating secretion across the inner membrane only (225). Consequently, components, or substrates, that mediate secretion across the mycobacterial outer membrane should not be present in these monoderm species.

The T7S systems found in the *Firmicutes* show a lower similarity to the ESX systems of mycobacteria. In fact, only the FtsK-SpoIIIE ATPase and (potential) substrates belonging to the WXG100 protein family are conserved (128, 129, 166). In addition to these conserved features, the *Firmicutes* systems contain a set of unique genes, encoding either substrates or system-specific (functional) components. The T7S systems within different *Firmicutes* species also show relatively high variation among each other, both in substrates and in (predicted) structural components.

While functional systems have been confirmed for *L. monocytogenes*, *Streptococcus agalactiae*, *S. intermedius*, *Bacillus anthracis*, and *B. subtilis* (166, 220, 266–269), most information on T7S in *Firmicutes* has been obtained for the T7S system of *S. aureus*, also called Ess (ESAT-6 secretion system) (220). The Ess system contains five structural components, conserved throughout different *S. aureus* strains (270), i.e., EssA, EssB, EssC, EsaA (Esa, ESAT-6 secretion accessory), and EsaB. Whereas EsaB is cytoplasmic, the other four components are membrane proteins (270), with EssC being the conserved FtsK-SpoIIIE ATPase. Interestingly, the C-terminal ATPase domain of EssC shows four variants within different *S. aureus* strains that cluster with genes encoding different potential substrates. It was recently shown that this domain is indeed involved in specific substrate recognition (270, 271). The role of EsaB is uncertain, because it is not required for Ess secretion in all *S. aureus* strains. An interesting feature of EsaB is the ubiquitin-like fold, resembling the soluble domain of EccD of mycobacteria (218, 272, 273). However, it is unknown how and if these proteins share a comparable function.

Recently, several papers were published describing the first structural data on the Ess secretion complex. Whereas one study only found homo-oligomers of EsaA, EssB, and EssC (274), other studies showed a complex consisting of EssC, EsaA, EssB, and EssA (275, 276). It is possible that both the heteromeric and homo-oligomeric complexes are present in *S. aureus*, because Ess secretion in *S. aureus* is highly variable both in different strains and at different growth phases (272). In addition, a flotillin-like protein has been found to catalyze the heteromeric oligomerization of the Ess complex (275). This opens the possibility that scaffold proteins are involved in complex assembly upon their specific upregulation during, e.g., different growth phases or during infection (272, 277). Based on these three studies, the Ess complex seems less stable than the ESX-complexes found in mycobacteria, as for instance, shown by the strong effect of different mild detergents on the oligomerization state (274). This considerably complicates the isolation and characterization of the Ess secretion complex.

The Ess system of *S. aureus* contains two proteins of the WXG100 family, EsxA and EsxB, which are, unlike the homologous proteins in mycobacteria, not produced from bicistronic transcripts and not cosecreted as a heterodimer (278). Interestingly, EsxA is reported to either self-interact or interact with the substrate EsxC, and EsxB interacts with EsxD (279, 280). All four of these secreted proteins have been linked to the pathogenicity of *S. aureus* (272, 273, 279). Inactivation of the Ess system results in a less persistent infection and reduced bacterial survival (220, 272, 273); more specifically, Ess-mediated secretion of EsxA and EsxB is required for the formation of staphylococcal abscesses and the blocking of apoptosis, indicating a role in intracellular survival (220, 273, 281, 282). Unlike the ESX-3 and ESX-5 systems of mycobacteria, which are required for bacterial viability, the Ess system of *S. aureus* is dispensable for *in vitro* growth (220, 273).

The *B. subtilis* T7S system (also known in the literature as the YukE-Yue system) resembles the Ess system of *S. aureus*. The notable difference is that it only seems to secrete a single substrate, the WXG100 protein YukE, which forms a homodimer (167, 283, 284). Similar to the Ess system, the YukE-Yue system also contains five functional components, the membrane proteins YukC, YukBA, YueB, and YueC and the cytoplasmic YukD, the latter resembling EsaB of *S. aureus* (167, 283, 285). YukBA is the FtsK/SpoIIIE ATPase of the system. A *yueB* mutant shows reduced conjugative DNA transfer, similar to the ESX-1 system *M. smegmatis* (286). WXG100 genes have also been found in the pathogenic strains *Bacillus cereus*, *Bacillus thuringiensis*, and *B. anthracis*, and at least several of their protein products are actively secreted (167, 267, 283). For example, *B. anthracis* contains six WXG100 genes, of which the gene products EsxB and EsxW are secreted during *in vitro* growth, while the other genes might only be expressed during infection (267).

One distinguishing feature of the T7S systems of *Firmicutes* compared to the ESX systems of mycobacteria is their involvement in bacterial competition by mediating the secretion of toxins. This intriguingly shows that *Firmicutes* use T7S systems in bacterial warfare similarly to how Gram-negative bacteria use type VI secretion systems. For example, *S. aureus* secretes a fifth substrate, EsaD, which functions as an antibacterial DNase (287). The toxic effects of EsaD are blocked by EsaG, an antitoxin produced also by *S. aureus* strains lacking EsaD (287). A T7S system in *S. intermedius* secretes so-called LXG proteins, with N-termini homologous to WXG100 proteins, that function as antibacterial toxins in a contact-dependent manner (266). LXG toxins with RNase activity have also been found in *B. subtilis* (288) and shown to have antibacterial properties when produced in *E. coli*. Although they contain a typical N-terminal WXG100 motif, it is not known whether these proteins are dependent on the YukE-Yue system for secretion (288). A genomic study found that predicted T7S substrate genes with putative toxin activities are present in a range of different species, indicating that T7S systems might be widely used by *Firmicutes* in bacterial competition (289).

OUTLOOK

In the past 15 years, considerable effort has been made to understand the different export pathways of mycobacteria. A major focus of research in this area has been the identification

of substrates of the different systems and their roles in mycobacterial physiology and virulence. In parallel, we are steadily obtaining insight into the components of these systems and their mechanisms of substrate recognition and transport. However, a major topic that needs to be addressed is the issue of how proteins transit the specific mycolic acid-containing second membrane for release into the extracellular environment. While T7S substrates are among the most abundant proteins found in culture supernatants, there are also signal peptide-containing proteins that are efficiently secreted into the extracellular environment (17, 18, 63, 120, 290–292), emphasizing the importance of an outer membrane translocation step. Protein transport across this highly impermeable outer membrane should be tightly regulated to maintain the permeability barrier, because this is crucial for pathogenic mycobacteria to withstand the harsh conditions of their intracellular niche. As discussed in this article, for T7S, some specific substrates might be involved in the second membrane transport event; however, the mechanism of outer membrane transport for the Sec, Tat, and SecA2 substrates is a complete mystery. Research focused on identifying and characterizing the proteins that are localized to this special mycobacterial outer membrane is urgently needed to gain insight into these processes.

Our work is supported by a VIDI grant (864.12.006) from the Netherlands Organization for Scientific Research (NWO) (to E.N.G.H.) and by grant AI054540 from the National Institute of Allergy and Infectious Disease (NIAID) (to M.B.).

We thank Brittany Miller and Wilbert Bitter for critical reading of the manuscript.

Corynebacterium diphtheriae: Diphtheria Toxin, the *tox* Operon, and Its Regulation by $Fe2^+$ Activation of apo-DtxR

SADIYA PARVEEN, WILLIAM R. BISHAI AND JOHN R. MURPHY

69

INTRODUCTION

Over the past 4 decades, perhaps no other infectious disease has been as successfully studied as diphtheria (1, 2). Indeed, the study of diphtheria toxin established the structure-function paradigm for the study of other toxins in the bacterial protein toxin field. Moreover, when coupled with the molecular genetic study of the iron-activated regulatory element, DtxR, that controls the expression of diphtheria toxin, we now have a detailed understanding of the entire *tox* genetic system, from the regulation of expression to the molecular mechanism of diphtheria toxin action. In this article, we review the development of our current understanding of diphtheria toxin, from its structure-function relationships to its mechanism of entry into the eukaryotic cell cytosol, the molecular mechanism of transition metal ion activation of DtxR and its regulation of *tox* expression, and finally, the protein engineering of diphtheria toxin for the development of highly potent and selective cell-surface receptor-targeted fusion protein toxins for the treatment of human diseases.

It is well known that to cause clinical disease, the etiologic agent of diphtheria, *Corynebacterium diphtheriae*, must first be infected with one of a closely related family of bacteriophages that carry the structural gene for the toxin. Humans are the only natural host for diphtheria, and disease is readily spread through close contact and aerosolized droplets. While clinical diphtheria remains prevalent in tropical developing countries where immunization with diphtheria toxoid remains sporadic, diphtheria is almost nonexistent in industrialized countries that have continued to maintain a comprehensive immunization program with diphtheria toxoid. Since diphtheria toxin is secreted into the culture medium, the high-yield-producing Park-Williams 8 strain of *C. diphtheriae* has been used almost worldwide to produce diphtheria toxin in sufficient yields to produce diphtheria toxoid (3). Once purified from the spent culture medium, native diphtheria toxin is then treated with formalin at 30 to 38°C for several weeks to produce the nontoxic toxoid. To produce the vaccine, diphtheria toxoid is absorbed to alumina, which acts as an adjuvant, and it is then combined with tetanus toxoid and either heat-killed *Bordetella pertussis* to produce the DPT vaccine or purified pertussis antigens to produce the diphtheria-tetanus-acellular pertussis vaccine.

Along with botulinum, tetanus, and Shiga, diphtheria toxin is one of the most potent bacterial protein toxins known. In humans the 50% lethal dose for diphtheria toxin was found to be approximately 100 ng/kg. This value was determined after a catastrophic accident in Kyoto, Japan, in 1948. Shortly after the end of World War II, a mass immunization program against diphtheria was initiated in Japan. After the production of diphtheria toxin and its distribution into vials for formalin detoxification in the preparation of toxoid, one vial of toxin was either inadvertently not treated or reverted to full toxicity after formalin treatment and was sent into the community as part of the program to immunize children. Of 606 children that were "immunized" from this vial, 68 children, mostly between the ages of 1 and 2, died of diphtheria intoxication (4, 5). Since the concentration of toxin in the vial, the dose that was administered, and the body weight of the children were all known, the human 50% lethal dose for diphtheria toxin could be calculated.

