The Editors

Richard T. Di Giulio is Professor of Environmental Toxicology in the Nicholas School of the Environment and Earth Sciences at Duke University, Durham, North Carolina. At Duke, he also serves as Director of the Integrated Toxicology and Environmental Health Program, Director of the Superfund Basic Research Center, and Director of the Center for Comparative Biology of Vulnerable Populations. He received a B.A. in comparative literature from the University of Texas at Austin, his M.S. in wildlife biology from Louisiana State University, and his Ph.D. in environmental toxicology from Virginia Polytechnic Institute and State University. Dr. Di Giulio has published extensively on subjects including biochemical and molecular mechanisms of adaptation and toxicity, mechanisms underlying chemical carcinogenesis and teratogenesis, and biomarkers for chemical exposure and toxicity. Most of this work has employed aquatic organisms, particularly fishes. Additionally, he has organized symposia and workshops and has written on the broader subject of interconnections between human and ecological health. Dr. Di Giulio is a member of the Computational Toxicology Committee for the Board of Scientific Counselors, U.S. Environmental Protection Agency; he has recently worked as a member of the National Academy of Science Committee on Assessment of the Health Implications of Exposure to Dioxin and is Associate Editor for *Toxicological Sciences*.

David E. Hinton is Nicholas Professor of Environmental Quality, Nicholas School of the Environment and Earth Sciences, at Duke University, Durham, North Carolina. At Duke, he serves as Chair of the Environmental Health and Ecotoxicology Program. Dr. Hinton received his B.S. in zoology at Mississippi College and his M.S. and Ph.D. in anatomy at the University of Mississippi. Prior to taking his post at Duke, Dr. Hinton served for four years as director of the Systemwide Ecotoxicology Lead Campus Graduate Program at the University of California, Davis, where he held increasingly responsible positions beginning in 1990. His experience at the University of California, Davis, included Professor of Aquatic Toxicology, Professor of Veterinary Medicine and Aquatic Toxicology, and Chair of the Graduate Group in Pharmacology and Toxicology. Dr. Hinton's expertise lies in mechanistic and integrative understanding of the manner in which environmental contaminants exert their effects, cellular pathobiology, and toxicopathology of persistent environmental contaminants in fishes (deciphering deleterious effects and establishing causal linkages). His primary area of expertise is ecotoxicology, and his secondary areas of study are related to applications of team efforts in watershed management, environmental health, and biomarkers of exposure and adverse effects in surface waters. Dr. Hinton, the author or coauthor of more than 200 papers in internationally refereed journals, served as the editor-in-chief for *Aquatic Toxicology* from 1995 to 2000. He currently is a member of the executive committee of the Research Triangle Environmental Health Collaborative and the ILSI Health and Environmental Sciences Institute Subcommittee on Emergence of Animal Alternative Needs in Environmental Risk Assessment.

Introduction

Richard T. Di Giulio and David E. Hinton

Toxicology, the study of the adverse effects of chemicals, has a rich history, the bulk of which revolves around understanding the effects of poisons on humans. Michael Gallo (2001) provided an excellent and lively historical perspective on human health-oriented toxicology, including historical and literary examples of inquiry from antiquity, the Middle Ages, and the Age of Enlightenment. As he noted, modern toxicology draws upon many fields of basic science; these include molecular biology, chemistry and biochemistry, genetics, organismal biology, ecology, and mathematics. Indeed, the solution to most important toxicological questions requires interdisciplinary approaches drawing on multiple forms of expertise. A distinction that has been used to categorize toxicology is biomedical vs. environmental (or *ecotoxicology*), the former focusing on human health and the latter on free-living flora and fauna and their populations, communities, and supporting ecosystems. The latter is a relatively young field, at least in the sense of a formal science; the term *ecotoxicology* was first used by Truhaut in 1969 (Truhaut, 1977) and is often used to stress the fate and effects of chemicals within an ecosystem (Kendall et al., 2001).

Ecotoxicology has been defined in various ways, but for most of us it means the study of effects that chemical pollutants exert on natural biota. Contributing to the biocomplexity that we are challenged with is the large number of species for which meaningful data are needed. To deal with effects at various levels of biological organization and in a large number of organisms, we must extrapolate findings between species. It should also be noted, however, that some definitions are broadened to include effects on any biosphere component, including humans (Newman and Unger, 2003), and increasing consideration for integrative connections between human health and the well-being of natural systems appears to be enhancing interactions between the fields of biomedical toxicology and ecotoxicology (Di Giulio and Benson, 2002) and also integrations of risk assessments for human health and ecosystem protection (Munns et al., 2003; Suter et al., 2003).

Fish occupy a prominent position in the field of toxicology; they have been employed amply in studies concerning both human and ecological health, probably bridging this divide more than any other class of organisms. Several reasons likely account for this. Fish are by far the most diverse class of vertebrates; the 28,000 species identified to date are greater than the combined numbers for the other classes (Cossins and Crawford, 2005). This taxonomic diversity is reflected in a diversity of body forms, lifestyles, and physiologies, which also reflect the great diversity of aquatic systems that fish inhabit, from freshwater to hypersaline waters, with temperatures ranging from below freezing to >45°C, pressures ranging from 1 to 1000 Atm, and other variabilities in solar radiation, oxygen concentrations, ionic and organic matter compositions, turbulence, bottom environments, and so forth. This species and habitat diversity has long driven the use of fishes for scientific inquiries into the influences of environmental variables on the evolution, genetics, and adaptations of organisms.

In the context of pollution, aquatic systems are highly vulnerable due to their tendency to accumulate relatively high concentrations of chemicals entering from surrounding terrestrial systems, as well from direct inputs; thus, regardless of their source of entry to the environment, aquatic systems are oftentimes repositories for a large array of stressor chemicals (for example, see Chapters 2 and 14 in this volume).

Downloaded From Vet-eBooks.com

Additionally, aquatic food chains are generally longer than terrestrial food chains; this also likely contributes to observations that many persistent pollutants tend to achieve greater concentrations in aquatic predators, including fishes, compared to terrestrial predators (Clements and Newman, 2002, pp. 300–302). Moreover, aquatic animals are often particularly vulnerable because of elevated exposures arising from their living immersed in the exposure medium (surface water), having highly permeable skin and gills, and other inherent sensitivities. Fish and amphibians, for example, are the only vertebrate groups with anamniotic eggs (lacking a shell or amniotic membrane) and that undergo metamorphosis in surface waters; hence, the embryo–larval stages of these animals are highly sensitive to chemical pollutants (Kendall et al., 2001). These issues likely contribute to lower water quality guidelines to protect aquatic life vs. human health, even though the calculations used to generate such guidelines are more conservative (i.e., protective) in the context of human health (http://www.epa.gov/safewater/mcl.html#mcls).

Fish, not surprisingly, play important roles in setting these water quality guidelines for freshwater and marine systems. U.S. Environmental Protection Agency (EPA) guidelines provide specific recommendations for freshwater and marine species to be used for acute and toxicity tests that are used in establishing these guideline and other chemical safety assessments (U.S. EPA, 1996; see Chapter 15 in this volume). In addition to their role in establishing surface water quality criteria, toxicity tests provide information concerning, for example, relative acute toxicities among various chemicals, relative sensitivities of different species to selected chemicals, and the sublethal effects of chemicals and chemical mixtures. Also, data generated from toxicity tests play important roles in ecological risk assessments (see Chapter 18 in this volume).

In addition to their central role in toxicity testing for ecological effects, fish are perhaps the most employed organisms for biomonitoring. This is likely due in part to the aforementioned propensities of aquatic systems to receive and accumulate environmental contaminants and the diversity and importance of fishes in these systems. Fish-targeted biomonitoring includes a wide variety of approaches for detecting impacts of aquatic contamination, from direct measures of mortality, to broad analyses of population dynamics and community structure, to detection of measures of subcellular change. This last approach, embedded in the term *biomarkers* (see Chapter 16 and the case studies in Unit IV in this volume), has perhaps benefited the most from modern toxicological research with fish models wherein elucidation of the mechanisms of toxic action has received serious consideration and great strides have been made.

In a relatively short time, several decades, aquatic toxicology has moved from a descriptive approach, which was necessary to explore those concentrations of single toxicants within water that were not compatible with the life of individual fishes, to considerations of sublethal concentrations that do not cause death over the short term but do harm the individual, thus making it expend resources to survive in a state of altered equilibrium. Biomarkers of exposure, response, and genetic susceptibility were derived from research in this area, and these helped to cut across questions of bioavailability as the emphasis shifted to host response. Biomarkers illustrate the multiple organ, tissue, and cellular sites of action and the spectrum of responses that were possible. The resultant toolkit, amply illustrated in this volume, is a suite of biomarkers and validated methods that are now used to assess chemical exposures and effects or responses arising from various forms of chronic toxicity.

Again, recent toxicological research with fishes has pursued the study of mechanisms of action. This approach has provided potential tools for ecotoxicologic investigations; however, problems of biocomplexity and issues at higher levels of biological organization remain a challenge. In the 1980s and 1990s and continuing to a lesser extent today, organisms residing in highly contaminated field sites or exposed in the laboratory to calibrated concentrations of individual compounds were carefully analyzed for their responses to priority pollutants. Correlation of biochemical and structural analyses in cultured cells and tissues, as well as *in vivo* exposures, led to the production and application of biomarkers of exposure and effect and to our awareness of important effects such as cancer and endocrine disruption in wild fishes. To gain acceptance of these findings in the greater environmental toxicology community, validation of the model vs. other, better established (often rodent) models was necessary and became a major focus. Resultant biomarkers were applied to heavily contaminated and reference field sites as part of effects assessment and in investigations following large-scale disasters such as oil spills or industrial accidents. It should be noted that the total number of fish species used in mechanistic research and for biomonitoring

Downloaded From Vet-eBooks.com

is nowhere near the total number of species, and for much of our current information we are dependent on a relatively small fraction of the species.

Through the use of an expanding aquatic toxicology toolkit, effects of stressor chemicals on aquatic organisms are being determined in an integrative manner on individuals and, in some instances, are being extended to population and community levels of biological organization, as well. Most recently, genomic approaches are being explored for their ability to reveal, for example, mechanisms of action, differential sensitivities, and similarities and differences among organisms (see Chapter 5 in this volume). Additionally, they may make substantial contributions to ecological risk assessments (Ankley et al., 2006), as well as promote the integration of human health-oriented and ecologically oriented research and policy (Benson and Di Giulio, 2006).

Why does one need to have a comprehensive treatment of the toxicology of fishes? Particularly with regard to certain aspects of the subject in which enormous and recent growth has taken place, a great deal of new information has been assembled and must be thoroughly reviewed to provide cohesive coverage and to integrate new findings with existing concepts. The next set of challenges that investigators may face in the field will likely cause additional attention to be drawn to organ, tissue, and cellular sites that are being targeted and lead to approaches embodying likely different perspectives.

The Toxicology of Fishes is organized into four units. Unit I, "General Principles," contains Chapters 1 through 6. Following this Introduction, Chapter 2 is devoted to the bioavailability of chemical contaminants in aquatic systems. To students new to this field, bioavailability is critical to our coverage because certain forms of potentially toxic substances in water are bound to particulates in the aquatic medium and are not available for uptake by fish. When uptake has occurred, distribution within the individual fish must be considered, and this is the subject of Chapter 3, "Toxicokinetics in Fishes"; for example, toxicokinetics permits us to understand the distribution within the individual and to approach an improved quantitative estimate of the dose. The fourth chapter is concerned with biotransformations in fishes and, among other things, covers the potential bioactivation of compounds into toxic forms and their conjugation and removal. Chapter 5, "Molecular Mechanisms of Toxicity," provides coverage of the process by toxic states are achieved. Completing this first unit is an additional chapter on mechanisms, particularly those arising through oxidative stress.

Unit II, "Key Target Systems and Organismal Effects," is comprised of Chapters 7 through 13. Chapter 7, "Liver Toxicity," covers the microscopic anatomy of the organ, important aspects of the liver physiology in fishes, and morphological, biochemical, and functional aspects of toxic injury and its consequences. Chapter 8, "The Osmoregulatory System," covers the anatomy and physiology of the gill and its perturbations by metals and other aquatic pollutants; given the extensive surface area and role in uptake of contaminants, the osmoregulatory function of this organ may be compromised by exposure to metals and selected organic compounds. Chapter 9, "Toxic Responses of the Fish Nervous System," provides a description of the central nervous system of fishes and describes a variety of toxic responses, some morphological and others physiological. The coverage leads to improved understanding of the nature of specific toxic induced alterations. Chapter 10, "The Endocrine System," describes the endocrine system of fishes and its toxicity, and receptor-mediated mechanisms and the effect of contaminants on hormone function are covered in detail. Chapter 11 describes the immune system of fish, a known target for certain toxicants that can directly affect the individual's host defense mechanisms. How these toxic responses arise and their significance are the subjects of this chapter. Chemical carcinogenesis of fishes is the subject of Chapter 12, in which a brief history of this interesting aspect of chronic toxicity is provided followed by coverage of molecular aspects of carcinogenesis. Discussions of procarcinogens illustrate important information about fish as models. Both laboratory and field studies are reviewed, and the various fishes that have been studied from contaminated and reference sites are presented. The final chapter in this section, Chapter 13, is a treatment of toxicity resistance; it is important to understand how animals including fishes can adapt to chemical contamination and the long-term consequences of such adaptations.

Unit III, "Methodologies and Applications," is an assemblage of five chapters. Chapter 14, "Exposure Assessment and Modeling in the Aquatic Environment," is followed by a chapter on fish toxicity studies which reviews methods and approaches for determining acute and chronic toxicities in various laboratory applications. Responses that indicate exposure, adverse effects, and genetic susceptibility are included

Downloaded From Vet-eBooks.com

in Chapter 16, "Biomarkers"; information provided here includes descriptions of a broad array of biomarkers and examples of their application in biomonitoring. In Chapter 17, "Aquatic Ecosystems for Ecotoxicological Research: Considerations and Design Analysis for Fish," the importance of research at higher, ecologically relevant levels of biological organization (populations, communities, and ecosystems) is described, and examples of appropriate designs are provided. Finally, Chapter 18, "Ecological Risk Assessment," deals with the translation of ecotoxicological research into environmental management and policy; the approach of risk assessment considers data on exposure to and toxicity of chemical contaminants, sensitivities of organisms that are likely to be exposed, and the quantitative assessment of risks to aquatic systems.

In Unit IV, "Case Studies," a group of seven chapters provides ample examples of how the principles and approaches presented in earlier units are actually deployed in studies, particularly in the field; for example, Chapter 19 presents an analysis of mining and effects on fish in a Montana river. The study combines chemistry, biological responses, and ecotoxicological findings. In Chapter 20, the effects of synthetic pyrethroid compounds in fish are covered. In Chapter 21, mechanistic insight into the early-life-stage toxicity of certain chemicals is used to assess risks to Great Lakes fish. Both the subject of this field evaluation as well as its use of early life stages are of great interest given recent recommendations by REACH legislation in the European Union to refine, reduce, and reevaluate the use of animals in toxicity testing. Chapter 22 is concerned with the effects of polycyclic aromatic hydrocarbons in fish from Puget Sound, Washington. Chapter 23 examines the effects of the *Exxon Valdez* oil spill on Pacific herring in Prince William Sound. This investigation involved successive years of evaluation and included pathology as a backbone of the field investigations. In Chapter 24 addresses the pulp and paper mill effects studied in streams of Canada; the authors present a consideration of various indicators for the health of surface waters downstream of paper mills. Chapter 25 provides a detailed review of the estrogen-mimicking agents released from treated sewage effluent and their effects on fish inhabiting rivers in England. These case studies illustrate the power of, and absolute need for, highly integrated interdisciplinary research teams to address complex issues of chemical pollution in the aquatic environment.

It is our sincere wish that *The Toxicology of Fishes* will provide a very important teaching tool to introduce new students to the field, and we envision this effort presenting an opportunity for experienced authors and investigators to share their findings and expertise with others. Finally, to prepare a thorough coverage of the toxicology of fishes is a major task and one not completed in a short time due to the multiple roles of those investigators that agree to take on the task of authorship of one or more chapters. To assume this responsibility means that yet another set of tasks was placed on an already busy schedule. To all the participants in this book, we offer our congratulations on a job well done and our sincere appreciation for your efforts on behalf of this endeavor. Due to these efforts we believe this text will become a source of useful information that guides worker and student alike.

Additional color figures are available on the CRC website: www.crcpress.com. Under the menu Electronic Products (located on the left side of the screen), click on Downloads & Updates. A list of books in alphabetical order with Web downloads will appear. Locate *The Toxicology of Fishes* by a search or scroll down to it. After clicking on the book title, a brief summary of the book will appear. Go to the bottom of this screen and click on the hyperlinked "Download" which is in a zip file. Or, readers can go directly to the Web download site, which is www.crcpress.com/e_products/downloads/default.asp.

Introduction

Toxicity in fish is the culmination of a series of events involving various physical, chemical, and biological processes (Figure 2.1). Chemicals are released to the environment from different sources; enter aquatic systems in effluents, atmospheric deposition, runoff, and groundwater; and become distributed throughout the water column and underlying sediment. Food organisms for fish become contaminated via contact with water or sediment and via their own food. Fish accumulate chemicals both by ingestion of this contaminated food and by contact of their respiratory surfaces and skin with contaminated water. Accumulated chemical is distributed throughout the fish, and some of this chemical reaches a site of action to elicit toxic effects.

An important aspect of this chain of events is chemical speciation, represented by the pie charts in Figure 2.1. Many chemicals exist in different forms (chemical species) as a result of chemical and biochemical reactions. The identities and relative concentrations of chemical species vary with location and time and differ among the components of an aquatic ecosystem. A fish can be exposed to a mixture of chemical species both in the water it contacts and in the food it ingests. Chemical accumulation and toxicity depend not just on total chemical concentration in the environment but also on how readily the fish can absorb these different chemical species at the gill, across the skin, and within the digestive tract and on how chemical speciation affects distribution throughout the organism. Thus, the chemical will be more or less "bioavailable" to a site of action depending on chemical speciation and various organism attributes.

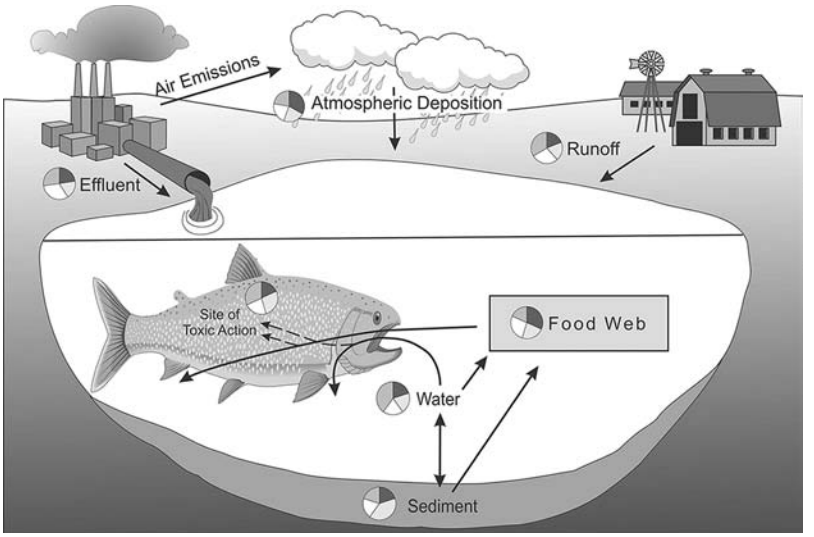

FIGURE 2.1 Chemical inputs to and distribution within aquatic systems, emphasizing accumulation by fish. Pie charts qualitatively represent chemical speciation and how it differs among system compartments.

Definitions of bioavailability vary markedly (National Research Council, 2003) and are often oriented to specific situations; however, these various definitions all address how readily chemicals are accumulated under different circumstances (e.g., for different chemicals, organisms, or environmental conditions). Bioavailability is therefore defined here as *the relative facility with which a chemical is transferred from the environment to a specified location in an organism of interest*. Although it is broad, this definition is still useful because it identifies important factors that must be considered in further refining and applying it for particular assessments:

1. Chemical uptake, and thus bioavailability, depend on certain morphological, physiological, and biochemical attributes of an organism. As such, bioavailability must be defined in terms of a particular type of organism and its physiological state. Caution is needed regarding how well bioavailability relationships for one type of organism can be extrapolated to other types.
2. Bioavailability must be referenced to a specific chemical concentration in the organism of interest. This could be the total chemical in the entire organism, the chemical within a particular tissue, the chemical associated with a specific molecular receptor, or any other measure appropriate to the nature of the toxicity and the goals of the assessment.
3. Bioavailability must also be referenced to a specific environmental concentration. Often this will be the total chemical concentration, with bioavailability being considered an aggregate property of the combined chemical species; however, assessments might also focus on selected subsets of the chemical species or address the comparative bioavailability of individual chemical species. The spatial context of this concentration is also important; often the reference concentration is that in immediate proximity to the organism, but sometimes it covers a large spatial extent. In addition, an exposure time frame might be required because bioavailability relationships can change with time.
4. Transfer pathways of interest must be specified. An assessment might be concerned with only a single route of exposure (e.g., food) or with all possible routes. Depending on how reference concentrations in the organism and the environment are defined, various transport pathways and reactions inside and outside the organism also must be considered.

Whatever the definition and context of bioavailability assessments, their success depends on adequately defining the processes that regulate chemical accumulation. Processes important for determining

Downloaded From Vet-eBooks.com

bioavailability fall into three categories. First, processes external to the fish determine the concentration and speciation of the chemical to which a fish is exposed. A detailed discussion of fate and transport of chemicals is not in the scope of this chapter, but this topic will receive some attention here because evaluating bioavailability requires some understanding of the nature and origin of the chemical species. Second, the fish can absorb the chemical by various routes and mechanisms that are functions of both chemical speciation and organism physiology. It cannot generally be said that a chemical species is either bioavailable or not; rather, bioavailability is relative and will reflect how much a chemical species contributes, directly or indirectly, to this absorption. Third, once absorbed, the chemical will be modified and distributed within the fish, thus determining the nature and amount of chemical at the site of toxic action.

This chapter is organized into two sections. The first section addresses some general principles of chemical bioavailability with regard to chemical fate in aquatic environments and chemical uptake via different routes of exposure. Additional information regarding chemical uptake and disposition in fish is provided in Chapter 3. This first section also discusses various measures that are used in evaluating bioavailability. The second section presents several case studies regarding the bioavailability of a wide variety of chemicals. These examples are not presented to give a comprehensive review of bioavailability for specific chemicals but rather to illustrate a range of issues and processes that can be important in defining and assessing bioavailability for any chemical.

Assessing Bioavailability: Principles, Processes, and Measures

Chemical Behavior in the Aquatic Environment

Chemicals may enter the aquatic environment via a variety of point and non-point sources, including direct discharges, soil and pavement runoff, and atmospheric deposition (Figure 2.1). Those chemicals that enter aquatic environments in large quantities, that are relatively persistent, or that are very potent typically are of most concern. Some types of anthropogenic chemicals are unlikely to enter the aquatic environment because of how they are used. In other cases, chemicals may not remain in aqueous solution; for example, relatively volatile chemicals usually are not persistent in aquatic systems. In other instances, degradation processes, such as microbial metabolism, aqueous hydrolysis, or photolysis, markedly decrease concentrations of chemicals before or after they enter aquatic systems, thus reducing the probability of significant exposure of aquatic organisms. Approaches exist (based on production volume, use pattern, chemical structure, toxicity, etc.) for predicting the potential hazard of newly manufactured chemicals in aquatic environments. Although consideration of these types of predictive models is beyond the scope of this text, they are generally the first step in determining the need for further application of prospective risk assessment methodologies.

A number of factors related to the structure and properties of a chemical in an aquatic environment will dictate its fate, distribution, and, ultimately, bioavailability to aquatic organisms. Aromatic rings and halogenated substituents, for example, tend to be associated with persistent organic contaminants such as polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), polychlorinated dibenzofurans (PCDFs), and dibenzo-*p*-dioxins (PCDDs), as well as organochlorine pesticides such as DDT (and DDE, DDD), dieldrin, and toxaphene. Chemical elements that are neither created nor destroyed but are redistributed in the environment by the activities of humans also are persistent contaminants. Some of the more toxic elements in this class are metals and metalloids such as cadmium, copper, mercury, nickel, zinc, lead, silver, and arsenic. There are also several relatively persistent and toxic organometals such as methylmercury and tributyltin. Even chemicals that are not persistent can be of concern if large quantities are released to aquatic systems or the chemicals are very potent. An example of the former situation would be ammonia, which, under appropriate conditions, can be converted via nitrification to nontoxic products but is a chemical of toxicological significance to fish because of large inputs to aquatic systems. An interesting example of a relatively labile compound that nonetheless remains of concern because of its potency is the synthetic estrogen ethynylestradiol. This component of birth control pills is found only in small concentrations in certain types of municipal effluents, but because of its great affinity for the estrogen receptor it has been associated with an increased incidence of feminized male fish in exposed populations (Desbrow et al., 1998).

Downloaded From Vet-eBooks.com

Chemical structure and properties dictate not only persistence in the aquatic environment but also the primary compartments (e.g., water, sediment, suspended particles) with which a chemical is associated and, by extension, routes through which a fish is likely to be exposed. One particularly important property controlling the behavior of a chemical in the aquatic environment is its hydrophobicity. A measure of relative hydrophobicity that is often used in aquatic toxicology is the octanol–water partition coefficient (K_{ow}).* Chemicals with large log K_{ow} values, in particular those with log $K_{ow} > 5$, are considered hydrophobic and tend to be associated with organic materials in aquatic systems, especially sediments. Hydrophobic chemicals of environmental concern in this class include most PAHs, PCBs, PCDFs, PCDDs, and some organochlorine pesticides and organometals.

An important variable in chemical fate and bioavailability is the fraction of chemical that is freely dissolved; for example, nonionic organic compounds or cationic metals complexed by dissolved organic carbon (DOC)† are often far less bioavailable than their uncomplexed forms. Although this is an important guiding principle in the area of bioavailability prediction, empirical demonstration of the concept has proved challenging in that it is very difficult to reliably measure freely dissolved chemicals. As an example, although a common operational definition of dissolved metal is the ability to pass through a 0.45-μm filter, it is well known that metals bound to some types of colloidal organic carbon also can pass through this pore size. Analogous problems exist in defining fractions of organic chemicals that are freely dissolved. Often, it is easier to predict than measure dissolved fractions of some chemicals using partitioning and speciation models. As a consequence, assessment of contaminant bioavailability might rely on predictive models that consider properties of both the chemical and the aqueous environment under consideration, in conjunction with measurements of total chemical concentrations. An example of this approach is provided in the case study below concerning 2,3,7,8-tetrachlorodibenzo-*p*-dioxin.

Another important property used to describe the behavior of many ionizable compounds is their degree of dissociation at pH values typically found in aquatic systems. Charged molecules are more water soluble, while neutral forms of the same chemical tend to be more hydrophobic and thus more associated with organic carbon than water. The speciation of strong acids (or bases) will not be affected by pH variations typical of most aquatic environments; however, the behavior of chemicals with pK_a‡ values in the range of approximately 5 to 9 can be greatly affected by system-specific variations in pH. Chemicals whose pK_a values are important determinants of fate and bioavailability include weak acids, such as phenolic compounds, some surfactants and resin acids, and weak bases such as ammonia.

The interaction of chemicals with biotic and abiotic ligands in the aquatic environment influences their speciation and partitioning into different environmental compartments. A major partitioning phase for many nonionic organic chemicals is DOC and particulate organic carbon (POC), both in the water column and sediments. The interaction between these types of chemicals and organic carbon can be modeled based on their K_{ow} values. A predictable and generally linear relationship exists between the log K_{ow} of a chemical and the log K_{oc},§ so knowledge of K_{ow} can be useful for deriving organic carbon partitioning relationships for predicting bioavailability. In the case of organic and inorganic ions, ionic constituents of the water can affect chemical speciation; for example, certain types of DOC (i.e., humic acids) as well as some inorganic anions can strongly complex cationic metals, thereby controlling partitioning and subsequent bioavailability.

---

* The octanol–water partition coefficient (K_{ow}) is the equilibrium ratio of the concentration of a chemical in *n*-octanol to its concentration in water, commonly expressed as its base 10 logarithm, log K_{ow}.

† Dissolved organic carbon (DOC) is the carbon present in the complex mixture of organic molecules dissolved in water, consisting largely of organic acids originating from the decomposition of plant material, including fulvic and humic acids. This is in contrast to particulate organic carbon (POC), which refers to the carbon present in the complex mixture of particulate material suspended in water, including resuspended sediment and detritis, soil particles, leaf litter, bacteria, phytoplankton, and zooplankton. POC and DOC are often defined operationally as that portion of the total organic carbon (TOC) in water retained and not retained, respectively, by a filter with a pore size of 1.0 μm or less (commonly 0.45 μm).

‡ The acid dissociation constant (K_a) is the equilibrium constant for the dissociation of an acid into hydrogen ion and its conjugate base. $pK_a = -\log_{10}(K_a)$ and is equal to the pH at which half of the chemical is ionized.

§ The organic carbon–water partition coefficient (K_{oc}) is the equilibrium ratio of the concentration of a chemical associated with organic carbon (measured as the mass of chemical per mass of carbon) to its free concentration in water. The value for this coefficient will depend on the composition of the organic carbon phase, which varies among aquatic systems, between the water column and sediment, and between dissolved and particulate phases.

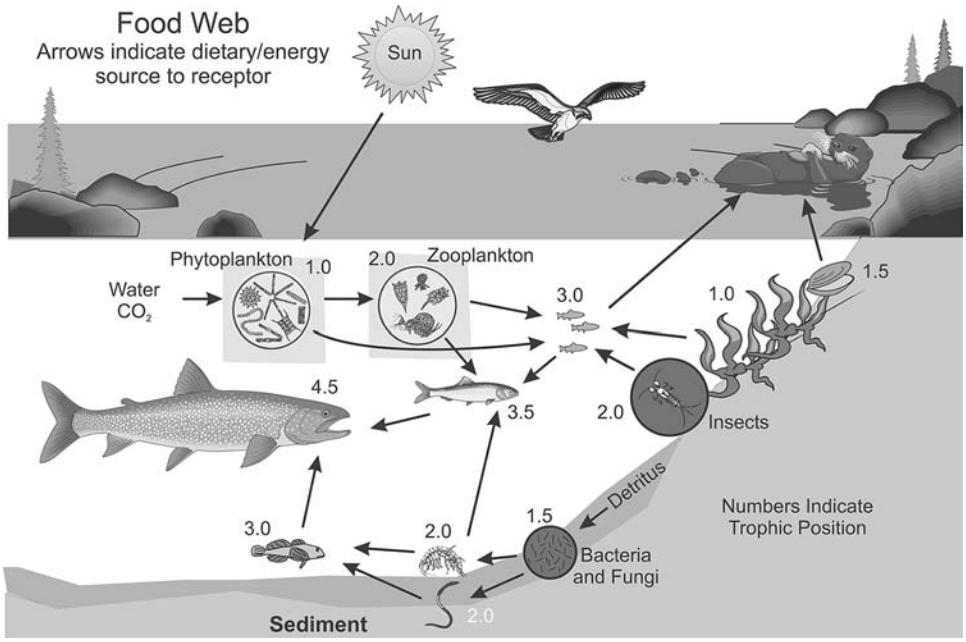

FIGURE 2.2 Movement of chemicals through aquatic food webs. Numbers denote trophic level of organism (e.g., 1.0, primary producers; 2.0, strict herbivores).

An additional type of interaction that can be important for the speciation of ionized chemicals is competition with other ions in speciation reactions. This is particularly important for divalent cationic metals, such as copper (see case study below), whose speciation and partitioning can be greatly influenced by structurally similar but relatively nontoxic cations such as calcium and magnesium.

An understanding of chemical bioavailability requires understanding not only the chemical reactions within an environmental compartment but also how the chemical moves among compartments. An important route of exposure for cationic metals, for example, is via the gill in fish, yet the major repository of some metals in many aquatic systems is the sediment. Therefore, to completely assess the potential for a cationic metal to produce toxicity requires an understanding of bioavailability as it relates to both water and sediment. In fact, the dynamic relationship between the water column and sediments, which serve both as a source and sink for contaminants, is so critical that most state-of-the-art fate and effects modeling at the watershed level explicitly considers interactions between the two compartments.

The interplay between the water column and sediments becomes particularly important for food webs that determine contaminant exposure in fish diets (Figure 2.2). Contaminants in these food webs can originate from the water column via absorption from solution by phytoplankton and other suspended particles, which are consumed by filter feeding animals, which in turn support a series of predators. The contaminants might also originate from sediments, where various invertebrates accumulate chemicals from pore water or ingested sediment particles, thus providing another food base for predators. The resulting dietary exposures to fish will have both water column and benthic components, the relative importance of which will vary depending on the distribution of contaminant between the water column and sediment, chemical speciation within the water and sediment, the nature of the food web, and the position of the fish within the food web.

Accumulation via Gills and Skin

Fish gills serve a variety of physiological functions, including respiratory gas exchange, osmoregulation, nitrogen excretion, and control of acid–base balance (Hoar and Randall, 1984). Because of these functions, fish gills have the following features important for the exchange of toxic chemicals between a fish and its environment:

Downloaded From Vet-eBooks.com

1. They process large volumes of water, ranging from several to hundreds of times the volume of the fish per hour, and are supplied by a large blood flow (typically about an order of magnitude lower than the water flow).
2. They have a large surface area with a small distance separating water and blood. To accomplish this, gills contain a grid of numerous small, parallel, plate-like structures called *secondary lamellae*. Each pair of lamellae delimits a narrow channel through which water flows, and each lamella contains a blood space separated from the water by a thin layer of epithelial tissue.
3. Within the gill lamellar system, blood and water generally flow counter-current to each other, which improves the efficiency of transfer of material between the two. This combination of counter-current exchange, large surface area, and short diffusion distance results in highly efficient extraction of the small concentrations of oxygen present in water. This high extraction efficiency also depends on oxygen being (a) a small, neutral molecule that readily diffuses across lipid cellular membranes, and (b) strongly bound to hemoglobin in blood (which helps to maintain steep diffusion gradients between water and blood as they flow through the gill).
4. Gill epithelial tissue contains a variety of biochemical systems that regulate or otherwise affect the exchange of various chemicals between blood and water passing through the gills. Sites on the cellular membranes for ion exchange (transport proteins, ion channels) can serve as uptake sites for toxic chemicals with suitable physicochemical properties.
5. Because of the chemical exchanges that are part of their normal functions, gills create a chemical environment adjacent to their surface that can differ markedly from that of the surrounding water. Due to excretion of carbon dioxide and ammonia, the pH at the gill surface of a fish can differ from that in the surrounding water (Lloyd and Herbert, 1960; Playle and Wood, 1989; Wright et al., 1991). Gill epithelial cells are also covered by a thin layer of polysaccharide mucus, which can affect chemical speciation at the gill surface and in the adjacent water (Tao et al., 2002).

Figure 2.3 illustrates transport pathways and chemical reactions that can be important for the uptake of toxic chemicals at fish gills. For simplicity, just two species of a toxic chemical (T) are shown here—that which is bound to some other chemical constituent (B) in water or blood and that which is not bound (free). These two species are connected by a double arrow to represent the speciation reaction by which they interconvert. Sometimes speciation reactions are slow enough that chemical species will not change during passage through the gill; however, many reactions are fast enough that chemical species can be altered within the gill, with possible consequences for uptake rates and bioavailability.

As the toxic chemical is swept along the water channel, free chemical can be absorbed into the epithelial tissue via various routes and mechanisms. If the chemical can readily cross lipid cellular membranes, a principal route of uptake will be passive diffusion across the epithelial tissue (arrow 1 on Figure 2.3). Other chemicals might have the appropriate size and electrochemical properties to be taken up via specific biochemical exchange sites on the epithelial tissue surface (arrow 2 and rectangular S). A significant site for ion loss in freshwater fish can be via junctions between epithelial cells. These junctions are not depicted on Figure 2.3 but might also be important for the uptake of chemicals that are not effectively absorbed via other routes.

The bound chemical might also be directly absorbed via one or more of the same routes as the free chemical, although probably at a different rate (arrow 3); however, the bound chemical can also affect uptake in other ways. If absorption of the free chemical significantly reduces its concentration within the lamellar channel and if the speciation reaction is fast enough, net dissociation of the bound chemical (arrow 4) will replenish the free chemical concentration, supporting additional uptake. In this way, the bound chemical can be considered bioavailable, even though it is not directly absorbed. Such shifts in speciation equilibrium require significant net absorption of the chemical during passage through the gill, and so will be important only when chemical concentrations in fish are below those in equilibrium with the surrounding water. This will be true during the early stages of exposure to a chemical but can also be true at steady state if the chemical is rapidly metabolized or eliminated via routes other than the gill.