While diphtheria toxoid as a vaccine was available as early as the 1920s, investigations into the development of a simplified medium for toxin production led Alwin M. Pappenheimer, Jr., to make one of the earliest observations that the concentration of iron in the growth medium was critical to obtain maximal yields of the toxin (6). In 1935, Pappenheimer, then a Bradford Fellow at the Harvard Medical School, started his laboratory at the Massachusetts Antitoxin and Vaccine Laboratory to work on diphtheria toxin production. At that time Pyrex glassware was newly available, and he used Pyrex flasks in his first attempts to produce toxin. While he followed established protocols for medium preparation and incubation temperature and time for maximal yields, Pappenheimer was able to produce only half as much toxin as that reported by his predecessors who used the older soft glassware flasks in the laboratory. The question was obvious: Why did the glassware make a difference in toxin production? Pappenheimer's experiment to address the question was equally obvious: He broke a flask made of soft glass and ground it into a powder. He then added varying amounts of powdered glass to the Pyrex flasks he was using and determined its effect on toxin production. Remarkably, Pappenheimer found that the addition of as little as 300 μg powdered soft glass resulted in a stimulation of both *C. diphtheriae* growth and toxin yield. Equally importantly, he found that the addition of 5 or 10 mg of powdered glass resulted in the almost complete inhibition of toxin production without a change in the growth of the diphtheria

doi:10.1128/microbiolspec.GPP3-0063-2019

bacillus. The irony (pun intended) of this story is that Pappenheimer wrote his Ph.D. dissertation at Harvard College on the effect of organic bases on the oxidation potential of heme. It is no surprise then that his first experiments were focused on the effect of adding increasing amounts of inorganic iron to the growth medium as a function of diphtheria toxin yield. As shown in his classic 1936 paper (6), the stimulation and subsequent inhibition of toxin production following the addition of either powdered glass or iron salts to the media were superimposable. The ability to produce a maximal yield of diphtheria toxin in the soft glass resulted from the leaching of small levels of iron from the glass into the culture medium. We now know that maximal yields of diphtheria toxin are produced only when iron becomes the growth-rate-limiting substrate. So, as early as 1936, it was realized that with respect to iron, an essential nutrient for the growth of the bacillus, the physiologic state of toxigenic *C. diphtheriae* was a determining factor in the production of diphtheria toxin.

TEMPERATE CORYNEBACTERIOPHAGES CARRY THE STRUCTURAL GENE FOR DIPHTHERIA TOXIN, *tox*, IN LYSOGENIC *C. DIPHTHERIAE*

While it had been known since the earliest observations of *C. diphtheriae* that there were both virulent and nonvirulent strains that could be isolated from healthy individuals, it was not until the remarkable discovery by Freeman (7) that one could isolate diphtheria toxin-producing strains following the exposure of nontoxigenic strains to corynebacteriophages. Thus, it became clear that not only the physiologic state of *C. diphtheriae* with respect to the concentration of iron in the growth medium but also its lysogenic state determined the ability of a given isolate to produce diphtheria toxin. As important as Freeman's observation was, the question of whether it was the host bacterium or the lysogenic phage that carried the structural gene for the toxin still remained.

Twenty years after Freeman's initial report, Uchida et al. (8) described the isolation of corynebacteriophage β mutant lysogens of *C. diphtheriae* that produced nontoxic proteins that were serologically related to diphtheria toxin. The discovery of these mutant serologically related cross-reacting materials (CRMs) was extremely important because they not only demonstrated that the structural gene for diphtheria toxin, *tox*, was carried by β-phage, but the isolation of CRMs that were the result of both nonsense (e.g., CRM45) and missense (e.g., CRM197) mutations established both the genetic orientation of the toxin, N- to C-terminal, and began to give both biochemical and genetic definition to its structural-functional domains.

While corynebacteriophage β has not been nearly as well studied as coliphage λ, it is a temperate phage and, as such, may either enter a vegetative lytic cycle or lysogenize a sensitive host (e.g., the nontoxigenic, nonlysogenic $C7_s(-)^{tox-}$ strain of *C. diphtheriae*) and convert it from a *tox*– to a *tox*+ phenotype. Both genetic and molecular genetic evidence suggest that the linear β-genome circularizes by ligation of its cohesive ends (*cos*) and integrates into the host chromosome as a prophage in a manner that corresponds to that for the integration of λ-phage into the *Escherichia coli* genome (9–11). It has been shown that the prophage map is a circular permutation of the vegetative map and that the *imm* marker is positioned at one end of the β-genome and *tox* is at the other end (Fig. 1). The $C_s7(-)^{tox-}$ genome carries two

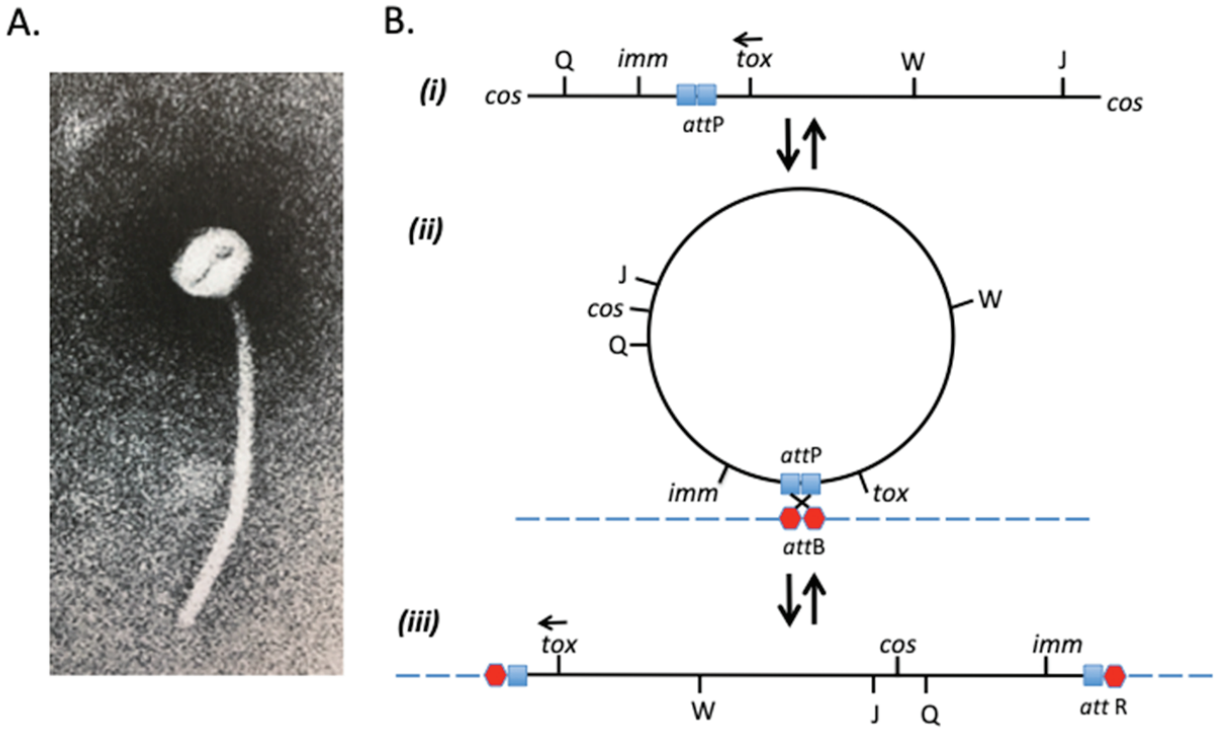

FIGURE 1 (A) Electron micrograph of corynebacteriophage β, which has a polyhedral head ~52 nm in diameter and a 270 nm long tail. (B) Genetic map of β-phage in its (i) vegetative phase, (ii) circularized form, and (iii) prophage state. (Modified from reference 9.)

separate *attB* sites, *attB1* and *attB2*, and as a result, β-phage can integrate and form single lysogens, double lysogens, and in rare instances, triple lysogens (12). In its lysogenic state, most β-phage genes appear to be repressed, and the lysogen is immune to superinfection by homoimmune corynebacteriophages. While triple lysogens are unstable and revert to stable double lysogens, under iron-limiting conditions, the final yield of diphtheria toxin that may be produced is directly related to the number of integrated prophage genomes (12).

CORYNEBACTERIAL DETERMINED DtxR REGULATES EXPRESSION OF THE CORYNEBACTERIOPHAGE *tox* GENE

As noted above, the discovery by Uchida et al. (8) that the structural gene encoding diphtheria toxin was carried by corynebacteriophage β raised the question of whether the iron-sensitive regulation of *tox* expression was mediated by either a corynebacteriophage or corynebacterial determinant. To address that question, Murphy et al. (13) used S-30 extracts of *E. coli* in a coupled transcription-translation system programmed with β-phage DNA to synthesize diphtheria toxin *in vitro*. In this system, diphtheria toxin was expressed in good yield, and remarkably, the *in vitro* synthesis of the toxin was not inhibited by the addition of iron. In contrast, the addition of cell-free extracts of the nontoxigenic, nonlysogenic $C7_s(-)^{tox-}$ strain of *C. diphtheriae* to the *E. coli* system resulted in the inhibition of *tox* expression but not that of other phage gene products. These results clearly suggested that the inhibitory effect of iron was mediated through a bacterial host-determined factor. Furthermore, the subsequent isolation of *C. diphtheriae* mutants which when lysogenized by β-phage constitutively expressed diphtheria toxin in the presence of excess iron (14), as well as the isolation of phage mutants which constitutively expressed diphtheria toxin when lysogenized in wild-type *C. diphtheriae* (15, 16), ultimately led to a hypothetical model for the regulation of *tox* expression (Fig. 2).

DNA sequence analysis of the structural gene for diphtheria toxin revealed a 27-bp interrupted palindromic sequence that overlapped the putative –10 region of the *tox* promoter (17–20). Based on these observations, this upstream region of the gene encoding diphtheria toxin was then designated the *tox* promoter-operator, *toxPO*. In 1989, Fourel et al. (21) used DNase protection assays to show that an element(s) found in crude cell-free extracts of *C. diphtheriae* specifically bound to *toxO*. Mutant strains of *C. diphtheriae* that are *cis*-dominant for toxin production were later found to carry mutations only in the *tox* operator (22–24).

To clone the *trans*-acting putative *tox* repressor, Boyd et al. (25) screened genomic libraries of the $C7_s(-)^{tox-}$ strain of *C. diphtheriae* in recombinant *E. coli* that carried a transcriptional fusion between *toxPO* and *lacZ*. This work led to the isolation of the structural gene for the diphtheria *tox* repressor, *dtxR*, which encoded a 226-amino acid protein. DtxR was shown to repress the expression of β-galactosidase from the *toxPO-lacZ* fusion in *E. coli* in an iron-dependent fashion. Schmitt and Holmes (23) subsequently demonstrated the functional activity of DtxR in *C. diphtheriae* by showing that expression of wild-type *dtxR* in the iron-insensitive host-mutant C7hm723(β^{tox+}) strain resulted in conversion to the wild-type iron-sensitive phenotype.

TRANSITION METAL IONS ACTIVATE DtxR BINDING TO THE *tox* OPERATOR

By using gel mobility shift assays, Tao et al. (26) demonstrated that the activation of apo-DtxR and its subsequent binding to a [^{32}P]-labeled *toxO* probe required the addition of divalent transition metal ions to both the binding reaction mixture and the gel matrix. Since binding of DtxR to the labeled *toxO* probe was blocked by the addition of excess unlabeled probe, anti-DtxR antibodies, or the chelator 2,2′-dipyridyl, DtxR binding was specific and dependent on metal ion activation. Both Tao and Murphy (27) and Schmitt and Holmes (28) demonstrated that the addition of Co^{2+}, Fe^{2+}, Ni2+, Cd^{2+}, or Mn^{2+} activated apo-DtxR and resulted in the protection of the *toxPO* probe in DNase protection assays. Zinc was found to be only a weak activator of apo-DtxR, and Cu^{2+} failed to activate repressor activity.

While apo-DtxR could be activated by a number of divalent transition metal ions, Tao and Murphy (29) demonstrated that the activated DtxR could also bind to a number of closely related DNA target sequences. To determine the consensus operator sequence for DtxR binding, Tao and Murphy used a gel electrophoresis mobility-shift assay and PCR amplification for *in vitro* affinity selection of randomized DNA sequences from a universe of $>6 \times 10^{10}$ variants. After 10 rounds of *in vitro* selection, each with 30 cycles of PCR amplification, a family of DNA sequences that functioned as DtxR-responsive elements both *in vitro* and *in vivo* was isolated and characterized. The consensus sequence for DtxR binding was found to be as follows: T.AGGTTAGC/GCTAACCT.A. Moreover, since this family of related target sequences was found to bind DtxR with the same apparent affinity as the 27-bp *tox* operator, it was clear that the iron-activated repressor was most likely to function as a global regulatory element in the regulation of iron-sensitive genes in *C. diphtheriae*. Indeed, a number of genes which have upstream DtxR-binding sites, including the operon essential for the expression of siderophores for iron acquisition, have been isolated and characterized (23, 28).

Since the cloning and characterization of DtxR from *C. diphtheriae*, homologous metal ion-activated repressors have been identified in a number of other Gram-positive prokaryotes. IdeR (iron-dependent regulator) which has been found in several species of *Mycobacterium* and is 78% identical and 90% homologous has been isolated and characterized (30). Remarkably, expression of the *C. diphtheriae* hyperactive repressor, DtxR(E175K), in merodiploid strains of both *Mycobacterium tuberculosis* and *Staphylococcus aureus* has been shown to attenuate virulence *in vivo*, presumably by repression of iron-sensitive genes (31–33). These results clearly suggest that there is a high degree of both function and DNA sequence target specificity between DtxR and IdeR. In addition, DtxR homologs have been identified in a number of genera, including the species *Enterococcus faecalis* (34), *Streptococcus mutans* (35), *S. aureus* (36), *Streptomyces pilosus* (37), and *Rhodococcus equi* (38). It is of interest to note that

both *M. tuberculosis* and *C. diphtheriae* also express additional DtxR-like proteins which are likely to be activated by different transition metal ions and have different DNA target sequences (39), including the MntR protein in *C. diphtheriae*, which is responsive to Mn^{2+}.

STRUCTURAL BASIS OF TRANSITION METAL ION ACTIVATION OF DtxR REPRESSOR ACTIVITY

As noted above, DtxR is a 226-amino acid protein. DNA sequence analysis revealed a single cysteine residue, Cys102, and disulfide-linked dimers are inactive. The substitution of Cys102 with all 20 amino acids, except for Asp, by site-directed mutagenesis results in the complete loss of repressor activity. Further characterization of the wild type and individual mutants demonstrated that Cys102 plays an essential role in the coordination of Fe^{2+} in the activation of apo-DtxR (40). In addition, Wang et al. (24) used bisulfite mutagenesis to inactivate DtxR and found that a high percentage of mutations were found in regions of DtxR that exhibited homology with other repressors. In addition, a number of mutations were also isolated in a predicted α-helical region with the sequence of His98-Cys102-His106 that resembled metal ion-binding motifs in other proteins.

A more complete understanding of the structural basis of metal ion-activated DtxR repressor activity was revealed by the solution of the crystal structures of apo-DtxR and holo-DtxR in complex with *toxPO* (41–44). As shown in Fig. 3, the structure of the C-terminal end of DtxR was found to fold into a SRC homology 3 (SH3)-like domain (45). The SH3 domain was first described as a conserved sequence in the viral adaptor protein v-Crk but has also been found to be present in phospholipases and the cytoplasmic tyrosine kinases, Abl and Src. In general, SH3 domains are found in proteins that either interact with other proteins or mediate the formation of specific protein complexes by binding to proline-rich peptide sequences.

DtxR contains a total of eight α-helices, six of which are contained in the N-terminal two-thirds of the protein. Helices B and C and the loop connecting them form the helix-turn-helix DNA-binding motif. Interestingly, Ni^{2+}-activated DtxR was shown to bind to the *toxPO* oligonucleotide as two pairs of dimers (44). In this instance, each DtxR dimer was found to bind to almost opposite faces of the palindromic *tox*O sequence (Fig. 4). As one would anticipate, the solution of the X-ray structures of DtxR and the ternary complex that forms with its binding to *tox*O confirms and extends the earlier observation that its footprint compasses a region of 30 bp immediately upstream of the transcription initiation signal (46).

While the overall mechanism of DtxR binding to *tox*O is similar to that of other prokaryotic repressors, there are some unique interactions that should be noted. The C-helix of DtxR is responsible for most interactions with DNA and inserts into the major groove of the DNA double helix. Each helix-turn-helix in the dimer makes a total of nine interactions with backbone phosphate groups. In addition, the guanidinium group of Arg60 binds in the minor groove of DNA and thereby makes a bridge to additional phosphate groups. Since there is a structural rearrangement of activated DtxR upon binding to the *tox* operator, Thr7 in helix A also interacts with a backbone phosphate group, and Ser37 and Pro39 contact methyl groups on thymine bases in the *tox* operator through van der Waals interactions (47).

While saturation and equilibrium dialysis experiments suggested that DtxR contained a single metal ion-binding site with an apparent dissociation constant of 2×10^{-6} to 9×10^{-7} M (46), X-ray crystallographic analysis of transition metal ion-DtxR complexes clearly revealed two metal ions bound to each monomer (41, 43). Using site-directed mutagenesis, Ding et al. (48) demonstrated that the primary metal ion-binding site of DtxR is composed of Met10, Cys102, Glu105, His106, and a water molecule form an octahedral coordination center. The second metal ion-binding site, or ancillary site, is composed of five residues: His79, His98, Glu83, Glu170, and Gln173 (41, 43, 49). The role played by the ancillary metal ion-binding site was elucidated through the analysis of DtxR(E175K), a hyperactive mutant that remained active *in vivo* even in the presence of the chelator 2,2′dipyridyl (50). *In vitro* studies with purified apo-DtxR(E175K) demonstrated that this mutant required very low levels of metal ion to transit from an inactive apo- to

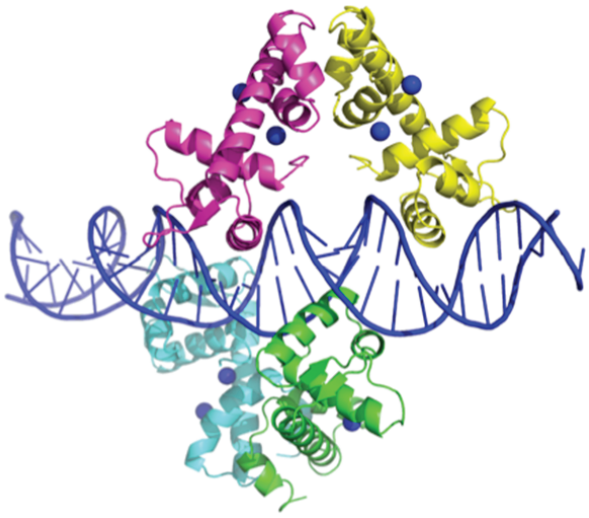

FIGURE 4 X-ray crystal structure of Ni^{2+}-activated DtxR (C102D) bound to the *tox* operator. Due to high thermal values, the C-terminal SH3-like domain is not shown in this Ni^{2+} activated structure. (Modified from reference 44 [Protein Data Bank ID 1DDN].)

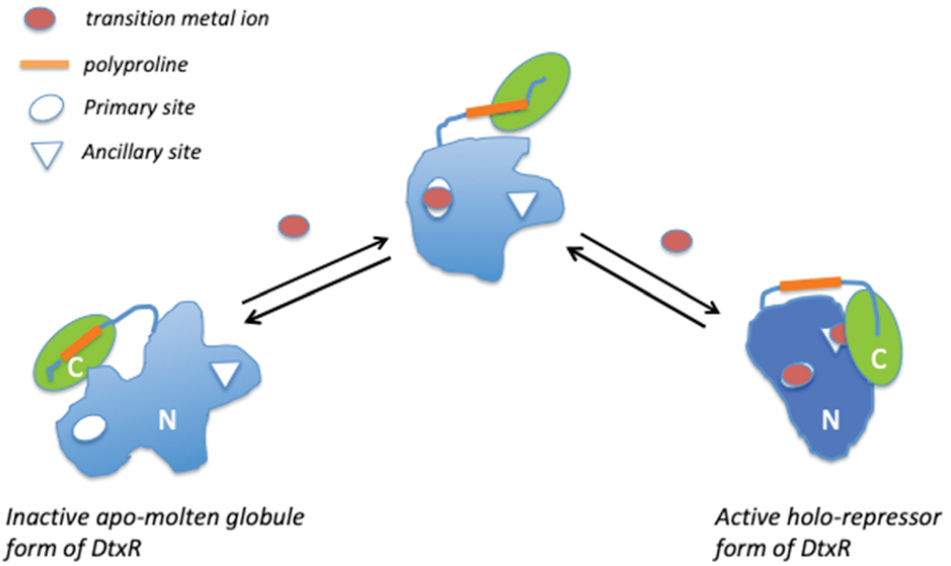

FIGURE 5 DtxR is a two-domain protein that is composed of the N-terminal [blue] and C-terminal SH3-like [green] regions and functionally distinct transition metal ion-binding sites (primary and ancillary). An activating transition metal ion first binds to the primary site. This binding event orients the DNA-binding helices and begins to induce the folding of the disordered N-terminal domain. Subsequent binding of a second metal ion to the ancillary site disassociates and reorients the SH3-like domain away from the poly-proline region of the repressor and completes the folding of the N-terminal domain, resulting in the formation of the dimer interface of the active holo-repressor. (Modified from reference 52.)

the active form of the repressor. Love et al. (51) demonstrated that the hyperactive phenotype of DtxR(E175K) was dependent on an intact ancillary metal ion-binding site and that this site facilitated the conversion of the inactive apo-repressor to its active *tox*O binding conformation.