These uptake relationships can be modified by the chemical characteristics of the water in the gill lamellar channels (C in Figure 2.3). This chemistry is a function of both the incoming exposure water

Downloaded From Vet-eBooks.com

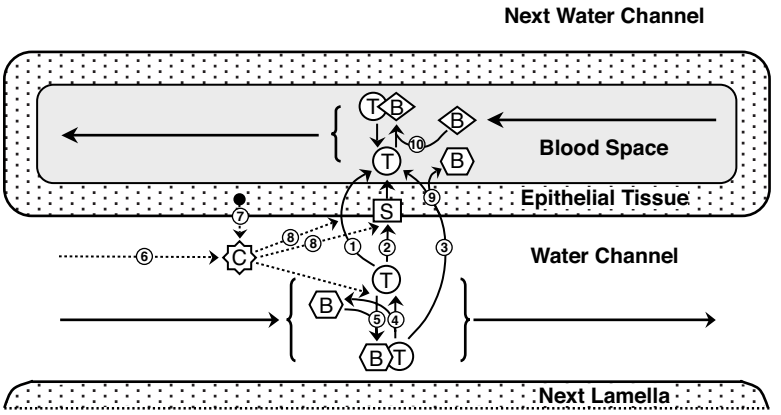

FIGURE 2.3 Conceptual model of contaminant uptake at fish gills. Diagram depicts a secondary lamella of a fish gill as epithelial tissue enclosing a space through which blood flows and shows an adjacent lamellar channel through which water flows. See text for explanation of symbols.

(dotted arrow 6) and various chemical exchanges at the gill surface (dotted arrows). Changes in this chemistry can shift the speciation of the toxic chemical, causing net increases or decreases in the amount of free chemical (arrows 4 and 5, respectively). Chemical characteristics of the exposure water can also affect uptake rates across the gill epithelium by affecting cellular membrane characteristics (dotted arrows marked 8); for example, certain chemical constituents might compete with the toxic chemical at, or otherwise modify the properties of, the exchange site.

After the chemical has been absorbed into and across the epithelium, its speciation can also change. Toxic chemical that is absorbed while bound to other chemicals will dissociate in the chemical environment of the organism (forked arrow marked 9), unless the dissociation reaction rate is slow or the same binding agent exists at similar concentrations within the organism. More importantly, the speciation of the toxic chemical can be affected by a variety of chemical constituents within the organism (arrow 10). These various reactions will alter chemical gradients and thus affect uptake, just as binding to hemoglobin helps maintain high uptake rates of oxygen. If these speciation reactions are rapid enough, each chemical species in the exposure water that is absorbed will contribute to the internal concentrations of *all* species and thus to the effective dose, in proportion to the rate at which it is taken up; however, in cases where speciation reactions are slow, toxic chemical species inside the fish may retain a "memory" of their identity outside the fish, such that different species may not contribute to toxicity to the same degree as they do total accumulation.

Various processes identified in Figure 2.3 are reflected in data from McKim et al. (1985), who measured the uptake of 14 organic chemicals across the gills of large rainbow trout (*Oncorhynchus mykiss*). For neutral organic compounds of moderate hydrophobicity ($3 < \log K_{ow} < 6$), chemical extraction efficiencies (i.e., the fraction of chemical removed from water flowing into the gill) were similar to that of oxygen. Efficiencies were high for these chemicals because, like oxygen: (1) they exist in exposure water almost entirely as uncomplexed, small, neutral molecules that can readily diffuse into and across the gill epithelium, and (2) they bind to certain components in the blood, thereby maintaining a strong diffusion gradient from water to blood. Accumulation rates for these chemicals are primarily limited by the rate at which water is pumped through the lamellar water channels.

Less efficient uptake occurred for chemicals with either lower (<3) or higher (>6) log K_{ow} values and for those chemicals that were partially ionized. These lower uptake efficiencies can be understood in terms of chemical speciation and membrane transport properties. For chemicals with $\log K_{ow} < 3$, uptake is slower because these chemicals do not bind as strongly to blood components, which results in the free chemical concentrations in the blood increasing significantly during passage through the gill, thereby reducing diffusion gradients. The accumulation rate of such chemicals is primarily limited by the rate at which blood flows through the secondary lamellae, in contrast to the water-flow-limited chemicals discussed above. Chemicals with $\log K_{ow} > 6$ will diffuse less readily across cellular membranes, either

Downloaded From Vet-eBooks.com

because the larger size of these molecules reduces their ability to penetrate lipid membranes (Opperhuizen et al., 1985) or because their high hydrophobicity results in them being bound to even larger organic substances in the exposure water (Black and McCarthy, 1988). For the partially ionized chemicals, lower uptake rates occur because the charged forms diffuse less readily across lipid membranes. For both of these latter two groups of chemicals, accumulation rates are limited primarily by their diffusion across the epithelium rather than by water and blood flows.

Uptake of toxic chemicals from water via the skin will generally be much less important than uptake via the gills because the skin of fish typically provides less surface area, a thicker and less permeable diffusion barrier, slower transport of water to the exchange surface, less blood flow, and no countercurrent flow of water and blood. McKim et al. (1996) reported uptake of chlorinated ethanes via skin to be only a few percent of total uptake in adult rainbow trout and channel catfish (*Ictalurus punctatus*). For smaller fish, however, uptake via skin can be important (Lien et al., 1994; Saarikoski et al., 1986), because, as size decreases, skin is generally more permeable and has an increasing surface area relative to the gills. This is especially true for fish embryos and larvae, whose gills are not well developed and for which respiration can be largely via their more permeable skin. Although many of the same general principles apply whether uptake is via skin or gill, details regarding epithelial permeabilities, transport mechanisms, and the chemical microenvironment differ between gill and skin and are not well characterized. The relative importance of gill vs. skin generally is not known or even explicitly considered in chemical risk assessments, but it should be remembered that there will be a skin component of uptake of waterborne chemicals that could be significant and might exhibit bioavailability relationships different from the gill.

Accumulation via Diet

When chemicals in water partition strongly into solid phases or exist as dissolved forms that are poorly absorbed at gill and skin surfaces, the major route of exposure to fish can be via ingestion of contaminated food (or sediment for some species) and subsequent absorption within the gastrointestinal tract (GIT). The contents of the GIT represent an extension of the external environment, albeit one that is substantially modified by the process of digestion. Structural and functional features of the GIT that contribute to dietary uptake of xenobiotic chemicals were reviewed by Kleinow and James (2001). Briefly, these features include:

1. The large absorptive surface area is increased in many species by the presence of blind diverticula called *pyloric ceca* (Buddington and Diamond, 1987).
2. One or a few epithelial cell layers separate the contents of the gut lumen from elements of the blood circulation.
3. A high degree of tissue vascularization is present; blood perfusion of the GIT increases following the consumption of a meal and is probably controlled at a regional level so blood flow is directed to gut segments where digestion is occurring (Axelsson et al., 2000).
4. The contact time between gut contents and the gut epithelium is relatively long; total gut transit times in fish vary widely but generally range from a few hours to a day or more.
5. Ingested food items are broken down by the combined effects of acidification, enzymatic action, and physical disruption, releasing chemical contaminants to the liquid environment within the GIT. The rate of digestion and efficiency of nutrient uptake depend in turn on factors such as temperature, feeding frequency, meal size, and food digestibility.

The processes that control chemical flux between gut contents and the general circulation are not as well understood as those occurring at the gills. In general, compounds for which dietary uptake is an important route of uptake tend to remain associated with components of the meal until these components are taken up by the fish. Mixed micelles resulting from the digestion of dietary lipid sequester lipophilic organic compounds. These micelles are subsequently broken down at the surface of intestinal epithelium, releasing their contents within the aqueous boundary layer. Metals that possess high affinity for protein

Downloaded From Vet-eBooks.com

thiol groups tend to complex with amino acids and small peptides. Specific transport systems may exist to move these complexes across the gut epithelium, thereby facilitating metal uptake. Simple diffusion across the gastrointestinal epithelium may control the rate of uptake of some compounds. Uptake of poorly diffusing chemicals may occur due to pinocytosis of proteins and associated bulk media (McLean and Donaldson, 1990).

When used in the context of dietary uptake, the term *bioavailability* generally refers to the fraction of chemical that is absorbed by an animal following the ingestion of a contaminated meal. *Dietary absorption efficiency* may in theory be determined by measuring the difference in chemical mass in food and feces (Penry, 1998). In practice, however, such measurements are difficult to make. More commonly, researchers estimate absorption efficiency by measuring the amount of chemical retained by a fish after feeding it a defined ration. This value is referred to as the *dietary assimilation efficiency* and represents the net result of absorption and elimination, including biotransformation. To the extent that elimination occurs during the course of such an experiment, dietary assimilation efficiency will be lower than true absorption efficiency. For this reason, feeding studies designed to estimate absorption efficiency based on accumulated chemical residues are most useful when the compound is eliminated from the animal very slowly. In prolonged feeding studies, dietary assimilation efficiency is expected to decline as fish accumulate chemical and approach a dynamic steady state.

Alternatively, researchers have used simple kinetic models and independently obtained estimates of elimination rate (generally from depuration studies) to estimate dietary absorption efficiency (Bruggeman et al., 1981; Niimi and Oliver, 1988). This method also relies on the use of measured whole-body concentration data. By using a kinetic model, however, it is possible to account for the effect of chemical elimination. The absorption efficiency constant determined in this manner does not change as fish accumulate chemical; instead, the fish's approach to steady state is determined by the balance between uptake and elimination processes. A portion of the chemical eliminated by fish may be contained in feces, but the contribution of these losses to total elimination is unknown. Using this approach, fitted absorption efficiency constants may be subject to error when the elimination rate is very low and therefore difficult to estimate.

Another way to characterize dietary uptake is to employ methods developed in pharmacokinetic studies with mammals to estimate the *oral bioavailability* of drugs. In this procedure, the compound of interest is administered in food, and samples are collected to characterize plasma concentrations of the chemical over time. Later, after the first dose has been cleared, the animal is administered an equivalent amount of compound as either an intravascular (i.v.) or intraperitoneal (i.p.) dose, which is considered to be 100% bioavailable. Oral bioavailability is then calculated as the ratio of the area under the plasma concentration–time curve (AUC) for oral dosing to the AUC for i.v. or i.p. dosing. A variation on this method involves the use of two groups of animals, one of which is dosed i.v. or i.p. and the other fed a contaminated diet. Oral bioavailability determined in this manner may be thought of as the fraction of the ingested dose that is absorbed across the GIT and enters the systemic circulation.

Feeding studies with fish have provided empirical dietary uptake data for a large number of organic compounds as well as some metals. Based on a review of literature values for organic compounds, Gobas et al. (1988) reported a dependence of absorption efficiency on chemical log K_{ow}; absorption efficiencies averaged about 50% for chemicals with log K_{ow} values between 4 and 7 and then declined progressively at higher log K_{ow} values. Other researchers have reported a lack of dependence of assimilation efficiency on chemical log K_{ow} (Burreau et al., 1997). Dietary uptake of some metals by fish appears to be regulated, resulting in a less-than-proportional increase in whole-body concentration for a given increase in the trace element concentration in food. This phenomenon has been observed for both essential (e.g., zinc) and nonessential (e.g., cadmium) metals (Douben, 1989; Spry et al., 1988). The mechanisms by which this regulation is accomplished remain poorly understood and could conceivably involve concentration-dependent changes in absorption across the gut, although adaptive changes in elimination pathways are also likely (Reinfelder et al., 1998).

Variability in estimated absorption efficiency values for fish may also be due in part to methodological considerations. Feeding studies with fish are generally conducted by spiking test chemicals into prepared diets. Less commonly, an effort is made to incorporate chemicals into live prey items. Limited data suggest that organic chemicals incorporated into live prey are taken up more efficiently than the same

Downloaded From Vet-eBooks.com

compounds spiked into synthetic diets or administered in oil (Burreau et al., 1997; Nichols et al., 2001). Comparisons of metal uptake from formulated and natural diets have yielded varying results (Clearwater et al., 2002).

Vetter et al. (1985) used autoradiographic methods to show that [^{14}C]-benzo(*a*)pyrene remains associated with lipid throughout lipolysis, lipid absorption, and the formation of intracellular fat droplets in the gut epithelium. These observations underscore the close association between hydrophobic compounds and lipids throughout digestion but provide little information on processes that actually limit the rate of absorption at the gastrointestinal epithelium. Working with goldfish, Gobas et al. (1993a) found that dietary uptake of some very hydrophobic compounds ($\log K_{ow} > 6.3$) declined with an increase in dietary lipid content, while uptake of some moderate to high $\log K_{ow}$ compounds ($4.5 < \log K_{ow} < 6.3$) did not vary among treatment groups. These findings were interpreted as evidence that simple diffusion controls the rate of uptake across the gut epithelium.

Using an *in situ* channel catfish intestinal preparation, Doi et al. (2000) showed that the bioavailability of [^{14}C]-3,3′,4,4′-tetrachlorobiphenyl ([^{14}C]-PCB 77) varied with the fatty acid composition of lipid micelles and that these differences were related to the ability of micelles to solubilize the compound. These observations suggest that dietary absorption of hydrophobic compounds depends on the capacity of lipid micelles to deliver chemical to the gastrointestinal epithelium and possibly on regional differences in fatty acid absorption. In addition, Doi et al. (2000) found that dietary pretreatment of fish with unlabeled PCB 77 reduced the bioavailability of a subsequent radiolabeled dose. This decrease in uptake efficiency was accompanied by lower concentrations of [^{14}C]-PCB in the cytosolic fraction of gut tissues. The mechanism responsible for this pretreatment effect is unclear but may have been due to unlabeled PCB occupying binding sites on proteins and lipids that transport chemicals through the cytosol.

To the extent that simple diffusion plays a role in controlling chemical uptake within the gut, the process of digestion will tend to promote uptake of hydrophobic compounds by increasing the chemical activity gradient between the gut contents and blood (Connolly and Pederson, 1988; Gobas et al., 1993b; Nichols et al., 2004). This happens for two reasons: (1) a reduction in meal volume increases the concentration of chemical remaining in the GIT, and (2) absorption of dietary lipid substantially reduces chemical affinity for material remaining within the GIT and at the same time causes a transient increase in chemical affinity for the absorbing tissues. Together, these two outcomes of digestion create a potential for the lipid-normalized chemical concentration in a predator to exceed that of its prey, a condition referred to as *biomagnification*. Initially, this finding might appear to violate thermodynamic principles but, in fact, does not if equilibria are evaluated relative to digested rather than ingested material.

Chemical uptake from dietary sources may be reduced by biotransformations mediated by gut microflora or occurring within the gastrointestinal epithelium. In studies with *in situ* gut preparations, the GIT has been shown to play an important role in the metabolism of PAHs by fish, altering their form and limiting transport to the systemic circulation (Kleinow et al., 1998; Van Veld et al., 1988). Operating in series with first-pass metabolism in the liver, this activity can substantially reduce the accumulation of contaminant residues by fish (James and Kleinow, 1994; Kleinow and James, 2001; Van Veld, 1990).

In an environmental setting, chemical uptake by an organism from its diet also depends on the accumulation relationships for the organisms that it consumes (Figure 2.2). Under these circumstances, it becomes necessary to extend bioavailability concepts to an entire assemblage of species. Organisms that occupy the base of an aquatic food web generally accumulate chemicals directly from water. For these animals, chemical speciation and the microenvironment within which the animal lives may be critical determinants of uptake. Chemicals that possess characteristics that favor dietary uptake will then pass through a series of trophic transfers, ultimately accumulating in fish that occupy the highest trophic level. At each step along the way, the chemical concentration in the organism represents a dynamic balance between uptake and elimination processes. Organism growth rate will also influence the concentration of slowly accumulating chemicals by determining the mass of tissue into which chemicals are distributed.

An extension of bioavailability concepts from individual animals to entire food webs must also take into account species differences in biotransformation; for example, some organic chemicals are efficiently metabolized by benthic invertebrates. In extreme cases, this metabolism proceeds to such an extent that organisms at higher trophic levels are exposed only to metabolites. Other organic chemicals may accumulate at lower trophic levels but may be absent or present at reduced concentrations in fish tissues

Downloaded From Vet-eBooks.com

because of preferential metabolism by vertebrates (see benzo(*a*)pyrene case study below). Similar considerations influence the ecosystem behavior of trace elements. With few exceptions (notably mercury as methylmercury and selenium as selenomethionine), concentrations of trace elements tend to decrease with increasing trophic level due to more efficient regulation by animals at higher tropic levels (Reinfelder et al., 1998). The overall effect of metabolism (or trace element regulation) on chemical exposure to higher trophic level organisms is one of the most difficult aspects of bioavailability to predict because of uncertainties associated with the metabolic capabilities of different species and life stages, as well as differences in food web structure and function.

Finally, a potential source of complexity in describing and predicting chemical accumulation by fish at high trophic levels exists when chemical concentrations in water and sediments are not in thermodynamic equilibrium with one another. This condition arises when the rate of chemical exchange between water and sediment is slower than the rate of change of chemical inputs to the system. The degree of disequilibrium between sediments and water is an important ecosystem characteristic that influences the relative contributions of benthic and pelagic food chains to bioaccumulation in higher trophic level aquatic organisms. A key element in assessing bioavailability in the presence of such disequilibria are food-web models that can address the relative contribution of sediment and water-column contamination to chemical accumulation in fish (Burkhard et al., 2003).

Measures Used in Assessing Bioavailability

Although bioavailability reflects various complexities, as discussed above and in the case studies below, it still is primarily the simple comparison of the amount of chemical accumulated by an organism to the amount of chemical the organism is exposed to. As such, a bioavailability assessment generally addresses the ratio of a measure of accumulation to a measure of exposure and how this ratio varies among exposure conditions, organisms, and chemicals. Various measures that are used in bioavailability assessments are addressed in this section.

In some cases, an absolute amount of chemical can be specified for the exposure an organism receives. This is the case in studies of dietary bioavailability when test organisms ingest a known amount of contaminated food, and bioavailability can be examined in terms of the fraction of this dose that is accumulated. As discussed in the dietary section above, measures of this include the *dietary absorption efficiency*, the fraction of the total amount of a compound consumed by an animal that is absorbed across the gastrointestinal epithelium, and the *dietary assimilation efficiency*, the fraction of the total amount of a compound consumed by an animal that is retained in body tissues. An analogous absolute measure, *chemical extraction efficiency*, can be determined for chemical uptake at fish gills using systems in which water flow and chemical concentration changes across gills can be directly measured (McKim et al., 1985).

More often, chemical exposure is measured in terms of environmental concentrations, not in terms of absolute amounts processed by the organism. When the environmental concentration is that in water, measures of accumulation often used are the *bioconcentration factor* (BCF) and *bioaccumulation factor* (BAF), both of which equal the ratio of the concentration of a substance in the tissue of an aquatic organism to its concentration in the exposure water. These measures differ in that *bioconcentration* refers just to uptake directly from exposure water (via gills, skin, ingestion of water), whereas *bioaccumulation* refers to uptake via all exposure routes, including food and sediments as well as water.

Defining a BCF or BAF requires specification of the chemical concentration of interest in both the organism and the exposure water. For the accumulated chemical, the concentration might be that in the entire organism or in a specific tissue and might be calculated on a wet or dry weight basis. For organic chemicals that partition strongly to lipid components in an organism, the concentration might also be calculated as the mass of chemical in the organism or tissue divided by the weight of lipids (i.e., lipid-normalized), rather than the total weight. Such a measure is more reflective of chemical activity and can provide more meaningful comparisons among organisms with different lipid contents. For the exposure water, the concentration might be the total chemical in a volume of water, or that which is dissolved or freely dissolved (that portion of the dissolved chemical that is free of any associations with other solutes). BCFs and BAFs also require specification of a time frame. They might be steady-state values that would result from long exposures or might refer to accumulation over some specified shorter time frame.

Downloaded From Vet-eBooks.com

Measures analogous to the BAF can also be defined when exposure is referenced to chemical concentrations in sediment or food. For example, the *biota-sediment accumulation factor* (BSAF) was developed for assessments of hydrophobic chemicals for which concentrations in the water column are difficult or impossible to adequately measure and for which sediment-based food chains are an important route of exposure (Ankley et al., 1992). This factor is defined as the ratio of a lipid-normalized chemical concentration in an aquatic organism to the organic carbon-normalized chemical concentration in the surface sediment. Organic carbon-normalized sediment concentrations are calculated relative to the weight of organic carbon in the sediment rather than the total weight. Like lipid normalization, this provides a measurement that is better related to chemical activity and is more useful for comparing and predicting accumulation of hydrophobic organic chemicals among different sites and exposure conditions.

As discussed in the previous section on dietary uptake, digestive processes can increase the activity of chemical within the gastrointestinal tract, resulting in higher concentrations in an organism than in the food it consumes (i.e., biomagnification). The *biomagnification factor* (BMF) is the unitless factor by which the concentration of a substance in an organism at one trophic level exceeds the concentration in organisms that occupy the next lower trophic level. For organisms at higher tropic levels whose chemical exposure is primarily via diet, biomagnification can be of great importance for determining their exposure concentrations. For such organisms, the bioavailability of a chemical relative to its environmental concentration will be a function of a set of accumulation relationships, including BMFs, for various organisms throughout the food web.

Chemical uptake rate constants (the ratio of the uptake rate to the exposure concentration) can also serve as useful measures in bioavailability assessments. Such coefficients are proportional to a BCF or BAF for short exposures in which chemical elimination is small compared to uptake. For longer exposures, these coefficients will also be proportional to the BCF or BAF, provided the elimination rate constants do not vary significantly across the different exposure conditions for which bioavailability is being assessed. If elimination rates do vary, then uptake rates would not be a good overall measure for assessing bioavailability but can still be useful for investigating some of the processes regulating bioavailability.

Sometimes chemical accumulation by an organism is not, or cannot be, adequately characterized; however, if a certain level of toxicity over a specified exposure period can be assumed to reflect a fixed amount of chemical accumulation, then exposure concentrations causing this level of toxicity can serve as a measure of bioavailability. By the relationship BAF = (accumulated concentration)/(exposure concentration), the exposure concentration is inversely proportional to the BAF if the accumulated concentration is constant. The inverse of a toxic effect concentration therefore can serve as a surrogate for the BAF. The case studies below for ammonia and copper will illustrate this, using 96-hour LC_{50} values (the concentration causing 50% lethality over a 96-hour exposure) as measures of how bioavailability is affected by exposure conditions.

Assessing Bioavailability: Case Studies

To further illustrate the general principles and processes discussed above and to introduce approaches for assessing and describing bioavailability, this section considers certain aspects of the bioavailability of selected chemicals with different physicochemical characteristics. Included in these case studies are (1) an ionizable inorganic compound (ammonia), (2) ionizable organic chemicals (phenols), (3) cationic metals (copper), (4) organometals (mercury), and (5) nonionic organics with differing properties (2,3,7,8-tetrachlorodibenzo-*p*-dioxin and benzo(*a*)pyrene). Although these examples address specific chemicals, they are intended to exemplify concepts of bioavailability that are more generally applicable.

Ionizable Inorganic: Ammonia

Aquatic systems can have ammonia concentrations high enough to adversely impact fish as a result of wastewater treatment plant discharges, degradation of nitrogen-containing organic matter, fertilizer runoff, and industrial sources. The two major chemical species of ammonia are weakly basic un-ionized

Downloaded From Vet-eBooks.com

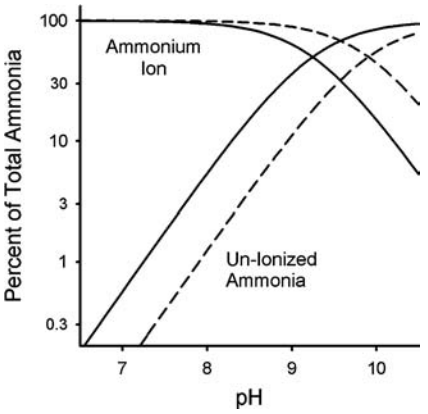

FIGURE 2.4 Effects of pH on the relative abundance of un-ionized ammonia vs. ammonium ion at 5°C (dashed lines) and 25°C (solid lines).

ammonia (NH_3) and its conjugate acid, ammonium ion (NH_4^+), which are in equilibrium with each other according to the following expression:

$$K_a = \frac{[H^+][NH_3]}{[NH_4^+]} \tag{2.1}$$

The acid dissociation coefficient (K_a) for this reaction ranges from approximately 10^{-10} at 0°C to 10^{-9} at 30°C (Emerson et al., 1975). The relative amounts of these species, therefore, can vary markedly across the ranges of pH and temperature found in natural aquatic systems (Figure 2.4).

Ammonia toxicity has been found to increase greatly with increasing pH for various fish species (see Figure 2.5A). This increased toxicity is correlated with large increases in the fraction of total ammonia that is un-ionized; therefore, un-ionized ammonia is presumably responsible for this increased toxicity and, because it is present at much lower concentrations, is apparently much more bioavailable than the ammonium ion. This has not been directly demonstrated based on uptake of ammonia at fish gills, but un-ionized ammonia is considered to be a primary component of ammonia excretion, despite its low concentration relative to ammonium ion, because its lack of charge and smaller size result in a higher permeability than ammonium ion across biological membranes (Wood, 1993).

When a single chemical species is the predominant bioavailable form, it can be useful to express toxicity on the basis of just that species. This results in relationships that are more constant relative to environmental variables and can better demonstrate the role speciation has in toxicity. Ammonia toxicity is therefore often reported on the basis of un-ionized ammonia. When the LC_{50} values in Figure 2.5A are recalculated based just on the concentration of un-ionized ammonia (Figure 2.5B), the overall variation of LC_{50} values is reduced, and the LC_{50} values are roughly constant for pH = 7.8 to 9.0. Such constancy of the LC_{50} values suggests that un-ionized ammonia is the predominant source of toxicity for this pH range, despite it being present at much lower concentrations than ammonium ion.

At near-neutral and acidic pH values, however, toxicity on the basis of un-ionized ammonia is not constant, but rather increases with decreasing pH (Figure 2.5B). This suggests that ammonium ion has enough bioavailability to cause it to be the predominant source of toxicity when concentrations of un-ionized ammonia are extremely low. Some bioavailability of ammonium ion is expected based on studies of ammonia excretion, which have demonstrated that ammonium ion can be excreted at fish gills by diffusion along an electrochemical gradient from blood to water and by carrier-mediated exchange with sodium or hydrogen ion (Wood, 1993).

These data qualitatively suggest that ammonia toxicity is a joint function of both un-ionized ammonia and ammonium ion. A quantitative description of this relationship can be derived as follows. If the uptake rate of each ammonia species is proportional to its environmental concentration and if the

Downloaded From Vet-eBooks.com

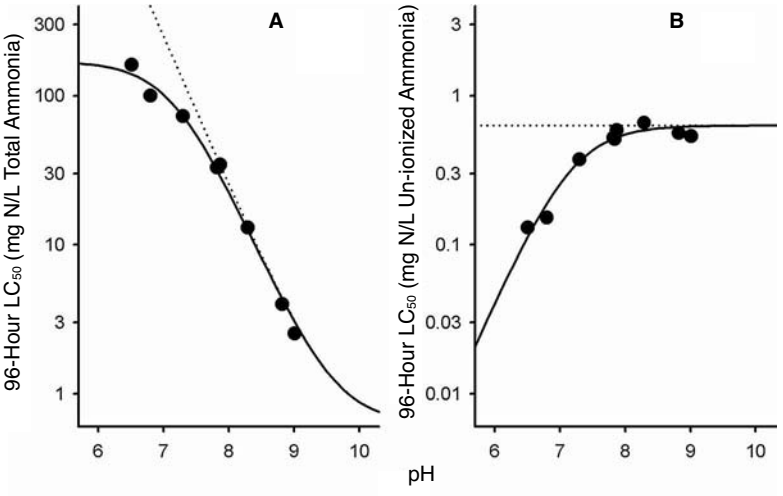

FIGURE 2.5 Effects of pH on toxicity of ammonia to rainbow trout expressed as a function of (A) total ammonia and (B) un-ionized ammonia. The solid lines denote fit of data to a model in which both un-ionized ammonia and ammonium ion contribute to bioavailability. The dotted lines denote expected effects of pH if only un-ionized ammonia is bioavailable. (Data from Thurston, R.V. et al., *Environ. Sci. Technol.*, 15, 837–840, 1981.)

elimination rate of ammonia is proportional to its total concentration within the fish, the accumulation of ammonia at a site of interest within a fish (C_F) can be described by the differential equation:

$$\begin{aligned}\frac{dC_F(t)}{dt} &= k_{U,NH_3}\cdot C_{NH_3}(t) + k_{U,NH_4^+}\cdot C_{NH_4^+}(t) - k_R\cdot C_F(t)\\ &= \left(k_{U,NH_3}\cdot f_{NH_3} + k_{U,NH_4^+}\cdot f_{NH_4^+}\right)\cdot C_{TAMM}(t) - k_R\cdot C_F(t)\end{aligned} \tag{2.2}$$

where C_{TAMM}, C_{NH_3}, and $C_{NH_4^+}$ are the environmental concentrations of total ammonia, un-ionized ammonia, and ammonium ion, respectively; f_{NH_3} and $f_{NH_4^+}$ are the fractions of the total ammonia consisting of un-ionized ammonia and ammonium ion, respectively; k_{U,NH_3} and k_{U,NH_4^+} are uptake rate constants for the un-ionized ammonia and ammonium ion species; and k_R is the elimination rate constant. When the exposure concentration is constant, this differential equation can be integrated to provide the following algebraic expression for C_F:

$$C_F(t) = \frac{k_{U,NH_3}\cdot f_{NH_3} + k_{U,NH_4^+}\cdot f_{NH_4^+}}{k_R}\cdot\left(1-e^{-k_R t}\right)\cdot C_{TAMM} \tag{2.3}$$

If a given level of effect is associated with a certain level of ammonia accumulation (EC_F), then the total ammonia environmental concentration required to elicit this effect (EC_{TAMM}) for an exposure duration t_E can be derived by substituting EC_F for C_F and EC_{TAMM} for C_{TAMM} in the above equation and rearranging as follows:

$$EC_{TAMM} = \frac{1}{\dfrac{f_{NH_3}}{EC_{NH_3}} + \dfrac{f_{NH_4^+}}{EC_{NH_4^+}}}, \quad \text{where } EC_x = \frac{k_R\cdot EC_F}{k_{U,x}\left(1-e^{-k_R t_E}\right)} \tag{2.4}$$

where EC_{NH_3} is the effect concentration when only un-ionized ammonia is present, and $EC_{NH_4^+}$ is the effect concentration when only ammonium ion is present. EC_{TAMM} is therefore a weighted harmonic mean of EC_{NH_3} and $EC_{NH_4^+}$, the weighting factors being the fractional concentrations of the species in the exposure water. Substituting formulas for f_{NH_3} and $f_{NH_4^+}$ as a function of pH results in the following:

Downloaded From Vet-eBooks.com

$$EC_{TAMM} = \frac{1 + 10^{pK_a - pH}}{\frac{1}{EC_{NH_3}} + \frac{10^{pK_a - pH}}{EC_{NH_4^+}}} \tag{2.5}$$

This describes a sigmoidal relationship of log EC_{TAMM} to pH, with the value for EC_{TAMM} approaching EC_{NH_3} at high pH and $EC_{NH_4^+}$ at low pH.

Erickson (1985) reported a good fit of the above model to the data in Figure 2.5A, with $LC_{50\,NH_3}$ estimated to be 0.63 mg N per liter and $LC_{50\,NH_4^+}$ estimated to be 170 mg N per liter. Substituting these values and $pK_a = 9.6$ (the value for 13.5°C, the average temperature in the study) into Equation 2.5 produces the solid line in Figure 2.5A, and multiplying these values by f_{NH_3} produces the solid line in Figure 2.5B. The good fit of this model depends not only on these estimated values for $LC_{50\,NH_3}$ and $LC_{50\,NH_4^+}$ but also on the adherence of the data to the model assumption that $LC_{50\,TAMM}$ is a weighted average of $LC_{50\,NH_3}$ and $LC_{50\,NH_4^+}$, with the weighting factors being the fractional species concentrations. An important consequence of this assumption is that $LC_{50\,TAMM}$ closely parallels the fractional concentration of the more bioavailable form (dotted lines in Figure 2.5) until this fraction is low enough that the less bioavailable form is responsible for a significant portion of the toxicity.

Other datasets on ammonia toxicity to fish also indicate that pH effects can be primarily attributed to joint toxicity of un-ionized ammonia and ammonium ion (Erickson, 1985); however, the relative bioavailabilities of these two chemical species can differ among fish species. The ratio of $LC_{50\,NH_3}$ to $LC_{50\,NH_4^+}$ varied from 0.001 to 0.006, mainly attributable to differences in the bioavailability of ammonium ion for different fish. In particular, studies with channel catfish (Sheehan and Lewis, 1986; Tomasso et al., 1980) have suggested little or no bioavailability of ammonium ion, with nearly constant LC_{50} values on the basis of un-ionized ammonia. Such differences among fish species may be related to differences in ionoregulatory and ammonia excretion mechanisms, but this has not been investigated.

Ammonia bioavailability to fish, however, is not just a matter of the above simple model. Several additional factors that can make ammonia bioavailability relationships more complex may have to be considered in specific assessment situations:

1. Excretion of respiratory carbon dioxide will depress the pH at the gill surface. This will cause a shift in equilibrium of ammonia speciation, resulting in less un-ionized ammonia and more ammonium ion at the gill surface than in the bulk exposure water. The degree of this effect depends on the exposure pH, the pH-buffering strength of the exposure water, and the physiology of the fish. Lloyd and Herbert (1962) and Szumski et al. (1982) suggested that this, rather than some bioavailability of ammonium ion, could account for toxicity on a un-ionized ammonia basis not being constant with pH. The analyses of Erickson (1985), however, indicated that this mechanism is generally of secondary importance to the joint toxicity of un-ionized and ammonium ion.
2. Ammonia is unique among toxicants of concern for fish because it is also an excretory product, and this endogenous ammonia will contribute to some degree to the accumulation of ammonia to toxic levels. If excretion rates are not constant with pH, this can affect the pH dependence of the relationship of toxicity to exogenous ammonia. High pH can inhibit ammonia excretion because more of the released ammonia remains in the un-ionized form, which reduces the blood–water gradient of un-ionized ammonia and thus the net diffusive loss. Russo et al. (1988) reported increased ammonia toxicity at pH values near and above 9 which might be related to such effects. Exogenous ammonia might also affect excretory mechanisms, thereby altering ammonia accumulation other than by direct uptake.
3. Sheehan and Lewis (1986) suggested that acute ammonia toxicity to channel catfish at low pH is partly attributable to osmotic effects of high ammonium salt concentrations (>1000 mg N per liter). To the extent their conclusions are true, the ammonium ion might be essentially nonbioavailable and exert its effects simply based on its contribution to the external osmotic pressure. Although this might be important for channel catfish, other fish species show apparent effects of ammonium ion at much lower concentrations (ca. 100 mg N per liter) where such

Downloaded From Vet-eBooks.com

osmotic effects are unlikely to be as significant. Nonetheless, this is a possibility that should be recognized in more comprehensive evaluations of ammonia bioavailability.

4. The bioavailability of ammonia might also be affected by other ionic constituents of the exposure water. Ammonia toxicity to fish has been reported to be reduced due to increases in the hardness or salinity of test water. Causes for this have been suggested in work with the amphipod *Hyalella azteca*. Ankley et al. (1995) reported ammonia toxicity to *H. azteca* to be lower in hard test water than in soft test water, especially at low pH. Borgmann and Borgmann (1997) further found that the toxicity of ammonia to *H. azteca* was reduced by sodium, but not by calcium, and suggested that this effect is greater at low pH because mechanisms for transport of ammonium ion across fish gills are affected by the ionic composition of the water, whereas the passive transport of un-ionized ammonia is not.
5. Because the fraction of the more bioavailable un-ionized ammonia increases with temperature, it might be expected that total ammonia toxicity would increase with temperature; however, for fish, there is little effect of temperature on ammonia toxicity expressed on the basis of total ammonia (U.S. EPA, 1999). Erickson (1985) noted that the effect of temperature on ammonia toxicity is inconsistent with the relative toxicities of un-ionized ammonia and ammonium ion inferred from the pH dependence of ammonia toxicity. The effects of temperature on ammonia toxicity thus apparently reflect multiple influences on ammonia metabolism, excretion, and toxicological response that are not yet well understood.

Evaluations of ammonia bioavailability, therefore, can involve various considerations beyond the simple model presented above, depending on the exposure circumstances, the fish species of concern, and the level of detail and precision desired in an assessment. Nonetheless, the pH dependence of ammonia toxicity still provides a good example of how the bioavailability of a chemical, to a good approximation, can reflect a simple weighted average of contributions of its constituent species. This type of model has broad applicability to bioavailability assessments.

Ionizable Organic: Phenol Derivatives

Some organic chemicals contain functional groups that are weak acids or bases. Such chemicals will exist as multiple species with different charges at these functional groups, which can affect how readily they will be accumulated by a fish. The relative amounts of these chemical species will vary with pH, so the bioavailability of the chemical can also vary with pH.

A group of chemicals that has received considerable study is phenol and its various substituted derivatives, especially pentachlorophenol (PCP), which has been extensively used as a wood preservative and is a widespread contaminant of soils and aquatic systems. This class of chemicals consists of a hydroxyl group (OH) on a phenyl ring (Φ) and can exist as un-ionized molecules (RΦOH) or as phenolate ions ($R\Phi O^-$), where R denotes other functional groups on the ring. These two chemical species are in equilibrium with each other according to the following expression:

$$K_a = \frac{[H^+][R\Phi O^-]}{[R\Phi OH]} \tag{2.6}$$

where the acid dissociation constant (K_a) varies with the nature of R. In the subsequent discussion, the term *phenol* refers to any member of this class of chemicals.