Nuclear magnetic resonance solution structures combined with other biophysical studies have suggested that apo-DtxR exists in a partially unstructured molten globule, which upon coordination with divalent transition metal ions undergoes a structural conversion to a discrete ordered tertiary structure that both dimerizes and is able to bind to the *tox* operator (52). As shown schematically in Fig. 5, in its inactive molten globule apo-form, the SH3-like domain forms an intramolecular complex with a proline-rich peptide segment of the repressor and, in doing so, destabilizes the ancillary metal ion-binding site of the repressor, and this leads to the complete inactivation of the repressor. Upon metal ion-binding to the primary site, the SH3-like domain disassociates from this proline-rich region, thereby allowing a structural conversion and stabilization of the ancillary metal ion-binding site. The resulting conformational changes then allow the binding of the second metal ion to the ancillary site and subsequent dimerization of DtxR and the formation of an active repressor (53).

STRUCTURE-FUNCTION RELATIONSHIPS OF DIPHTHERIA TOXIN AND THE MOLECULAR MECHANISM OF ITS ACTION

Diphtheria toxin is expressed and secreted into the culture medium as a single polypeptide chain of 62 kDa by *C. diphtheriae*. The toxin is readily purified from the spent culture supernatant by ammonium sulfate precipitation followed by ion exchange chromatography on a diethylaminoethyl matrix. While the intact toxin is enzymatically inactive, exposure of purified toxin to trypsin or other serine proteases results in "nicking" of the protein and the subsequent activation of adenosine diphosphate ribosyl (ADPR) transferase. Under reducing and denaturing conditions, nicked diphtheria toxin may be separated into an enzymatically active N-terminal 24-kDa fragment A and its 38-kDa C-terminal fragment B (54, 55). Honjo et al. (56) and Gill et al. (57) demonstrated that nicked diphtheria toxin and fragment A were enzymatically active in catalyzing the following reaction:

$$\text{NAD}^+ + \text{elongation factor 2} \leftrightarrow \text{ADPR-elongation factor 2} + \text{nicotinamide} + \text{H}^+$$

Yamaizumi et al. (58), in a series of elegant experiments, loaded erythrocyte ghosts with various concentrations of purified fragment A and a known concentration of fluorescein isothiocyanate-labeled bovine serum albumin. These preloaded red cell ghosts were then fused to diphtheria toxin-resistant mouse L-cells by Sendai virus. Using a fluorescence-activated cell sorter, L-cells that fused with a single red cell ghost were then isolated and grown for 7 days. Careful analysis of the colony-forming ability of the recipient cells compared to the control cells clearly demonstrated that the delivery of a single molecule of fragment A to the cytosol was sufficient to kill that cell.

Comparison of the nontoxic mutants CRM197 and CRM45 revealed that the C-terminal 38 kDa fragment B of diphtheria toxin carried two functional domains: a hydrophobic domain (59), which under denaturing conditions behaved like an integral membrane protein, and the native receptor-binding domain. As such, it was realized through biochemical and genetic analyses that native diphtheria toxin was a protein with at least three structural-functional domains: (i) catalytic, (ii) transmembrane or translocation, and (iii) receptor-binding domains. As shown in Fig. 2, this prediction

proved to be correct with the determination of the crystal structure of diphtheria toxin (60, 61). While DNA sequence analysis of the *tox* structural gene revealed the presence of a 21-amino acid signal sequence (18–20), the mature form of diphtheria toxin is a 535-amino acid polypeptide. The N-terminal catalytic domain consists of amino acids Gly1 to Cys186 and is composed of eight β-strands that form two β-sheets forming a core structure that is surrounded by seven short α-helices. The β-sheets that form the central core also form the active site cleft. The catalytic domain is connected to the centrally positioned translocation domain by a 14-amino acid loop that is subtended by a disulfide bond between Cys186 and Cys201. This exposed loop carries an ArgArgValArg protease recognition site for either furin or other trypsin-like proteases. The proteolytic cleavage of this site is essential for the release of the catalytic domain into the eukaryotic cell cytosol (62). The translocation domain encompasses amino acids Cys186 to K385 and is composed of nine α-helices and their connecting loops. The translocation domain plays an essential role in the intoxication process by forming an 18- to 22-Å channel, or pore, through which the catalytic domain is threaded from the lumen of acidified endocytic vesicles into the cytosol. This channel is formed by translocation helices 5 to 7 and 8 to 9, which are highly hydrophobic and form two membrane-soluble "daggers" (61). The loops connecting translocation helices 8 to 9 and 5 to 6 are highly acidic and carry a total of six Asp and Glu residues. Upon internalization of the toxin into an endosomal compartment and the acidification of the vesicle lumen by the vacuolar ATPase, the carboxylic acid groups on these Asp and Glu residues become protonated and lose their respective charges, allowing for membrane insertion and channel formation.

Ratts et al. (3) developed an *in vitro* assay system composed of partially purified endosomes that were preloaded with either diphtheria toxin or the fusion protein toxin DAB389IL-2 in the presence of the vacuolar ATPase inhibitor bafilomycin A1 to probe the requirements necessary for catalytic domain translocation from the endosomal lumen to the external medium. Upon removal of bafilomycin A1 and addition of ATP, the endosomal lumen becomes rapidly acidified; however, catalytic domain translocation to the external medium was shown to require the addition of eukaryotic cytosolic fractions to the assay mixture. Using this assay system, Ratts et al. (3) demonstrated that both coatomer complex 1 (COPI) and thioredoxin reductase were essential for *in vitro* translocation of the catalytic domain. Ratts et al. (63) also described a highly conserved motif, T1, in translocation helix 1 of diphtheria toxin that played an essential role in the delivery of the catalytic domain to the cytosol. In 2010, Trujillo et al. (64) used both site-directed mutagenesis and a COPI complex precipitation assay to demonstrate that the interaction(s) between at least three lysine residues in the T1 motif are essential for both COPI binding and delivery of the catalytic domain to the eukaryotic cell cytosol. Further, Trujillo et al. (64) demonstrated that substitution of the lysine-rich region in translocation helix 1 with the COPI binding portion of the p23 adaptor cytoplasmic tail results in a mutant form of toxin that displays full wild-type activity against sensitive eukaryotic cells.

The above-described studies demonstrate that diphtheria toxin has evolved to become an extremely efficient nanomachine in which all of its structural domains play an essential role in the intoxication of sensitive eukaryotic cells. The molecular mechanisms leading toward intoxication require at least the following steps: (i) binding of the toxin to its cell surface receptor, the heparin-binding epidermal growth factor precursor, (ii) furin-mediated nicking of the protease-sensitive RVRR site in the 14-amino acid exposed loop between the catalytic and translocation domains, (iii) internalization of toxin into an endosomal compartment that becomes acidified through the action of its vacuolar ATPase, (iv) insertion of translocation helical loops formed by TH5-7 and TH8-9 into a vesicle membrane forming a channel or pore, (v) the insertion of the disulfide-linked C-terminal end of the catalytic domain and N-terminal end of the translocation domain into the channel, (vi) protein::protein interactions between the dibasic KXKXX signatures in translocation helix 1 with COPI, which facilitates the threading and translocation of the catalytic domain through the channel, (vii) reduction of the disulfide bond between the catalytic and translocation domains by thioredoxin reductase, (viii) the release and refolding of the catalytic domain into an enzymatically active ADP-ribosyltransferase, and (ix) the NAD^+-dependent ADP-ribosylation of elongation factor 2, which results in the cessation of protein synthesis and death of the cell (65).

MOLECULAR EPIDEMIOLOGY OF DIPHTHERIA AND DtxR

Outbreaks of clinical diphtheria almost always occur in individuals who have not been immunized with either the DPT or diphtheria-tetanus-acellular pertussis vaccine and who have been exposed to a "carrier" (a person who carries a toxigenic strain of *C. diphtheriae* as part of their normal flora) who has recently traveled to a country where mass immunization against diphtheria is not performed and disease is still prevalent. *C. diphtheriae* is usually transmitted via the aerosol route; close contact with an individual presenting with cutaneous diphtheria may also result in transmission. While colonization of a susceptible individual with a toxigenic strain certainly plays a role in pathogenesis, Pappenheimer and Murphy (66) demonstrated that transmission of toxigenicity may also occur by *in situ* lysogenic conversion of an autochthonous nontoxigenic strain of *C. diphtheriae* to toxigenicity. It is remarkable that immunization with diphtheria toxoid results in the production of neutralizing antibodies that not only block diphtheria toxin from binding to its cell surface receptor, but also protects against clinical disease (67, 68). It is well known that mass immunization of populations with diphtheria toxoid has led to a dramatic decrease in the incidence of clinical disease (69). For example, in 1958, before mass immunization with diphtheria toxoid in Romania, only 60% of the population was immune to diphtheria toxin, whereas by 1979, the percentage dramatically increased to 97%. At the same time, diphtheria morbidity dropped from ca. 600 per 100,000 in 1958 to only 1 per 100,000 in 1972 (67, 70).

The consequence of either stopping or dramatically reducing a mass immunization program against diphtheria is also known. During the 1990s, the Newly Independent States (NIS) of the former Soviet Union experienced a sweeping epidemic of clinical diphtheria. With the breakup of the Soviet Union, public health immunization programs were dramatically affected and by 1990 only 68% of Russian children had received the appropriate vaccination regimen (71). As a result, by 1995 the incidence of clinical diphtheria in the NIS peaked at over 50,000 cases. From the onset of the diphtheria outbreak in 1990 through 1999, more than 157,000 cases and 5,000 deaths were reported.

Given the increased incidence of clinical diphtheria in the NIS, Kolodkina et al. (72) characterized 129-bp single-strand conformational polymorphism DNA fragments that contained the *toxPO* region from 81 strains of *C. diphtheriae*.

From this group, only two strains had mutations. Nucleotide sequence analysis revealed T to C mutations in positions –54 and –184 of the *tox* operon. The –54 mutation was found in the 9-bp interrupted palindromic sequence of *toxPO*, and these two strains had the highest level of toxin production out of the 81 strains characterized. In addition, these investigators also analyzed the nucleotide sequence of the *dtxR* gene. Fifteen strains in this collection were found to carry two missense mutations in DtxR, A147V and L214I in the C-terminal region of the repressor. Interestingly, the *dtxR* alleles in the two strains that expressed the highest levels of diphtheria toxin were not found to carry a nucleotide substitution. This initial study was extended by Kombarova et al. (73), who found seven point mutations in the structural gene for diphtheria toxin. While most of these mutations did not result in an amino acid substitution, two strains from the Otchakov ribotype carried a G393R mutation in the native receptor-binding domain of the toxin. In contrast, 16 point mutations in *dtxR* were found. Of these, the A147V mutation is characteristic of the epidemic clonal group Sankt-Peterburg/Rossija, which was the dominant strain isolated in the Russian diphtheria epidemic in the 1990s.

It is remarkable that the amino acid sequence of diphtheria toxin encoded by the omega-phage in the Park-Williams strain of *C. diphtheriae*, PW8, which was isolated in 1896 (74), is identical to the amino acid sequence of the toxin produced by all but two of the clinical isolates carrying the G393R mutation that have been characterized from the NIS diphtheria epidemic. While several missense mutations within the *tox* gene have been described, they encode the same amino acid as found in the PW8 allele. It is interesting to note that in the single exception, the G393R substitution falls early on in the toxin's receptor-binding domain and is far removed from the region of that domain which interacts with the toxin's eukaryotic cell surface receptor-binding region. This extraordinary conservation of amino acid sequence strongly suggests the highly evolved nature of the toxin's structure-function relationships. This conservation of amino acid sequence for at least 100 years suggests that the evolution of new *tox* alleles that might encode a toxin sufficiently different to avoid neutralization by antitoxoid antibodies is highly unlikely.

In contrast, this high degree of conservation does not hold for DtxR. In the case of this metal ion-activated repressor, the N-terminal region of *dtxR* was found to carry several missense mutations that did not give rise to an amino acid substitution. In contrast, missense mutations in the C-terminal region of the repressor were often found to encode amino acid substitutions that appeared to subtly affect DtxR activity (51, 75–77).

TURNING THE SWORD OF DIPHTHERIA INTO THE PLOWSHARE OF TARGETED THERAPEUTICS

Shortly after Köhler and Milstein (78) described the methodology to produce monoclonal antibodies, many in the bacterial protein toxin field seized on this technology in an attempt to fulfill Paul Ehrlich's idea of developing "magic bullets," therapeutic compounds that were selectively targeted toward a disease-causing organism or cell (79). In an early series of experiments, Gilliland et al. (50) independently coupled ricin A chain and diphtheria toxin fragment A to monoclonal antibodies directed against a cell surface antigen on colorectal carcinoma cells. While the ricin A chain-coupled immunotoxin was highly potent (i.e., the half maximal inhibitory concentration [IC_{50}] < 10^{-12} M), the diphtheria toxin fragment A immunotoxin, surprisingly, was found to be at least 1,000-fold less potent (i.e., $IC_{50} \sim 5 \times 10^{-9}$ M). These results prompted Bacha et al. (80) to ask whether fragment A alone contained sufficient structural information to deliver the catalytic domain across the endocytic vesicle membrane. Since Boquet et al. (59) had previously demonstrated that under denaturing conditions, the hydrophobic domain in the B fragment of CRM45 displayed properties of an integral membrane protein, Bacha et al. (80) independently coupled fragment A (CRM26) and CRM45 to thyrotropin-releasing hormone (TRH) and assessed their relative cytotoxic potency against GH3 rat pituitary cells. While the fragment A-TRH construct was nontoxic even at concentrations of 10^{-7} M, the CRM45-TRH construct was highly active ($IC_{50} \sim 3 \times 10^{-9}$ M). These results clearly demonstrated that fragment B translocation domain sequences were required to facilitate the delivery of fragment A, the catalytic domain, into the eukaryotic cell cytosol.

Since additional preparations of CRM45-TRH varied by greater than 10-fold in cytotoxic potency, Murphy et al. (81) turned to recombinant DNA and protein engineering methods to redesign native diphtheria toxin by receptor-binding domain substitution. The hypothesis was that by choosing a surrogate receptor-binding domain that bound to a cell surface receptor that was both limited in distribution and was internalized into an endosomal compartment that became acidified, it might be possible to develop a family of fusion protein toxins that could potentially serve as a new class of targeted toxins for the treatment of human diseases. Moreover, we reasoned that, if successful, these genetically engineered proteins would constitute a unique family of reagents to deplete discrete subsets of cells and to study the molecular process by which the diphtheria toxin catalytic domain was delivered to the cytosol of targeted eukaryotic cells.

To begin to test this hypothesis, Leong et al. (82, 83) demonstrated that cloned fragment A of diphtheria toxin was expressed and secreted by the SecA apparatus in recombinant *E. coli*. Despite the controversial nature of deliberately designing and constructing a recombinant gene that encoded a toxic protein that the world had not seen previously, in 1985, we were finally granted approval to genetically construct, express, and evaluate the biosafety of the first fusion protein toxin under biosafety level 4 (BSL-4) containment. Murphy et al. (81) described the assembly of a fusion gene that was composed of a portion of diphtheria *tox* that encoded first 486 amino acids of diphtheria toxin and a synthetic gene encoding the 13-amino acid polypeptide α-melanocyte-stimulating hormone (α-MSH). While this fusion protein was expressed and secreted into the periplasmic space of recombinant *E. coli*, the yield of full-length fusion protein toxin was extremely low due to proteolytic degradation. Since this degradation appeared to have occurred close to the fusion junction between diphtheria and α-MSH sequences, we reasoned that increasing the molecular size of the substitute receptor-binding domain with a larger polypeptide might at least partially solve the degradation problem by stearic hindrance. In 1987, Williams et al. (84) described the genetic construction and properties of a fusion protein toxin in which the 133-amino acid sequence of human interleukin-2 (IL-2) was genetically fused to amino acid 486 of diphtheria toxin. Surprisingly, DAB486IL-2 was expressed, and full-length fusion protein toxin was secreted into the periplasmic space in good yield.

Since the DAB486IL-2 construct used a naturally occurring *SphI* restriction endonuclease site in the *tox* gene as the fusion junction between diphtheria toxin and IL-2 sequences, we then asked how much fragment B sequence was required to deliver the catalytic domain of the fusion

protein into the target cell cytosol. Williams et al. (85) constructed a series of in-frame deletion mutants and found that the removal of 97 amino acids from Thr387 to His485 increased both the cytotoxic potency and the apparent dissociation constant of the resulting fusion toxin, DAB389IL-2, for cells that expressed the high-affinity IL-2 receptors (IL-2R). Upon the subsequent solution of the diphtheria toxin X-ray structure (Fig. 6), we realized that quite by chance our internal in-frame deletion of 97 amino acids resulted in an almost perfect receptor-binding domain substitution (Fig. 7). Since that time, more than a dozen diphtheria-based fusion protein toxins have been constructed and characterized using amino acid 388 or 389 as the junction between diphtheria toxin and surrogate receptor-binding domain polypeptides.

In 1999, the U.S. Food and Drug Administration (FDA) approved denileukin diftitox (Ontak; DAB389IL-2) for the treatment of refractory cutaneous T cell lymphoma (CTCL), making it the first-in-class recombinant targeted biologic to achieve approval. Phase III trials conducted with CTCL patients who had failed other therapeutic interventions demonstrated that 30% of the total number of patients had a 50% or greater reduction in their tumor burden for at least 6 weeks following treatment (86, 87). In the case of peripheral T cell lymphomas, an aggressive form of non-Hodgkin's lymphoma with a median overall survival of 5.5 months, Ontak has been used both as a monotherapy and in combination with traditional chemotherapy (88). Both Fuentes et al. (89) and Wong et al. (90) reported individual cases where Ontak therapy, when used as a long-term maintenance therapy over a span of 1 to 2 years, resulted in sustained remissions of 9 and 4 years that are ongoing. In addition to its effective use in T cell malignancies, Ontak has also been successfully used in the treatment of steroid-resistant graft-versus-host disease. Ho et al. (91) conducted a phase I trial of Ontak in 30 patients presenting with steroid-resistant graft-versus-host disease and reported that 50% of the patients responded with complete resolution, and an additional 21% of the total number of patients responded with partial resolution of their disease.

While Ontak selectively targets the high and intermediate IL-2R on malignant T cells in both CTCL and peripheral T cell lymphomas, as well as on activated T effector cells in graft-versus-host disease, in recent years it has also shown promise as an immunotherapeutic in the transient depletion of T regulatory cells in solid tumors. Both phase I (92) and phase II (93) studies have shown that Ontak is also effective as an immunotherapeutic as a monotherapy in patients presenting with unresectable stage IV malignant melanoma. In these instances, Ontak was shown to transiently deplete T regulatory cells and, as such, apparently break tolerance and allow for a more robust host-mounted T-effector cell antitumor response.