When based on concentrations in water, the toxicity and accumulation of various phenols in fish have been found to decrease with increasing pH (see Figure 2.6). The inverse relationship between uptake rate constants and toxic water concentrations in Figure 2.6 suggests that the degree of accumulation required to elicit a given level of toxicity does not vary much with pH. This is more evident in Figure 2.7, which shows that LC_{50} values for PCP increase with pH by about the same factor as the BCFs decrease, resulting in estimated body burdens at death being approximately constant with pH. Kobayashi and Kishino (1980) reported that PCP concentrations measured in dead fish were similar at different

Downloaded From Vet-eBooks.com

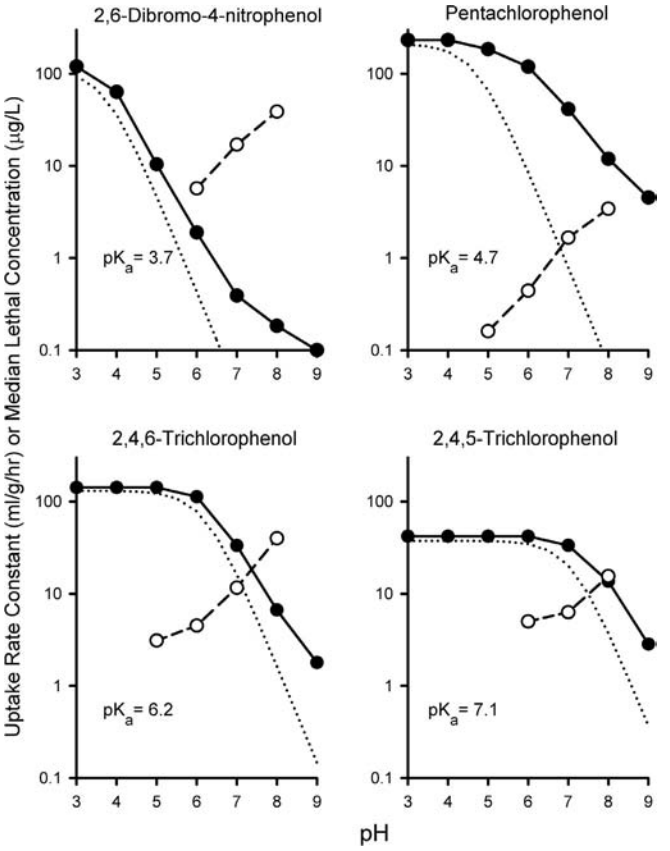

FIGURE 2.6 Observed pH dependence of uptake rate constants (closed circles; see Saarikoski et al., 1986) and median lethal concentration (open circles; see Saarikoski and Viluksela, 1981) of several substituted phenols for guppies. Dotted line denotes the expected uptake rate constant based on the value of the constant at pH 3 and the assumption that uptake is proportional to the fraction of the chemical in exposure water that is un-ionized.

pHs. This indicates that the pH dependence of toxic water concentrations is largely attributable to processes that affect accumulation; thus, toxicity as well as accumulation can be an indicator of bioavailability, at least for assessing the effects of pH.

Because the relative amount of un-ionized phenol decreases and that of phenolate ion increases with increasing pH, a likely explanation for these effects of pH on phenol bioavailability is that the ionic form is less readily accumulated. This is a reasonable expectation because fish gill epithelial cell membranes should be more permeable to un-ionized phenol molecules than to their phenolate ions. This explanation is further supported by the observation that significant effects of pH are only observed when the pH is near or above the pK_a of a particular phenol (Figure 2.6). For pH below the pK_a, the phenol is almost entirely in the un-ionized form, so phenol bioavailability should not depend greatly on environmental pH. At higher pH, the relative amount of the un-ionized species declines appreciably with increasing pH, thereby reducing the overall bioavailability of the mixture of species.

The effect of pH on bioavailability, however, is not simply a matter of the un-ionized phenol in the exposure water being the sole basis for accumulation. If this were the case, the observed uptake rate constants should decline in proportion to the fraction of the phenol that is not ionized (dotted lines in Figure 2.6). Instead, once a chemical is appreciably ionized, uptake is greater than expected based on the un-ionized phenol in the exposure water, sometimes by more than an order of magnitude. For uptake of several chlorinated phenols by large rainbow trout, Erickson et al. (2006b) reported even greater deviations of uptake rate constants from that expected based on the amount of un-ionized phenol (see Figure 2.8).

Downloaded From Vet-eBooks.com

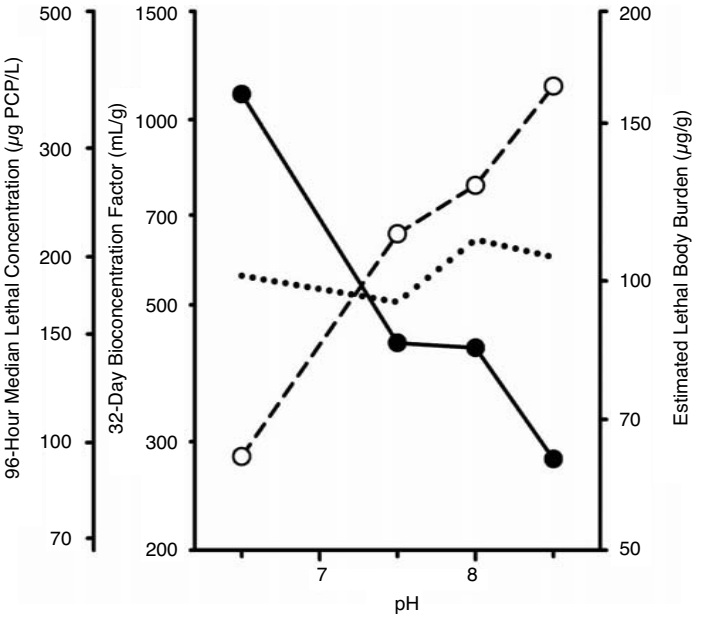

FIGURE 2.7 Observed pH dependence of median lethal concentrations (open circles) and bioconcentration factors (closed circles) of pentachlorophenol for juvenile fathead minnows. Dotted line denotes estimated lethal body burden as product of bioconcentration factor and median lethal concentration. (Data from Spehar, R.L. et al., *Environ. Toxicol. Chem.*, 4, 389–397, 1985.)

Such high uptake rates in the presence of substantial ionization indicate that phenolate ions do contribute in some way to phenol bioavailability. The processes within fish gills discussed earlier (Figure 2.3 and associated text) are responsible for this, and three specific mechanisms have been suggested to be important for phenol bioavailability (Erickson et al., 2006a; McKim and Erickson, 1991; Saarikoski et al., 1986).

The first mechanism arises from rapid kinetics for the interconversion of the un-ionized phenol and phenolate ion. When un-ionized phenol diffuses across the outer gill epithelium cell membrane, its concentration in the water adjacent to the gill surface is depleted, but this depletion will be moderated by a rapid net conversion of the phenolate ions to the un-ionized species to maintain the chemical equilibrium represented by Equation 2.6. The phenolate ion thus acts as a buffer, maintaining the concentration of the uncharged form adjacent to the gill surface higher than it would be in the absence of the ion or if the kinetics of this reaction were slow. In addition, efficient uptake depends on rapid diffusion of chemical across the gill lamellar water channels to the epithelial surface. The presence of phenolate ion will facilitate uptake by contributing to this diffusion.

The importance of these rapid speciation changes does not stop at the external gill surface. After crossing the outer cellular membrane, there will be net conversion of un-ionized phenol molecules to phenolate ions to maintain equilibrium within the cytosol of the epithelial cells. This increases the diffusive gradient, and thus the rate of diffusion, across this membrane. In addition, the phenolate ions so formed will contribute to diffusion across the cytosol, increasing diffusive transport compared to what would occur if slow kinetics kept all the absorbed chemical in the un-ionized form. This process will be repeated at each membrane and any other diffusion barriers that are more permeable to the un-ionized molecules than to phenolate ions. The phenolate ions thus facilitate diffusion across the epithelium by supporting diffusion to and from the membranes and by helping to maintain steeper gradients of the un-ionized phenols across the membranes than would otherwise exist. Because membranes constitute a small fraction of the total diffusion path across the epithelium, this mechanism can result in gradients across the membranes steep enough to maintain high rates of diffusion even if little of the phenol is in its un-ionized form.

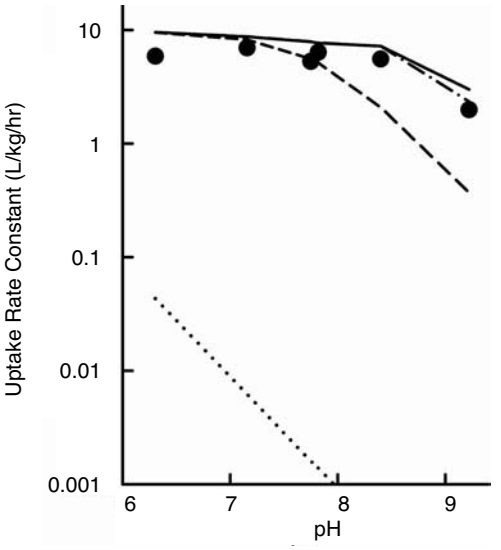

FIGURE 2.8 Observed (closed circles) and predicted (solid line) rate constants vs. pH for PCP uptake by large rainbow trout. Dashed–dotted line denotes predictions when the model was modified to have no membrane permeability of pentachlorophenolate ion. Dashed line denotes predictions when the model was also modified to have no pH changes in water passing through the gill. Dotted line denotes predictions when the model was also modified to have no interconversion of pentachlorophenolate ion and un-ionized pentachlorophenol. (Data from Erickson, R.J. et al., *Environ. Toxicol. Chem.*, 25, 1522–1532, 2006.)

A noteworthy feature of this mechanism is that chemical uptake depends not just on ionization in the exposure water but also on ionization within the organism. This might explain the higher uptake rate constant at low pH for 2,4,6-trichlorophenol than for 2,4,5-trichlorophenol in Figure 2.6. In the exposure water, both chemicals are >99% in their un-ionized forms at the lowest pH and should be similar in their diffusive properties and partitioning relationships; however, both chemicals will be appreciably ionized at the higher pH within fish tissue. Because the 2,4,6-trichlorophenol has a lower pK_a, it will be more ionized than 2,4,5-trichlorophenol within the epithelial cytosol and in the blood, which could account for the difference in their uptake rates.

The second mechanism by which phenolate ion can contribute to phenol bioavailability arises from fish respiration causing a reduction of the pH in the water passing through gill lamellar channels (Lloyd and Herbert, 1960; Playle and Wood, 1989; Wright et al., 1991). This reduction in pH will increase the fraction of the more bioavailable un-ionized phenol, increasing uptake beyond that expected based on the concentration of un-ionized phenol in the bulk exposure water. This mechanism would shift the uptake rate constant vs. pH curve to a higher pH, the degree of this shift being roughly equal to the difference between the pH of the bulk exposure water and the average pH at the gill surface. The magnitude of the increased uptake will depend on the magnitude of the pH reduction at the gill surface and on how sensitive uptake is to changes in pH at the gill surface, which in turn depend on the pH and alkalinity of the exposure water, the morphology and physiology of the fish, and the pK_a and other properties of the chemical. Erickson et al. (2006b) demonstrated that increased alkalinity reduces phenol uptake by moderating the pH reduction in water passing through the gills.

For these first two mechanisms, the effects of phenolate ion on bioavailability depend on its interconversion with un-ionized phenol and require diffusion barriers that are more permeable to the un-ionized than the ionized species. The third mechanism of interest here is that gill epithelia do not contain continuous diffusion barriers completely impermeable to phenolate ions. Saarikoski et al. (1986) suggested the possibility of phenolate ions bypassing membranes by passing through gill epithelial cell junctions; however, some partitioning of phenolate ions into organic solvents and lipid membranes and some mobility of phenolate ions within membranes have been reported (Escher and Schwarzenbach, 1996; Escher et al., 1999; Jafvert et al., 1990; Smejtek et al., 1996), suggesting the possibility of some phenolate diffusion across membranes. Whatever the mechanistic details, this would result in sigmoidal

Downloaded From Vet-eBooks.com

bioavailability relationships similar to that discussed above for ammonia, with the lower part of this sigmoidal curve reflecting the contribution of phenolate ions. This mechanism would explain reduced slopes of uptake vs. pH when uptake becomes low at high pH, such as can be observed for three of the chemicals in Figure 2.6; however, it could not explain high rates of uptake in the presence of substantial ionization.

Figure 2.8 explores the relative importance of these mechanisms by applying a mathematical model for predicting gill uptake of ionizable organic chemicals (Erickson et al., 2006a,b). In the absence of the above mechanisms by which phenolate ion can contribute to uptake, the model-predicted uptake (dotted line) is extremely low because PCP is so highly ionized, and is two to four orders of magnitude below the observed uptake rate constants. This rate would be expected if the epithelium contained barriers completely impermeable to the phenolate ion and if the kinetics of interconversion between the un-ionized and ionized species were slow compared to transport processes in the gill. Adding the first mechanism discussed above (rapid interconversion of phenolate ion and un-ionized phenol) to the model (dashed line) accounts for most of the difference between the dotted line and the data. Also, adding pH changes in gill water to the model (dash-dotted line) provides additional improvement to model predictions at high pH, bringing the predictions very close to the observed data. Adding the final mechanism (some permeability of cellular membranes to the phenolate ion) to the model has only a small effect on the full model predictions (solid line), because the rate constants in this dataset are relatively high.

The example in Figure 2.8 should not be treated as being generally reflective of the relative importance of these different mechanisms to phenol bioavailability. As already noted, membrane permeability for the phenolate ion will become more important when uptake rates drop to levels lower than addressed in this example, such as in Figure 2.6. The rapid interconversion of phenolate ion and un-ionized phenol has a particularly large effect in the example in Figure 2.8 but appears to be less important for the conditions of PCP uptake in Figure 2.6 and even less important for the other chemicals in Figure 2.6. The relative importance of these mechanisms will vary substantially depending on properties of the chemical, fish, and exposure of interest.

This section considered a more complicated bioavailability situation than for ammonia, addressing a variety of the physical, chemical, and biological processes introduced earlier in Figure 2.3. Of particular note is that a chemical species in exposure water can contribute to bioavailability even if it is not directly absorbed by the organism, because of changes in chemical speciation that occur within the gill. Phenol bioavailability might be even more complicated due to processes and factors not discussed here (e.g., the influence of other chemical constituents, such as organic matter, on phenol speciation), so the material here should be treated as an example of how to approach certain aspects of bioavailability assessments, not as a comprehensive discussion of all aspects of phenol bioavailability.

The mechanisms discussed above for the contribution of phenolate ion to phenol uptake can also affect phenol elimination (Erickson et al., 2006b), and this can have consequences for bioavailability assessments. Because any such effects on elimination are more important for steady-state accumulation than during the initial stages of accumulation, the pH dependence of phenol accumulation would be expected to vary with time. Available data do not allow confirmation of such an effect of time on bioavailability, but this possibility illustrates how the meaning of bioavailability might be conditional on the specific exposure situation and must be carefully defined.

Cationic Metals: Copper

The assessment of the risks of metals to fish is often difficult because of large and complex effects of exposure water characteristics on metal toxicity. The nature and magnitude of these effects can differ among metals, toxicity endpoints, fish species, and routes of exposure. This section focuses on the acute lethality of copper to freshwater fish which has been reported by various authors to vary with pH, hardness, alkalinity, suspended solids, dissolved organic compounds, and various other inorganic cations and anions. Most, although not all, of this variation in toxicity can be attributed to effects of these physicochemical factors on copper bioavailability.

Some understanding of toxicity mechanisms can help in understanding the effects of environmental factors on toxicity and bioavailability. Acute copper lethality in freshwater fish has been related to disruption of osmoregulation at fish gills. In particular, copper has been demonstrated to reduce sodium

Downloaded From Vet-eBooks.com

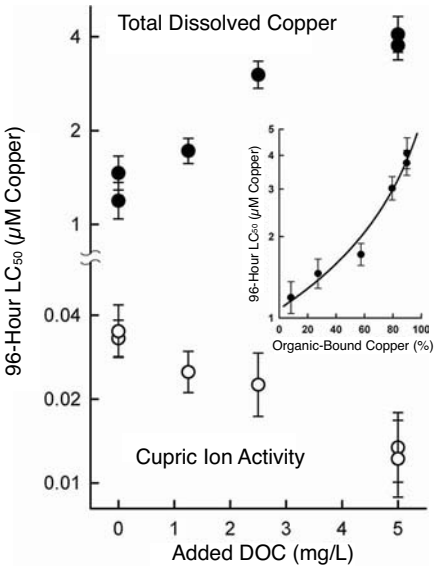

FIGURE 2.9 Effects of humic acid additions on acute copper toxicity to fathead minnows. The main figure shows observed LC_{50} values on the basis of both dissolved copper concentrations and cupric ion activities vs. the amount of added dissolved organic carbon (DOC). The inset figure shows dissolved copper LC_{50} values vs. the fraction of copper bound by the organic matter, with the symbols denoting the observed LC_{50} values and the line denoting expected trends if the organic-bound copper is 20% as bioavailable as copper not bound to organic carbon. (Data from Erickson, R.J. et al., *Environ. Toxicol. Chem.*, 15, 181–193, 1996.)

uptake and increase sodium loss at fish gills, with death occurring because of decreased blood sodium concentration (Lauren and McDonald, 1986; Paquin et al., 2002a,b; Wood, 1992; Wood et al., 1997). An important component of sodium uptake that can be affected by copper is the active transport of sodium via Na^+/K^+-ATPase across basal membranes of gill epithelial cells. Copper toxicity therefore is related to how readily copper is taken up at the apical (external) membrane of gill epithelial cells to reach this site of action. Sodium uptake across these apical membranes is coupled to the release of hydrogen ion, and these processes might also be important in the relationship of copper toxicity to environmental factors. Sodium loss at gills is largely via passive diffusion through paracellular junctions, and copper toxicity increases this loss. Calcium plays an important role in regulating the permeability of these junctions and might thereby also affect copper toxicity.

Many of the factors affecting copper toxicity cited above also affect copper speciation and thereby copper bioavailability. Copper in oxygenated water will be in a positive oxidation state, predominantly Cu(II), which will be present to some degree as a hydrated cation, $Cu^{+2}{\cdot}nH_2O$, often referred to as *free copper ion*. Free copper has a high affinity for various ligands found in natural waters, including hydroxide, carbonate, sulfide, and various dissolved organic molecules; consequently, dissolved copper in freshwater mostly exists as complexes with such ligands. Copper also adsorbs to mineral and organic particles, and in saline water copper is largely complexed by chloride. These various species generally are in rapid flux, with any specific copper atom associating with, and dissociating from, various ligands. The fraction of copper that exists as a particular species is not some fixed subset of the copper atoms but rather the portion of the copper atoms existing as that species at a given moment. As discussed above for phenol, this dynamic speciation can have important consequences for bioavailability. Kramer et al. (1997), Bryan et al. (2002), and Smith et al. (2002) provide useful starting points for further information on copper speciation.

Increased complexation of copper by various inorganic and organic ligands generally is associated with decreased toxicity, suggesting that these complexes are less bioavailable than the free metal (see reviews by Campbell, 1995; Hunt, 1987; Paquin et al., 2002a; Sprague, 1985). Figure 2.9 provides an example of this, where the addition of humic acid (5 mg C per liter) increased the median lethal concentration of total dissolved copper to fathead minnows by more than threefold. The inset on Figure 2.9 indicates that this

Downloaded From Vet-eBooks.com

decrease in toxicity was associated with an increase in the fraction of copper that was complexed by organic matter. That these effects on toxicity reflect changes in bioavailability is supported by studies that have demonstrated that accumulation of copper in fish gills and other tissues is reduced by complexation of copper with organic compounds in exposure water (Buckley et al., 1984; MacRae et al., 1999; Muramoto, 1980; Playle et al., 1993a,b).

Some studies, especially with phytoplankton and zooplankton, have shown a given level of toxicity to be associated with a constant activity of free copper over a wide range of total copper, suggesting that some copper complexes contribute little, if anything, to bioavailability (see review by Campbell, 1995). In other cases, however, toxicity on the basis of free copper activity has been reported to increase as complexation by various inorganic and organic ligands increases, suggesting some contribution of copper complexes to bioavailability (see reviews by Campbell, 1995; Hunt, 1987; Paquin et al., 2002a; Sprague, 1985). This bioavailability might arise from release of free copper from a complex in the microenvironment at the gill surface or by a copper complex directly crossing over, or interacting with, the gill epithelial surface. In some cases, organic ligands can even increase copper toxicity, presumably because certain hydrophobic complexes of copper are able to more readily cross lipid cellular membranes (Florence and Stauber, 1986). The study summarized in Figure 2.9 suggested some bioavailability of the organic-complexed copper, because, although the addition of humic acid reduced the toxicity of copper to fathead minnows on the basis of total dissolved concentrations, toxicity on the basis of free copper ion was increased. The line in the inset in Figure 2.9 indicates the fit of a joint toxicity model (such as that used for ammonia above), for which the humic-complexed copper is estimated to be about 20% as toxic as the rest of the copper. Such a contribution to bioavailability by copper complexed to such large ligands could be due to partial dissociation of these complexes at the gill surface, perhaps because of the reduced pH expected at this surface; however, in the absence of direct evidence from accumulation measurements, other explanations for the apparent bioavailability of organic-complexed copper cannot be completely discounted. The organic matter might also affect the speciation of other ionic constituents important in copper toxicity or exert some direct effect on the gill surface.

Although copper speciation and its role in bioavailability can explain the effects on toxicity of many of the physicochemical factors cited at the start of the section, some of these factors will have little or no effect on copper speciation in the exposure water. One such factor is water hardness, which refers to certain cationic components in the water, primarily calcium and magnesium. Such cations would not affect aqueous copper speciation except to the extent that they compete with copper for ligands, and such effects are generally so small that they could not be responsible for any appreciable effects on toxicity. Increased hardness has been long reported to be associated with decreased metal toxicity, but the nature of these effects is not particularly clear or consistent. In some cases, reported effects of hardness are actually combined effects of hardness, pH, and alkalinity, so any effects of the hardness cations were confounded with those of copper complexation by hydroxide and carbonate. In several studies with fish, however, hardness was varied in association with anions that do not significantly affect copper speciation. Usually, reductions in toxicity were still found (Chakoumakos et al., 1979; Erickson et al., 1987; Inglis and Davis, 1972; Miller and Mackay, 1980), an example of which is shown in Figure 2.10. In other cases, little or no effect of hardness was found (Lauren and McDonald, 1986; Zitko and Carson, 1976). The effect of hardness can also depend on the relative amounts of calcium and magnesium and on the test species (Naddy et al., 2002). Figure 2.10 suggests that the incremental effects of hardness are greater at low hardness than at high hardness. This nonlinearity is further evident in other data for fathead minnows from this same study (Erickson et al., 1987) and from studies with cladocerans (Gensemer et al., 2002). To further complicate the situation, Lauren and Macdonald (1986) proposed that apparent effects of hardness on acute copper toxicity can be affected by inadequate acclimation of fish to the hardness, and that hardness effects could be manifested more strongly in longer exposures. Erickson et al. (1997), however, found similar effects of hardness on acute toxicity for both acclimated and unacclimated fish.

Zitko (1976), Zitko and Carson (1976), and Pagenkopf (1983) suggested that hardness cations can affect metal toxicity by competing for biochemical receptors on fish gills involved in the uptake or effects of toxic metals, thereby necessitating higher concentrations of the toxic metal to result in enough toxic metal accumulation on these receptors to elicit effects. The uptake of copper might also be affected by the effects of calcium on the permeability of paracellular junctions. Such mechanisms would represent

Downloaded From Vet-eBooks.com

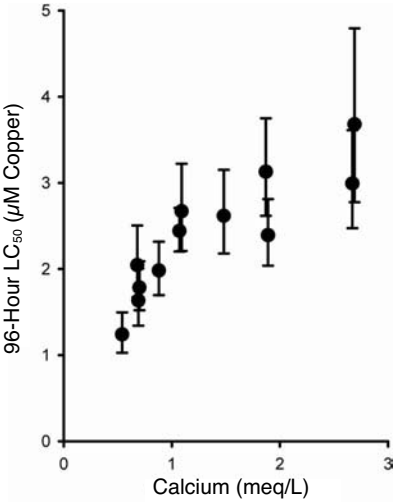

FIGURE 2.10 Effects of calcium on acute copper toxicity to fathead minnows. Symbols denote observed LC_{50} values (±95% confidence limits) on the basis of dissolved copper. Just the calcium component of hardness is included because it was considered to be the primary source of hardness effects in this study. (Data from Erickson et al., *A Prototype Toxicity Factors Model for Site-Specific Copper Water Quality Criteria*, U.S. Environmental Protection Agency, Duluth, MN, 1987.)

effects on copper bioavailability because they concern how much metal is taken up relative to the total amount of metal in the exposure water; however, the effects of calcium on gill permeability might also simply make it more or less difficult for a fish to osmoregulate and thus change its susceptibility to copper without altering copper bioavailability.

Little copper accumulation information is available to demonstrate to what degree hardness effects on copper toxicity represent actual changes in copper bioavailability. Playle et al. (1992) demonstrated that copper accumulation in fish gill tissue is reduced by increased calcium concentrations under some exposure conditions, but they also found no such effects for other conditions under which effects of hardness on toxicity might be expected. In contrast, good demonstrations that hardness affects toxicity by reducing metal accumulation have been provided by Meyer et al. (2002) for copper toxicity to oligochaete worms and by Meyer et al. (1999) for nickel toxicity to fathead minnows.

Cations other than those associated with water hardness might also influence copper bioavailability. Erickson et al. (1987) reported that increased sodium concentrations reduced toxicity. Because copper toxicity involves disruption of sodium exchange, this ameliorative effect of sodium might not be an issue of bioavailability but rather might simply reflect a more favorable gradient for sodium uptake, which would necessitate more copper accumulation to disrupt osmoregulation enough to elicit toxicity. For silver, however, Janes and Playle (1995) reported that increased sodium reduced metal accumulation in gills. Whether sodium has similar effects on copper bioavailability is uncertain. Hydrogen ion also could be a competitor with metals for gill binding sites and a modifier of gill epithelial properties; thus, pH could influence copper bioavailability beyond its effects on copper speciation in the exposure water. The effects of pH on toxicity could therefore be quite complex, with several processes altering bioavailability as pH changes. Although not clearly demonstrated in fish, competitive effects of hydrogen ion have been strongly indicated in some algal copper toxicity data (Peterson et al., 1984).

The various effects of water chemistry on copper bioavailability discussed thus far are summarized in the conceptual framework shown in Figure 2.11. For simplicity, Figure 2.11 depicts just two species of copper: free copper ion and copper complexed by a ligand (L), which has an unspecified charge and represents the various constituents in the exposure water or within the fish that can complex copper. The vertical arrows connecting Cu^{+2} and CuL represent the association and dissociation reactions that are continually occurring among the various forms. Free and bound copper in the bulk exposure water are transported by advection and diffusion (horizontal arrows) to near the gill surface, into a chemical microenvironment created by the gill. These arrows converge to indicate that all species contribute to

Downloaded From Vet-eBooks.com

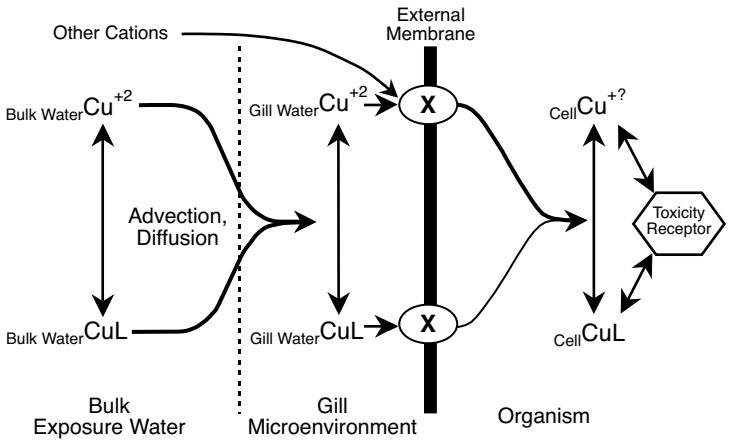

FIGURE 2.11 Conceptual model for chemical interactions regulating copper bioavailability at fish gills. See text for explanation of symbols.

the total pool of copper within the gill microenvironment. The various speciation reactions will result in a distribution of copper species within the gill microenvironment different from that in the bulk exposure water. These reactions are not necessarily at equilibrium, so bioavailability also can be a function of the kinetics of these reactions.

Some of these species will interact with or cross the external surface of the gill by various mechanisms denoted by the ovals marked with an X in Figure 2.11. The extent to which copper is absorbed by the fish and reaches internal toxicity receptors is represented by the horizontal arrows penetrating the surface. These arrows are of different thicknesses to denote that the gill surface is often less permeable, but not necessarily completely impermeable, to copper bound to ligands. Other cations, such as calcium, hydrogen, and sodium, might exert an effect on copper bioavailability by competing with copper for sites on the gill surface, or otherwise affecting the permeability of the gill surface to copper. The arrows again converge on the other side of the membrane to indicate that any copper entering the organism contributes to the total pool of copper within cells. This pool of copper is further affected by various speciation reactions (including changes in copper oxidation state) and is transported to where the different chemical species can interact with toxicity receptors.

Many of the processes and concepts depicted in Figure 2.11 have been the basis for metal bioavailability models proposed by various authors. These include model equations presented by Zitko (1976), the *gill surface interaction model* described and evaluated by Pagenkopf (1983), the *free ion activity model* (FIAM) described by Morel (1983), further developments of the FIAM by Brown and Markich (2000), and more recently the *biotic ligand model*, so named because biochemical sites such as those marked with an X in Figure 2.11 are viewed as other ligands that the metal interacts with (DiToro et al., 2001; Meyer et al., 1999; Santore et al., 2001). Reviews and critiques of these models are available from Campbell (1995) and Paquin et al. (2002a).

These models have similar basic features. Toxicity is a function of the amount of metal bound to a site on the organism surface. This is not necessarily a site of toxic action but rather might be an uptake site that defines how much metal gets to the toxicity receptors. This site is of central importance to bioavailability because its external location allows interaction with the exposure water chemistry. The metal bound at this site is assumed to be in equilibrium with the free metal in the water to which it is exposed. Complexation by various ligands in the exposure water will therefore limit the amount of metal binding to the site. Various cations can also bind with the site, creating competitive interactions that also limit binding of the toxic metal. The models include, or can be readily modified to include, binding of other species of the toxic metal at the site as mixed ligand complexes, so these species can also contribute to uptake and toxicity. Of course, it is an oversimplification to depict all relevant effects as arising from simple chemical mass action of these chemical entities at a single type of site; however, such a mathematical treatment can still be a useful approximation for the processes that do occur.

Downloaded From Vet-eBooks.com

When just the free form of the toxic metal (M) binds to the gill sites (X), this model can be expressed as follows:

$$EC = \left(\frac{f_{EX}}{(1 - f_{EX}) \cdot K_{MX}} \right) \cdot \left(1 + \sum_{j}^{m} \left(K_{CjX} \cdot [C_j] \right) \right) \cdot \left(1 + \sum_{i}^{n} R_i \right) \quad (2.7)$$

where EC is the total concentration of metal in the exposure water required to elicit a specified effect and is a product of the three mathematical expressions on the right side of the equation. The first expression is a baseline effect concentration that is expected in the absence of any cation competition and ligand complexation. It is a function of (1) f_{EX}, the fraction ($[MX_{EFF}]/[X_{TOT}]$) of the gill sites that must be occupied by the toxic metal to elicit the effect of concern, and (2) K_{MX}, the association constant for the binding of the toxic metal to the gill sites.

The second expression provides the factor by which the EC increases (bioavailability decreases) due to cations that compete with the toxic metal for the gill sites. This factor increases with increasing products of $[C_j]$, the free concentration of the j-th of m competing cations, and K_{CjG}, the association constant for the binding of this cation to the gill sites.

The third expression provides the factor by which the EC increases (bioavailability decreases) due to ligands that complex the toxic metal in the exposure water. This factor increases with increasing concentration ratios (R_i) of each metal complex to the free metal. For single-ligand complexes, this ratio is simply the product of the free concentration of the ligand and the association constant for this complex; however, in general, calculation of the R_i values requires a chemical speciation model that can address more complicated speciation relationships and relate calculations to total chemical concentrations, because free concentrations generally are unknown.

When only one competing cation or complexing ligand is varied, this model predicts a linear relationship between the EC and the free concentration of that cation or ligand, with the intercept equal to the baseline EC. De Schamphelaere and Janssen (2002) provided good examples of such linear relationships for copper toxicity to a cladoceran and also addressed how this mathematical framework can be expanded to address the toxicity of species other than free metal.

Recent efforts have demonstrated that this bioavailability modeling approach can be useful for describing the toxicity of various metals to fish and other aquatic organisms (see review by Paquin et al., 2002a). Santore et al. (2001) and Di Toro et al. (2001) accounted for a high percentage of the variation of toxicity within a large dataset for acute copper lethality to fathead minnows, nearly always predicting toxicity to within a factor of two. Figure 2.12 shows a subset of these data consisting of a series of test waters with the same pH, low organic matter content, and similar relative amounts of major cations and anions but different total ion concentrations. The large range of copper toxicity in this dataset primarily reflects the combined effects of changes in alkalinity, calcium, and sodium. The model is very successful in predicting relative changes in toxicity and underestimates LC_{50} values by only about 30% on average. This underestimation of LC_{50} values might be due to uncertainties in model parameterization and sample characterization (especially regarding the organic complexation in these samples) or to uncertainties in model formulation discussed below.

One strength of this modeling approach is that parameters can be primarily, or even entirely, estimated independently of the toxicity relationships of interest. Estimation of metal speciation in exposure water does not depend at all on toxicity data, and association constants for binding of metal to gill sites can be estimated from accumulation experiments. Only the gill accumulation associated with the toxic effect has to be determined under toxic conditions, and it does not have to involve any consideration of the effects of exposure conditions on toxicity (MacRae et al., 1999). If such independent parameter estimates are not feasible or are uncertain, this model can also be used to estimate or refine parameter values from the toxicity relationships (De Schamphelaere and Janssen, 2002); however, to the extent that model parameters are derived from toxicity data, there is less confidence that the model truly describes the processes regulating bioavailability rather than just providing a reasonable framework for data-fitting.

Despite the successes of this approach for modeling metal bioavailability, certain uncertainties and limitations in the model formulation must be noted:

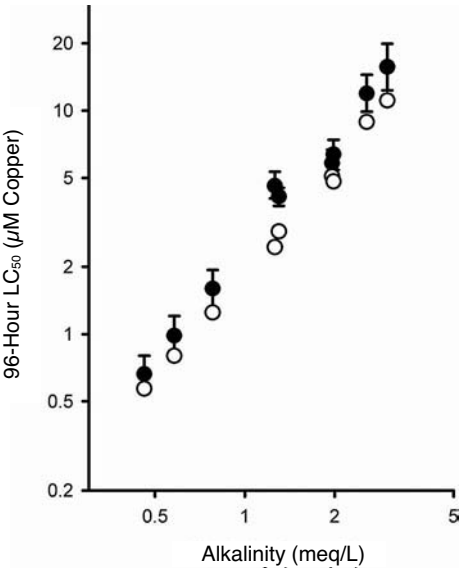

FIGURE 2.12 Observed and predicted lethality of copper to fathead minnows. (Data from Erickson et al., *A Prototype Toxicity Factors Model for Site-Specific Copper Water Quality Criteria*, U.S. Environmental Protection Agency, Duluth, MN, 1987.) Solid circles denote observed LC_{50} values (±95% confidence limits). Open circles denote predicted LC_{50} values using Biotic Ligand Model Version 2.0.0 (Hydroqual; Mahwah, NJ).

1. Most model applications to date do not address effects of changes in chemistry at the gill microenvironment. Tao et al. (2002) reported large effects on apparent metal–gill association constants if the effects of pH changes and mucous secretions on copper binding are accounted for. The implications of this to bioavailability assessments might be significant in some cases and have not been determined.
2. The model assumes chemical equilibria within the exposure water and between the exposure water and the gill surface. In addition, there is a fixed proportionality between the metal bound at the surface and the level of uptake or effect within the organism. Under some circumstances, the kinetics of these processes might be important to bioavailability (Hudson, 1998); for example, speciation changes in the gill microenvironment might not reach equilibrium because of the short residence time of water in the gill.
3. The effects of cations are not necessarily just a matter of competition with the gill sites, as assumed in the model. The effect of hardness on toxicity appears to be nonlinear, whereas the model predicts a linear effect. This might reflect changes in gill permeability that either affect copper bioavailability in a nonlinear fashion or affect toxicity without affecting bioavailability. The amelioration of copper toxicity by sodium should, to some degree, reflect direct effects on sodium exchange rather than competition with copper. Merging this simple bioavailability model with models for ion regulation (Paquin et al., 2002b) would address this issue.
4. The role of copper species other than the free ion in uptake across, or interaction with, the gill surface is poorly established. Efforts to include additional bioavailable species in model calculations (De Schamphelaere and Janssen, 2002) require inferences from toxicity data trends that are difficult, given uncertainties in the data and in model formulation. Better information is needed to establish the actual role of these species.