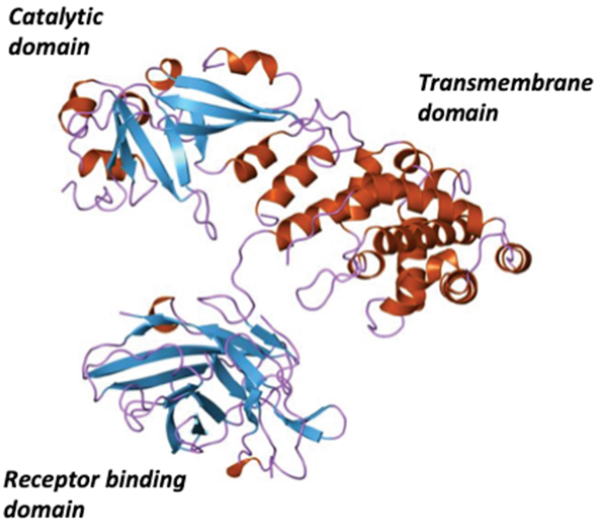

FIGURE 6 X-ray structure of native diphtheria toxin showing its catalytic, translocation, and receptor-binding domains.

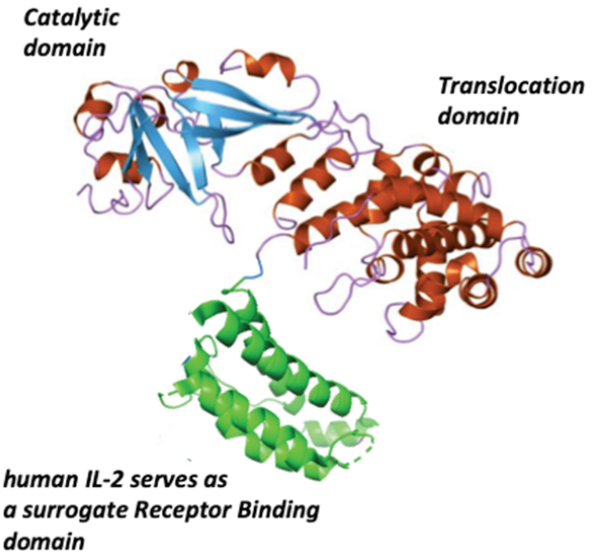

FIGURE 7 Molecular model of denileukin diftitox (Ontak, DAB389IL-2). The catalytic and translocation domains are composed of amino acids Gly1 through Thr387 of native diphtheria toxin, to which the 133-amino acid polypeptide of human IL-2 is genetically fused. The additional two amino acids in the construct are the result of the introduction of a unique *SphI* restriction endonuclease site at the fusion junction between diphtheria toxin and human (h)IL-2 sequences.

Despite its clinical effectiveness, Ontak was placed on clinical hold in 2011 because of the presence of drug aggregates, contaminating DNA, varying concentrations of Tween20, and batch-to-batch variations in its final formulation. Since Ontak was expressed as inclusion bodies in recombinant *E. coli*, the agent had to be completely denatured and refolded into a biologically active conformation. During the refolding process, it was necessary to add Tween20 to partially prevent the formation of insoluble drug aggregates and allow for refolding of the drug into a biologically active conformation.

We (94) recently solved the production issues associated with refolding of the drug by recloning the structural gene for Ontak, DAB389IL-2, in an *E. coli*-*C. diphtheriae* shuttle vector. Furthermore, we modified the gene by adding back the native *tox* signal sequence so that the fusion protein toxin would be secreted into the culture medium. Finally, we introduced mutations into the downstream half of the palindromic *tox* operator so that expression was constitutive even in medium with high iron concentrations. Thus, this second-generation Ontak, s-DAB389IL-2, is expressed and secreted from recombinant *C. diphtheriae* in good yield as a fully folded monomeric protein that may be readily isolated and purified from the culture medium. Cheung et al. (94) also demonstrated that s-DAB389IL2 has great potential when used in a sequential combination regimen with anti-PD-1 in

the treatment of B16F10 melanoma in the mouse. In these studies, either s-DAB389IL-2 or s-DAB389IL-2(V6A), a vascular leak motif modified mutant, was first used to transiently deplete T regulatory cells, thereby removing one of the immune suppression signals that dampen a T effector cell antitumor response. Anti-PD-1 was then administered to block the PDL-1–PD-1 interaction between the tumor and the immune system, thereby blocking a second suppressive signal to the T effector arm of the immune system. The combined effect of this sequential therapeutic regimen was found to be at least additive and perhaps synergistic in the treatment of this aggressive murine melanoma. These results are encouraging and prestage the use of s-DAB389IL2(V6A) in clinical medicine in a sequential checkpoint inhibitor blockade for the treatment of solid tumors.

Ontak (denileukin diftitox, DAB389IL-2) and the second-generation form of the biologic, s-DAB389IL-2 (V6A), while not magic and certainly not bullets, have shown remarkable efficacy in the treatment of human malignancies and in murine models of melanoma and colon and renal cell carcinomas, both as a targeted monotherapy against the tumor itself and as an immunotherapeutic to reset immunologic balance by transient depletion of T regulatory cells. In the latter instance, the transient depletion of T regulatory cells appears to break tolerance and thereby allows a robust patient-mounted antitumor response. Thus, through the biochemical and biochemical genetic study of diphtheria toxin, the diphtheria *tox* operon, and the iron-activated repressor DtxR, which regulates expression, and through modern molecular biologic methods, one of nature's most potent bacterial protein toxins has been tamed. Diphtheria toxin, once the primary virulence determinant of a dreaded infectious disease of children, has now been retargeted to selectively eliminate specific disease-causing cells as a protein therapeutic, thereby at least partially fulfilling Paul Erlich's magic bullet concept of a "chemical that binds to and specifically kills microbes or tumor cells" (79).

We thank Pankaj Kumar for his critical review of the manuscript and very helpful comments.

Actin-based motility, cell-to-cell spread, 856
Actinobacillus actinomycetemcomitans, 706, 776
Actinobacteria spp., 724, 1027, 1030, 1087, 1129
  ESX system, 1135
  oral microbiome, 428
  T7S system, 1136, 1142, 1143
Actinomyces naeslundii, 28
Active Bacterial Core program, 186
Acute glomerulonephritis, *Streptococcus dysgalactiae* subsp. *equisimilis* (SDSE), 276–277
Acute poststreptococcal glomerulonephritis, M proteins and, 95
Acute rheumatic fever (ARF), 86
  adhesion and extravasation of T lymphocytes in ARF valve in valvulitis, 90
  epidemiology, 188
  group A streptococci and, 86, 90
  M proteins and, 89–92
  potential mechanisms of pathogenic antibodies in, 88
Adaptive immunity against *Mycobacterium tuberculosis*
  B-cell and antibody response during, 1066–1067
  CD1-restricted T cells, 1067
  γδ T cells, 1067
  inhibitory receptors during, 1066
  kinetics and homing of CD4 T cells after, 1063–1064
  MAIT cells, 1067
  memory T-cell responses, 1066
  quality and specificity of CD4 T-cell response, 1064–1065
  role of CD8 T cells in, 1065–1066
Adaptive immunity of *Listeria monocytogenes*, 814–818
  antigen processing and presentation of T cells, 814–815
  effector functions of T cells, 816–817
  humoral immunity, 818
  magnitude and kinetics of primary response, 815–816
  memory T cell responses during secondary infection, 817–818
Adhesins, 108
  binding streptococcal, to host cell receptors, 126–128
Adults
  meningoencephalitis, 795–796
  Streptococcus agalactiae in, 229–230
Aduro BioTech, Inc., 820
Advaxis, Inc., 820
Aeromonas hydrophia, 1019
Aggregatibacter actinomycetemcomitans, 452
Agmatine deiminase system (ADS), 439
Agr quorum-sensing system
  agr regulon, 670–672
  AIP types (autoinducing peptides), 670, 672
  architecture of, 669–670
  environmental cues, 672
  host-derived factors, 672
  impact of environment and host stimuli on, 672–673
  importance of *agr* during infection, 673
  regulators impacting, 673
  S. aureus, 669–673
  schematic of, 671
AIDS patients
  corticosteroids and *S. aureus* infection, 767–768
  infection risk, 700
Alkaliphilus, relationships within *Clostridiaceae*, 942
Allobaculum, 845
Alloprevotella, 845
American Type Culture Collection (ATCC), 158
Aminoglycosides, 748
  history and mode of action, 753–754
  resistance, 754
  resistance in enterococci, 379
Amniotes, associated with enterococcal colonization, 379
Ampicillin
  invasive GBS disease, 232
  treatment of listeriosis, 797–798
Animal diseases, *Clostridium perfringens*, 985
Animal models
  anthrax, 882–883
  Bacillus thuringiensis and *B. cereus*, 883–884
  Clostridioides difficile infections (CDI), 995–996
  enterococci pathogenicity, 388
  hyaluronic acid enhancing virulence of group A streptococci, 49
  Mycobacterium tuberculosis infection, 1057–1058
Anthrax, 873
  animal models of, 882–883
  Bacillus anthracis, 878
  prophylaxis and treatment, 888–889
  vaccines, 889
Antibiotic resistance
  enterococci, 378–380
  staphylococcal biofilm formation for, 704–706
Antibiotic resistance of *S. aureus*
  aminoglycosides, 753–754
  beta-lactam antibiotics, 747–750
  cell envelope active agents, 747–752
  chloramphenicol, 753
  compounds and alternatives in development, 756
  daptomycin, 751–752
  fluoroquinolones, 755
  fosfomycin, 751
  fusidic acid, 754–755
  linezolid and tedizolid, 752–753
  lipoglycopeptides, 751

macrolides, lincosamides and streptogramins, 753
mupirocin, 754
pleuromutilins, 753
protein synthesis inhibitors, 752–755
rifampicin, 755
small molecule biosynthesis inhibitor, 755–756
tetracyclines, 754
tigecycline, 754
transcription inhibitors, 755
trimethoprim-sulfamethoxazole, 755–756
vancomycin resistance and VISA, 750–751
Antibiotic resistance reservoir, *Streptococcus sanguinis*, 453–454
Antibiotics
enterococcal resistance, 404
small colony variants (SCV), 556
treatment of *Clostridioides difficile* infection, 1002
vancomycin resistance, 379, 402–404
Antibodies and antibody conjugates, *S. aureus* infection, 782
Anticancer strategies, peptides from evasion molecules, 631
Antigenicity, lactococci, 474
Antimicrobial peptides (AMPs)
biofilms, 777
microbiocidal activities of, 125
neutrophils interaction with *S. pyogenes*, 129, 131
staphylococcal biofilm-associated infection, 706
Streptococcus mutans and, 443
Antimicrobial resistance, methycillin-resistant *Staphylococcus aureus* (MRSA), 490–491
Antimicrobials, targeting *L. monocytogenes* regulation, 845–846
Apoptosis
group A streptococcal-mediated, 135–138
term, 137
Arabidopsis thaliana, 877
Arginine Catabolic Mobile Element (ACME), 713
Arginine deiminase system (ADS), 430–431, 439
Artemis Comparison Tool (ACT), 487
Arthrobacter, 1030, 1032
Arthropods, associated with enterococcal colonization, 379
Artificial transformation, *S. pneumoniae*, 351
Atomic force microscopy (AFM), 4
Atopobium spp., oral microbiome, 428
AureoWiki, 487
Autophagy, 855
Autophagy (xenophagy), *Streptococcus pyogenes*-mediated, 133–135