Interpreting the toxicity of copper and many other cationic toxic metals is difficult because of complex chemical speciation and various other processes that affect their accumulation at, and interaction with, biological receptors. Although the bioavailability modeling approach described here is a rather simple representation of a complex system, it addresses important aspects of the complexity by incorporating

Downloaded From Vet-eBooks.com

reasonable formulations for some fundamental aspects of metal toxicity: (1) the absorption of bioavailable metal into the organism to achieve toxic metal levels at some site of action, (2) reductions in this absorption due to the formation of less bioavailable metal species in the exposure water, and (3) reductions in this absorption due to the effects of other cations. This section demonstrated how this approach can form the basis for understanding and predicting the role of bioavailability in the effects of exposure conditions on acute copper lethality to fish, as well as how some effects might be related to processes other than bioavailability. The same general considerations will apply to other endpoints, routes of exposure, and metals, although details will vary. Broader and more extensive discussions of metal bioavailability in water can be found in many of the references cited herein. The possible role of dietary metal in the overall bioavailability of metals to fish and other aquatic organisms has been recently reviewed by Meyer et al. (2005). There also is extensive literature concerning metal bioavailability in sediments which, although not directly impacting most fish, is nonetheless important for assessing the broader impacts of metals on aquatic ecosystems (Ankley et al., 1996).

Organometals: Mercury

The behavior of metals in biological systems can change dramatically when they occur as organometallic compounds. Although several metals have the potential to form organometallic compounds, organic species of mercury, tin, and lead have attracted the most attention because of their occurrence in the environment and demonstrated toxicity (Pelletier, 1995). For each of these metals, covalent binding to one or more organic groups yields compounds that may accumulate in fish and other aquatic biota.

A general model for membrane diffusion of trialkyltin compounds was developed in the 1970s (Tosteson and Wieth, 1979; Wieth and Tosteson, 1979). According to the model, positively charged trialkyltin species diffuse across biological membranes in association with an aqueous anion, usually Cl^- or OH^-, and the presence of one or more organic substituents contributes to this uptake by increasing the molecule's relative hydrophobicity, in effect giving it a partially "organic" character. The ion pair model does not, however, account for the fact that organometals tend to retain their metallic (i.e., electrophilic) character, including high reactivity with protein thiols. Transport across a biological membrane is likely, therefore, to reflect a balance between simple diffusion of the neutral ion pair and interactions with membrane proteins (Boudou et al., 1991). Membrane flux of some organometallic compounds may also occur by active transport of complexes formed with small organic molecules (see below).

The dual character of organometals is also reflected in factors that control their speciation in natural waters. As discussed in the previous section regarding copper, pH, alkalinity, and hardness can have a large effect on the speciation, accumulation, and toxicity of inorganic metals. Uptake of organometals also may be impacted to some extent by ionic constituents of water, particularly as they affect the formation of neutral diffusing species. In addition, binding to DOC and POC is likely to be important for controlling the concentration of freely dissolved species, thereby influencing bioavailability in waterborne exposures.

Because organometallic compounds tend to accumulate in organisms that occupy the base of aquatic food webs, the diet may represent the principal route of exposure for higher trophic level organisms, including fish. An understanding of organometal accumulation by fish therefore requires that bioavailability concepts be extended to the entire aquatic food web. Additional consideration must be given to factors that control interconversions of inorganic and organic metal species. This is particularly true when (as is often the case) the concentration of the organometal in fish is referenced to the total concentration of parent metal in sediment or water. In this section, methylmercury accumulation by fish is examined as a means of illustrating these points.

Historically, demonstrated impacts of methylmercury on humans due to consumption of contaminated fish and shellfish have focused attention on point-source releases of mercury to the aquatic environment such as mining, smelting, and wastewater treatment (U.S. EPA, 1997a). Most of the mercury released in these cases exists as elemental or inorganic mercury. Biotic and abiotic processes then transform a portion of this mercury to the methylated form. These releases continue to occur, particularly in countries with emerging industrial economies. Increasingly, however, the focus of mercury research in the United States and elsewhere has been on airborne mercury emissions. Important anthropogenic sources of mercury to the atmosphere include the combustion of fossil fuels, municipal waste incineration, and

Downloaded From Vet-eBooks.com

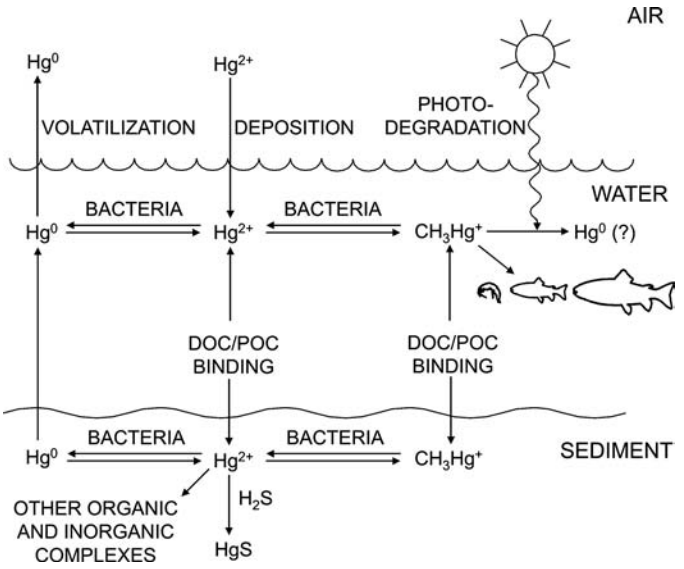

FIGURE 2.13 Biogeochemical cycling of mercury. This figure shows reactions that transform airborne Hg^{2+} into CH_3Hg^+ and the subsequent fate of CH_3Hg^+. Currently, the photodegradation products of CH_3Hg^+ are unknown, although it has been speculated that Hg^0 is produced.

gold mining (also an important point source). To date, 48 states in the United States have issued fish consumption advisories for one or more water bodies because mercury levels in fish muscle tissue exceed state or federal guidelines, and 23 states have issued statewide advisories (U.S. EPA, 2007). Many of these fish reside in water bodies for which there are no known point sources.

Mercury can exist in three valence states:

- Hg^0, metallic mercury (elemental mercury)
- Hg_2^{2+}, monovalent mercury (mercurous mercury)
- Hg^{2+}, divalent mercury (mercuric mercury)

Hg_2^{2+} is unstable under most environmental conditions. The overwhelming percentage of total mercury in the environment therefore occurs as either Hg^0 or Hg^{2+}. Hg^{2+} is commonly associated with sulfur in the mineral cinnebar (HgS) but may complex with other inorganic ligands, including chlorine, oxygen, and hydroxyl ions. Hg^{2+} can also react covalently to form a variety of organic derivatives including CH_3Hg^+ (methylmercury), $(CH_3)_2Hg$ (dimethylmercury), and $C_6H_5Hg^+$ (phenylmercury). Of these, methylmercury (henceforth, MeHg) is by far the most common and is the form of greatest interest to toxicologists due to its high toxicity and propensity to accumulate in aquatic biota (Wiener and Spry, 1996).

The biogeochemical cycling of mercury in freshwater systems has been extensively reviewed (Driscoll et al., 1994; Ullrich et al., 2001; Winfrey and Rudd, 1990; Zillioux et al., 1993). Figure 2.13 shows a subset of known reactions that result in conversions among major mercury species. The same reactions are thought to occur in estuarine and marine environments, but their relative importance is less well known. The focus of this figure is on reactions that transform airborne Hg^{2+} into MeHg, and the subsequent fate of MeHg. Potentially important reactions that do not appear in this figure include the photooxidation of Hg^0 (LaLonde et al., 2001), photoreduction of Hg^{2+} (Amyot et al., 1994), microbial conversion of MeHg to dimethylmercury (Baldi et al., 1993), and formation of soluble sulfide complexes with Hg^{2+} (see below). The percentage of total mercury in freshwater that exists as MeHg varies among systems but is generally <15% and often closer to 5% (U.S. EPA, 1997b). Contaminated sediments serve as an important reservoir for Hg^{2+}, and it is likely that sediment-bound mercury can recycle back into an aquatic ecosystem for many years (Kudo, 1992).

Downloaded From Vet-eBooks.com

The issue of greatest importance in predicting the environmental fate and effects of mercury is the net rate of methylation (Gilmour and Henry, 1991; Ullrich et al., 2001; Winfrey and Rudd, 1990). Most of the methylation in freshwater systems occurs in sediments, although methylation in the water column has also been described. Anaerobic sulfur-reducing bacteria represent the primary source of MeHg in freshwater systems (Gilmour et al., 1992) and are also active in estuarine (Compeau and Bartha, 1985) and near-shore marine (King et al., 2001) environments. Fulvic and humic material may abiotically methylate mercury, but the mechanism is poorly understood (Weber, 1993). Demethylation is also mediated largely by microorganisms (Robinson and Tuovinen, 1984). Photodegradation of MeHg is known to occur, but the end-products of this reaction and its relative contribution to the mercury cycle are poorly understood (Sellers et al., 1996).

In pore water that contains excess sulfide, dissolved Hg^{2+} complexes with HS^- to form several charged and uncharged sulfide species. Laboratory studies with sulfate-reducing bacteria suggest that the neutral complex HgS^0 can diffuse across bacterial cell membranes and is the principal source of Hg^{2+} for subsequent formation of MeHg (Benoit et al., 1999, 2001). The relative concentration of each sulfide species varies with total sulfide concentration. High sulfide concentrations favor the formation of the charged species $HgHS_2^-$, which is thought to be poorly absorbed by microbes. The addition of sulfate can stimulate methylation in sediment by providing the energy substrate for sulfate-reducing bacteria (Gilmour et al., 1992); however, high levels of sulfate may have a negative impact on mercury methylation due to corresponding increases in sulfide and the resultant removal of mercury from solution as HgS.

Oxides of Fe and Mn may contribute to the formation of MeHg by precipitating Hg^{2+} out of the water column. The formation and dissolution of Fe and Mn oxides are controlled by the redox state and oxygen content of water and sediment. Under the anaerobic conditions often found in sediments, these particles dissolve, making Hg^{2+} available for other reactions. The presence of Fe in sediment can also reduce the inhibitory effect of high sulfide levels on methylation rate, presumably through substrate competition (i.e., the formation of FeS) (Furutani and Rudd, 1980; Gagnon et al., 1996).

Both Hg^{2+} and MeHg accumulate in aquatic biota. Hg^{2+} may predominate at lower trophic levels because it comprises the largest percentage of total mercury in water and sediment. In most instances, however, differences in dietary assimilation and retention of Hg^{2+} and MeHg result in an enrichment of MeHg with each trophic level transfer. The end result is that nearly all of the mercury in fish exists as MeHg (U.S. EPA, 1997b).

By far the largest concentration step for MeHg in the aquatic environment occurs at the base of the food web. Reported BCFs for MeHg in freshwater primary producers (trophic level 1) average about 1×10^5. Methylmercury also biomagnifies in food webs; that is, MeHg concentrations tend to increase at successively higher trophic levels. BMFs for MeHg in freshwater forage fish (concentration at trophic level 3/concentration trophic level 2) and large piscivorous fish (trophic level 4/trophic level 3) range from 2 to about 10 and average around 5 (U.S. EPA, 1997b). Altogether, biomagnification may result in a 20- to 200-fold increase in MeHg concentration from trophic level 1 to trophic level 4. These observations are important because they suggest that factors that control uptake directly from water will determine the amount of MeHg that enters the food web, while those that control uptake from dietary sources will influence the extent to which biomagnification occurs at higher trophic levels.

The dominant form of freely dissolved MeHg in most seawater systems is MeHgCl. Uptake of MeHg by marine phytoplankton was found to be controlled by the concentration of aqueous MeHgCl (Mason et al., 1996). This finding is consistent with earlier work showing that MeHgCl can diffuse readily across artificial lipid membranes (Bienvenue et al., 1984). In freshwater systems, most of the MeHg free in solution exists as MeHgOH. Watras et al. (1998) reported that MeHg concentrations in microseston from 15 freshwater lakes correlated with modeled concentrations of MeHg (free ion) or MeHgOH, but not MeHgCl; however, the diffusion rate for MeHgOH across biological membranes is only 0.04 times that of MeHgCl (Mason et al., 1996). For this reason, Watras et al. (1998) speculated that the uptake of MeHg by microseston was controlled by an active transport mechanism. MeHg complexed with cysteine, thiourea, or thioglycolate was taken up directly from water by sheepshead minnows (Leaner and Mason, 2001). In mammals, MeHg–cysteine complexes are actively transported across placental membranes and the blood–brain barrier by a neutral amino acid carrier system (Kajiwara et al., 1996; Kerper et al., 1992). It is not known whether this or a similar mechanism is active in aquatic biota.

Downloaded From Vet-eBooks.com

Studies of MeHg accumulation in natural systems are often complicated by the fact that a given factor may impact both bioavailability and net methylation rate. In poorly buffered freshwater systems that are susceptible to acid deposition, MeHg concentrations at all trophic levels tend to be inversely correlated with pH (Watras et al., 1998; Winfrey and Rudd, 1990). Decreased pH, particularly when associated with the deposition of sulfuric acid, has been associated with increased microbial production of MeHg (Gilmour et al., 1991); however, biogeochemical processes that release mercury from soils and sediments at low pH values may also play a role by contributing to the pool of Hg^{2+} available for bacterial methylation. In well-buffered systems and those that drain relatively large watersheds, pH and MeHg accumulation by fish may be poorly correlated (Richardson et al., 1995).

The DOC content of water is an important determinant of MeHg accumulation and, in many systems, a better predictor of fish mercury residues than pH. DOC levels usually correlate positively with MeHg residues in fish, although in a study of Adirondack lakes very high levels of DOC were associated with a decline in MeHg (Driscoll et al., 1995). DOC may contribute indirectly to increased levels of MeHg in fish by promoting the translocation of Hg^{2+} and MeHg from watersheds to water bodies (Hurley et al., 1995). The addition of DOC to a system tends to increase sediment microbial activity, hence the potential for Hg^{2+} methylation. An increase in the DOC content of water may also promote the release of MeHg from sediment to the water column, making it more available for uptake by fish and other aquatic biota (Miskimmen, 1991).

At low Hg^{2+}/DOC ratios, DOC binding of Hg^{2+} is dominated by covalent interactions with thiol groups (Drexel et al., 2002; Haitzer et al., 2002). These complexes are very stable, and it has been suggested that high levels of DOC reduce Hg^{2+} methylation in the water column by reducing uptake of Hg^{2+} by microbes (Gilmour and Henry, 1991). In laboratory studies, DOC addition to water reduced the uptake of Hg^{2+} and MeHg by larvae of a benthic dipteran (*Chaoborus*) (Sjöblom et al., 2000). DOC addition was also shown to reduce MeHg uptake by fish directly from water (Choi et al., 1998).

The affinity of DOC for MeHg and other metals varies with pH. In general, a decrease in pH results in lower MeHg binding to DOC because of competition with hydrogen ion for anionic binding sites (Hintelmann et al., 1995). The binding of MeHg to DOC may also be affected by the presence of other cationic metals. For example, Driscoll et al. (1995) found that MeHg levels in fish were positively correlated with concentrations of monomeric aluminum and suggested that this was because aluminum competes with MeHg for binding sites on DOC, thereby increasing the concentration of unbound MeHg.

In many aquatic systems, benthic organisms contribute substantially to the transfer of energy and contaminants from sediments to the food web. Uptake of Hg^{2+} and MeHg from ingestion of contaminated sediment was investigated by feeding mussels a suspension of sediment particles (Gagnon and Fisher, 1997). Assimilation efficiencies for Hg^{2+} were uniformly low (<10%). Those for MeHg were generally higher (all but one value > 30%) but varied with sediment type. Pretreatment of artificial sediment with organic material (fulvic acid) increased MeHg assimilation in all cases. In contrast, uptake of Hg^{2+} and MeHg from sediment by an estuarine amphipod (*Letocheirus plumulosus*) was negatively correlated with sediment organic matter content, and it was suggested that binding to organic matter prevented MeHg from becoming solubilized within the intestinal tract (Lawrence and Mason, 2001).

Methylmercury levels as a percentage of total mercury are generally very low in sediment but tend to increase in pore water and overlying waters, suggesting that sediment-to-water binding constants for MeHg are lower than for Hg^{2+}. The natural cycling of biological material may also cause MeHg to be retained by organisms living in the water column (Watras et al., 1998). Benthic and pelagic environments may become coupled, however, when sediment-dwelling organisms consume algae or detritus contaminated with MeHg (Lawrence and Mason, 2001) or fish consume benthic species.

Laboratory studies and modeling efforts both indicate that the diet is the primary route of uptake of MeHg for large piscivorous fish (Wiener and Spry, 1996). The predominant route of uptake by smaller fish is less well known, and it has been suggested that uptake from water may contribute substantially to accumulated residues depending on seasonal changes in prey selection and environmental factors (Post et al., 1996). The relative importance of food and water exposure routes in accumulation of MeHg by herbivorous fish and fish that ingest large quantities of sediment is unknown. Depuration studies suggest that the elimination half-life for MeHg in fish may range from weeks to years (Trudel and Rasmussen, 1997). Indeed, elimination proceeds so slowly that MeHg may accumulate throughout a

Downloaded From Vet-eBooks.com

fish's lifetime, resulting in positive correlations between MeHg concentration and fish age or length (U.S. EPA, 1997a).

Reported assimilation efficiencies for MeHg in dietary uptake studies with fish vary considerably. Several authors have reported dietary assimilation efficiencies ranging from 50 to 90% (Wiener and Spry, 1996), and values in this range have been used successfully in environmental modeling efforts to describe observed rates of MeHg accumulation (Borgmann and Whittle, 1992; Norstrom et al., 1976; Post et al., 1996). In contrast, a low assimilation efficiency (30%) was reported when channel catfish were fed a prepared diet spiked with MeHg (McCloskey et al., 1998), and an even lower value (20%) was obtained when northern pike were fed MeHg-contaminated forage fish (Phillips and Gregory, 1979). This latter finding is particularly interesting because it suggests that the bioavailability of MeHg incorporated into food may be lower than that of MeHg spiked into prepared diets.

The factors that control dietary MeHg uptake by fish are poorly known. Following the digestion of a prey item, much of the MeHg in the gastrointestinal tract probably remains bound to organic compounds and, in particular, to sulfhydryl-containing peptides and amino acids. Although speculative at this time, it is possible that dietary assimilation efficiency may be determined by the extent to which these complexes are actively taken up across the gastrointestinal epithelium.

In summary, the interactions between aquatic organisms and major mercury species are varied and complex. Field surveys have repeatedly shown that MeHg concentrations in large predatory fish from the same general region may differ by a factor of 10 or more. To understand how this can happen we must extend the concept of bioavailability to consider factors that control MeHg production as well as its uptake and accumulation in aquatic organisms. Three critical interactions are thought to control MeHg production and accumulation in a wide range of systems. The first of these occurs in anaerobic sediments and involves the uptake of Hg^{2+} by sulfate-reducing bacteria. Recent work suggests that in the presence of sulfide this uptake is controlled by the formation of a neutral sulfide complex. The second interaction involves the uptake of MeHg by lower trophic level organisms living in the water column. In saltwater systems, this uptake is probably dominated by simple diffusion of neutral MeHgCl, while in freshwater systems the diffusing species is more likely to be MeHgOH. Strong binding to DOC limits the amount of MeHg available to form these complexes. Other modes of uptake into lower trophic level organisms (e.g., active transport of MeHg complexes) have also been proposed. The third interaction involves dietary uptake of MeHg by fish. The identity of the chemical species that is absorbed within the gastrointestinal tract is unknown but may include MeHg complexes with small organic molecules.

Nonionic Organics: 2,3,7,8-Tetrachlorodibenzo-*p*-Dioxin

The compound 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) provides an excellent example of how bioavailabilities of persistent, hydrophobic, nonpolar organic chemicals influence exposures and consequent toxicity risks to aquatic organisms. With a molecular weight of 322, a log K_{ow} of approximately 7, and a planar molecular structure, TCDD strongly associates with organic carbon, whether it be in soils, sediments, POC, or DOC. The hydrophobic character of TCDD not only thermodynamically drives its partitioning in the abiotic environment but also is responsible for a strong bioaccumulation/biomagnification potential which causes TCDD to accumulate in the lipid-containing tissues of biota in food webs. In most risk assessments concerned with the toxicity of TCDD, it is now recognized that the combined contributions of all chemicals with a TCDD-like mode of action to overall risk must be evaluated (Van den Berg et al., 1998). The identification of chemicals that act additively with TCDD is based on their persistence in the environment and ability to act through an aryl hydrocarbon receptor (AhR)-mediated mechanism of action as does TCDD. Typically, the contribution of specific congeners with polychlorinated dibenzo-*p*-dioxin, dibenzofuran, and biphenyl structures are considered. Thus, differences between these congeners and TCDD, in bioavailability as well as relative potencies, are important in quantitative risk assessments for complex mixtures of these chemicals which commonly occur in the environment. The retrospective assessment of AHR-mediated toxicity to lake trout sac fry in Lake Ontario provides a case study that validates this predictive capability (Cook et al., 2003).

The bioavailability of TCDD to fish involves both the amount of TCDD available for direct uptake by fish from water and sediment and the amount of TCDD in their food, which is influenced by the

Downloaded From Vet-eBooks.com

bioavailability of TCDD to organisms in the food chain. Theoretically, more organic carbon in the water and sediments of an aquatic ecosystem should result in reduced bioavailability of TCDD to fish. A consequence of low amounts of organic carbon in an aquatic ecosystem would be increased bioavailability and thus bioaccumulation of TCDD.

In water, the bioavailability of a nonpolar, hydrophobic organic chemical is proportional to the fraction of chemical that is freely dissolved (f_{fd}), which is related to the concentrations of POC and DOC as follows:

$$f_{fd} = \frac{1}{1 + (POC)\left(K_{poc}\right) + (DOC)\left(K_{doc}\right)} \approx \frac{1}{1 + (POC + DOC/10)\left(K_{ow}\right)} \tag{2.8}$$

where organic carbon partition coefficients for POC (K_{poc}) and DOC (K_{doc}) can be approximated as K_{ow} and $K_{ow}/10$, respectively (Eadie et al., 1992). Slightly different values of K_{poc} are commonly used based on laboratory studies, such as those of Karickhoff (1981), which determine organic carbon partition coefficients for sediment organic carbon (K_{soc}) from sorption/desorption rates for sediment rather than suspended solids. As a first approximation, one may assume $K_{poc} \approx K_{soc}$. In the past decade, considerable debate occurred among environmental chemists concerning the nature of organic chemical binding to particles in water and the degree to which equilibrium models for the distribution between water and organic carbon on particles are appropriate for modeling hydrophobic organic chemical distribution in natural systems (Schrap and Opperhuizen, 1992). Measurement of K_{poc} or K_{soc} for TCDD is complicated by the inability to conduct experiments with no organic carbon in the water. Extrapolation of TCDD sediment desorption measurements to zero aqueous organic carbon resulted in an estimate of log K_{soc} of 7.25 to 7.59 (Lodge and Cook, 1989), a value significantly greater than the estimated log K_{ow}. Aside from the possibility that log K_{ow} has been underestimated for TCDD, this discrepancy might be due to higher affinities of planar aromatic compounds such as TCDD for *black carbon** in sediments (Barring et al., 2002) than for other sediment carbon, for which TCDD partitioning more closely follows K_{ow}.

The degree to which values of K_{doc} are less than K_{poc} or K_{soc} is also uncertain and may vary with the chemical composition of dissolved organic carbon in different ecosystems (Burkhard, 2000; Chin and Gschwend, 1992; Eadie et al., 1990). Clearly, accuracy in the prediction of concentrations of freely dissolved TCDD in different waters depends heavily on the accuracy of the determination of K_{ow} for TCDD. Figure 2.14 demonstrates how, under different POC conditions, f_{fd} varies for TCDD with an estimated log K_{ow} of 7 vs. an estimated log K_{ow} of 8. A major impediment to the direct determination of concentrations of freely dissolved TCDD in water is the difficulty of separating freely dissolved TCDD from bound TCDD in water samples, combined with the challenge of detecting and measuring concentrations on the order of femtograms/liter (parts per quintillion).

Because a major fraction of TCDD in aquatic systems is associated with organic carbon, exposure of aquatic organisms to TCDD and the resulting bioaccumulation depend greatly on each organism's connectivity to sediments or suspended particles. Benthic organisms have direct contact with sediment and accumulate hydrophobic aromatic chemicals to a greater extent through ingestion of sediment than from exposure to pore water (Leppänen and Kukkonen, 1998). If the concentration of TCDD varies with depth in the sediment, the depth to which the organism burrows in the sediment will influence exposure. Ingestion of TCDD with food by oligochaetes (*Lumbriculus variegatus*) and midges (*Chironomus tentans*) results in accumulation of TCDD in the organisms at levels close to equilibrium with the food (West et al., 1997). Slow rates of elimination from these benthic invertebrates suggest an inability to metabolize TCDD. Bioaccumulation of organic chemicals with log K_{ow} values greater than 5.5 by pelagic fish can be strongly influenced by the presence of a benthic food chain component in the diet (Burkhard,

* *Black carbon* refers to carbon from a variety of sources such as combustion particles (soot), fly ash, coal dust, and tire dust. The different forms of black carbon can have different partitioning properties than carbon originating from low-temperature biogenic processes. For sediments, the term *organic carbon* includes both biogenic and black carbon, in contrast to inorganic forms of carbon such as carbonates. Black carbon usually comprises a small fraction of the total organic carbon measured yet has the potential to exert a greater relative influence on partitioning and bioavailability of planar organic chemicals such as TCDD and BaP.

Downloaded From Vet-eBooks.com

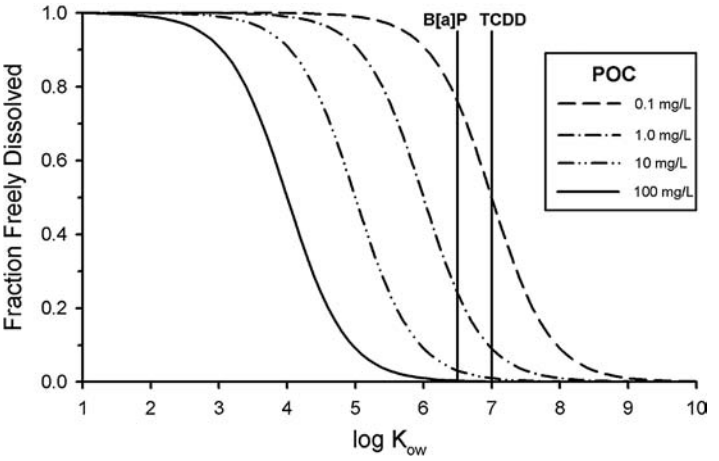

FIGURE 2.14 Effect of particulate organic carbon (POC) concentrations and octanol–water partition coefficient (K_{ow}) on the fraction of freely dissolved chemical. Vertical lines intersect expected fractions at different POC concentrations for benzo(*a*)pyrene (BaP) and 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD).

1998); thus, the high degree of bioavailability of TCDD and related chemicals from sediment to benthic invertebrates is often passed on to fish and wildlife through their diet.

Bioaccumulation of TCDD by epibenthic invertebrate or benthic vertebrate organisms often may not attain equilibrium with sediments due to disequilibrium between sediments and overlying water. The concentration of the chemical in the overlying water influences not only uptake through respiration and dermal absorption but also dietary uptake, because concentrations in some food items at the sediment–water interface are more related to water than sediment. The extent of this disequilibrium can be expressed by the variable:

$$\prod_{socw} = \frac{C_{soc}}{C_w^{fd}} \tag{2.9}$$

where C_{soc} is the organic-carbon-normalized chemical concentration in the sediment, and C_w^{fd} is the freely dissolved concentration in the overlying water. At equilibrium, $\prod_{socw}$ should approximately equal K_{ow}, so the ratio $\prod_{socw}/ K_{ow}$ indicates the degree of disequilibrium between sediment and overlying water (Cook and Burkhard, 1998). Field sampling as well as dynamic chemical mass balance models indicate that $\prod_{socw}/K_{ow}$ for TCDD and other hydrophobic organic chemicals is often greater than 1.0 (Burkhard et al., 2003). This disequilibrium appears to be largely attributable to two factors: (1) slow mixing of surface sediment with and diffusion of TCDD to overlying water when concentrations of TCDD in sediments reflect greater chemical loadings to the system in the past, and (2) the presence of greater amounts of biogenic organic carbon in water particulates than in sediment, which causes the fraction of freely dissolved chemical in the overlying water to be less than in sediment pore water. Difficulty in measuring C_w^{fd} and K_{ow} for very hydrophobic chemicals such as TCDD can complicate direct determinations of $\prod_{socw}/K_{ow}$. On the other hand, it often is not difficult to semiquantitatively determine this ratio with knowledge of the hydrodynamic characteristics of the aquatic ecosystem and the relative chemical loading rate over time.

The bioavailability of TCDD and related chemicals is not just a function of their hydrophobicity and how this affects environmental partitioning and uptake via water and food. Bioaccumulation of these chemicals by vertebrates is reduced by biotransformation, which increases the rate of elimination. Chlorinated dioxins and furans are eliminated faster by fish than PCBs with similar log K_{ow} values (Van der Linde et al., 2001). Biotransformation of TCDD is specifically indicated by measurement of TCDD metabolites in the bile of rainbow trout (Kleeman et al., 1986a) and yellow perch (Kleeman et al., 1986b). The rate of elimination of a chemical similar to TCDD, 2,3,4,7,8-pentachlorodibenzofuran, from rainbow

Downloaded From Vet-eBooks.com

trout is reduced by the metabolic inhibitor piperonylbutoxide (Sijm et al., 1990). In aquatic food webs, TCDD does not appear to biomagnify in fish as do PCBs with similar K_{ow} values. Because dietary assimilation efficiencies of TCDD are high (Isosaari et al., 2004; Nichols et al., 1998), this difference between TCDD and PCBs cannot be attributed to lower dietary bioavailability for TCDD than PCBs, but rather is likely due to biotransformation in both prey and predator species of fish (Burkhard et al., 2004; Endicott and Cook, 1994).

This discussion of TCDD illustrated how the bioavailability of hydrophobic organic chemicals is strongly influenced by their partitioning to organic carbon in aquatic systems. The freely dissolved (most bioavailable) fraction of such chemicals is reduced by DOC and POC, and much of the chemical is partitioned into sediments. The importance of dietary exposure increases with chemical hydrophobicity, especially for organisms at higher trophic levels whose dietary exposures can be affected by biomagnification through the food chain. Bioavailability for such organisms becomes a function, not just of their exposure to water and food but also of the bioavailability relationships for their entire food chain. Under these circumstances, chemical accumulation in fish is determined by both chemical speciation in the water and in the sediments associated with the benthic-based part of the food web. These processes have been addressed in food-web-based bioaccumulation models that can assess the bioavailability to fish of hydrophobic organic contaminants throughout entire aquatic systems (Burkhard et al., 2003). The next case study considers a chemical in which biotransformation is even more important for determining bioavailability.

Nonionic Organics: Benzo(*a*)pyrene

Benzo(*a*)pyrene (BaP) is a polycyclic aromatic hydrocarbon (PAH) with a planar structure composed of five fused benzene rings, a molecular weight of 252.3 Daltons, and log K_{ow} of 6.5 (Bruggeman et al., 1982). Unlike TCDD, BaP concentrations in most surficial sediments have not declined significantly since the 1970s (Lima et al., 2003). BaP also provides an interesting contrast to TCDD with regard to bioavailability. Both chemicals have gained notoriety because of their potential carcinogenicity, but, although only slightly less hydrophobic, BaP appears to be much less bioaccumulative in fish than TCDD. Fish BSAFs for PAHs in the environment are about three orders of magnitude less than for chlorinated aromatic hydrocarbons (Connor, 1984). For more extensive reviews of PAH bioaccumulation in marine organisms, see Meador et al. (1995).

One factor responsible for lower bioaccumulation of BaP in fish than for TCDD appears to be a much greater affinity of BaP for organic carbon, despite these two chemicals having similar molecular weights and hydrophobicities. As noted in the TCDD case study above, partition coefficients of organic chemicals to DOC are typically about tenfold less than the K_{ow} for the chemical; however, the binding of BaP with dissolved humic material was found to be completely reversible with a partition coefficient approximately equal to its K_{ow} (McCarthy and Jimenez, 1985). For POC, partition coefficients for Baltic Sea water (Broman et al., 1991) were 20-fold greater for BaP than for TCDD, which is slightly more hydrophobic.

This low availability of BaP in water is also evident in sediments, which is consistent with the low bioaccumulation observed in fish dependent on benthic food chains. In general, PAHs in sediments seem to be less bioavailable to benthic invertebrates than other persistent organic chemicals. Bioaccumulation of PAHs by various benthic-coupled organisms in both field and laboratory exposures is an order of magnitude less than for PCBs or pesticides, which, unlike the PAHs, tend to reach equilibrium distributions between sediment organic carbon and organism lipid (Tracey and Hansen, 1996). This low bioavailability of PAHs may be attributable to lower concentrations of PAHs in pore water than expected based on their K_{ow} and their total concentrations in the sediment. The uptake of chemicals by benthic organisms, however, is not just via pore water. Ingestion of sediment appears to be an important route for accumulation of PAHs from sediment by oligochaetes (Leppanen and Kukkonen, 1998). The greater uptake of BaP from ingested sediment particles by an oligochaete in comparison to the less hydrophobic PAH phenanthrene is attributable to the greater assimilation efficiency of BaP which causes a greater uptake from the ingested particles than from pore water (Lu et al., 2004). For such organisms, the overall bioavailability of BaP from sediments will not be as restricted as suggested by the partitioning between water and sediment.

Downloaded From Vet-eBooks.com

One complication that impacts the bioavailability of BaP and other pyrogenic PAHs in aquatic systems is an association with the black carbon phase in sediments and suspended particles. Because BaP is derived from combustion reactions, it may largely be transported through the atmosphere to aquatic systems in fine soot particles to which it is more strongly bound than to biogenic organic carbon in sediment. Thus, K_{oc} values measured for ambient environmental conditions may be significantly greater than predicted from K_{ow} because the black carbon component of sediments significantly reduces the amount of BaP in the sediment available for desorption to the water phase. Activated carbon–water partition coefficients have been suggested for prediction of the effect of black carbon in sediments on PAH concentrations in pore water (Gustafsson et al., 1997). This requires that the fraction of black carbon in the sediment be determined in addition to the fraction of biogenic organic carbon. Although PCBs were observed to be 100% available for equilibrium partitioning to water from sediments in desorption experiments, only a small fraction of pyrogenic PAHs in the sediments were similarly available (McGroddy et al., 1996). This partitioning difference is probably related to whether the chemical is sorbed on the surface (available for desorption) vs. incorporated into the particle matrix (less available for desorption). The degree to which a chemical formed during a combustion process is locked into the matrices of fine combustion particles probably depends on the volatility of the chemical, the combustion temperature, and the gas/particulate emission conditions.

Another factor that may limit benthic food chain transfer of BaP to fish is biotransformation in benthic invertebrates at the base of the food chain. Two species of deposit-feeding marine amphipods (*Rhepoxynius abronius* and *Eohaustorius washingtonianus*) were found to extensively metabolize BaP accumulated from sediment into three different BaP–diol and two hydroxy–BaP molecules (Reichert et al., 1985). Similarly, there was evidence of formation of phase I and phase II metabolites of BaP accumulated from sediment by larvae of a midge (*Chironomus riparius*) and a fingernail clam (*Spaerium corneum*), although much of the BaP remained unmetabolized after 5 days following a 5-day exposure (Borchert et al., 1997). Shorter exposures of *C. riparius* to BaP in water seemed to result in faster rates of metabolism and elimination (Leversee et al., 1982). This difference could be related to an inability to reach an internal steady-state distribution of BaP in shorter exposures. Three species of polychaete worms exposed for 8 days to BaP on sediment showed different rates of metabolism, with half-lives for elimination ranging from 3.7 to 10.3 days (Driscoll and McElroy, 1996). The fraction of BaP identified as metabolites in ten small invertebrate species ranged from 7 to 96% (McElroy et al., 2000). Despite this metabolism in invertebrates, fish can still receive significant PAH exposure from the consumption of benthic invertebrates. Zebra mussels (*Dreissena polymorpha*) in the Detroit River and western Lake Erie were found to accumulate BaP to concentrations up to 8 ng/g. Freshwater drum (*Aplodinotus grunniens*) from this area had large concentrations of PAH metabolites in their bile, indicating extensive exposure to PAHs (Metcalfe et al., 1997). The stomach contents of bottom-feeding fish have been found to contain substantial concentrations of PAHs, including BaP (Maccubbin et al., 1985). The bioavailability of BaP to fish is complicated by the degree to which metabolism affects rates of BaP elimination in organisms throughout aquatic food webs and the possibility of direct exposure through ingestion of sediment.

Accumulation of PAHs in tissues within fish is further limited by biotransformation by the fish. Reports of BaP metabolism in fish trace back at least to 1972 (Lee et al., 1972). The BCF for unmetabolized BaP in bluegill sunfish (*Lepomis macrochirus*) was determined to be 490, which was about 60 times less than that predicted from the K_{ow} (Spacie et al., 1983). The BCF measured for unmetabolized BaP in gizzard shad (*Dorosoma cepedianum*) after a 3-day exposure via water was only 3.2, but preexposure to the fungicide clotrimazole, which inhibits P450 activity, increased the BCF to 35 (Levine et al., 1997), illustrating the potential for chemical interactions that might influence BaP metabolism under environmental exposure conditions. BaP is extensively metabolized in fish livers, so unmetabolized BaP is usually not detectable in liver tissue (Varanasi and Gmur, 1981). In fact, the distribution of BaP and metabolites in northern pike (*Esox lucius*) tissues, following water exposure for 8.5 days with [^{3}H]-BaP, was dominated by the disposition of metabolites, with 15, 40, and 1300 times more radioactivity in liver, kidney, and gallbladder, respectively, than in adipose tissue (Balk et al., 1984). Temperature was shown to influence both the rate of metabolism and the composition of the metabolite mixture produced by the gulf toadfish (*Opsanus beta*) (Kennedy et al., 1989). Dietary exposure of fish to BaP results in metabolism

Downloaded From Vet-eBooks.com

in the intestine, so BaP absorbed from food enters circulation with its metabolites (Van Veld et al., 1988). When bluegill sunfish during aqueous exposure to BaP were fed uncontaminated food, the rate of elimination of BaP and metabolites was ten times greater than with no food, and the rate of conversion of BaP to polar metabolites was also increased (Jimenez et al., 1987). This suggests that having food in the gastrointestinal tract, in addition to increasing elimination of BaP by partitioning to feces, facilitates the exchange of BaP from blood to the gastrointestinal mucosa where metabolism can accelerate elimination through the digestive tract.