Bacillaceae, 565
Bacillithiol, biosynthesis in *S. aureus*, 690
Bacillus spp., 873
germination, 918
rolling circle replicating (RCR) plasmids, 500
T7S system, 1143
Bacillus anthracis
anthrax pathogen, 878
capsule of, 7
future directions, 889
germination dynamics and signals, 880
germination in host, 880
inhalation anthrax in humans, 877–878
prevalence in soil, 877

Clostridium bolteae, 948
Clostridium botulinum
activation of cortex hydrolases in, 916–917
germination, 918
importance of spores, 903
neurotoxin (BoNT), 907–908, 965–966, 967, 968–969
non-proteolytic, 968
proteolytic, 968
schematic of spore germination, 916
sporulation initiation in, 905, 907
toxin-encoding mobile genetic elements (MGE), 965–966, 968–969
transcriptional programs controlling sporulation, 909, 910
transmembrane germinant receptors in, 914
Clostridium butyricum, 969
Clostridium cellulolyticum, 934
Clostridium cellulovorans, 928
Clostridium chauvoei, 948
Clostridium haemolyticum, 945
Clostridium novyi, 945
Clostridium novyi sensu lato, 968–969
Clostridium perfringens
activation of cortex hydrolysis in, 914–916
allelic exchange and homologous recombination, 931
clostridial myonecrosis by, 1012–1013
comparative analysis of pCW3-like antibiotic resistance and toxin plasmids, 961
current model for Tcp-mediated conjugation, 961–962
E. coli and, 928
enterotoxin (CPE), 907
germination, 918
germination regulators, 915
importance of spores, 903
inducible vector systems, 929–930
model of pCW3 conjugation apparatus, 962
multiple pCW3-like toxin plasmids, 962–963
nucleotide alignment of pCW3-like plasmids from, 960
pCP13-like plasmids, 963–964
perfringolysin O, 853
plasmid cloning vectors, 928–929
plasmid-encoded toxins, 958–959
plasmids, 959, 961
proteolytic activation of cortex hydrolase, 914–916
schematic of spore germination, 916
sequence alignment of pCP13-like plasmids from, 964
sporulation initiation in, 906–907
toxin association with insertion sequences, 959
toxins withih toxinotypes, 945
TpeL toxin, 907
transcriptional programs controlling sporulation, 909, 910
transmembrane germinant receptors in, 914
transposon-mediated random mutagenesis, 933
type F food poisoning, 977–984
typing toxins, 945–946, 956–958
see also Clostridial genetics; *Clostridium perfringens* enterotoxin (CPE)
Clostridium perfringens α-toxin
activation of phospholipid metabolism and hemolysis, 1015–1016
binding model of, and membrane phospholipids, 1014
biological activities of, 1015
effect on erythropoiesis, 1017–1018
effect on hematopoietic cells, 1016–1017
function of, 1013–1014
inhibition of granulopoiesis and erythropoiesis, 1018
interaction with gangliosides, 1016
interaction with host cells, 1014–1018
membrane-damaging activity on phospholipid bilayers, 1014–1015
model of α-toxin-induced membrane dynamics, 1017
structure of, 1013
Clostridium perfringens enterotoxin (CPE), 1019
chromosomal *cpe* loci, 982
CPE binding, 979–981
CPE-induced cytotoxicity, 979–981
enteritis necroticans, 984–985
epidemiology, 977
genetics, 981–983
immunology, 984
inducing bystander killing effect, 981
model of mechanism of action, 980
model of sporulation and production, 983
nonfoodborne human GI diseases, 984
pathogenesis, 977–978
plasmid *cpe* loci, 982
postbinding steps in CPE action, 981
protein, 978–979
regulation of CPE production, 983–984
small acid-soluble protein 4, 984
structure of, 979
treatment and prevention, 984

Clostridium perfringens perfringolysin O, 1018
host cell interactions, 1018–1019
structure of, 1019
Clostridium saccharobutylicum, 928
Clostridium septicum, 948, 1012
clostridial myonecrosis by, 1012–1013
crystal structure of aerolysin, 1020
function and host cell interactions of α-toxin of, 1019–1020
molecular model of α-toxin, 1020
Clostridium tetani, 771
blast analysis of tetanus toxin plasmid family, 965
tetanus neurotoxin (TeNT), 944–945
toxin plasmid of, 964–965
Clos Tron technology, clostridial genetics, 932–933
Collagen-building proteins (CBPs), *Streptococcus mutans*, 436
Collagens
Gram-positive pathogens and, 113–114
structure and function of, 109–110
Colonization mechanisms
oral streptococci, 429–430
Streptococcus sanguinis as commensal colonizer, 449–451
Combination protein vaccines, combination, 368–369
Commensal oral flora, 430–431
Community-associated methicillin-resistant *S. aureus* (CA-MRSA), 713, 737, 749
Community development, *Streptococcus sanguinis* in, 452–453
Companion animals, methicillin-resistant *S. aureus* (MRSA), 738–739
Competence development, *S. pneumoniae*, 348–350
Competence-stimulating peptide (CSP), death health, 431
Complement receptor of immunoglobulin superfamily (CRIg), 809
Complement system
main pathways and components of, 624
opsonization by, 622–623
proteins targeting, 624–625
Conjugation, *S. pneumoniae*, 351–352
Conjugative transposons
enterococci, 410–412
genetic organization of Tn916, 411
integrated conjugative elements (ICEs), 404, 410–412
Conventional embedding, electron microscopy, 12–13, 14
Cortical actin, rearrangements, 856
Corticosteroids and AIDS, *S. aureus* infections, 767–768
Corynebacteriales, 1027, 1087, 1088, 1129
Corynebacterium, 723, 724, 1027–1028, 1030
Corynebacterium accolens, interactions with nasal bacteria, 727
Corynebacterium diphtheriae, 3, 1028
agent of diphtheria, 1154
corynebacteriophages carrying gene for diphtheria toxin (*tox*), 1155–1156
corynebacteriophage *tox* gene, 1156
denileukin diftitox (Ontak), 1161–1162
DtxR two-domain protein, 1158
electron micrograph of corynebacteriophage β, 1155
genetic map of β-phage, 1155
molecular epidemiology of diphtheria and DtxR, 1159–1160
molecular mechanism of action of *tox*, 1158–1159
molecular model of denileukin diftitox, 1161
schematic of Fe^{2+} activation of apo-DtxR, 1156
structural basis of transition metal ion activation of DtxR repressor activity, 1157–1158
structure-function relationships of *tox*, 1158–1159
targeted therapeutics for diphtheria, 1160–1162
transition metal ions activating DtxR binding to *tox* operator, 1156–1157
X-ray structure of native diphtheria toxin, 1161
Corynebacterium striatum, nasal spray of, 569
Cows, *Staphylococcus aureus* in, 732–733, 735–736, 739
CPE. *See Clostridium perfringens* enterotoxin (CPE)
CPILE/BEC toxin, *Clostridium perfringens*, 985
CRISPR (clustered regularly interspaced short palindromic repeat)-associated system (Cas) function
adaptive immunity systems in *Staphylococcus aureus*, 566–568
antibacterial drones (ABDs), 546
enterococcal defense system, 413–414
future for infection models, 138
genetic manipulation, 934
genome sequences, 927
immune system against phages, 473
mycobacteriophages, 1044
S. aureus infection, 780
Cross-feeding, *Lactococcus lactis* and interbacterial, 472
Cross-inhibition, *Lactococcus lactis* and interbacterial, 472–473
Cross-reactive antigens
advent of monoclonal antibodies (mAbs), 86
in Group A streptococci, 90, 95
human and murine antistreptococcal/antimyosin mAbs, 88
human cardiac myosin peptide epitopes in rheumatic heart disease, 94–95
mAbs group A streptococci and human heart tissues, 87–88
mAbs identifying streptococcal, 88–95
model of valvular heart disease by Group A or Group G streptococcal M proteins in Lewis rat, 94
molecular basis of mimicry in streptococcal M protein, 92
mouse antistreptococcal mAb with human tissue, 87
M proteins and cross-reactive T cells, 92–94
M proteins and poststreptococcal acute glomerulonephritis, 95
M proteins and rheumatic fever, 89–92, 101
potential mechanism of antibody in pathogenesis of rheumatic heart disease, 88
Cryo-electron microscopy (cryoEM), 1087, 1088
Cryo-electron microscopy of vitreous sections (CEMOVIS), 1087–1089
Cryo-electron tomography (CET), 3, 9–10, 14–15
Cryo-focused ion beam (cryo-FIB), 3
Cryo-focused ion beam with scanning electron microscope (cryo-FIB-SEM), 3, 10, 13
Cryo-methods, 13–15
CEMOVIS (cryo-electron microscopy of vitreus sections), 13–14, 15
cryo-electron tomography (CET), 14–15
freeze-fracturing and freeze–etching, 13
high-pressure freezing and freeze–substitution, 13
outlook of new, 15
C-terminal anchored (LPxTG motif), 20, 23, 24
C-terminal-anchored surface proteins
characteristics of, 25
conformational analysis, 25, 26
seven–residue periodicity, 25–26
Cutaneous listeriosis, 796
Cutaneous T cell lymphoma (CTCL), denileukin diftitox for, 1161
Cutaneous wound infections, ecology of, 178
Cutibacterium, 723, 1032
Cytochrome C, 691
Cytokine production, staphylococcal sepsis and, 768–770
Cytolytic toxins, of *Streptococcus pyogenes*, 55–56
Cytoplasmic stage
cytoplasmic innate immune responses, 855–856
Listeria monocytogenes, 855–856
persistence, 856
utilization of host metabolites, 855
Cytotoxicity, pneumococcus, 322–324
Cytotoxins, β-barrel pore-forming toxins, 640–645