The role of metabolism in limiting the bioavailability of BaP to fish, and thus risk to fish populations, is uncertain because this has been investigated mainly for juvenile and adult fish, not for the embryo–larval stages, which are likely more sensitive. The bioavailability of BaP to fish early life stages may be particularly critical for determination of the phototoxicity risks of PAHs such as BaP because larvae appear to be especially sensitive for such toxicity (Oris and Giesy, 1987). Some studies have indicated that BaP is more bioaccumulative in the early life stages of fish than in older stages. Comparison of BCFs for PCBs and PAHs provides an effective measure of the degree to which fish metabolize PAHs. The lipid-normalized, steady-state BCFs for BaP (measured as total [^{14}C]-BaP) and PCB 105 in zebrafish (*Brachydanio rerio*) larvae were found to be approximately equal to K_{ow}, suggesting a lack of metabolism of BaP during the 7 days of exposure (Petersen and Kristensen, 1998). Similar results were found for other PAHs tested with larvae of three other fish species; however, the retention of [^{14}C] from labeled BaP in fish embryos does not necessarily indicate the absence of metabolites, as clearance of [^{14}C]-labeled metabolites from an embryo may be slow. Exposure of trout embryos to BaP in water/DMSO resulted in retention at hatch of 60 to 80% of the initial concentration in the egg, with indications that some metabolites were being excreted (Kocan and Landolt, 1984). Confocal microscopy more recently revealed that both BaP and its metabolites remained in water-exposed medaka embryos during very early development (Hornung et al., 2005). A further complication is that PAH mixtures consist of both inducers and inhibitors of CYP1A activity, and inhibition of CYP1A in fish embryos has been observed to increase the embryotoxicity of BaP in mummichog (*Fundulus heteroclitus*) (Wassenburg and Di Guilio, 2004).

This section has examined two factors that distinguish the bioavailability of BaP from TCDD and should be considered in the assessment of the bioavailability of any hydrophobic organic chemical. First, the strength of the association of a chemical with organic carbon can deviate from simple correlations to hydrophobicity measures such as K_{ow}. This can be true for reversible adsorption to or partitioning into organic phases but is especially important for systems contaminated with combustion products, in which a portion of some chemicals might have low bioavailability due to occlusion within particles. Second, biotransformation of PAHs both within the food chain and the receptor fish can greatly reduce bioaccumulation within the fish compared to that expected in the absence of such metabolism. For hydrophobic chemicals with slow rates of elimination, even slow rates of metabolism can contribute substantially to overall elimination and thus to steady-state bioaccumulation. The impact of biotransformation will vary with the species and lifestage of the organism of concern. Both of these factors involve various components in a food web, and the resultant bioavailability to a fish must be assessed in terms of the entire web and its spatial extent.

Summary

The bioavailability of chemical contaminants to fish can vary greatly among chemicals, organisms, and exposure conditions, so it is therefore of great importance to fish toxicology and risk assessments. Although bioavailability is a conceptually simple concept—addressing the amount of chemical accumulation by an organism relative to an environmental expousure—it is often difficult to assess and apply. Bioavailability assessments must start with a clear definition of the risk situation of interest. Across what exposure conditions are bioavailability comparisons being made? What organisms and chemicals are of concern? What environmental concentrations and what concentrations within an organism are the references for defining bioavailability? What are the spatial and time frameworks? What exposure pathways should be considered? Chemical speciation is a primary focus for understanding and describing

Downloaded From Vet-eBooks.com

bioavailability. Bioavailability assessments must address the various chemical species to which an organism is exposed and how readily each of these species is absorbed into the organism. Sometimes, assessments must also address how these species are formed and reach the organism of interest and how they are processed by the organism after absorption prior to reaching a site of action. This involves consideration of a variety of processes in the organism's environment, at the interface between the organism and its environment, and within the organism. The materials presented in this chapter exemplify the issues and approaches that have to be considered when developing bioavailability assessments for specific problems, to ensure that the assessments adequately address the relationship of accumulation to environmental exposures.

Acknowledgments

We thank Drs. D. Hinton and R. Di Giulio for inviting us to prepare this overview. Review comments on an earlier version of the manuscript were provided by Drs. L. Burkhard, P. Schoff, and S. Degitz. Valuable assistance in manuscript preparation was provided by D. Spehar and R. LePage. This chapter has been reviewed in accordance with EPA policy. Mention of trade names does not indicate endorsement by the federal government.

Introduction

Fish are intimately linked to their aqueous habitat. They respire, osmoregulate, achieve acid–base balance, and obtain their thermal character in relation to the surrounding water. In addition, water serves as a common conduit for many essential life processes. Most fish eat, drink, urinate, defecate, swim, obtain sensory information, reproduce, and spatially orient within a single surrounding and contiguous medium. The structural and physiological adaptations that allow fish to thrive in an aqueous environment also strongly impact their interactions with xenobiotic substances. The solvent properties of water and its contrasting character relative to many important contaminants further shape these interactions.

Absorption, distribution, biotransformation, and excretion of xenobiotics by fish are important determinants of chemical toxicity. These processes influence whole-organism dose–response relationships by altering the effective concentration over time at a target site. The degree to which any individual process alters the concentration and activity of a toxicant depends on the character of the toxicant and attributes of the exposed organism. The role that individual organs play in each process and the molecular susceptibility of specific tissues and organs provide the basis for specific toxicities.

Most of the literature dealing with the movement of chemicals into, through, and out of living systems addresses drugs and their behavior. The term *pharmacokinetics* is used to describe the study of such movements, particularly as they vary in time. *Toxicokinetics* deals with the movement of toxicants or compounds that are present at toxic concentrations. This distinction aside, the two terms are synonymous; thus, *toxicokinetics* refers to the study of time-dependent absorption, distribution, biotransformation, and excretion of toxic substances with the goal of providing a description of the chemical concentration time course at the site of action. Most of the toxicokinetic studies published to date have been conducted using well-known mammalian laboratory species. Although they utilize many of the same basic tenets employed in these mammalian efforts, studies with fish may require customized mathematical modeling formats and experimental approaches due to structural, physiological, and lifestyle differences.

The processes of absorption, distribution, biotransformation, and excretion also determine the extent to which xenobiotics bioconcentrate and bioaccumulate in fish. *Bioconcentration* refers to the uptake and accumulation of chemicals directly from water. *Bioaccumulation* is a more inclusive term that describes chemical uptake and accumulation from all sources: water, diet, and sediments. Bioconcentration and bioaccumulation, particularly of persistent compounds, serve as indicators of past exposure for the animal; as indicators of potential exposure for higher trophic levels, including the human consumer; and as markers of potential toxicity.

This chapter examines the topic of toxicokinetics in fish by first reviewing the anatomical, physiological, and environmental determinants of chemical uptake and disposition. The goal of this chapter is to link these structural and physiological determinants with empirical data and kinetic modeling approaches that describe this composite behavior.

Basic Concepts

Fish as Wet Vertebrates

The basic requirements for life are the same for fish as other organisms. Life in water, however, presents a number of challenges to fish that are not equitably shared by most terrestrial animals. Water has a high specific heat capacity, which makes it impossible for all but the largest fish to maintain internal temperatures different from those of the immediate surroundings. Compared with air, water contains low levels of dissolved gases. The solubilities of physiologically important gases in water also differ. These facts necessitate both specialized gas-exchange surfaces and a different approach to acid–base balance. The viscosity of water requires that fish employ specialized approaches to locomotion and expend considerable energy to support respiration. A number of the adaptive physiological and structural modifications that these challenges elicit either directly or indirectly influence xenobiotic toxicokinetics. As an example, poikilothermy influences membrane structure and function, enzymatic isozyme profiles, cardiac output, bile flow rate, and the intestinal passage rate.

Although the mechanisms available to fish for homeostasis are similar to those of other vertebrates, the ways that they are used may or may not be the same. This is important to keep in mind when comparing the kinetics of xenobiotics between fish and mammals, among fishes of diverse groups, and even among individuals of the same species held under different environmental conditions. Table 3.1 lists some generalized structural and functional differences between fish and mammals (Cunningham, 1997; Evans, 1993; Ruckesbusch et al., 1991). It will become clear through the course of this chapter that many of these differences influence xenobiotic absorption, distribution, and elimination in fishes.

Uptake of xenobiotics by fish may occur by inhalation, ingestion, or dermal exposure, as is the case for their mammalian counterparts (Figure 3.1). Likewise, the excretion of xenobiotics by fish and mammals occurs by diffusion or transport across respiratory and skin surfaces, as well as by urinary, biliary, and fecal routes. Even with these commonalities, there are some obvious and not so obvious differences between fish and mammals with regard to the nature of these pathways, the relative importance of each pathway, and xenobiotic movements at the exchange surfaces that separate the animal from its environment.

Two of the more obvious differences between fish and mammals are that fish live in water and respire using gills. The fact that the surrounding medium is water rather than air strongly influences the nature of chemicals delivered to and eliminated at the gills. The mammalian lung, for example, is exposed primarily to volatile chemicals and chemicals associated with or existing as particulates. In contrast, the gill is commonly exposed to water-soluble chemicals, as well as nonpolar compounds adsorbed to dissolved and particulate organic matter. Branchial uptake requires diffusion across the gill membranes, which possess a hydrophobic core. For nonpolar compounds bound to organic matter in water, uptake requires first that they dissociate from the organic material and traverse a polar water and mucus interface before diffusing across a compatible hydrophobic membrane. The same phase transitions exist for chemical excretion across the gills. In general, the gills play a much greater role in the absorption and excretion of xenobiotics by fish than the lung plays in mammals.

The skin of mammals is dry, dead, and keratinized and does not possess a circulatory component. When present, fur may further limit dermal uptake of xenobiotics in mammals. In contrast, the skin of fishes is a living epidermis that is perfused by an underlying secondary circulation. In very small fish or benthic species that are in constant contact with contaminated sediment, the skin becomes an important exchange surface for xenobiotic compounds. The solvent fluid nature of water, combined with the foregoing considerations, suggests that this route of exposure is more important for these fish than for most mammals.

TABLE 3.1

Generalized Structural, Functional, and Environmental Differences between Fish and Mammals

Characteristic	Fish	Mammals
Media		
Surrounding media	Water	Air
Specific heat	High	Low
Solvent properties	Universal solvent	Nonsolvent
Dissolved gases	Low levels	High levels
Viscosity	High	Low
Temperature		
Modality	Poilkilotherms	Homeotherms
Metabolic rate	Slow	Fast
Primary energy currency	Amino acids and lipid	Carbohydrates
Feed/weight conversion	Very efficient	Less efficient
Membrane composition	Homeoviscous adaptation	No adaptation necessary
Body temperature regulation	Behavioral	Internal setpoint
Respiratory surface		
Primary organ	Gill	Lung
Blood/gas flows	Counter-current	Directional/tidal flow
Gas exchange	Yes	Yes
Acid–base balance	Yes	Yes
Nitrogen excretion	Yes	No
Osmoregulation	Yes	No
Primary driver of respiration	Low oxygen	High carbon dioxide
Acid–base balance		
Primary organ	Gill	Lung and kidney
Primary mechanism	Ion based	Gas (lung) and ion (kidney) based
Nitrogenous waste elimination		
Primary organ	Gill	Kidney
Primary form	Ammonia	Urea
Circulation		
Heart	Two chambers	Four chambers
Arrangement	Heart and gill in series	Heart and lung in parallel
Vessels	Arteries and veins less distinct	Distinct arteries and veins

The gastrointestinal tract plays an important role in the absorption of xenobiotics in both fish and mammals. The structure and function of the gastrointestinal tract in both taxa are similar in many respects. In fish, however, the absence of a lymphatic system and lack of classical mammalian villi may substantially influence the absorptive process. The feces represent an important route of elimination in fish, both as a purveyor of bile and as a matrix with affinity for exsorbed compounds. Although bile formation is slow in fishes relative to mammals, many xenobiotic compounds are readily excreted in bile.

In most cases, urinary elimination of xenobiotics is less important in fish than it is for mammals. This is due in part to the contribution of the gills to chemical elimination and to the modified role of the kidneys in comparison with mammals. In other cases, however, the urine may represent the primary route of elimination. Urinary elimination is particularly important for ionic compounds that act as substrates for active transport systems within the renal tubular epithelium.

The Environment

Large differences often exist among environmental toxicant concentrations, the concentration in the systemic circulation of the fish, and the concentration involved in specific target organ toxicity. The basis for these differences resides with both environmental factors and factors associated with the fish. The amount of chemical released to the environment, its movement among compartments (e.g., air, water, sediment), and susceptibility to transformation are primary determinants of toxicant exposure to the

TABLE 3.1 (cont.)

Generalized Structural, Functional, and Environmental Differences between Fish and Mammals

Characteristic	Fish	Mammals
Lymphatics	No	Yes
Secondary circulation	Yes	No
Blood pressure and flow	Low	High
Red blood cells	Nucleated	Non-nucleated
Plasma proteins	Lower levels	Higher levels
Blood pH	Higher that mammals	Lower than fish
Kidney		
Nephron	Less complex. SW—no distal tubule; aglomerular. FW, SW—modified loop of Henle	More complex, including glomerulus, distal tubule and loop of Henle
Blood supply	Renal artery and renal portal	Renal artery
Hematopoiesis	Many fishes	NA
Waste excretion	Minor site	Primary site
Fluid balance	Primary site	Primary site
Ion balance	Secondary site	Primary site
Acid–base balance	Secondary site	Primary site
Liver		
Functional unit	Tubule, with no triads or zonal relationships	Lobule, with triads and zonal arrangement
Gallbladder	May or may not be present	May or may not be present
Bile flow	Slower than mammals	Faster than fish
Biotransformation rates	Slower than mammals	Faster than fish
Gastrointestinal tract		
Structural divisions	Gradual transitions	Clear delineations
Gastric stomach	Absent in 15% of species	Present
Absorptive surface	Longitudinal folds	Villi
Lipid absorption	Primarily into blood	Size dependent into lymph
Change in temperature	Change in length/morphology	NA
Skin		
Epidermis	Living, moist	Dead, dry, keritinized
Mucous	Present	Absent

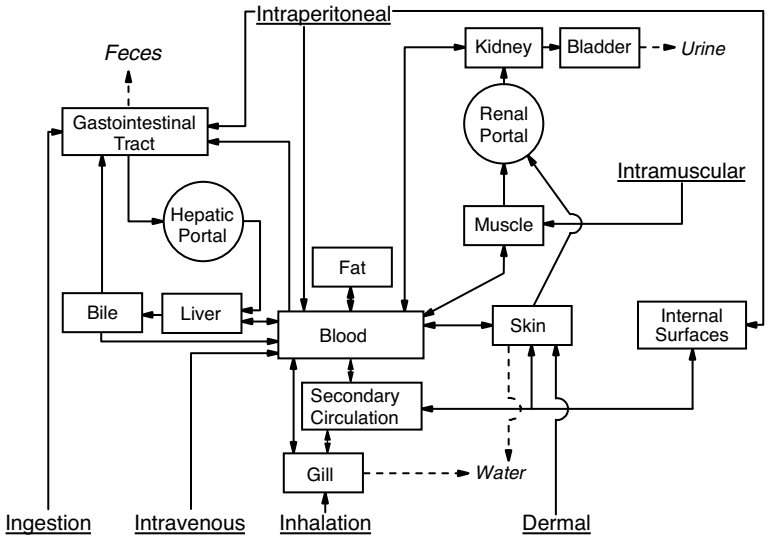

FIGURE 3.1 Pathways for absorption, distribution, and elimination of xenobiotic compounds in fish.

exchange surfaces of fish. Conceptually similar processes operate within the fish, modulating exposure to the sites of toxicity.

Water dissolves more substances and dissolves them more completely than any other liquid; nevertheless, some nonpolar substances are relatively insoluble in water. This solubility or insolubility is a primary determinant of the distribution and availability of contaminants to aquatic organisms. In general, polar compounds that are nonvolatile will remain freely dissolved in the water column. Alternatively, if the compound is nonpolar and nonvolatile, it will partition to organic matrices in the water, reducing the amount that is freely dissolved. In doing so, these chemicals may exhibit an apportioning equilibrium that reflects their relative polarity. These characteristics influence not only toxicant availability to the fish but also the primary routes of uptake.

Water in natural systems is a composite of H_2O and the materials dissolved and suspended in it. Because these materials influence the complexation, binding, precipitation, and chemical form of many compounds, water cannot be viewed as a uniform or generic medium. Water quality as it relates to aquatic toxicology includes both biotic and abiotic components. Living organisms and organically derived substances contribute to the biotic character of water. Abiotic factors include pH, hardness, alkalinity, salinity, dissolved solids, and temperature. Collectively, water quality can influence the chemical form, availability, and ultimately toxicity of chemicals in the aquatic environment. Often the influence of water quality on toxicity is a collective action, with each characteristic exerting independent as well as interdependent effects. A comprehensive discussion of chemical bioavailability, focusing on environmental processes that control chemical uptake and accumulation by fish, is presented in Chapter 2.

Membranes and Xenobiotic Movement

Xenobiotic absorption, distribution, and elimination are dependent on transport across one or more biological membranes. All known cellular membranes are composed of lipid bilayers arranged with hydrophilic polar regions facing the outer surfaces and hydrophobic regions oriented toward the interior. On either surface or traversing the entire width of the membrane are globular proteins. Hydrophobic and electrostatic molecular interactions, along with the cytoskeleton, maintain the association of components, regionalization, and structural integrity of the membrane. Throughout the fish, and even within each cell, membranes may possess different morphological and biochemical attributes (Crockett and Hazel, 1995; Schulthess and Hauser, 1995). External influences such as diet and temperature may also alter membrane composition and character (Crockett and Hazel, 1995). Specific membranes may contribute to the characteristic disposition of xenobiotics according to their particular properties. All membranes, however, exhibit a basic structural similarity, which provides an operative model for their interaction with xenobiotic chemicals.

Diffusion

A primary pathway for xenobiotic transport across lipid membranes is by passive diffusion. Moderately nonpolar, lipid-soluble compounds diffuse easily across biological membranes. Polar and very nonpolar compounds diffuse across membranes less easily, although for different reasons. Polar compounds have limited access to the nonpolar portion of membranes, due to their low lipid solubility. In contrast, evidence suggests that very nonpolar compounds may be sequestered by membranes, limiting their movement. The net result of these interactions is that chemical transport from the external environment into plasma, interstitial fluid, intracellular fluid, and even into cell organelles is dictated by the ability of the compound to diffuse across membranes.

In general, the rate of diffusion across a membrane is directly proportional to the membrane–water partition coefficient of a chemical (assuming that the membrane is bathed on both sides by an aqueous medium), as well as its diffusion coefficient (for diffusion within the membrane) and the concentration gradient (Hunn and Allen, 1974; Spacie and Hamelink, 1982). The diffusion coefficient is a function of molecular size, conformation, and the presence or absence of particular functional groups. Specific to each membrane is a molecular weight or size discrimination profile, and the passive diffusion of large molecules may be prevented altogether. The membrane–water partition coefficient is a measure of the

Downloaded From Vet-eBooks.com

relative solubility of the compound in the membrane and water. This coefficient may be difficult to measure. Lipid–water partitioning is often used, therefore, as a surrogate for membrane–water partitioning. The relationship of these factors can be summarized using Fick's law of diffusion:

$$\text{Flux} = \left(DP_{mw}/h\right)\left(C_1 - C_2\right) \tag{3.1}$$

where D is the diffusion coefficient (cm^2/sec), P_{mw} is the membrane–water partition coefficient (unitless), h is the thickness of the diffusion path or membrane (cm), and C_1 and C_2 are toxicant concentrations on each side of the membrane (mg/cm^3). When collected together, D, P_{mw}, and h define a permeability coefficient with units of cm/sec. For a unit area membrane, the rate of toxicant transfer across the membrane (flux) has units of mg/sec/cm^2. Multiplication by the membrane surface area provides a measure of total flux with units of mg/sec.

Flux that is directly proportional to the concentration gradient ($[C_1 - C_2]/h$) is first order and linear and progresses by a fractional rate constant. Numerous factors may influence the concentration of chemical available for diffusion, including external and internal pH partitioning phenomena, binding to organic material in water, and plasma protein binding. Composite fractional rate constants take these features into account for a given compound.

Empirical evidence suggests that non-ionized compounds diffuse more readily across membranes than ionized forms. These observations have important implications for membrane flux of weak organic acids and bases. If the non-ionized moiety has a lipid–water partition coefficient that favors membrane penetration, it will tend to reach an equilibrium concentration on both sides of the membrane, while the ionized form may be much more limited in its movements. As an approximation, therefore, the equilibrium concentration across the membrane will be based on the concentration of the non-ionized or lipophilic form, with Fick's law of diffusion applying only to this non-ionized form. The ratio of the two ionization states is dependent on the dissociation constant (pK_a) of the compound and the pH of the surrounding media. This relationship is described by the Henderson–Hasselbach equation:

$$\textit{For weak organic acids:}\ \text{pH} = pK_a + \log\ (\text{ionized/non-ionized}) \tag{3.2}$$

$$\textit{For weak organic bases:}\ \text{pH} = pK_a + \log\ (\text{non-ionized/ionized}) \tag{3.3}$$

For a weak organic acid, a decrease of one pH unit results in a tenfold increase in the concentration of the non-ionized form. Conversely, an increase of one pH unit results in a tenfold increase in the concentration of the ionized form. Weak organic bases behave in the opposite manner; for example, a weak organic acid (pK_a of 7) in moderately acidic water (pH of 5) would exist in a non-ionized/ionized ratio of 100/1. For a weak organic base, the ratio would be 1/100. The effect of pH on the non-ionized/ionized ratio can be extreme; thus, a pH change from 5 to 1 would change the non-ionized/ionized ratio of a pK_a 7 organic acid from 100/1 to 1,000,000/1.

Differences in pH across biological membranes will cause the degree of ionization to differ on either side of the membrane. The side with the greatest degree of ionization may have a much higher total xenobiotic concentration because the equilibrium distribution of chemical is based on concentrations of the diffusing non-ionized form (Figure 3.2). This phenomenon is referred to as *ion trapping*. The theoretical equilibrium concentration ratio (R_{xy}) of a xenobiotic across a membrane with two sides, x and y, can be calculated as follows:

$$\textit{For weak organic acids :}\ R_{xy} = \frac{1 + \text{anti}\log\left(pH_x - pK_a\right)}{1 + \text{anti}\log\left(pH_y - pK_a\right)} \tag{3.4}$$

$$\textit{For weak organic bases :}\ R_{xy} = \frac{1 + \text{anti}\log\left(pK_a - pH_x\right)}{1 + \text{anti}\log\left(pK_a - pH_y\right)} \tag{3.5}$$

With respect to these relationships, fish present a number of interesting nuances that are not typically encountered in mammals. While ion trapping in mammals is generally limited to internal membranes

Downloaded From Vet-eBooks.com

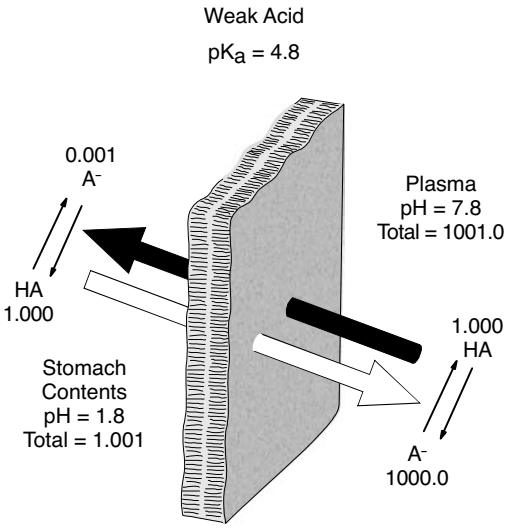

FIGURE 3.2 Distribution of a weak organic acid (pK_a = 4.8) on either side of a membrane separating the plasma and stomach contents, illustrating the concept of ion trapping as a result of pH differences. HA is the non-ionized form of a xenobiotic which can easily diffuse across the membrane; A^- is the ionized form with restricted diffusion. Numerical values represent the relative abundance of each form predicted by the Henderson–Hasselbach equation using compartment pH and the xenobiotic pK_a.

(e.g., blood to gastrointestinal tract, blood to milk, blood to urine), ion trapping in fish may occur across external surfaces such as the gills and skin (blood to water). The range of environmental pH values that will support fish populations is about 5 to 10. For a given compound, therefore, chemical flux across the gills and skin may occur rapidly or very slowly, depending on the ambient pH. Physiological differences between fish and mammals also exist. Most fish species have blood pH values that range from 7.7 to 8.0. For most mammals, the blood pH is approximately 7.4. In addition, nearly 15% of all fish species do not possess an acid-secreting stomach (Grondel et al., 1987). Finally, the pK_a for a particular compound or functional group will vary somewhat with temperature. Because fish are poikilotherms, changes in chemical dissociation may occur as they encounter different temperature environments.

Specialized Membrane Transport

Although simple diffusion controls many aspects of xenobiotic disposition, there are, in addition, specialized membrane transport systems that control chemical movements in specific cells and tissues. The specificity of these systems may be broadly based or extremely narrow. An example of the former is provided by systems that generically transport charged molecules, while the latter would include transporters responsible for nutrient and mineral uptake. Many of these carrier-mediated processes may contribute to membrane transport of xenobiotic compounds.

Compounds that are lipophilic and remain so throughout their residence in the body tend to be retained for extended periods of time. Processes such as glomerular filtration, passive tubular diffusion, and biliary excretion contribute to their elimination; however, the amount of compound associated with the aqueous phase of tissues, blood, and excretory products may be a small fraction of the total contained within the animal. Biotransformation accelerates the elimination of many lipophilic compounds by the converting them to more polar metabolites. Some of these metabolites retain enough lipid solubility to diffuse across membranes while exhibiting enough polarity to partition into aqueous phases. Other metabolites, including conjugated products of phase II metabolic pathways, are highly polar and do not diffuse as readily as theh parent compound across biological membranes. Membrane transporters play an important role in the elimination of these compounds.

Because the total number of enzyme molecules and membrane transporters contained within a tissue is finite, the kinetics of these systems is often saturable or capacity limited. The result is that somewhere

Downloaded From Vet-eBooks.com

along the substrate concentration continuum competition for reaction sites results in a maximal rate of metabolism or transport. Under these conditions, the rate of metabolism or transport becomes independent of substrate concentration and is said to exhibit zero-order kinetics. Saturation of capacity-limited systems can result in profound effects on xenobiotic distribution and disposition.

Carrier-Mediated Transport

Carrier-mediated membrane transport occurs by rapidly reversible interactions between components of the membrane and the transported substance. These carriers generally exhibit selectivity for chemicals that possess specific characteristics; however, multiple chemicals possessing these characteristics may compete for the carrier. Saturability and competitive inhibition are characteristic of carrier-mediated transport. Active transport is a transmembrane carrier-mediated process that requires the direct expenditure of energy. The biological energy source may exist in several forms, including the nucleoside adenosine triphosphate (ATP) or as a transmembrane ion gradient. Of the latter, sodium gradients are most common. Active transport mechanisms are widely found in aquatic species and support a variety of physiological processes; for example, amino acids and carbohydrates are actively absorbed in the intestine of fish using a coupled sodium gradient (Ash, 1985; Jobling, 1995). Documentation of xenobiotic transport by such systems is increasing. Transporters with structural and functional similarities to multidrug resistance-associated proteins (Mrps), P-glycoprotein (Pgp), and organic anion transporter polypeptides (Oatps) have been identified in fish (Ballatori et al., 1999; Curtis et al., 2000; Doi et al., 2001; Hemmer et al., 1995; Kleinow et al., 2000; Masereeuw et al., 1999, 2000; Miller, 1995; Rebbeor et al., 2000). These carriers may transport xenobiotics in the canaliculi of the liver, the mucosa of the intestine, and the proximal tubule of the kidney. Additional carrier proteins have been associated with the movement of metals in fish such as silver across the gill (Bury et al., 1999) and iron transport across the yolk sac to the circulation (Donovan et al., 2000). Facilitated diffusion is a carrier-mediated process that does not require energy. Movement of the transported compound may occur in either direction across the membrane but the net movement follows the downhill electrochemical gradient much like passive diffusion. Unlike passive diffusion, however, facilitated diffusion may be capacity limited because the number of carriers is limited.

Pinocytosis

Pinocytosis is a process whereby the cell membrane invaginates, capturing external material within the lumen of a vesicle. The vesicle may empty its contents within the cell or fuse with another portion of the cell membrane, releasing its contents to the intercellular space. Uptake of macromolecular proteins by pinocytosis is well documented in the fish intestine (Rombout et al., 1985; Stroband and Kroon, 1981; Stroband et al., 1979). It is likely that transport of particulate or proteinaceous toxicants in fish occurs by this process, but verification is required.

Paracellular Pathway

Evidence in mammals suggests that tight junctions between neighboring cells are permeable to water, inorganic cations, and to a limited extent xenobiotics (Hoensch and Schwenk, 1984). The degree to which xenobiotics move by diffusion along these pathways is currently unknown for fishes.

Absorption, Distribution, and Excretion

Xenobiotic Absorption

Xenobiotics are absorbed by fish across the gills, skin, and gut. In terms of gross morphology, these structures differ greatly from one another. All three, however, possess two basic features that contribute to their role as chemical exchange surfaces: (1) large surface area, and (2) separation of the environment, or extension thereof, from the circulatory system by a membrane consisting of one, two, or a few cell layers. The path that a chemical takes when it is absorbed at one of these surfaces can be generally

Downloaded from Wet-Books.com

described as follows: (1) presentation to the absorbing epithelium in water or gut contents; (2) transport across the epithelium into blood; (3) incorporation into blood, including binding to plasma proteins; (4) transport via the systemic circulation of freely dissolved and plasma-bound chemical to various tissues; and (5) transport from blood into tissues. The character of the external medium may substantially determine which forms of a compound are presented to these exchange surfaces, thereby influencing the overall rate of uptake. The external medium may also impact uptake through its effects on the structure and function of the membrane itself. From mass-balance considerations, the rate of uptake cannot exceed the rate at which chemical is presented to the exchange surface. Rates of diffusion across the membrane barrier and removal by the circulatory system also have the potential to limit the overall rate of chemical uptake.

The Gills

Branchial Structure and Function

The anatomy of fish gills reflects their primary function as a gas-exchange, osmoregulatory, and excretory organ (Figure 3.3). Gill ventilation is accomplished using a two-phase pump system (Figure 3.3A). The first phase involves suction generated by opening the opercular flaps that cover the posterior portion of the branchial cavity. This draws water through the mouth into the buccal cavity. The second phase utilizes pressure, generated by the contraction of muscles lining the buccal cavity, to force water from the buccal cavity through the gill arches into the opercular cavity. During the pressure phase of the respiratory cycle, the oral valve prohibits water flow out of the mouth and directs water over the respiratory surface.

The respiratory surface, where branchial uptake of oxygen occurs, is composed of eight gill arches, four on each side of the branchial cavity. Each gill arch has two rows of gill filaments, and each filament is covered, top and bottom, with gas-exchange units called *secondary lamellae* (Figure 3.3B). The lamellae are thin-walled, sac-like structures composed of two epithelial cell layers held together by numerous pillar cells (Figure 3.3C). These pillar cells create a blood space between the two epithelial layers. Oxygen-depleted venous blood flows through the lamellae, while oxygen-rich inspired water flows between the lamellae. In most species, blood and water flow in opposite directions, creating an efficient counter-current system for gas exchange. Oxygen that diffuses across the lamellar epithelium binds to hemoglobin and is transported by blood to the tissues where it is utilized. Diffusion of oxygen from the blood into tissues occurs at a rate dependent on the concentration gradient between the blood and individual cells of the tissues. A general model for gas transfer in teleosts is presented in Figure 3.3D.

Emphasis in this chapter is placed on those aspects of normal gill function that control branchial uptake of xenobiotic compounds. For further information on respiratory function in teleosts, the reader is referred to pertinent reviews (Perry and McDonald, 1993; Piiper and Scheid, 1984; Randall and Daxboeck, 1984). For detailed discussions of gill anatomy, see Hughes (1984) and Laurent (1984). Additional reviews cover osmotic, ionic, and acid–base regulation (Evans, 1993; Heisler, 1993; McDonald, 1983) and excretory function (Wood, 1993).

Branchial Absorption of Xenobiotics

The anatomical and physiological features of fish gills that promote efficient exchange of respiratory gases also contribute to uptake of xenobiotic compounds directly from water—namely, a thin membrane separating blood and water, large surface area, and high rates of counter-current blood (perfusion) and water (ventilation) flow. Direct measurements of chemical uptake across fish gills have been obtained using fish respirometer-metabolism chambers, which separate inspired and expired water flows (McKim and Goeden, 1982; McKim and Heath, 1983). Using this model system, McKim et al. (1985) measured branchial uptake rates in adult rainbow trout (*Oncorhynchus mykiss*) for a heterogeneous group of organic chemicals. These measurements suggested a consistent relationship between the uptake rate of a chemical and its relative hydrophobicity, as indicated by the log of its octanol–water partition coefficient (log K_{ow}; Figure 3.4A). Rate constants measured in subsequent studies with rainbow trout (Bradbury et al., 1986; McKim et al., 1986, 1987a,b) further substantiated this relationship. Uptake rates were low for chemicals with log K_{ow} values less than 1, increased about fourfold between log K_{ow} 1 and 3, leveled off between log K_{ow} 3 and 6, and declined when log K_{ow} exceeded 6. Working with a series of phenols, anisoles, and

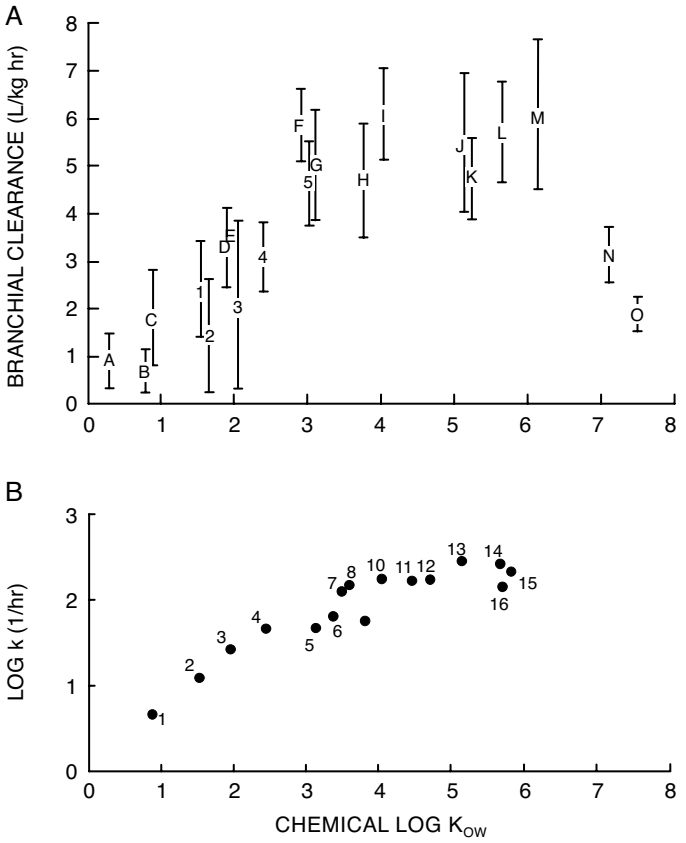

FIGURE 3.4 Relationship between the branchial uptake of chemicals by rainbow trout and guppies, and chemical hydrophobicity expressed as the log of the octanol–water partitioning coefficient. The uptake rate for rainbow trout is expressed as a clearance constant; that for guppies is given as the log of the uptake rate constant from water when pH < chemical pK_a. (A) *Rainbow trout sublethal exposures:* A, ethyl formate; B, ethyl acetate; C, 1-butanol; D, nitrobenzene; E, *p*-cresol; F, chlorobenzene; G, 2,4-dichlorophenol; H, 2,4,5-trichlorophenol; I, 1-decanol; J, 1-dodecanol; K, pentachlorophenol; L, hexachlorobenzene; M, 2,2′,5,5′-tetrachlorobiphenyl; N, dinitrophenol; O, mirex. *Rainbow trout lethal exposures:* 1, benzaldehyde; 2, 2,4-dinitrophenol; 3, MS-222; 4, malathion; 5, 1-octanol. (Data from Erickson and McKim, 1990a.) (B) *Guppy sublethal exposures:* 1, butyric acid; 2, phenol; 3, benzoic acid; 4, 4-phenylbutyric acid; 5, 2,4-dichlorophenol; 6, 2-sec butyl-4,6-dinitrophenol; 7, 3,4,-dichlorobenzoic acid; 8, 2,6-dibromo-4-nitrophenol; 9, 2,4,5-trichlorophenol; 10, 2,4,6-trichlorophenol; 11, 2,3,4,6-tetrachlorophenol; 12, tetrachloroverathrol; 13, pentachlorophenol; 14, pentachloroanisol; 15, 2,4,6-trichloro-5-phenylphenol; 16, DDT. (Adapted from Saarikoski, J. et al., *Ecotoxicol. Environ. Saf.*, 11, 158–173, 1986.)

carboxylic acids, Saarikoski et al. (1986) found a similar relationship between absorption rate and log K_{ow} in the guppy (*Poecilia reticulata*) (Figure 3.4B). Additional studies with a homologous series of chlorinated ethanes in the channel catfish (*Ictalurus punctatus*) (McKim et al., 1994), fathead minnow (*Pimephales promelas*) (Lien et al., 1994), and lake trout (*Salvelinus namaycush*) (McKim et al., 1999a) have extended these observations to other species.

Several physiological and chemical factors may account for these trends in gill uptake with chemical hydrophobicity. Gobas et al. (1986) proposed that branchial uptake was regulated by chemical partitioning into lipid phases and diffusion through lipid membranes and associated aqueous layers. Both McKim et al. (1985) and Saarikoski et al. (1986) attributed increases in absorption between log K_{ow} 1 and 3 to greater membrane permeability for the more lipophilic compounds. Opperhuizen et al. (1985) suggested that gill membranes inhibit the uptake of lipophilic compounds that exceed a critical molecular volume. Other researchers, noting a downward trend in bioconcentration factors (BCFs; defined as the ratio of the chemical concentration in the fish to that in water) for compounds with log K_{ow} values greater than

Downloaded From Vet-eBooks.com

6, proposed that structural attributes of these compounds limit branchial uptake (Bruggeman et al., 1984; Konemann and Van Leeuwen, 1980; Sugiura et al., 1978; Tulp and Hutzinger, 1978; Zitko, 1974; Zitko and Hutzinger, 1978). Alternatively, because uptake of these compounds is extremely slow, steady-state concentrations may not have been achieved in these studies, leaving the false impression of a downward deflection in BCF. Branchial uptake of highly lipophilic compounds may also be limited by binding to dissolved organic matter in the water, thereby reducing the concentration of the free or bioavailable form of the compound. Ionized organic compounds exhibit limited ability to cross the gill membranes and must be dealt with as a special group.

Water and blood flows through the gills maintain xenobiotic diffusion gradients across the gill epithelium. Norstrom et al. (1976), Neely (1979), and Bruggeman et al. (1981) suggested that branchial uptake may be correlated to the rate of water flow across the gills and thus to respiration rate. Gobas and MacKay (1987) considered multiple diffusion and flow steps to be part of the branchial exchange process. Barber et al. (1988) presented a hydrodynamic-based model for chemical bioconcentration in fish that incorporates effects of advection and diffusion in water flowing through the gills. Hayton and Barron (1990) suggested that blood flow, water flow, and diffusional barriers all have the potential to influence branchial flux, and they proposed a model based on the concept of serial resistance. Erickson and McKim (1990a,b) developed a counter-current model of branchial flux for non-ionized compounds that includes both flow and diffusion limitations, as well as chemical binding to dissolved organic material. Detailed descriptions of both models are given later in this chapter.

Physiological Impacts on Branchial Absorption

Gill ventilation and blood perfusion rates vary with activity level, temperature, and environmental oxygen tension (Barron et al., 1987a; Hughes, 1984; Randall and Daxboeck, 1984). Differences in environmental conditions and activity level also impact the toxicity and bioconcentration of chemicals in fish. We now understand that these observations are linked; changes in environment and activity increase or decrease branchial absorption of xenobiotics by impacting the rate-limiting processes that control this uptake.

Dissolved Oxygen—Four decades ago, Lloyd (1961) observed increases in the toxicity of several chemicals to rainbow trout as ambient oxygen concentrations were reduced from 100% to 30% of saturation. He suggested that the increase in toxicity was caused by an increase in ventilation volume that occurred at reduced oxygen concentrations, resulting in a larger quantity of chemical being brought in close contact with the gills. Lloyd's (1961) observations were supported by those of McKim and Goeden (1982), who measured changes in branchial uptake of endrin (log K_{ow} 5.02) in response to a stepwise decrease in afferent water oxygen concentration. Initial oxygen and endrin extraction efficiencies were nearly constant at oxygen saturation values of 100% and 80% but dropped progressively at oxygen saturation values of 50% and 30% (Figure 3.5A). Apparently, endrin extraction efficiency was maintained in the face of moderate increases in ventilation volume because diffusion was fast enough to clear lamellar channels of most of the chemical (i.e., there was no change in physiological dead space; see Hughes, 1984), or because the number of blood-perfused gill lamellae increased (Randall and Daxboeck, 1984). Observed declines in extraction efficiency may have been due to an increase in ventilatory stroke volume, resulting in greater bypass of water around the lamellar channels (i.e., increased anatomical deadspace), or an increase in physiological deadspace associated with increased water velocities. Because ventilation volume increased more than extraction efficiency decreased, total endrin uptake rate at 50% of oxygen saturation was about double that at 100% (Figure 3.5B). The additional decrease in oxygen saturation from 50% to 30% did not result in higher endrin uptake rates.

Opperhuizen and Schrap (1987) examined the impact of aqueous oxygen concentration on uptake of two polychlorinated biphenyl (PCB) congeners by guppies. Over the range of oxygen concentrations tested (60%, 40%, and 25% of saturation) they saw no differences in uptake of either chemical and suggested that a drop in chemical extraction efficiency occurred as ventilation volume increased in response to lower oxygen saturations. Based on these observations, the authors concluded that diffusional constraints have more impact on total chemical flux at the gill than changes in water flow. The results of McKim and Goeden (1982) suggest that this conclusion does not apply at higher oxygen concentrations (>60% of saturation), where uptake appears to be related to ventilation volume, at least for some fish.

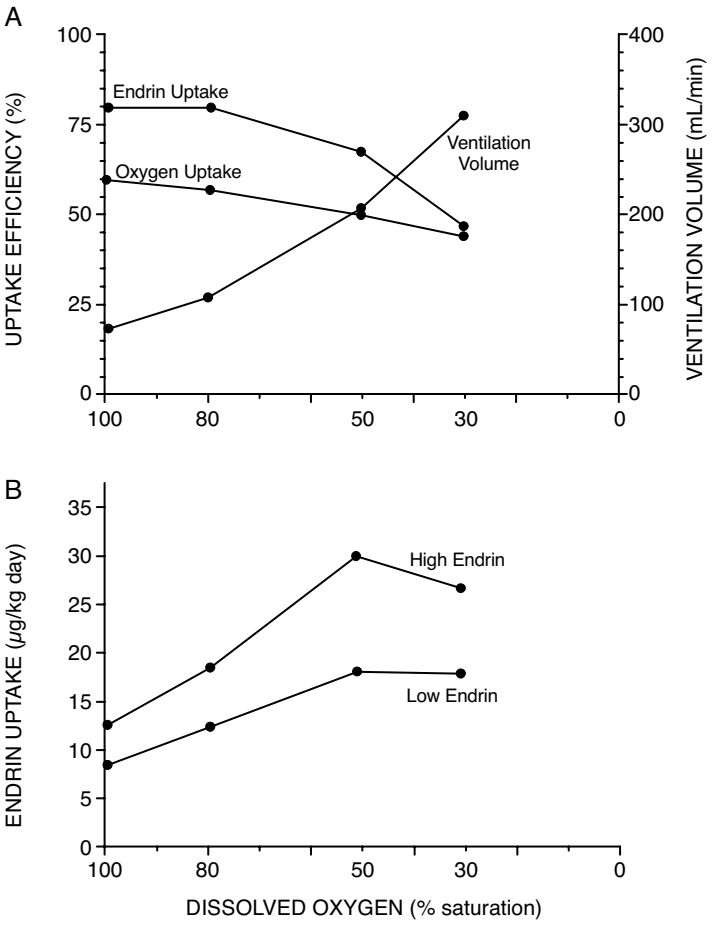

FIGURE 3.5 Effect of dissolved oxygen concentration on branchial uptake of endrin by brook trout. (A) Changes in ventilation volume, oxygen uptake efficiency, and endrin uptake efficiency. (B) Changes in endrin uptake rate at high (0.072 mg/L) and low (0.046 mg/L) waterborne concentrations. (Adapted from McKim, J.M. and Goeden, H.M., *Comp. Biochem. Physiol*., 72C, 65–74., 1982.)

Complicating these comparisons, however, is the issue of fish size. For small fish, such as the guppy, dermal absorption may account for up to 50% of total uptake of waterborne chemicals with high log K_{ow} values (Lien and McKim, 1993). Assuming that skin perfusion as a fraction of cardiac output remains constant, chemical absorption across the skin would change very little with a decrease in the oxygen content of water, reducing the overall effect of any change in oxygen content on total chemical uptake.

Temperature—Environmental temperature changes can cause dramatic changes in the metabolic rates of poikilothermic animals (Prosser, 1973), which affects their demand for oxygen. An increase in oxygen demand due to increased temperature is especially problematic because the solubility of oxygen in water is inversely related to temperature. To obtain more or less oxygen, a fish in most cases adjusts its ventilation volume and the number of perfused lamellae in contact with respiratory water (Randall, 1982). This suggests that, if chemical uptake was controlled by water flow across the gills, an increase in temperature would increase branchial uptake rate in a manner qualitatively similar to that of a decrease in oxygen content. Changes in temperature also affect cardiac output and could potentially impact branchial absorption if blood flow to the gills was a limiting factor. Several authors have investigated the relationship between chemical uptake and oxygen consumption at different water temperatures. Using rainbow trout, Rodgers and Beamish (1981) reported that branchial uptake of methylmercury was

Downloaded From Vet-eBooks.com

positively correlated with that of oxygen at two temperatures (10 and 20°C) and two levels of forced swimming. There was no indication of change in uptake efficiency for either methylmercury or oxygen. Similarly, Murphy and Murphy (1971) demonstrated a positive correlation between oxygen consumption and uptake of waterborne dichlorodiphenyltrichloroethane (DDT) by the mosquito fish (*Gambusia affinis*) at 5 and 20°C. The ratio of DDT uptake rate to fish weight was proportional to the ratio of oxygen consumption to fish weight at each of the two temperatures. The authors concluded that the uptake of DDT across the gills was influenced by changes in respiratory volume. Black et al. (1991) found that the branchial uptake of three moderately hydrophobic compounds—benzo(*a*)pyrene, 2,2′,5,5′-tetrachlorobiphenyl, and naphthalene—changed in direct proportion to oxygen consumption when rainbow trout were subjected to an acute reduction in temperature from 17°C to 8°C (Figure 3.6A). The decrease in oxygen consumption was accompanied by reductions in ventilation volume and ventilation rate (Figure 3.6B). Finally, it is well known that chemical diffusion rates in solution increase with temperature. Similar changes are expected to occur in biological membranes and would be important if diffusion across the gill epithelium limited the rate of branchial flux. Fish may also respond to prolonged changes in temperature by altering the molecular structure of the gill epithelium, changing its permeability to xenobiotic compounds.

The Gastrointestinal Tract

Gastrointestinal Tract Structure and Function

The gastrointestinal tract (GIT) of fishes functions in digestion, nutrient absorption, and excretion and as a barrier to the external environment. For some groups of fishes, the GIT also plays a role in osmoregulation, buoyancy, ion regulation, and placental nutrition. Diverse structural adaptations in different fish species reflect a wide array of digestive strategies. Gross differences among species include the presence or absence of an acid-secreting stomach, presence or absence of a gizzard, large differences in GIT length, and an absence or varying number of blind diverticula called *pyloric ceca* that project from the intestine near the pylorus of the stomach. Detailed reviews of fish GIT structure and function are provided elsewhere (Kapoor et al., 1975; Kleinow and James, 2001; Smith, 1989).

Common to most species, the buccal cavity is followed by a short and distensible esophagus; some type of stomach; proximal, middle, and distal intestine; and finally a rectal region. Along its length, the GIT changes histologically. Major features of the esophagus include numerous goblet cells, which provide lubrication, and primary, secondary, and tertiary folds, which allow distension during the ingestion and swallowing of food. A true stomach, when present, often contains cardiac glands that extend between the lamina propria and columnar epithelial cells lining the stomach lumen.

The structure of the intestine, including its diameter and the abundance of goblet cells and longitudinal folds, varies along its length. Villi and crypt regions, as classically defined in the mammalian intestine, are not evident in many fishes but are replaced by the longitudinal folds which exhibit varying degrees of branching (Field et al., 1978; Kapoor et al., 1975). As with mammals, the intestinal lumen of most fishes is lined by a simple columnar epithelium that possesses a brush border. Pyloric ceca are lined with columnar absorptive cells and are histologically similar to the adjacent intestine.

The proximal intestine (including, when present, pyloric ceca) provides the greatest surface area for absorption due to the relative abundance and length of longitudinal folds. Comparisons among species suggest that total absorptive surface area varies inversely with diet quality (Horn, 1989). For a given species, intestinal length, mucosal weight, and total gut surface area may vary inversely with acclimation temperature (Lee and Cossins, 1988).

The absorptive surface of the intestine consists of several structural and functional layers. On the lumen margin, overlying the mucosal epithelium, is an unstirred layer consisting of water and a layer of mucus. The mucus is an organic-based permeable gel that is constantly renewed by goblet cells of the mucosa. The thickness of the mucus layer changes by region and is generally greatest in distal sections of the intestine. The composition of mucus may also differ among intestinal regions (Trevisan, 1979) and species (Jirge, 1970). A third, largely functional layer is interposed between the epithelial cell surface and the unstirred layer. Often referred to as the *acid microclimate*, this layer is a cell membrane charge barrier associated with the epithelial cells. The absorptive pathway extends through

(B) Changes in ventilation rate (solid squares) and ventilation volume (solid circles). Each point represents the mean percentage change (±SE) from the control value measured at the acclimation temperature, calculated by pooling data for all three compounds. (Adapted from Black, M.C. et al., *Physiol. Zool.*, 64, 145–168, 1991.)

and beyond the epithelial cells to the lamina propria, where vascular elements of the intestinal tract are located. The lamina propria, besides providing a structural matrix supporting the mucosal epithelia, serves as a storage and staging area for vascular transport of nutrients and associated xenobiotics.

Along the length of the GIT are regional differences in luminal pH, fluid fluxes, transporter systems, enzymes, and enzymatic activities. Qualitatively, the digestive process in fish is similar to that of other vertebrates. Quantitative differences exist, however, especially in relation to digestive enzyme concentrations and activities. Regional differences in these parameters, combined with structural differences, restrict specific functions to more or less discrete locales. The regional nature of nutrient absorption is one outcome of these differences. The residence time of a food bolus in any given part of the GIT depends on many physical and physiological factors. In general, nutrient uptake and blood flows are highly regionalized and respond to local stimuli initiated by the food bolus. As the food bolus moves through the GIT, the character of the ingesta changes, as does the volume. Nutrients are absorbed and mucus, bacteria, and epithelial cells are added. As a result, different regions of the absorptive surface are presented with ingesta that differs in composition.

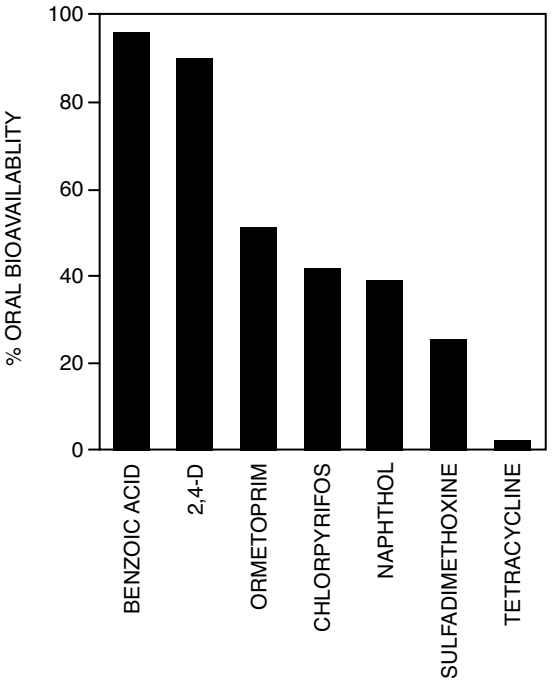

FIGURE 3.7 Oral bioavailability of seven chemicals in channel catfish, expressed as a percentage of the administered dose. (Data are from Barron et al., 1991; Michel et al., 1990; Plakas and James, 1990; Plakas et al., 1990, 1992b; Stehly and Plakas, 1992.)

Gastrointestinal Absorption of Xenobiotics

The absorption of xenobiotics from the GIT depends on a multiplicity of events in four general spheres of interaction: (1) within the intestinal lumen, (2) at the absorptive surface, (3) within the enterocytes, and (4) at the enterocyte–vascular interface. Physical, chemical, and biochemical events within the intestinal lumen determine the chemical form and integrity of a compound and its availability for uptake across the gut epithelium. Qualitative and quantitative characteristics of the diet play an especially important role in this environment. On the apical surface of the enterocytes, physical and chemical properties of the membrane and associated unstirred layer, as well as the transporter complement within the membrane, significantly influence xenobiotic uptake. Within the enterocytes, biotransformation enzymes, carrier molecules, and cellular components further impact xenobiotic concentration and movement. Transport across the enterocyte basolateral membrane into blood is dependent on factors similar to those operating at the apical membrane. The composition and flow rate of blood may also influence uptake. Directly impacting all of these processes is the character of the xenobiotic and fish species under consideration. The relative amount of an ingested compound that reaches the systemic circulation is defined as *dietary* or *oral bioavailability.* Oral bioavailability may be expressed relative to 100% (complete bioavailability) using the area under the blood concentration–time curve (AUC), referenced to that of an intravascular dose (Gibaldi and Perrier, 1982). Oral bioavailability in fish is species and chemical specific and varies widely (Figure 3.7).

Dietary uptake also may be characterized by measuring chemical residues in tissues after feeding fish a defined ration of contaminated food. The uptake efficiency calculated in this manner is termed *dietary assimilation efficiency*, and it reflects the net result of dietary uptake and subsequent elimination (Penry, 1998). A third means of characterizing dietary uptake is to estimate the efficiency with which ingested compounds are absorbed across the GIT. Typically, this is done by fitting the whole-fish chemical concentration data to a derivative form of the mass-balance equation that describes dietary uptake and elimination (Bruggeman et al., 1984). This approach yields a dietary absorption efficiency constant, the

Downloaded From Vet-eBooks.com

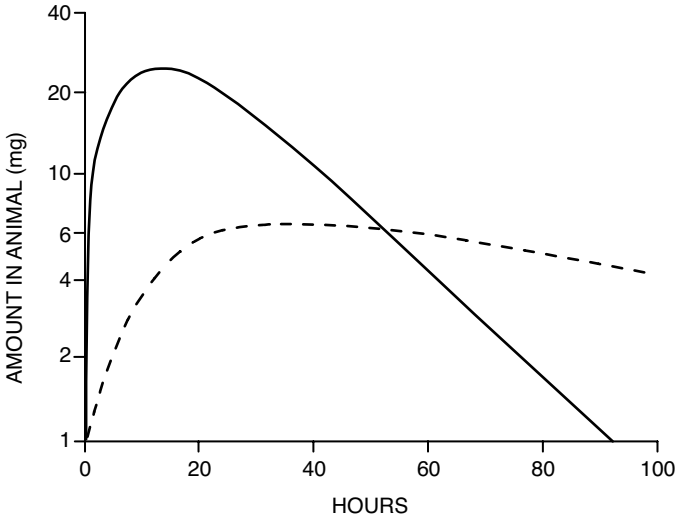

FIGURE 3.8 Simulated effect of gut absorption rate on whole-animal chemical kinetics. Simulation conditions: one-compartment open model; dose, 50 mg; elimination half-life, 20 hours; absorption half-life, 7 hours (solid line) or 70 hours (dashed line).

calculation of which mathematically factors for the effect of chemical elimination, including biotransformation. Dietary absorption efficiencies have been reported for a number of halogenated organic chemicals in several fish species (Burreau et al., 1997; Gobas et al., 1988; Muir and Yarechewski, 1988; Niimi and Oliver, 1988; Opperhuizen and Sijm, 1990). Gobas et al. (1988) compiled much of this information and related measured absorption efficiencies to chemical log K_{ow} (Figure 3.9). At log K_{ow} values less than 6, reported values range from 30 to 70%, averaging about 50%. A log K_{ow}-dependent decrease in absorption efficiency is apparent for compounds with log K_{ow} values greater than 7. When a compound is administered as a single dietary dose, the rate of absorption influences chemical concentrations achieved in tissues. At a fixed rate of elimination, an increase in the rate of absorption results in relatively higher maximum concentrations. Decreasing the rate of absorption results in relatively lower maximum concentrations that tend to be maintained for longer periods of time (Figure 3.8). When multiple doses of a compound are administered in the diet, the rate of absorption does not generally impact steady-state concentrations.

Bengtsson et al. (1979) fed bleaks (*Alburnus alburnus*) a technical mixture of chlorinated paraffins (CPs) and found that dietary uptake was inversely related to carbon-chain length and the extent of chemical chlorination. In a subsequent study, dietary uptake and accumulation of CPs by rainbow trout was variably related to the extent of chlorine substitution, depending on carbon-chain length (Fisk et al., 1996). Chlorination of short-chain-length compounds appears to increase accumulation by reducing biotransformation. In contrast, high levels of chlorine substitution may limit the diffusion of CPs with longer chain lengths across the mucosal membrane and perhaps incorporation into micelles. In several fish species, dietary uptake of high-molecular-weight CPs (MW > 600) was low or nonexistent (Bengtsson et al., 1979; Lombardo et al., 1975; Zitko, 1974). In general, lipophilic contaminants are more readily taken up from the diet if they have a molecular weight less than 600 (Bruggeman et al., 1984; Niimi and Oliver, 1988), low extent of chlorine substitution (Tanabe et al., 1982), and small molecular volume (<0.25 nm^3) (Niimi and Oliver, 1988).

Dietary uptake of lipophilic contaminants may depend on the existing contaminant burden in the fish. Doi et al. (2000) showed that the uptake of [^{14}C]-3,3′,4,4′-tetrachlorobiphenyl ([^{14}C]-PCB 77) from *in situ* perfused catfish intestines was reduced by dietary pretreatment with unlabeled PCB 77. The cause of this decrease was unclear but did not appear to be related to changes in first-pass intestinal metabolism. *In vivo* studies with catfish have also demonstrated lower dietary uptake of PCBs following preexposure in the diet (Hansen et al., 1976) or exposure to contaminated sediments (Dabrowska et al., 1996). Kinetic

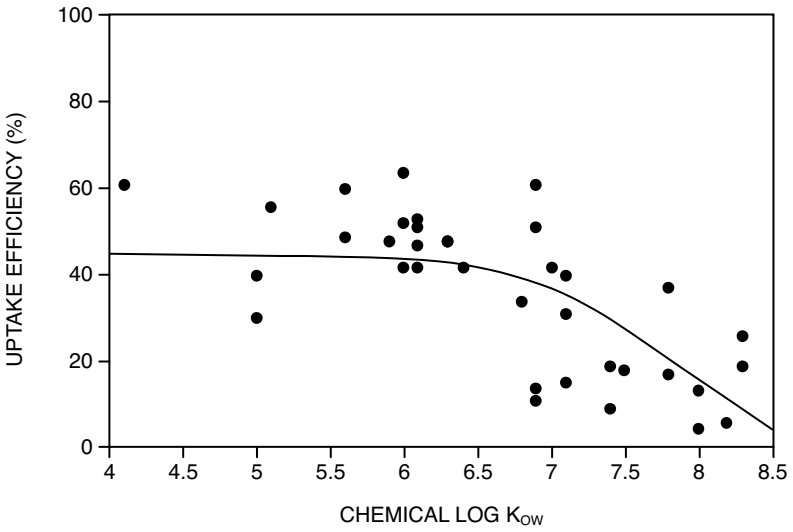

FIGURE 3.9 Dependence of dietary absorption efficiency on chemical log K_{ow}. Solid circles represent values summarized by Gobas et al. (1988). The solid line was generated using the fugacity model presented by Gobas et al. (1988).

models developed by Barber et al. (1991) and Clark et al. (1990) were used to simulate dietary uptake of PCBs by fish. Both models predicted that dietary uptake will decrease with increasing chemical body burden due to a decrease in the concentration gradient for uptake.

A few studies have examined the effect of dosage on the oral bioavailability of more water-soluble xenobiotics in fish. The bioavailability of the antibiotic oxolinic acid in rainbow trout was reported to be 14.3% (Cravedi et al., 1987), 13.6% (Bjorklund and Bylund, 1991), 38.1% (Cravedi et al., 1987), and 91% (Kleinow et al., 1994) after oral administration of the drug at 100, 75, 20, and 5 mg/kg, respectively. These results suggest that the bioavailability of oxolinic acid is higher at lower dosages. Other studies with Atlantic salmon (*Salmo salar*) indicated no difference in bioavailability when fish were administered oxolinic acid in feed at 9 and 26 mg/kg (Hustvedt et al., 1991). The bioavailability of sulfadimethoxine in rainbow trout decreased slightly when the dosage was increased threefold from 42 to 126 mg/kg (Kleinow et al., 1992).

Studies with oxolinic acid in yellowtail (*Seriola quinqueradiata*) showed that oral bioavailability was inversely related to particle size (Endo et al., 1987). The bioavailability of the sodium salt of sulfadimethoxine was nearly double that of the non-salt form (63 to 34%) (Kleinow et al., 1992). In each case, bioavailability appears to have been controlled in part by solubility considerations.

Physiological Impacts on Gastrointestinal Absorption

Relatively little information is available regarding the direct effects of GIT structure and function on dietary uptake of xenobiotics by fish. It is evident from nutritional studies, however, that pH gradients, gastrointestinal passage times, blood-flow patterns, and other aspects of digestive physiology vary with temperature and feeding frequency, as well as meal composition and size. Work with the mammalian GIT also indicates that these physiological features influence the absorption of xenobiotics.

Digestion—Approximately 15% of teleost fishes lack a true stomach (Grondel et al., 1987). Significant longitudinal pH gradients are not observed in these agastric species. The stomach pH of gastric species generally ranges from 1 to 4 (Bowen, 1981; Moriarty, 1973; Payne, 1978), and that of the intestine ranges from 6.5 to 9 (Fish, 1960; Nagase, 1964). Regional pH in the GIT may be an important determinant of absorption for some xenobiotics (Guarino et al., 1988). This would be especially true for weak organic acids and bases. In addition, pH can impact xenobiotic integrity, suggesting that differences in this regard may exist between gastric and agastric species.

Downloaded From Vet-eBooks.com

Because of its location, high surface area, and role in nutrient uptake (Gauthier and Landis, 1972; Noaillac-Depeyre and Gas, 1976, 1979), the proximal intestine is the most important site for xenobiotic absorption in fish. It is also clear that other regions of the teleost intestine are capable of significant chemical uptake (Kleinow et al., 1992; Nichols et al., 2004a). Regionally selective absorption has been demonstrated with both organic chemicals and metals (Pentreath, 1976; Shears and Fletcher, 1983).

Many xenobiotics are absorbed concurrently or in conjunction with specific nutrient classes. Digestive processes liberate xenobiotics from the food matrix, transport them to the mucosal epithelium, and control their presentation to the absorptive surface. Gut uptake of lipophilic contaminants has been strongly associated with digestion and assimilation of dietary lipid. Mechanical mixing, pancreatic lipases, and bile salts disperse dietary lipid and contribute to the formation of an equilibrium phase consisting of small mixed micelles (Kleinow and James, 2001). Lipophilic contaminants reside in the interior of these micelles, while the hydrophilic exterior allows the micelles to remain soluble in the aqueous milieu of the luminal contents. Micelles provide a packaging and transport phase that can traverse the unstirred water layer of the mucosa. Upon reaching the enterocytes, the micelles are dissociated by the combined action of pH changes and mucosal lipases, liberating stored xenobiotic. This process creates a highly localized concentration gradient of both xenobiotic and fatty acids across the absorptive epithelium.

Changes in the character of the ingesta can facilitate or hinder the absorption of xenobiotics; for example, moderate levels of dietary lipid appear to facilitate the absorption of lipophilic contaminants, but low or very high lipid diets are associated with reduced uptake efficiency (Andrews et al., 1978; Van Veld, 1990). High levels of dietary fat may overwhelm the ability of the system to digest and remove this material. Unprocessed lipid would then provide a partitioning phase for lipophilic compounds within the gut lumen. In addition, qualitative features of dietary lipid such as fatty acid chain length and composition may determine xenobiotic solubility in micelles and subsequent systemic availability (Doi et al., 2000).

Dietary lipids absorbed by the enterocytes are exported as lipoproteins to interstitial spaces of the lamina propria and to the vasculature. Mammals release these products as chylomicrons and very-low-density lipoproteins. Fish appear instead to release very-low-density lipoproteins, high-density lipoproteins, and free fatty acids (Babin and Verneir, 1989; Iijima et al., 1985, 1990). Because fish do not possess a lymphatic system, the potential for xenobiotics in lymph to bypass the liver, as seen in mammals, does not exist. This feature may contribute to the hepatic extraction of some xenobiotics before they reach the systemic circulation.

Gastric Evacuation and Gut Transit Time—Considerable effort has been expended to characterize rates and patterns of gastric evacuation in fish. Exponential decay models have been successfully employed to describe gastric evacuation in several species (Brodeur and Pearcy, 1987; He and Wurtsbaugh, 1993; Persson, 1986; Ruggerone, 1989). This approach suggests that the gastric emptying rate at any time point is proportional to the amount of food remaining in the stomach. Generally, the rate constant for gastric emptying increases with acclimation temperature and decreases with food particle size (Jobling, 1987; Windell et al., 1976). Meal size has been reported to increase, decrease, and have no effect on gastric evacuation rates. These apparent differences may be due in part to the use of dry and wet weights to express stomach contents data (Elliott, 1991). Variable relationships also exist between dietary composition and gastric emptying; increased dietary lipid has been shown to delay gastric emptying in some cases (Windell et al., 1969) but not others (Persson, 1982).

Relatively little is known of total gut transit times in fish. When blennies (*Blennius pholis*) were fed a single meal of fresh lugworms, the time required for intestinal emptying ranged from 20 to 30 hours and tended to increase with meal size (Grove and Crawford, 1980). Gut transit times for a stomachless species, the bighead carp (*Aristichthys nobilis*), ranged from about 7 to 13 hours and decreased with increasing body size (Opuszynski and Shireman, 1991). The time required for rainbow trout to completely digest a meal of live fathead minnows was less than 48 hours; however, a small amount of material was retained within the intestines between feedings (Nichols et al., 2004a). This finding suggests that complete evacuation of one meal depends on the consumption of additional meals. Gut transit times tend to decrease with increased acclimation temperature (Hofer et al., 1982; Shrable et al., 1969).

Downloaded From Vet-eBooks.com

In mammals, an increase in feeding rate generally results in decreased gut transit time and reduced digestibility. Both of these outcomes may contribute to reductions in xenobiotic bioavailability. Limited information suggests that similar considerations also apply to fish; for example, the oral bioavailability of methylmercury in catfish was found to be inversely related to meal size (McCloskey et al., 1998). In other studies, the bioavailability of oxolinic acid to catfish was found to increase with acclimation temperature (Kleinow et al., 1994), and that of enrofloxacin in rainbow trout decreased (Bowser et al., 1992). The apparent disagreement between these observations may be due to competing effects of temperature on gut transit time and digestibility. By increasing the transit time, a decrease in temperature might be expected to promote bioavailability; however, an accompanying decrease in digestibility might slow the release of chemical from the food matrix. The effect of temperature on bioavailability may depend, therefore, on which factors limit dietary uptake for a given compound, diet, and species. In some cases, chemical desorption from the food source may be the rate-limiting determinant of dietary uptake; for example, desorption half-lives for hydrophobic contaminants from ingested sediments may be greater than a week, which most likely exceeds the intestinal transit time of most organisms (Schrap, 1991).

Blood Flow—The GIT is supplied by a relatively complex vascular network (Farrell et al., 2001; Thorarensen et al., 1991). Blood flow to the GIT as a percentage of cardiac output in resting, unfed fish appears to vary considerably among species. Values based on the distribution of injected microspheres range from less than 1% in channel catfish (Schultz et al., 1999) to nearly 20% in rainbow trout (Barron et al., 1987a). Doppler flow probes were used to measure blood flow through the coeliaco-mesenteric arteries of Chinook salmon (Thorarensen et al., 1993), Atlantic cod (*Gadus morhua*) (Axelsson and Fritsche, 1991), and red Irish lord (*Hemilepidotus hemilepidotus*) (Axelsson et al., 2000). In each case, the measured flow rate accounted for 30 to 40% of total cardiac output, leading to the suggestion that microsphere methods underestimate blood flow to the GIT (Thorarensen et al., 1993). In addition to the GIT, however, the coeliaco-mesenteric artery provides blood to several internal organs including (depending on species) the liver, spleen, swim bladder, and gonads (Smith and Bell, 1975). Blood flow to the GIT increased substantially after feeding (Axelsson and Fritsche, 1991; Axelsson et al., 1989, 2000) and decreased during strenuous exercise (Axelsson and Fritsche, 1991). In mammals, the increase in blood flow that occurs with feeding tends to be localized to regions that contain food, and an increase in flow through the coeliac artery generally precedes a flow increase in the mesenteric arteries. Similar changes probably occur in fish (Axelsson et al., 2000). The effect of these changes in blood flow on dietary uptake of xenobiotic compounds is currently unknown. It may be speculated, however, that an increase in blood flow would promote uptake by maintaining an inward gradient for chemical diffusion.

The Skin

Skin Structure and Function

The skin of a fish functions as a physical barrier to separate the internal and external environments. As such, it maintains the ionic and osmotic integrity of the internal environment, provides protection from abrasion and disease, and participates in the exchange of respiratory gases. The skin is one of the largest organs of the fish body (approximately 10% of body weight) and may act as an important exchange surface for the absorption and excretion of xenobiotic chemicals.

Grossly, the structure of fish skin varies enormously among species. In nearly all cases, however, it is possible to identify two major layers: an outer layer (epidermis) and an inner layer (dermis). These two layers are separated from the underlying muscle by the hypodermis (also called *subcutis*). Accessory structures associated with the skin include sensory receptors, scales, mucous glands, poison glands, luminous organs, and electric organs.

The epidermis can be divided further into two layers. An outer layer made up of interlocking stratified epithelial cells forms a tough barrier at the skin surface. Below this is the basal lamina layer, or stratum germinativum, which is composed of highly metabolic cells that differentiate into the various cell types found in the epidermis. Goblet cells produce mucus that is continually secreted at

Downloaded From Vet-eBooks.com

the skin surface. To support this function there is a continual upward movement of differentiating goblet cells that begins at the basil lamina. The mucus produced by goblet cells serves a protective role and reduces the hydrodynamic resistance to swimming. Chemical irritation or physical stress will stimulate an increase in mucus secretion and bring about an increase in the number of differentiating goblet cells. Leydig cells also differentiate from the basal lamina but do not release their contents unless the epidermis is damaged. An alarm substance pheromone produced by Leydig cells acts to warn other fish of possible danger.

The dermis is also divided into two distinct zones, the upper stratum spongiosum and the lower stratum compactum. The stratum spongiosum contains fibroblasts, collagen, scale pockets, and pigment cells. The stratum compactum is made up of large collagen bundles attached at right angles to the skin surface. This architecture provides rigidity and allows the fish to swim without wrinkles forming at the skin surface. The stratum compactum also contains sense organs (touch and taste), nerves, and pigment cells. The dermal vascular system supplies the two dermal layers and the basal lamina of the epidermis. The dermis is connected to the underlying muscle by the hypodermis (subcutis), which is largely composed of connective tissue and fat cells.

Physiological functions of fish skin include respiration, ion exchange, and acid–base regulation. The skin of rainbow trout contributes to Ca^{+2} balance through active transport within the epithelial cells (Marshall et al., 1992) and to acid–base balance through Cl^{-}/HCO_3^{-} exchange across the extrabranchial epithelium (Ishimatsu et al., 1992). The skin of large fish (>100 g) consumes oxygen but in most species takes up only enough to satisfy the skin oxygen demand (Kirsch and Nonnotte, 1977; Nonnotte, 1981, 1984; Nonnotte and Kirsch, 1978). Based on morphometric and anatomical information, researchers have long suggested that cutaneous oxygen flux contributes significantly to total respiration in small larval fishes (McDonald and McMahon, 1977; McElman and Balon, 1980; Oikawa and Itazawa, 1985). Because the gill epithelium of both small and large fish consists of one or a few cell layers, its thickness does not change much with fish size. In contrast, skin thickness tends to decrease with decreasing fish size and in small fish may approach the thickness of the gill epithelium. In larval Chinook salmon (*Oncorhynchus kisutch*), as much as 80% of oxygen uptake takes place across the skin (Rombough and Moroz, 1990).