Dale, James, 150
Daptomycin
enterococci resistance, 379
history and mode of action, 751–752
resistance, 752
Dendritic cell failure, *S. aureus* infections, 766
Dendritic cells (DCs), 803
antigen-laden, activating T cell responses, 812–813
Denileukin diftitox (Ontak), 1161–1162
Dental caries, oral streptococci, 428, 430
Dental health, good streptococci for, 430–431
Dental plaque
oral streptococci, 428
Streptococcus mutans in, 439–440

Dichelobacter nodosus, bacterial attachment sites for prophages, 161
Diphtheria
epidemic in Newly Independent States (NIS), 1159
molecular epidemiology of, 1159–1160
targeted therapeutics for, 1160–1162
see also Corynebacterium diphtheriae
Directed mutagenesis
allelic replacement using linear DNA, 70, 72
considerations for, 76
counterselection markers, 74
directed insertional inactivation, 72–74
in-frame deletion, 74, 75
in-frame deletion using CRISPR/Cas9, 74–76
Streptococcus pyogenes, 70, 72–76
DNA (deoxyribonucleic acid)
influence of listeriolysin O (LLO) on stability of, 857
pathogenic clostridia, 940
randomly amplified polymorphic (RAPD) fingerprinting, 240
repair of *S. pneumoniae*, 353–354
replication and modification in *S. pyogenes* genome, 163
role of mycobacterial ESX systems in DNA transfer, 1141
DNA Master, 1034
Dogs, methicillin-resistant *S. aureus* (MRSA), 738–739
Dolosigranulum pigrum, 724
Drosophila melanogaster, alginate, 246
Dynamin, 132

Eagle effect, 279
Ecology of group A streptococcus (GAS)
GAS (agent) factors, 179–180
GAS-microenvironment factors, 179
host tissues and diseases, 177–179
human (host) factors, 179
macroenvironment risk factors, 179
transmission, 179–180
transmission routes for, 178
Ectopic expression, techniques for, 81
Ehrlich, Paul, 1160
Elastin
Gram-positive pathogens and, 114
structure and function of, 110
Electrococcus faecium, field emission scanning electron microscopy (FESEM), 11
Electron microscopic techniques, 9–15
conventional embedding, 12–13
cryo-electron tomography (CET), 9–10
cryo-methods, 13–15
field emission scanning electron microscopy (FESEM), 10–11
heavy metal coating or shadowing, 11
negative staining, 11–12
surface proteins of Gram-positive bacteria, 20–21
Electron transparent zone, 1088
Electron transport, metabolic pathways and mutations, 551
Embden-Meyerhof-Parnas glycolytic pathway, 688, 865
Endocarditis
enterococci, 383–384
Streptococcus dysgalactiae subsp. equisimilis (SDSE), 279
Endoplasmic reticulum (ER), influence of listeriolysin O (LLO), 857
Endosomal sorting complex required for transport (ESCRT), 1063
Enteric diseases. *See Clostridium perfringens* enterotoxin (CPE)
Enteritis necroticans (EN), *Clostridium perfringens*, 984–985
Enterobacter cloacae, conjugative plasmid, 505
Enterobacteriaceae, 724
Enterococcal genetics
aggregation substance (AS), 404, 406–407
bacteriophage, 413–414
chromosomal replication, partition and cell division, 398–399
conjugation apparatus, 406–407
conjugative transposons (ICES), 410–412
genome defense systems, 413–414
landmark discoveries, 398
mobilome features, 412–414
model for EutV- and EutX-mediated regulation of *eut* regulon, 401
model of RNAI-RNAII interaction, 409
non-pheromone-responding plasmids, 412
organization of pheromone-responsive plasmid replicon, 408
organization of transposon Tn916, 411
organization of VanA and VanB vancomycin resistance genes, 403
PAIs (pathogenicity islands) and intercellular transfer by Hfr formation, 412, 413
pheromone-responsive plasmids, 404–410
regulating pheromone signal transduction circuit, 404–406
regulation of gene expression, 399–402
regulatory circuitry of pheromone response, 405
replication and stable inheritance, 407–410
resistance to antibiotics, 404
TA (toxin-antitoxin) systems, 408–410, 412–413
transposon Tn916, 410–412
two-component signal transduction system (TCSTS), 399–400, 402–403
vancomycin resistance, 402–404
Enterococci
animal models for study of pathogenic mechanisms, 388
animals associated with colonization of, 379
antibiotic resistance, 378–380
bacteremia, 382–383
biology and characteristics, 378
comparing genomics of *E. faecalis* and *E. faecium*, 387–388
endocarditis, 383–384
environmental persistence, 380
human colonization, 380–382
immune evasion, 384–385
invertebrate models, 388
pathogenic mechanisms, 380
population structure of *E. faecium* and *E. faecalis*, 386
root canal failure, 384
surgical site infections, 384
tissue damage, 385, 387
toxic metabolites, 387
translocation from gut into bloodstream, 382
urinary tract infection, 383
vertebrate models, 388
virulence factors, 381
see also Enterococcal genetics
Enterococcus, term, 378
Enterococcus spp. interbacterial cross-feeding, 472
Enterococcus faecalis, 28, 69, 137, 378
alkaline phosphatase of, 80
biofilm formation and, 451
conjugative plasmids, 503
DtxR repressor in, 1156
Fst toxin sequence, 409
gene expression, 399–402
genetics, 398, 414
genomics of, 387–388
human colonization, 380–382
hyaluronic acid synthesis in, 46
population structure, 386
S. aureus and, 492
transposon mutagenesis, 933
transposon Tn916, 410–412
Enterococcus faecium, 378
gene expression, 399–402
genetics, 398, 414
genomics of, 387–388
human colonization, 380–382
population structure, 386
Enterococcus hirae, 400
Entner-Doudoroff pathway, 429
Envelope assembly
cell wall synthesis and, 592
protein secretion across cell wall, 593
teichoic acid synthesis and, 592
Environment
anthrax and *Bacillus anthracis*, 878
Bacillus cereus group, 877–879

B. cereus and gastrointestinal disease, 878
B. thuringiensis infection of invertebrates, 878–879
peptidoglycan recycling, 585
Environmental persistence, enterococci, 380
Environmental stress
lactococci and, 470–471
regulation of *L. monocytogenes* in response to, 842
Enzymes
Clostridioides difficile transferase, 999–1000
dental health, 430–431
staphylococcal biofilm-associated infection, 706
see also Exoenzymes
Epidemiology
acute rheumatic fever (ARF), 188
building evolutionary models, 190–191
Clostridioides difficile, 993–994
core housekeeping genes, 186
diversity within host communities, 188
evolution of markers (EMM), 188–190
global trends, 186–188
infection at epithelium of throat and skin, 186–187
invasive disease, 187–188
Listeria monocytogenes, 793–795
molecular, of diphtheria and DtxR, 1159–1160
molecular markers, 180–186

sequenced surface proteins, 21
signaling pathways, 441–442
stress tolerance, 439–440
as therapeutic target in caries prevention, 443–444
two-component signal transduction systems (TCSTSs), 441
Streptococcus parasanguinis
alginate, 246
colonization mechanisms, 430
oral microbiome, 428
Streptococcus parauberis, 170
Streptococcus pneumoniae
adhesion and invasion of, 118
bacterial adhesins of, 108
bacterial cell wall backbone, 4
at blood-brain barrier, 321
in bloodstream, 320–321
capsular polysaccharides (CPSs) of, 304
capsule of, 7, 8
cell growth regulation during cell cycle, 293–298
comparing *cps* loci, 308–309
complete genomes of, 346–347
CPS-based vaccines, 305–306
CPS biosynthesis genes, 306–308
cryo-studies, 15
cytotoxicity and, 322–324
dissolution of fibrin clot by, 118
fibronectin and, 115
functional anatomy of cell wall, 284–285
functions of cell wall choline residues, 293
GBS genome and, 212
in heart, 321
horizontal gene transfer, 348–353
image of conventional embedded, 12
inflammation and, 233, 323
membrane vesicles (MVs) of, 8
murMN operon, 288–290
penicillin resistance, 288
peptidoglycan biosynthesis and remodeling, 286–288
peptidoglycan composition, 288
phage, 165
phase variation of, 332–333
in placenta and fetus, 321–322
polysaccharide structures, 206
preservation under in vivo conditions, 8
PspA surface protein, 27
regulation of CPS production, 309–311
in respiratory tract, 316–320
role of CPS in pathogenesis, 304–305
schematic of spread and progression of infection, 319
sequenced surface proteins, 21
sialic acid and, 210–211
size variation of M protein, 26
structure of peptidoglycan, 285–286
structure of WTA and LTA, 290–292
surface glycolytic enzymes, 27
surface proteins recognizing ECM molecules, 109
synthesis of teichoic acids and modifications, 292–293
see also Cell wall of *S. pneumoniae*; Pneumococcal genomes; Pneumococcal phase variation
Streptococcus pseudopneumoniae, 170
Streptococcus pyogenes, 26, 33, 35
analysis of gene expression, 79–81
autophagy and infection, 133–135
bacterial adhesins of, 108
capsule and, attachment to epithelial cells, 50–51
capsule and, entry into epithelial cells, 51
capsule and host immune defenses, 48–49
capsule as virulence factor, 49–51
collagens and, 113–114
cytolytic toxins of, 55–56
diseases by pathogen, 148
diseases in humans, 67
DNases of, 59–60
experimental infection models, 49–50
fate of intracellular, 40–41
fibronectin (Fn)-binding proteins as invasins, 37–38, 39
field emission scanning electron microscopy (FESEM), 11
focal adhesion and signal transduction, 38–40
GBS genome and, 212

growth factor TGF-β1 activation, 41–42
human oral environment, 426, 427
hyaluronic acid synthesis in, 45–47
IgG-targeting enzymes of, 60
infection and IL-1β/inflammasome signaling pathways, 131–132
initial interaction with neutrophils and neutrophil extracellular traps (NETS), 129, 131
intracellular invasion of, 35–36
invasins and host receptors for, 36
laminin and, 114
LPxTGase from, 24
map of region of chromosome for hyaluronic acid synthesis, 47
mechanisms for ingestion, 36–37, 41–42
membrane vesicles on surface of, 9
M protein, 19, 20, 37–38
noncanonical inflammasome, 132–133
protein export, 474
regulation of hyaluronic acid biosynthesis, 47–48
sequence comparison with *Escherichia coli*, 249
sequenced surface proteins, 21
streptolysin O from, 853
superantigens of, 56–59
tonsils and, 36
zipper-like mechanism, 36