Dermal Absorption of Xenobiotics

Direct measurements of dermal uptake in rainbow trout and channel catfish were obtained by exposing fish confined in Plexiglas® chambers to a mixture of three chloroethanes (McKim et al., 1996). Although the rates at which both species approached steady state were similar to those observed in inhalation exposures to the same compounds, steady-state blood concentrations were much lower. A kinetic analysis of these data suggested that dermal uptake flux was about three to five times greater in catfish than in trout (Nichols et al., 1996). Some of this difference may have been due to differences in chemical diffusion rates at the experimental temperatures used for catfish (21°C) and trout (12°C); however, differences in skin anatomy and physiology, including the presence (trout) or absence (catfish) of scales were also likely factors. In addition, the analysis suggested that for adult trout dermal absorption would contribute 2 to 4% of initial uptake (dermal plus branchial) in a hypothetical waterborne exposure, but for catfish it would contribute 7 to 9%. Based on these findings, it appears that dermal uptake is a minor route of exposure in large fish, except perhaps for species that live in intimate contact with contaminated sediments.

In contrast, several studies have suggested that dermal uptake contributes substantially to total uptake of waterborne chemicals by small fish and juveniles of larger species. Tovell et al. (1975) measured anionic detergent uptake across the skin of small goldfish and found that 20% of total uptake occurred by this route. Saarikoski et al. (1986) obtained dermal uptake values for guppies exposed to a series of phenols, anisoles, and carboxylic acids. To distinguish between gill and skin absorption, fish were positioned into a hole cut in a rubber membrane separating two exposure chambers. Estimates of dermal absorption ranged from 25 to 40% of total absorption. Japanese medaka exposed to 2,2′,5,5′-tetrachlorobiphenyl in water accumulated considerably more chemical than could be explained by inhalation uptake (Lien and McKim, 1993). Similar results were reported for fathead minnows exposed to three chloroethanes (Lien et al., 1994). Lien and McKim (1993) suggested that dermal uptake should increase

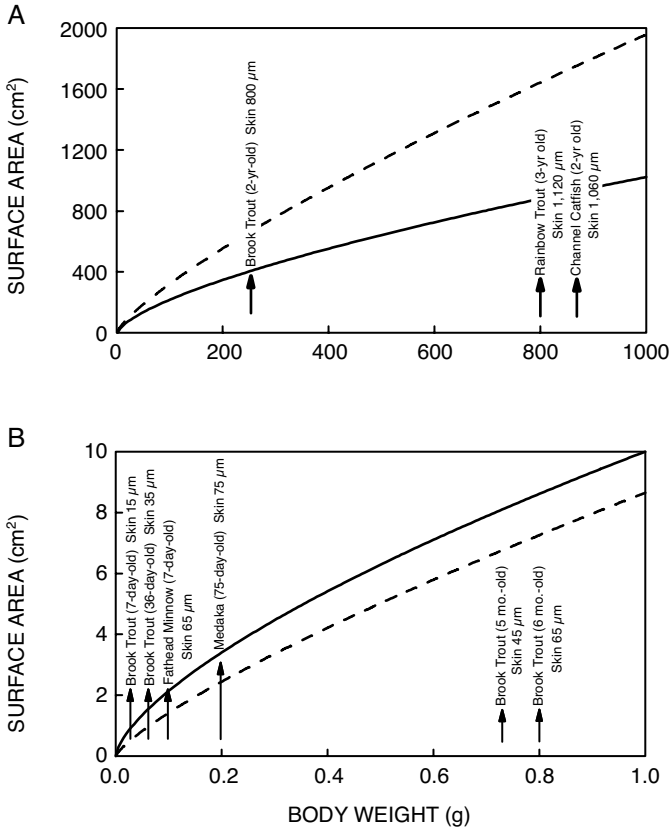

FIGURE 3.10 Skin (solid line) and gill (dashed lines) surface areas as a function of body weight. Arrows represent body weights of different species and life stages and their measured skin thickness (Rodney Johnson, personal communication). (A) Fish weighing up to 1000 g; (B) fish weighing less than 1 g.

in relative importance in small fish because of the way in which gill and skin surface areas scale to fish body weight. In smallmouth bass, gill surface area scales to body weight by a fractional exponent of about 0.78, consistent with the role of the gill in supporting metabolic activity (Price, 1931). Skin surface area scales instead to a body weight exponent of about 0.67 (Schmidt-Nielson, 1984). Using these values, Lien and McKim (1993) predicted that skin surface area approaches and may even exceed that of the gills in fish weighing less than 5 g (Figure 3.10). Reduced skin thickness and increased skin vascularization (Rombough and Moroz, 1990) also contribute to relatively greater dermal uptake in small fish.

Xenobiotic Distribution

Primary Determinants

A variety of processes act to distribute absorbed toxicants within fish. A portion of the absorbed compound may distribute to a site of action (organ, tissue, fluid) where toxic effects are expressed. Other sites serve as repositories for the chemical over short or long periods of time, while others are mobile and provide a means of transit within and out of the animal. During its residence in the body, a toxicant will redistribute continuously due to changes in chemical concentration gradients that drive xenobiotic movement.

Five primary factors control the distribution of xenobiotics from blood to peripheral tissues: (1) the physicochemical characteristics of the compound (e.g., pK_a, lipid solubility, molecular volume), (2) the concentration gradient between blood and tissues, (3) the ratio of blood flow to tissue mass, (4) the relative affinity of the chemical for blood and tissue constituents, and (5) the activity of specific membrane

Downloaded From Vet-eBooks.com

transport proteins. For many compounds, movement out of blood and into tissues occurs by simple diffusion following a concentration gradient. When a compound diffuses rapidly across biological membranes, organ blood flow and the maintenance of a concentration gradient are primary determinants of distribution. In other cases, the rate of membrane diffusion may control chemical flux between blood and tissues. Chemical affinities for blood and tissue constituents can further influence the distribution process, both as an impediment to distribution (e.g., plasma protein binding) and as a means of facilitating uptake by creating a favorable tissue-to-blood concentration gradient. As discussed below, distribution processes controlled by simple diffusion or blood-flow rate generally exhibit first-order kinetics. Under these circumstances, the rate of chemical flux between blood and tissue is proportional to the magnitude of the concentration gradient. In contrast, membrane transport proteins often exhibit nonlinear (saturable) kinetics.

The distribution of a xenobiotic can also be viewed in terms of the fluid spaces that it occupies. Blood and extracellular and intracellular fluid spaces may individually or collectively define the distribution volume of a compound. This distribution is determined by: (1) binding to nondiffusing molecular species, and (2) the ability of the unbound compound to diffuse across biological membranes. If a xenobiotic is confined to plasma, low (perhaps unmeasurable) concentrations will be found elsewhere. If the same quantity of toxicant were distributed to interstitial fluid or total body water, the plasma concentration would be markedly lower.

Local Distribution

At early time points in an exposure, chemical distribution to tissues may be highly influenced by the route of administration. High concentrations in the skin following exposure to contaminated sediments, the gastrointestinal mucosa following dietary exposure, or muscle following an intramuscular injection are obvious examples. These distribution patterns are generally restricted to the absorption phase of the exposure.

Anatomical and physiological peculiarities of fish may also result in characteristic distribution patterns; for example, xenobiotics administered by intramuscular injection in the trunk muscle may be initially transported to the kidney. Venous blood from the trunk muscle collects in the caudal vein, which is part of the renal portal circulation in fish (Figure 3.1). Similarly, compounds taken up from the GIT or intraperitoneal cavity are transported first to the liver by the hepatic portal vein and then to the gills via the ventral aorta before distributing into the general circulation. The systemic availability of a compound taken up by this route may be influenced, therefore, by elimination pathways operating in the gut, liver, and gills. The fish anesthetic tricaine methane sulfonate (MS 222), for example, when given by intraperitoneal injection will not produce anesthesia because of its rapid metabolism in the liver and the ease with which both metabolites and parent compound diffuse out across the gills (Hunn and Allen, 1974). Anesthetic concentrations of MS 222 in arterial blood can only be achieved by maintaining high MS 222 concentrations in water.

The Circulation

Blood flow, expressed per unit of tissue mass, is a major determinant of the rate of chemical distribution to tissues. The tissues with the highest blood perfusion rates in fish are kidney, red muscle, pyloric ceca, intestine, spleen, and liver (Barron et al., 1987a). Tissues receiving an intermediate level of blood perfusion include the gonads, skin, and white muscle, while adipose tissue and bone are poorly perfused. The influence of blood flow on chemical distribution was demonstrated in rainbow trout exposed to linear alkylbenzene sulfonate (LAS) in water (Tolls et al., 2000). LAS concentrations in the internal organs (primarily kidney and GIT) and liver exceeded 80% of their steady-state values after 8 hours of exposure, while concentrations in the muscle and skin continued to increase until 78 hours.

Blood flow to some tissues may change substantially in response to physiological stimuli. An example of this phenomena is provided by the pre- and post-prandial intestine (Axelsson and Fritsche, 1991; Axelsson et al., 1989, 2000). Exercise (Neumann et al., 1983) and hypoxia (Cameron, 1975) altered blood-flow patterns in rainbow trout and arctic grayling (*Thymallus arcticus*), respectively. Stress,

Downloaded From Vet-eBooks.com

exercise, and hypoxia related to netting and venipuncture were associated with changes in xenobiotic kinetics (Kleinow, 1991). It is likely that these changes were due in part to changes in tissue blood flow.

Ambient temperature affects both cardiac output and the pattern of blood flow to tissues. An increase in temperature was associated with an increase in cardiac output (Barron et al., 1987a). Blood flow as a percentage of cardiac output decreased in most organs, maintaining perfusion rates at a constant level. These changes were offset, however, by a redistribution of blood flow to white muscle, substantially increasing the perfusion rate of this tissue.

Another circulatory feature of fish with unknown but potential significance to xenobiotic distribution is the secondary circulation. This network of anastomosing vessels arises from the walls of the primary arteries and parallels the primary circulation of arteries, capillaries, and veins (Olson et al., 1986). The secondary circulation shares some characteristics with the mammalian lymphatic system, such as structural attributes of the vessels and restricted access for formed elements, but is more limited in its distribution. Tissues perfused by the secondary circulation include the gill filaments, skin, peritoneal lining, and oral mucosa. Limited studies suggest that the secondary circulation has a volume greater than that of the primary circulation and a turnover time of several hours (Steffensen and Lomholt, 1992). When the primary and secondary circulations are combined and expressed as a percentage of body weight, the total circulatory volume places teleost fishes well into the upper range for vertebrates.

Xenobiotic Transport and Binding in Plasma

Several transport modalities contribute to the circulatory distribution of xenobiotics. Although many compounds are transported in blood as freely dissolved forms, others may be transported in association with proteins, lipoproteins, or cellular components. Xenobiotics interact with these components by several mechanisms. Covalent binding usually restricts further distribution of the compound. In contrast, noncovalent ligand–protein interactions result in reversible binding that follows the law of mass action. When more than one binding interaction is possible, the distribution of a compound among binding proteins depends on both the binding affinity of each protein and their relative concentrations. Binding affinities may change with changes in ionic strength, pH, temperature, and protein conformation. As long as binding is reversible, however, an equilibrium will tend to be reestablished, providing an efficient means by which xenobiotics are transported and redistributed. Binding to plasma proteins can have a large effect on chemical distribution and clearance; for example, in trout, the plasma free fractions of parathion and paraoxon were determined to be 1.2 and 52.5%, respectively. Clearance rates determined for each compound were 21.4 and 3020 mL/hr/kg, respectively (Abbas et al., 1996).

Fish and mammals differ somewhat with regard to the total concentration of plasma proteins as well as qualitative properties of individual protein classes. Total protein concentrations in fish are generally much lower than those in mammals, possibly resulting in a reduced number of binding sites. In mammals, plasma albumin plays an important role in binding weak organic acids, and weak organic bases bind to plasma glycoproteins. It is clear, however, that some fish species either do not possess albumin at all, such as sharks and rays (Metcalf et al., 1999; Weisiger et al., 1984), or exhibit only very low concentrations (De Smet et al., 1998). The plasma albumin of rainbow trout has been described as "*para*-albumin" because of significant functional differences from the albumin of mammals (Perrier et al., 1977). Thus, the characteristic binding of xenobiotics to mammalian albumin and other plasma proteins may not directly extrapolate to fish; for example, low concentrations of the antibiotic sulfadimethoxine become highly (>90%) bound when added to rat plasma, but this binding saturates over a concentration range of 0.2 to 10 m*M* (Figure 3.11). In contrast, sulfadimethoxine binding in rainbow trout plasma ranges from 13 to 17% over the same concentration range, suggesting a nonsaturable, nonspecific interaction. This low degree of protein binding in trout facilitates the elimination of sulfadimethoxine and may result in a relatively larger apparent volume of distribution when compared with mammals (Kleinow and Lech, 1988). Similar differences between fish and mammals have been reported for the antimicrobial ormetroprim (Droy et al., 1990).

For other compounds, plasma binding in fish and mammals appears to be very similar; for example, the binding of 1-butanol, phenol, nitrobenzene, and pentachlorophenol was shown to correlate positively with chemical log K_{ow} in plasma obtained from both the rainbow trout and rat (Schmieder and Henry,

Downloaded From Vet-eBooks.com

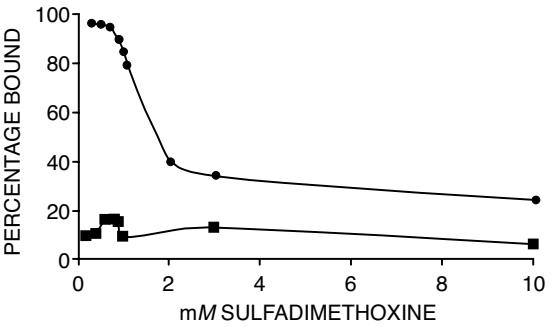

FIGURE 3.11 Plasma binding of sulfadimethoxine in rats (solid circles) and rainbow trout (solid squares) over a dosage range of 0.2 to 10 m*M*.

1988). This type of binding appears to be relatively nonspecific and nonsaturable and may be dominated by chemical interactions with lipid and lipoprotein. Similar relationships are obtained, however, when chemicals are added to solutions containing bovine serum albumin or human serum albumin (Figure 3.12). Using blood serum from mosquitofish (*Gambusia affinis*), Denison and Yarbrough (1985) found that the binding of lipophilic organochlorine insecticides increased with chemical polarity. Moreover, pretreatment of serum with endrin or aldrin substantially reduced the amount of subsequent DDT binding. Both of these observations are indicative of chemical binding to proteins.

Methylmercury in plasma binds reversibly to sulfur-containing molecules such as glutathione and the amino acid cysteine. The cysteine-bound form is of particular interest to toxicologists because it is transported by a neutral amino acid carrier system into sensitive tissues such as the brain (Kerper et al., 1992). In rainbow trout, however, 90% of whole-blood methylmercury is bound to hemoglobin in red blood cells (Giblin and Massaro, 1975). By limiting the amount of methylmercury available to interact with plasma molecules, this binding to hemoglobin becomes an important determinant of methylmercury kinetics and toxicity.

Heavy metals are transported in association with a variety of free proteins in plasma. Most of the cadmium in the plasma of brown trout and humans is bound to albumin or an "albumin-like" protein. Studies with carp, however, suggest that cadmium in plasma is primarily bound to a Mr 70,000 protein identified as transferrin (De Smet et al., 2001). The very low levels of "albumin" in carp plasma may account for this difference among species. Similarly, catfish serum proteins were shown to have much higher affinity and binding capacity for zinc than the primary transport protein (albumin) identified in other species (Bentley, 1991).

Tissue Affinity

Although chemical distribution at the beginning of an exposure is often determined by relative tissue blood flows, many chemicals redistribute over time in accordance with their relative affinity for tissue constituents. Lipophilic xenobiotics such as PCBs possess high affinity for tissues that have a high lipid content. Distributional differences among species may therefore occur due to different patterns of lipid deposition in organs and tissues; for example, Guiney and Peterson (1980) found that 60% of a dose of 2,2′,5,5′-tetrachlorobiphenyl in rainbow trout was contained in skeletal muscle and carcass, but in yellow perch 70% was contained in viscera and carcass (excluding skeletal muscle). These patterns were correlated with differences in the lipid content of each tissue, relative to that of other tissues. Similarly, Zitko et al. (1974) found that differences in muscle lipid content of Atlantic herring (*Clupea harengus*) and yellow perch correlated with differences in total PCB concentration.

Tissues that contain a large amount lipid may act as storage depots for lipophilic compounds. This storage may protect against adverse effects by isolating a chemical away from its sites of toxic action. Conversely, storage in these sites may prolong the overall residence time of a compound in the body and promote accumulation during chronic exposures. By reducing adipose lipid stores, starvation may result in a relatively rapid mobilization of accumulated chemical. When the rate of elimination from the

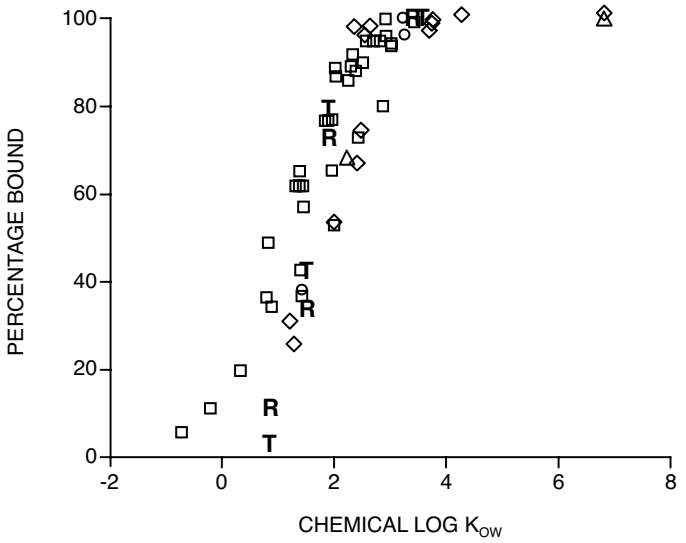

FIGURE 3.12 Chemical binding to plasma proteins as a function of chemical log K_{ow}. The symbols (T) and (R) represent values reported by Schmieder and Henry (1988) for trout and rat plasma proteins. Other symbols represent values summarized by the authors: open squares, bovine serum albumin; open circles, rat plasma; open triangles, shark plasma; open diamonds, human serum albumin. (Adapted from Schmieder, P.K. and Henry, T.R., *Comp. Biochem. Physiol.*, 91C, 413–418, 1988.)

whole animal is low, this starvation-induced decrease in whole-body lipid content may cause chemical concentrations in relatively lean tissues to increase substantially, even as whole-body chemical concentrations remain relatively constant (Gruger et al., 1975; Lieb et al., 1974).

Affinity considerations also determine the tissue distribution of lead during chronic exposures. In this instance, the accumulation of lead occurs because of its structural similarity to calcium. In fish, as in mammals, most of the accumulated lead is contained in bone (Camusso et al., 1995).

Lipid Mobilization and Xenobiotic Redistribution in Reproducing Fish

Female fish support egg development by mobilizing lipids from body stores. This lipid may be transferred to the growing egg mass or incorporated into larger energy storage molecules such as vitellogenin. Additional lipid may be mobilized in males and females to provide energy for spawning behaviors such as migration and nest defense (Jobling et al., 1998). In either case, xenobiotics may redistribute from fat storage depots to the developing gonads. To investigate this phenomena, Vodicnik and Peterson (1985) exposed female yellow perch to [^{14}C]-2,2′,5,5′-tetrachlorobiphenyl in water for 24 hours and then monitored tissue distribution and elimination for 5 months. Two weeks after exposure, 30% of chemical retained by fish was present in the developing ovaries. This value increased to 50% just prior to spawning, which occurred 4 months into the study. Similar studies with rainbow trout demonstrated the redistribution of [^{14}C]-2,2′,5,5′-tetrachlorobiphenyl to eggs and sperm (Guiney et al., 1979). Developmental stage may be an important determinant of xenobiotic transfer to eggs. When steelhead trout were given an intravascular dose of trifluralin (log K_{ow} 5), little or no chemical was transferred to mature eggs (Schultz and Hayton, 1997).

The percentage of an accumulated lipophilic contaminant that is redistributed to the developing gonads depends on several factors including: (1) the lipid content of the fish prior to gonad development, (2) the fraction of whole-body lipid content that is mobilized and incorporated into the gonads, and (3) the size of the gonads relative to total body weight. Niimi (1983) examined these features in five fish species: rainbow trout, yellow perch, smallmouth bass, white bass, and white sucker. Yellow perch were the leanest of these five species (5.1%) and transferred the greatest percentage of accumulated contaminants (25.5%) to their eggs. In contrast, rainbow trout had the highest starting lipid content (11.4%) and transferred the lowest percentage of contaminants to their eggs (5.5%). The high percentage of

Downloaded From Vet-eBooks.com

contaminant transfer in spawning yellow perch was due to the large size of its egg mass (22.3% of body weight) and the fact that it transfers a high percentage of its limited whole-body lipid stores to the developing ovaries (27.1%).

Reproductive life history may also influence the redistribution of lipophilic contaminants in fish. The Chinook salmon, a semelparous (once-bearing) species, transfers most of its stored lipid into a single spawn of eggs. By comparison, iteroparous (multiple-bearing) lake trout invest a lower proportion of stored lipid into each reproductive effort. In a study of these two species in Lake Michigan, Miller (1993) found that female salmon transferred 28 to 39% of their accumulated PCB body burden to the eggs during a single spawn, but female lake trout eliminated 3 to 5% of whole-body PCBs during each of what may be several spawns.

Other Features of Distribution

In mammals, modifications to membranes within the eye and central nervous system limit the movement of many xenobiotics. Similarly, chemical uptake by the mammalian testis may be limited by the presence of active transport systems and high levels of biotransformation enzymes. Membrane structure and function within these tissues in fish are essentially unknown. Xenobiotic movements are also limited within the placenta and mammary gland of mammals, but these tissues have no counterparts in fish. An important consideration for fish and other poikilotherms is the impact of temperature on chemical distribution. Reductions in temperature lower cardiac output (Barron et al., 1987a); alter membrane composition (Crockett and Hazel, 1995); change tissue perfusion patterns (Barron et al., 1987a), xenobiotic fluid space distribution (Van Ginneken et al., 1991), and partitioning to storage tissues (Barron et al., 1987b; Karara and Hayton, 1989); and elicit a hypertrophic response in the intestine and liver (Das, 1967; Lee and Cossins, 1988). For many xenobiotics, an inverse relationship exists between environmental temperature and chemical retention (generally characterized using the terminal elimination half-life) (Bjorklund et al., 1992; Collier et al., 1978; Jacobsen, 1989; Kasuga et al., 1984; Kleinow et al., 1994; Salte and Liestol, 1983; Van Ginneken et al., 1991; Varanasi et al., 1981). These observations may be due in part to changes in distribution, although changes in the activities of chemical elimination pathways are likely to contribute.

Xenobiotic Elimination

Branchial Excretion

In teleosts, the most important route of elimination for neutral, water-soluble, low-molecular-weight chemicals is across the gills. Working with the Dolly Varden char (*Salvelinus malma*) in a split chamber system, Thomas and Rice (1981) showed that aromatic hydrocarbons with low to moderate lipid solubility (log K_{ow} 1 to 4) are eliminated across the gills at a greater rate than those with high lipid solubility (log K_{ow} 4 to 7). A similar finding was reported for goldfish exposed to a series of substituted phenols with log K_{ow} values ranging from 1 to 5 (Nagel and Urich, 1980). Erickson and McKim (1990b) compiled data from several studies involving guppies (Bruggeman et al., 1984; Gobas et al., 1989; Konemann and van Leeuwen, 1980; Opperhuizen et al., 1985) and found that elimination rates declined linearly with chemical log K_{ow} across a wide range (3 to 8) of values (Figure 3.13). These rate calculations were based, however, on retained chemical residues and may have reflected elimination by branchial and non-branchial routes.

Current models of chemical flux at fish gills (Erickson and McKim, 1990b) suggest that this dependence of branchial elimination on chemical lipophilicity (or hydrophobicity) is due largely to chemical binding in blood. The effect of this binding is to lower the diffusion gradient across the gill epithelium by reducing the concentration of chemical in blood that is in a "free" (diffusing) form. Direct tests of this hypothesis for high log K_{ow} compounds are difficult to perform due to very low chemical concentrations in expired water and the tendency of these compounds to adsorb to tubings, glassware, and other experimental apparatus. Dvorchik and Maren (1972) injected dogfish sharks (*Squalus acanthias*) with [^{14}C]-DDT and collected samples of expired water but were unable to detect any radioactivity eliminated by this route. More recently, Fitzsimmons et al. (2001) developed a method using continuous column extraction of expired water, coupled with high-resolution mass spectrometry, to measure

Downloaded From Vet-eBooks.com

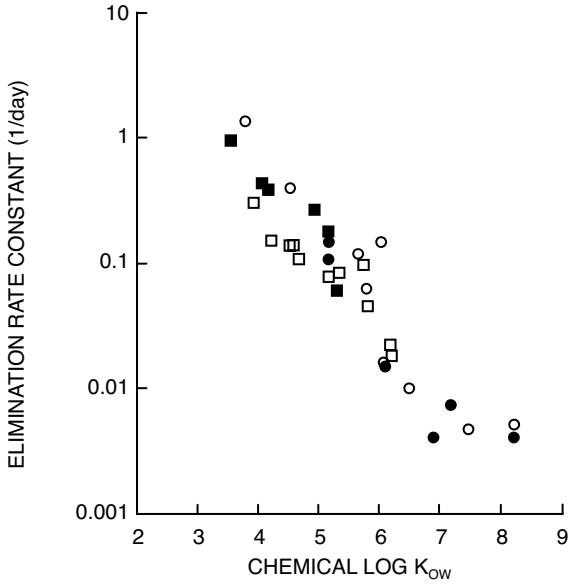

FIGURE 3.13 Dependence of elimination rate in guppies on chemical log K_{ow}: solid squares, chlorinated benzenes; solid circles, chlorinated benzenes/biphenyls; open squares, chlorinated benzenes/naphthalenes; open circles, brominated benzenes/biphenyls and chlorinated biphenyls. (Adapted from Erickson, R.J. and McKim, J.M., *Aquat. Toxicol.*, 18, 175–198, 1990.)

branchial elimination of four PCBs with log K_{ow} values ranging from 5.8 to 8.2. All four compounds were eliminated at low, but measurable rates. An analysis of these data suggested that a near-equilibrium condition was established between chemical in venous blood entering the gills, including dissolved and bound forms, and dissolved chemical in expired branchial water. At the other end of the spectrum, organic chemicals such as detergents (Schmidt and Kimerle, 1981) and drugs with low (<1) log K_{ow} values, or those that are ionized at the pH of fish blood (Maren et al., 1968), tend not to be eliminated across the gills but are eliminated in urine or bile.

Biliary and Fecal Elimination

Several hepatic and intestinal processes in fish may contribute to the elimination of xenobiotic chemicals. Compounds incompletely absorbed from the diet will be eliminated in feces. The absorbed fraction will be transferred to the liver and subjected to a variety of elimination pathways, including biotransformation and biliary secretion. Parent compounds and their metabolites in bile may be reabsorbed or expelled with the feces (Statham et al., 1976). Lipophilic xenobiotics that are poorly metabolized or cleared by renal and biliary routes can be transferred from blood to the intestinal lumen (Ingebrigtsen and Solbakken, 1985; Ingebrigtsen et al., 1988; Kleinow et al., 1996). Passive diffusion is an important mechanism for this process, although active transport (Leu and Huang, 1995) and exfoliation of intestinal cells may contribute.

Contribution of the Liver

The liver in fishes is a major site for amino acid homeostasis, glucose regulation, lipid processing, hormone metabolism, and the production of numerous plasma constituents, including albumin-like proteins and fibrinogen (Hinton et al., 2001). The liver also plays an important role in the excretion of xenobiotic compounds. The excretion of xenobiotics by the hepatic parenchyma depends on chemical uptake by hepatocytes, the formation and secretion of bile, and the transport of these compounds into bile. In this excretory process, hepatic and intestinal biotransformation often plays a pivotal role by producing polar anionic metabolites that are readily acted upon by the transport mechanisms of the liver.

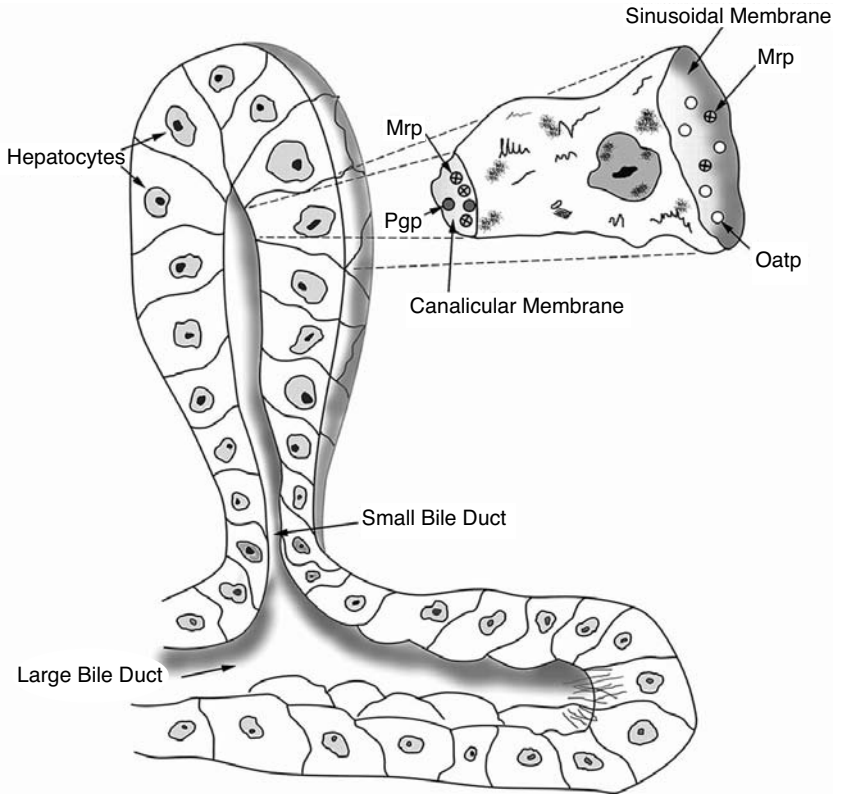

FIGURE 3.14 Hepatic tubule of the fish liver showing the origins of the biliary system and locations of xenobiotic transporters. Efflux transporter isoforms of the multidrug resistance-associated protein family (Mrp) are located on both the sinusoidal and canalicular membranes. P-glycoprotein (Pgp) is localized to the canalicular membrane, and isoforms of the organic anion transporter polypeptide family (Oatp) are located on the sinusoidal membrane.

A variety of structural arrangements have been described for the liver and biliary tree of fish. In general, fish do not possess the lobular structure and zonally oriented portal tracts observed in mammalian livers (Eurell and Haensly, 1982; Hampton et al., 1989; Hinton and Couch, 1998; Robertson and Bradley, 1992; Schar et al., 1985). Instead, the hepatocytes are commonly arranged into tubular elements. In rainbow trout, hepatocyte apices are directed toward the center of the tubule (Figure 3.14). At the center of the tubule, plasma membranes of adjacent cells form bile canaliculi. Where a biliary space exists, the biliary epithelial cells form junctional complexes with each other, and the hepatocytes on either side form a wall of the biliary passageway. These biliary passageways lead in turn to the cholangioles, small bile ducts, and large bile ducts. The contralateral or basal side of each hepatocyte faces a blood-filled sinusoid surrounding the tubule. Individual tubules curve, branch, and anastomose to form a complex network of parenchyma.

In salmon, multiple hepatic bile ducts empty into an elongated major duct that runs along the posterior ventral margin of the liver. The cystic duct branches from the major bile duct and serves to divert bile to the gallbladder. Bile originating from the major bile duct and gallbladder is collected in the common bile duct and empties into the proximal intestine just posterior to the pyloric curvature of the stomach. Some fish species, including members of the cod family, do not possess a gallbladder. It is thought that for these species bile is secreted continuously into the intestine.

Studies with mammals have shown that the excretory function of the liver and bile is greatly facilitated by the activity of specialized efflux transport proteins, including multidrug resistance-associated proteins (Mrps) and P-glycoprotein (Pgp) (Ayrton and Morgan, 2001; Keppler and Konig, 2000; Yamazaki et al., 1996). Mrps and Pgp belong to the highly conserved superfamily of ATP-binding cassette (ABC) transporters, which have been identified in organisms ranging from yeast to humans. Both groups of

Downloaded From Vet-eBooks.com

transporters are plasma-membrane-bound export pumps; however, their amino acid sequence identity and substrate specificity differ.

At least nine forms of the Mrp subfamily have been identified in humans. Some, such as MRP2, MRP3, and MRP6 (capital letters indicate that these are human gene products), are primarily expressed in the liver, kidney, and GIT. Others, such as MRP1, MRP4, MRP5, MRP7, and MRP8, occur in a variety of tissues, including the prostate, testis, ovaries, pancreas, and lung, as well as the blood–brain and blood–testis barriers. Most Mrps reside on the basolateral side of the plasma membrane, although MRP2 has been localized to the apical side in epithelial tissues. Mrps actively transport organic anions into bile and urine. Substrates for these transporters include xenobiotics conjugated with sulfate, glutathione (GSH), and glucuronic acid. Several Mrps have also been shown to transport endogenous molecules such as cyclic nucleotides, nucleoside analogs, and free GSH.

P-glycoprotein is an apical transporter of weakly cationic compounds and is expressed in a variety of secretory cell types. Substrates for Pgp (also referred to as Mdr1) generally possess a molecular weight between 350 and 1000, contain two planar rings, and exhibit a moderate degree of hydrophobicity. Known substrates for Pgp include steroids, lipids, and peptides, as well as a variety of xenobiotics and drugs such as adriamycin and vinblastin. Pgp appears to contribute to the regulation of some steroid hormones. This regulation is achieved by the secretion of hormones from sites of synthesis, such as the adrenal gland, and the modulation of hormone concentrations in target tissues such as the brain and testis.

A third class of transporters, organic anion transporter polypeptides (Oatps), are found in the liver, as well as in other tissues. Members of the Oatp family reside on the sinusoidal (basolateral) membrane of hepatocytes and transport negatively charged compounds. Unlike the Mrps and Pgp, Oatps function as influx transporters.

Localization studies and functional experiments suggest that homologs to these transport proteins operate in fish liver as well. Using immunohistochemical methods, homologs of mammalian Pgp have been shown to exist in the bile canaliculi of several species (Curtis et al., 2000; Hemmer et al., 1995; Kleinow et al., 2000). Studies with prototypical Pgp substrates have demonstrated the existence of an ATP-dependent transporter function in both trout and channel catfish (Doi et al., 2001; Sturm et al., 2001). Ballatori et al. (1999) used competitive inhibition methods as well as transport inhibitors to demonstrate that uptake of lucifer yellow (a model organic anion) by skate hepatocytes is carrier mediated. Additional studies with the skate suggest that glutathione conjugates are secreted into bile by an efflux transporter with Mrp-like activity, located on the canalicular membrane (Rebbeor et al., 2000).

Fish excrete a wide variety of xenobiotics in the bile. A partial listing of these compounds includes antibiotics (Samuelsen et al., 1995), insecticides (Lech et al., 1973), dyes (Plakas et al., 1992a), herbicides (Schlenk and Moore, 1993), polyaromatic hydrocarbons (Collier and Varanasi, 1991), metals (Grosell et al., 2001), and natural products (Sahin et al., 1996). Early studies with rainbow trout showed that chemical concentrations in bile may be much higher than those in the surrounding water (Lech et al., 1973; Statham et al., 1976). Guarino and Lech (1986) summarized the results of studies with fish exposed to more than 40 drugs and chemicals of varying molecular weight. The data were examined to determine bile/plasma concentration ratios and the percentage of compound eliminated in bile or urine. Bile/plasma concentration ratios were greater than 1 for over 85% of compounds examined, suggesting that fish were capable of concentrating xenobiotics in bile relative to plasma. The relative importance of biliary excretion as a route of elimination increased with molecular weight, although other factors such as the charge on the molecule were important. Generally, chemicals that are highly polar and have molecular weights greater than 600 are excreted largely in bile (Gingerich et al., 1977; Schmidt and Weber, 1973). Compounds of intermediate molecular weight (300 to 600) and polarity may be eliminated in bile as well as by other routes (Allen et al., 1979; Hunn and Allen, 1975; Kobayashi et al., 1977). From these limited datasets we may conclude that the same criteria (molecular weight and polarity) that apply to biliary excretion in mammals are operative in fish.

Metabolic and Physiological Impacts

Biotransformation may substantially increase biliary elimination of xenobiotics by increasing their solubility and creating conjugated compounds that are substrates for active transport systems. Stehly and Hayton (1989c) examined the metabolism and biliary excretion of pentachlorophenol in several fish

Downloaded From Vet-eBooks.com

species and found that the amount of metabolites in bile was species dependent. In each case, however, the bile was selectively enriched in glucuronide conjugates, and all of the metabolites in water were sulfate conjugates. These findings illustrate the potential selectivity of elimination pathways for metabolites as well as the inadvisability of defining metabolite profiles based solely on either bile or urine samples. Similar considerations apply to the elimination of some metal–ligand complexes. In the little skate (*Raja erinacea*) and dogfish shark, biliary elimination of methylmercury, which binds to glutathione and other sulfur-containing biomolecules, was reduced by inhibiting the biosynthesis of glutathione or its excretion in bile (Ballatori and Boyer, 1986).

Once secreted into the intestine, biliary conjugates may undergo enzyme-mediated hydrolysis, liberating the parent compound for reabsorption and enterohepatic recirculation (Collicutt and Eales, 1974; James, 1987; Fricker et al., 1997; Layiwola et al., 1983; Schultz et al., 2001). These processes modulate the amount of metabolites eliminated via the feces. In addition, *in situ* intestinal studies in fish suggest that conjugated metabolites of highly lipophilic compounds such as benzo(*a*)pyrene (benzo(*a*)pyrene 9-sulfate and benzo(*a*)pyrene 9-glucuronide) may be absorbed intact from the GIT (James et al., 1996). The uptake these conjugates appears to be due to their relatively low molecular weight and appreciable lipophilicity.

Secretion of bile into the intestinal tract is stimulated by nutritional and digestive signals. Due to the episodic nature of bile secretion and potential for xenobiotic reabsorption within the intestine, it is difficult to assess the contribution of biliary excretion to the overall process of elimination. The gallbladder of a recently fed fish is generally void of bile. By necessity, therefore, chemical concentrations in bile are generally determined using fasted animals.

Techniques for continuous collection of bile in unanaesthetized rainbow trout were described by Schmidt and Weber (1973), Gingerich et al. (1977), and Sanz et al. (1993). Similar methods have been developed for the skate (*Raja erinacea*) and dogfish shark (*Squalus acanthias*) (Boyer et al., 1976a,b,c). Basal bile flows measured using these techniques range from 50 to 200 μL hr^{-1} kg^{-1} in rainbow trout, 30 to 70 μL hr^{-1} kg^{-1} in the skate, and 80 to 110 μL hr^{-1} kg^{-1} in the dogfish. Bile flow rates in mammals may be 50 times greater than these values (Klaassen and Plaa, 1967). Differences in the rates of biliary elimination of bromosulfophthalein between rainbow trout and rats were found to be well correlated with differences in bile flow rate (Gingerich et al., 1977). This finding suggests that bile formation rate limits the rate of bromosulfophthalein excretion in bile. Fish have been shown to efficiently concentrate a large number of xenobiotics in bile, leading to the suggestion that bile can be used as a tool for monitoring environmental chemical exposures (Statham et al., 1976). This concentrating effect may be a result of slow bile flow relative to the secretion of xenobiotics into bile.

In rainbow trout, the biliary excretion of two organic anions, phenolphthalein (Curtis, 1983) and taurocholate (Curtis et al., 1986; Kemp and Curtis, 1987) increased with an increase in acclimation temperature. Similar results were obtained for a polyaromatic hydrocarbon, benzo(*a*)pyrene (Curtis et al., 1990). Hepatic blood flow has the potential to limit biliary clearance and is likely to increase with increased temperature (assuming that hepatic blood flow as a proportion of cardiac output remains constant). In the case of phenolphthalein, however, biliary elimination appeared to saturate at the two lower temperatures tested (Curtis, 1983). The mechanistic basis for these observations may be related, therefore, to changes in saturable processes responsible for chemical transport from blood to bile as well as the rate of chemical delivery to liver.

Urinary Excretion

Fish kidneys perform two major functions: (1) ion and water balance, and (2) excretion of endogenous and exogenous solutes. The diversity of kidney structure–function across species is enormous, but basic features are shared by both freshwater and saltwater teleosts. This section provides an overview of fish kidney function with an emphasis on mechanisms responsible for renal excretion of xenobiotic chemicals. Reviews of kidney structure–function in fish are provided elsewhere (Hickman and Trump, 1969; Pritchard, 1981; Nishimura and Imai, 1982; Pritchard and Miller, 1993; Pritchard and Renfro, 1984).

The functional unit involved with urine formation in the freshwater fish is the kidney (Figure 3.15), consisting of an encapsulated capillary network called the *glomerulus* and a tubule lined with epithelial

Downloaded From Vet-eBooks.com

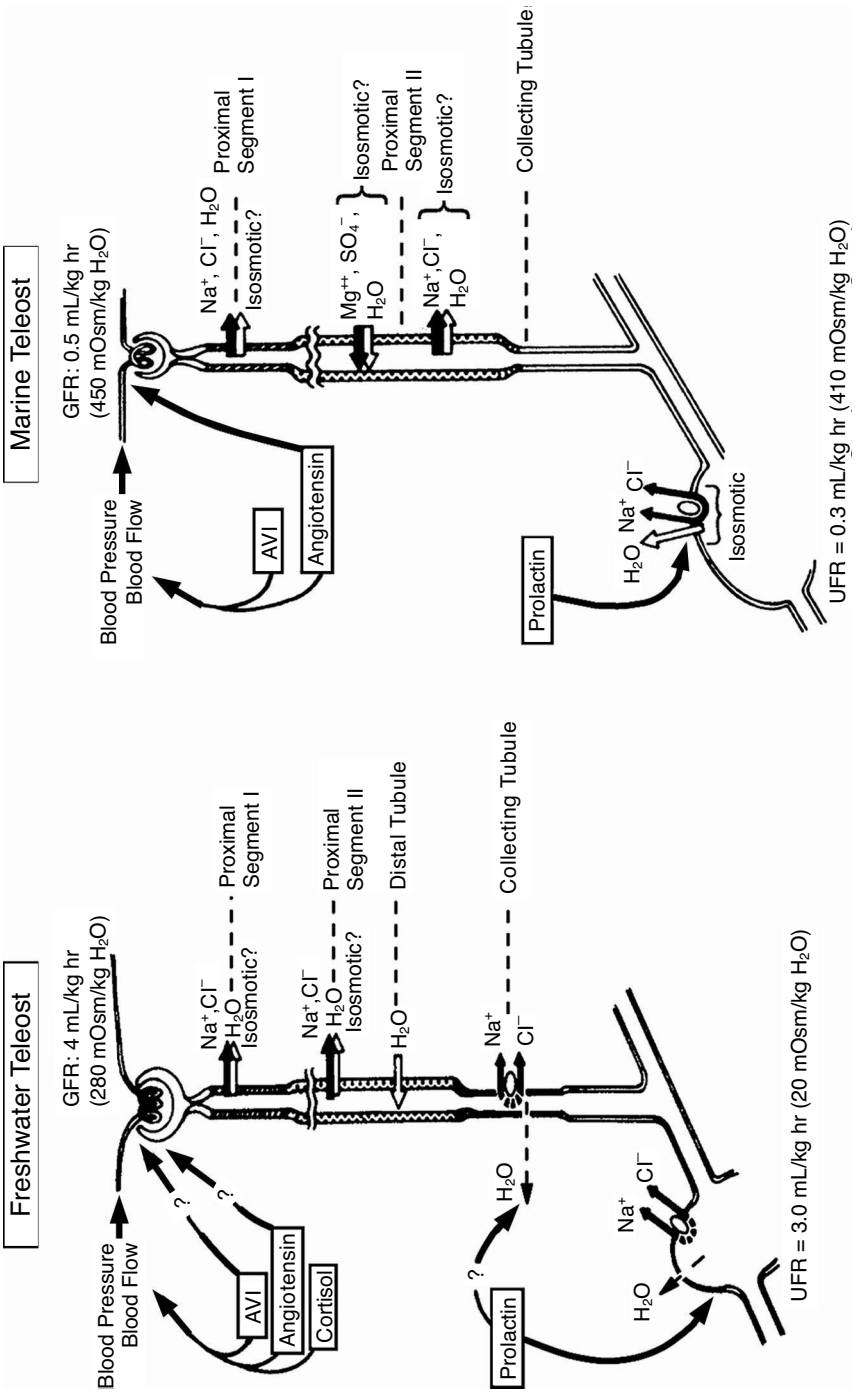

FIGURE 3.15 Renal structure, proposed handling of water and NaCl, and effects of hormones in freshwater and marine teleosts. Solid and open arrows indicate active and passive movements, respectively. GFR, glomerular filtration rate; UFR, urine flow rate. Broken straight and U-shaped arrows indicate low permeability to water and possible Na and Cl cotransport, respectively. Downloaded From Vet-eBooks.com

cells, as well as the urinary bladder. The kidney tubule can be subdivided further into two proximal segments (I and II): a distal tubule and a collecting tubule. The functional kidney unit of saltwater fish is similar to that of freshwater fish but lacks the distal tubule. In some saltwater species, the glomerulus may also be absent.

Because they are hyperosmotic with respect to their environment, freshwater fish must eliminate large volumes of dilute urine and retain salt (principally NaCl). High urine flow rates are supported by a high glomerular filtration rate (GFR), which is controlled by hormones (arginine vasotocin, angiotensin, and cortisol) that act primarily on blood pressure. Additional control of GFR may exist at the local level via the recruitment of glomeruli. Epithelial permeabilities to water within the collecting tubule and bladder are controlled in part by the hormone prolactin and tend to be very low. In contrast, saltwater teleosts are hypoosmotic with respect to the environment and must overcome dehydration by drinking seawater and absorbing water and minerals (primarily monovalent ions) through the gut. Excess salts are eliminated across the gills (both mono- and divalent ions) and kidney (primarily divalent ions), and water loss is minimized by producing small quantities of relatively concentrated urine. Divalent ions that are not absorbed within the gut (primarily Mg^{2+} and SO_4^{2+}) are eliminated in feces. The GFR in saltwater fish is much lower than that of freshwater fish. Urine osmolarity is maintained by an exchange of divalent and monovalent ions within the proximal tubule. Water is then reabsorbed with NaCl in the bladder. Because it comprises up to 40% of total tubular surface, the proximal tubule of saltwater fish has been used extensively for both *in vitro* and *in vivo* studies of kidney function (Kinter, 1966, 1975; Miller and Pritchard, 1997; Pritchard and Miller, 1993; Pritchard and Renfro, 1984).

The mechanisms that have evolved for handling ions and water in the fish kidney also contribute to the excretion of endogenous and exogenous organic solutes. The first step in urine formation is ultrafiltration of plasma through the capillary network of the glomerulus. In the lumen of the tubule, solutes may be reabsorbed back into plasma or added to the filtrate by secretion of free chemical from the plasma across the renal epithelium. The final composition of urine is determined by characteristics of the epithelium in both the tubule and bladder (Miller, 1987).

Two important attributes of organic solutes that determine the effectiveness of their renal excretion are (1) molecular size, and (2) plasma binding. Molecules with a radius of less than 20 Å are completely filtered at the glomerulus, those with a radius between 20 and 42 Å are partially filtered, and those with a radius greater than 42 Å are retained in plasma (Miller, 1987). Molecular size also limits renal tubular secretion. In fish as in mammals, chemicals with molecular weights greater than 500 tend to be secreted in the liver rather than the kidney (Pritchard and Renfro, 1984). Plasma binding is important because glomerular filtration and tubular secretion act primarily on free or unbound chemicals in plasma. Because they bind to plasma proteins, lipophilic compounds are generally retained by plasma as it flows though the glomerulus. Lipophilic chemicals contained within the glomerular filtrate may be reabsorbed from the tubule. This is particularly true of saltwater fish due to the concentrating effect of water reabsorption.

Some of the xenobiotics that fish are exposed to exist as organic anions or cations. Other compounds are initially taken up as neutral species and then converted to anions and cations by various biotransformation pathways. In all vertebrates studied to date, including fish, anionic and cationic secretory systems located in the proximal tubule transport charged compounds from plasma into the tubule urine (Pritchard and Miller, 1993). The caudal vein in fish drains into the kidney, providing a substantial supply of portal blood. Most of this portal blood bathes the kidney tubules and contributes to the renal secretory system (Pritchard and Renfro, 1984). Overall, up to 80% of the cardiac output flows through the fish kidney, as compared with about 20% in mammals.

Tubular Anion Secretion

The organic anion secretory system uses metabolic energy to move substrate molecules into the tubule epithelial cells against their electrochemical gradient (Figure 3.16). This mechanism is carrier mediated, saturable, and inhibited competitively by other substrates (Pritchard, 2001). Organic anion secretion is a three step process: (1) ATP is hydrolyzed to drive the Na^+ pump and create an inward Na^+ gradient; (2) the Na^+gradient into the cell drives the uptake of α-ketoglutarate (αKG^{-2}), thereby creating an outward

Downloaded From Vet-eBooks.com

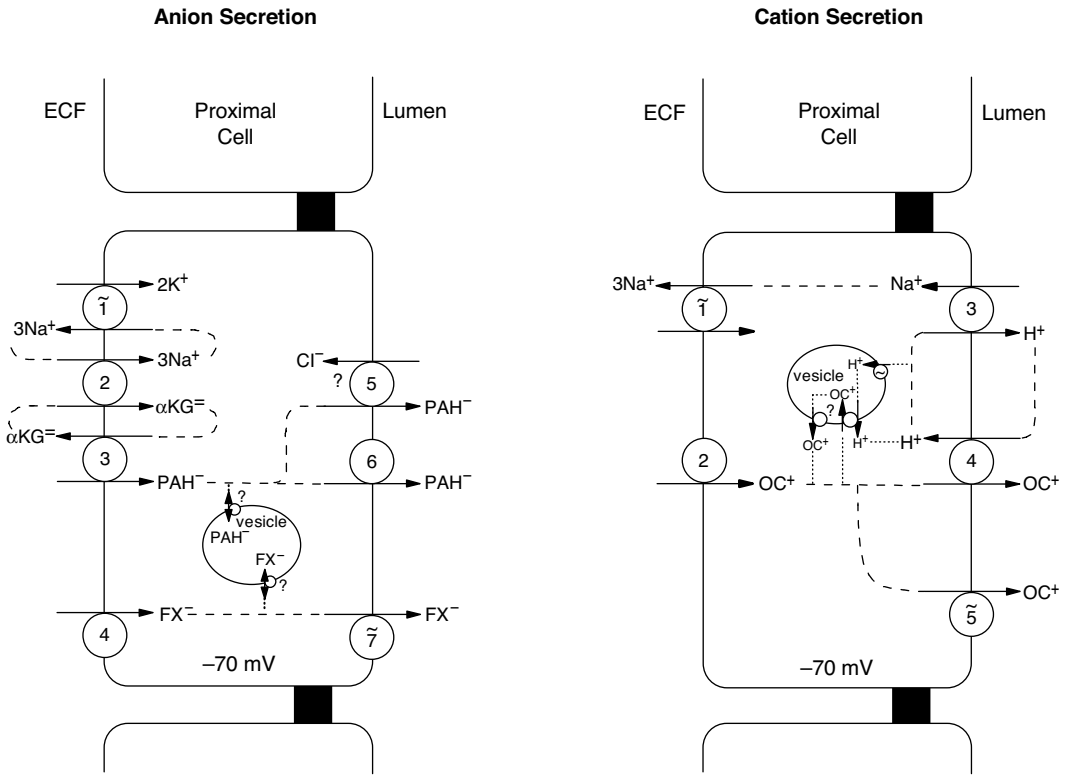

FIGURE 3.16 Mechanisms for renal secretion of organic anions and organic cations. Open circles represent carrier proteins, the symbol ~ within a circle indicates an ATPase, and arrows show the preferred direction of transport. (A) *Organic anion secretion:* The transport of *p*-aminohippuric acid (PAH^-), a prototypical organic acid, is coupled to ATP hydrolysis and the movement of α-ketoglutarate (αKG^{-2}) (components 1 and 3). Larger organic acids, such as fluoroscein-methotrexate (FX^-), may enter the proximal tubule cell by a Na-independent path (4) or simple diffusion. Intracellular organic anions may diffuse to the luminal membrane, bind to macromolecules, or be transported into vesicular structures. Uptake into vesicles is carrier mediated but the mechanisms are unknown. Efflux to the lumen may occur by facilitated diffusion (6) or through the activity of a drug-transporting ATPase such as Mrp2 (7). The luminal anion exchanger (5) is primarily responsible for the reabsorption of urate but may play a role in the secretion of other anions. (B) *Organic cation secretion:* Facilitated transport of an organic cation (OC^+) across the basolateral membrane is favored by a negative membrane potential (2). Some of the OC^+ may be sequestered in vesicles; the rest is transported to the lumen by two pathways. The first pathway involves H^+/OC^+ exchange (4), which is driven by a pH gradient (3) that is coupled to the Na^+ pump (1). The second pathway involves the multidrug transport ATPase MDR (5). (Adapted from Pritchard, J.B., in *The Textbook of Nephrology*, 4th ed., Massry, S.G. and Glassock, R.J., Eds., Lippincott Williams & Wilkins, Baltimore, MD, 2001, pp. 93–97.)

αKG^{-2} gradient; and (3) the organic anion moves into the cell in exchange for the outward movement of αKG^{-2}. Efflux from the epithelial cells into the tubule may occur by facilitated diffusion. Other compounds are transported across the luminal membrane of the cell by the drug-transporting ATPase Mrp2 (Miller and Pritchard, 1997).

Tubular Cation Secretion

Renal cation secretion is also a multistep process (Figure 3.16). In contrast to anion secretion, however, chemical movement into the epithelial cell (by facilitated diffusion) is energetically favored because of the strong negative charge on the cell interior. Movement into the lumen of the tubule is opposed by the membrane potential and must be tied to the hydrolysis of ATP (Pritchard, 2001). As with anion secretion, the cationic secretory system is highly susceptible to substrate competition.

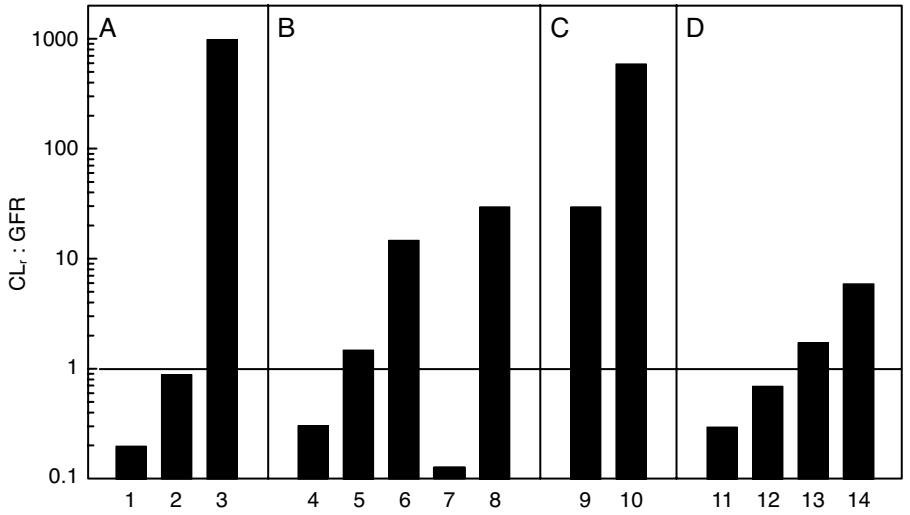

FIGURE 3.17 Influence of tubular transport, biotransformation, and plasma binding on renal excretion in marine teleosts (A–C) (Pritchard and Renfro, 1984) and freshwater teleosts (D) (McKim et al., 1999b). Data for each compound are expressed as the ratio of renal clearance (CL_r) to glomerular filtration rate (GFR). (A) *Reference compounds:* (1) glucose, reabsorbed by active transport; (2) 2-deoxyglucose, with no net tubular transport; (3) *p*-aminohippuric acid, a prototypical substrate for active anion secretion pathway. (B) *Effect of metabolism:* (4) benzo(*a*)pyrene (BaP), reabsorbed passively; (5) BaP-7-phenol conjugates (largely glucuronide), limited anion secretion; (6) BaP-7,8-dihydroxydiol conjugates (largely sulfate), a better substrate for anion secretion; (7) DDT, passive reabsorption; (8) DDA, effective tubular secretion. (C) *Effect of plasma protein binding:* (9) DDA, plasma binding of 97%; (10) 2,4-D, plasma binding of 70%. DDA and 2,4-D are transported similarly *in vitro* (without binding). (D) *Effects of reabsorption and metabolism:* (11) hydroquinone, strong passive reabsorption; (12) phenol, slight passive reabsorption; (13) phenyl glucuronide, limited anion secretion; (14) phenyl sulfate, better substrate for anion secretion.

Renal Clearance

The mechanisms responsible for renal excretion of chemicals can be distinguished by dividing measured renal clearance rates (CL_r) by the GFR (McKim et al., 1999b; Pritchard and Renfro, 1984). CL_r is the volume of plasma completely cleared of chemical by the kidney in a given period of time and is calculated by dividing the excretion rate of chemical in urine by the chemical concentration in plasma at the midpoint of a sampling period. The GFR is the total amount of plasma filtered by the kidney and may be estimated using an *in vivo* [^{14}C]-polyethylene glycol method (Beyenbach and Kirschner, 1976). Figure 3.17 shows CL_r-to-GFR ratios for several compounds in both freshwater and saltwater fish. A CL_r-to-GFR ratio less than 1 suggests that a chemical is reabsorbed within the kidney tubule, a ratio of 1 indicates no net tubular transport, and a ratio greater than 1 signifies active secretion into the tubular fluid. Chemical binding in plasma can reduce renal tubular secretion as well as chemical filtration at the glomerulus. Generally, however, the effect of plasma binding on CL_r is greater than that on GFR, decreasing the ratio of CL_r to GFR. For a given mechanism of renal excretion, CL_r-to-GFR ratios in saltwater fish tend to exceed those of freshwater fish. This pattern appears to be due primarily to higher GFR values in freshwater fish.

Dermal Excretion

The extent to which chemicals and their metabolites are eliminated across the skin is poorly known; however, anatomical and physiological factors that promote chemical uptake across the skin of some fish species (e.g., high degree of vascularization and large ratio of skin area to gill area) also might be expected to facilitate chemical elimination. Lead and cadmium diffuse across the skin of juvenile rainbow trout and into the mucous layer, which is then sloughed from the fish (Varanasi and Markey, 1978). Naphthalene was recovered from the mucus of rainbow trout soon after it was administered by

Downloaded From Vet-eBooks.com

intraperitoneal injection or dietary exposure (Varanasi et al., 1978). At later time points, only naphthalene metabolites were found. Whether or not these metabolites were formed in skin prior to their diffusion into mucus was not investigated. Using an *in vitro* skin strip preparation, Ali et al. (1987) showed that the skin of the African catfish (*Clarias gariepinus*) exhibits both phase I and phase II metabolic activity toward some endogenous steroids.

Elimination Via the Gametes

The redistribution of lipophilic chemicals from somatic lipid stores to developing gametes was described earlier in this chapter. Compounds for which this phenomenon has been demonstrated include anthracene, 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), DDT and its metabolites, PCBs, dibenzofurans, mirex, heptachlor epoxide, toxaphene, chlordane, and dieldrin (Kleinow et al., 1999). Additional studies have demonstrated the accumulation of zinc, lead, mercury, and cadmium in gametes of several fish species (Morrison et al., 1985). Vitellogenin binds several micronutrient metals, including iron, copper, and zinc; however, little is known about its role in transporting pollutant metals to developing oocytes (Kleinow et al., 1999).

The triggers for gamete-based elimination are gonadal maturation and reproductive behavior. These events may occur only seasonally for some fish species and year-around for others. Spawning may consist of a single event or multiple events (fractional spawners) occurring over a short or extended time interval. Although spawning eliminates xenobiotics from the animal, reducing the whole-animal contaminant load, whole-body chemical concentrations may increase (Tietge et al., 1998), decrease (Guiney et al., 1979; Niimi, 1983; Vodicnik and Peterson, 1985), or stay the same (Niimi, 1983), depending on the chemical concentration in gametes relative to the rest of the body. If the contaminant concentration in the gametes is lower than that of the rest of the fish, gamete release actually increases the chemical concentration in the remaining tissues (expressed on a whole-body basis). The reverse is true if the contaminant becomes highly concentrated in the gametes, relative to the rest of the animal.

The importance of maternal transfer in viviparous species is currently unknown. Wourms et al. (1988) estimated that, among teleosts, live-bearing strategies have developed in only 2 to 3% of species; however, two of these species, the mosquitofish and guppy, have been used extensively in aquatic toxicology research. To the extent that an exchange of blood occurs between female fish and the developing young (as in Poeciliidae), it can be speculated that maternal transfer of chemicals to offspring occurs in some live-bearing species. In species for which most early development takes place after the egg has left the follicle (Embiotocidae and live-bearing sharks), the opportunity for maternal transfer may be reduced.

Toxicokinetic Modeling

The uptake and disposition of xenobiotic chemicals in fish have been described quantitatively using both compartmental and physiologically based modeling approaches. Compartmental models are comprised of one or more compartments, each of which represents tissues and organs with similar kinetic properties. These compartments do not generally correspond to any particular anatomical or physiological entity. Physiologically based models also represent the fish using a set of compartments. The structure of the model, however, is based on anatomical, physiological, and biochemical information for the species of interest. The compartments in a physiologically based model often correspond to specific tissues and organs, although kinetically similar tissues may be lumped to form a single compartment. In a compartmental model, parameter values and the number of compartments are determined by nonlinear regression analysis of measured kinetic data. Physiologically based models may, in theory, be developed in the absence of experimental data. In practice, however, measured values are often required to fit a small number of critical parameters.

Both modeling approaches may be used to project toxicokinetic behavior beyond the experimental dataset on which the model is based. Using compartmental models, this may be done by determination of model parameter values for fish of different sizes or for different values of an environmental variable such as temperature. Empirical relationships that relate model parameters to fish size or an environmental

Downloaded From Vet-eBooks.com

variable are then developed and used to estimate model parameter values for other sizes of fish or other values of the environmental variable. For physiologically based models, prediction of toxicokinetic behavior is accomplished by appropriate adjustments to model parameters such as organ and tissue masses, blood flows to organs and tissues, and water flow across the gills.

The following text provides an overview of clearance concepts common to both compartmental and physiologically based toxicokinetic modeling approaches. These two modeling approaches are then described in detail. Both have advantages and disadvantages with respect to their utility and requirements for development. Guidance on the application of each approach is given in separate summaries. A section on noncompartmental modeling is also provided. Noncompartmental models are used extensively in mammalian pharmacology and toxicology and offer important advantages when using sparse datasets.

Clearance Concepts

Toxicants taken up by fish may be eliminated by several pathways, including metabolism and excretion into bile, urine, and respiratory water. In some cases, elimination rates are extremely slow and chemicals are retained for days, weeks, or even months after the fish are transferred to a clean environment (Niimi and Oliver, 1983). Alternatively, elimination pathways may clear >99% of an absorbed dose within just a few hours. In either case, elimination may be characterized by an *elimination clearance* (CL). The CL is defined as the rate of toxicant elimination (dX/dt) divided by the concentration in the reference region (C):

$$CL = (dX / dt)/C \tag{3.6}$$

and has units of flow (e.g., L/hr or mL/min). Normalization to body size (weight or surface area) may also be appropriate, particularly when averaging values from fish of different sizes. The CL is the sum of the individual clearances for all relevant elimination pathways; for example, the toxicant may be simultaneously metabolized by the liver and excreted by the kidney and at the gills:

$$CL = CL_h + CL_r + CL_b \tag{3.7}$$

where the subscripts refer to hepatic (h), renal (r), and branchial (b) clearance.

Hepatic Clearance

CL_h is limited by the rate of blood flow to the liver. If blood perfusing the liver is completely cleared of chemical, then CL_h is equal to hepatic blood flow. The CL_h may be less than hepatic blood flow, however, if a chemical is poorly metabolized within the liver or if it is reversibly bound to plasma proteins, impeding its transfer from the plasma into hepatocytes. A physiologically based model of hepatic clearance may be developed by assuming that the liver is a well-stirred compartment (Figure 3.18). Toxicant concentrations in blood entering and leaving the liver are denoted as C_a (arterial concentration) and C_v (venous concentration), respectively. Blood flow is represented by Q, and –dX/dt is the rate of toxicant elimination by the liver (the minus sign indicates that chemical is being lost from the system). Metabolizing enzymes may be envisioned as a coating on the walls of the compartment. For this well-stirred model, the rate of elimination of toxicant is:

$$-dX / dt = Q\left(C_a - C_v\right) \tag{3.8}$$

If the right-hand side of this equation is multiplied by C_a/C_a, one obtains:

$$-dX / dt = Q\left(C_a - C_v\right)C_a/C_a \tag{3.9}$$

The ratio $(C_a - C_v)/C_a$ is the hepatic extraction ratio (E). Substituting, the rate of elimination can be written as:

Downloaded From Vet-eBooks.com

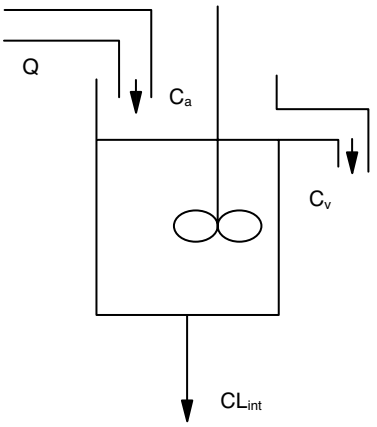

FIGURE 3.18 Well-stirred model of the liver. The liver is represented as a well-stirred volume supplied by a blood flow of Q which contains chemical at a concentration of C_a. The concentration of chemical inside the liver and in blood exiting the liver is C_v, and the activity of metabolizing enzymes is represented by CL_{int}.

$$-dX/dt = QEC_a \tag{3.10}$$

Because $(dX/dt)/C_a$ is equal to CL_h, it is apparent that $CL_h = QE$. Thus, CL_h is that part of the hepatic blood flow that is totally cleared of toxicant.

With this model, the drug concentration in the liver is equal to C_v. Because the rate of elimination is controlled by both Q and by the capacity of hepatic metabolizing enzymes, it is useful to separate these two influences. This can be accomplished by defining the *intrinsic hepatic clearance* (CL_{int}). The CL_{int} is the rate of toxicant elimination divided by the toxicant concentration in the liver; that is, the concentration in contact with metabolizing enzymes:

$$-dX/dt = CL_hC_a = CL_{int}C_v \tag{3.11}$$

and

$$CL_{int} = CL_hC_a/C_v = CL_h/(1-E) \tag{3.12}$$

The rate of chemical elimination by the liver is therefore proportional via the hepatic clearance to the toxicant concentration entering the liver or via the intrinsic hepatic clearance to the toxicant concentration leaving the liver.

A more general model for hepatic clearance that accounts for the possibility of chemical binding to plasma proteins may be written by defining a new reference concentration, the unbound toxicant concentration in the liver ($C_{v,u}$), and a new clearance parameter, the intrinsic unbound hepatic clearance ($CL_{int,u}$). Accounting for plasma binding, the rate of elimination may be written as:

$$-dX/dt = CL_{int,u}C_{v,u} = CL_{int,u}f_uC_v \tag{3.13}$$

where f_u is the fraction of chemical unbound in plasma. $CL_{int,u}$ represents the activity of the metabolizing enzyme toward the toxicant and can be expressed in terms of Michaelis–Menten kinetics as $V_{max}/(K_m + C_{v,u})$. When $C_{v,u}$ is low relative to K_m (< 10%), the relationship simplifies to V_{max}/K_m, and metabolism becomes first order with respect to $C_{v,u}$:

$$-dX/dt = \left(V_{max}/K_m\right)C_{v,u} \tag{3.14}$$

Values for $CL_{int,u}$ and CL_{int} can be calculated from CL_h, Q, and f_u as follows:

Downloaded From Vet-eBooks.com

$$CL_{int,u} = CL_{int}/f_u \tag{3.15}$$

where

$$CL_{int} = CL_h/(1-E) \tag{3.16}$$

and

$$E = CL_h/Q \tag{3.17}$$

Given values for CL_{int}, f_u, and Q, questions can then be answered about how CL_h, E, and F (oral bioavailability) will change if a change occurs in hepatic blood flow, plasma protein binding, or hepatic metabolism activity. The useful working equations for this model are:

$$E = f_u CL_{int,u}/\left(Q + f_u CL_{int,u}\right) = CL_{int}/\left(Q + CL_{int}\right) \tag{3.18}$$

$$CL_h = Qf_u CL_{int,u}/\left(Q + f_u CL_{int,u}\right) = QCL_{int}/\left(Q + CL_{int}\right) \tag{3.19}$$

The letter F is commonly used to represent the fraction of an oral dose that enters the systemic circulation and has two contributing parts: F_{ab}, which represents the fraction of the dose that is absorbed from the GIT into the blood, and F_{fp}, which represents the fraction of the absorbed dose that escapes elimination by the liver. The overall bioavailability of an orally administered compound is the product of these two fractions:

$$F = F_{ab}F_{fp} \tag{3.20}$$

F_{fp} can also be calculated from CL_{int}, f_u, and Q using the following relationship:

$$F_{fp} = 1 - E = Q/\left(Q + f_u CL_{int,u}\right) = Q/\left(Q + CL_{int}\right) \tag{3.21}$$

The independent variables in Equations 3.18, 3.19, and 3.21 are $CL_{int,u}$, f_u, and Q. The dependent variables are E, CL_h, and F_{fp}. This is an extremely important concept and is reinforced by the diagram shown in Figure 3.19.

The appropriate value to use for Q depends on the reference region. If the reference region is whole blood, then Q should be the whole blood flow to the liver; if plasma, then plasma flow should be used. If the external water is the reference region, then plasma water flow to the liver should be used. In this latter case, if no binding of toxicant occurred in the exposure water, then CL_{int} and $CL_{int,u}$ would have the same value.

The relationships among $CL_{int,u}$, f_u, and Q and the dependent variables E, CL_h, and F_{fp} are simplified when the value of E is small (<0.25) or large (>0.75); for example, for larger E, $CL_{int} >> Q$, and Equation 3.19 becomes $CL_h = Q$. For some toxicants, the value of E lies between 0.25 and 0.75, and the full

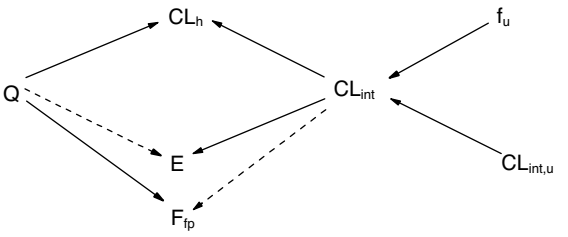

FIGURE 3.19 Relationships between independent physiological and biochemical determinants (Q, $CL_{int,u}$, f_u), and dependent pharmacokinetic parameters (CL_h, E, F_{fp}) of the well-stirred hepatic clearance model: Q, hepatic blood flow; $CL_{int,u}$, intrinsic unbound clearance; f_u, fraction of toxicant unbound in blood; CL_{int}, intrinsic hepatic clearance; CL_h, hepatic clearance; E, hepatic extraction ratio; F_{fp}, fraction of an oral dose that escapes first-pass elimination. Dashed lines depict an inverse relationship between variables; solid lines depict a direct relationship between variables.

Downloaded From Vet-eBooks.com

equations for E and CL_h have to be used. In such cases, there are no direct proportionalities; $CL_{int,u}$, f_u, and Q all determine E, CL_h, and F_{fp}, and a change in any one of the former variables produces a less than proportional change in the latter.

Renal Clearance

The kidney has two processes by which it clears blood of chemicals: filtration and extraction. Filtration involves the passage of plasma water across the glomerular membrane. Toxicant dissolved in water is transported across the membrane and ends up in the pre-urine. When protein binding occurs, protein-bound compounds remain with the protein in plasma. The plasma concentration of unbound toxicant remains constant during filtration, as both water and toxicant are removed by the filtration process. The equilibrium between bound and free toxicant is therefore not disturbed; consequently, the maximum possible clearance via filtration is the volume flow of plasma water across the glomerular membrane (GFR) multiplied by the fraction of toxicant that is unbound in plasma.

The extraction mechanism only applies when a toxicant is a substrate for an active tubular secretory pathway. Unbound toxicant contained in postglomerular and renal portal blood is transported across the proximal tubule into pre-urine. As in the liver, this may be a high E or low E process, depending on the toxicant. The same extraction model described for the liver can be used for active tubular secretion. In this case, CL_{int} is the activity of the secretory mechanism.

Total clearance by the kidney reflects the net result of filtration, active secretion, and passive reabsorption:

$$CL_r = \text{filtration clearance} + \text{secretion clearance} - \text{reabsorption}$$

Passive reabsorption is expected to be minimal in freshwater fish because the kidney does not reabsorb much water from urine and thereby concentrate the toxicant. In marine fish, the kidney conserves water by reabsorption and a greater potential exists for toxicant reabsorption from urine.

Branchial Clearance

Fish gills are an important site for toxicant uptake and elimination, and both processes can be described using clearance concepts. Unlike hepatic and renal clearance, however, the mathematical description of branchial clearance must be bidirectional to reflect the fact that chemical flux occurs in both directions. Depending on the concentration gradient across the gills, fish may clear chemical from inspired water or from blood flowing through the gills. The principal limitations on chemical uptake at fish gills were identified by Hayton and Barron (1990). If the permeability of the gill epithelium to a toxicant is low, diffusion can limit exchange, and branchial clearance is controlled by the product of gill permeability (K_d) and the surface area for diffusion (A):

$$CL_b = K_dA \tag{3.22}$$

The permeability coefficient is proportional to chemical diffusivity in the gill epithelium (D) and is inversely related to the effective thickness of the diffusion barrier (h):

$$K_d = D/h \tag{3.23}$$

If diffusive flux is limited by chemical diffusion within nonaqueous portions of the gill epithelium, it is appropriate to incorporate a membrane–water partition coefficient (P_{mw}), which would be expected to correlate positively with chemical lipophilicity:

$$K_d = DP_{mw}/h \tag{3.24}$$

The resulting permeability coefficient is identical to that given previously in Equation 3.1. Alternatively, if chemical diffusion in the aqueous phase of the membrane limits flux, Equation 3.23 is appropriate. Similarly, the value of D applies to the phase that constitutes the principal barrier to diffusive flux.

Downloaded From Vet-eBooks.com

Chemical diffusivity in aqueous solution may be calculated from equations given in standard physical chemistry texts and is expected to decline with increasing molecular volume.

If the permeability of the gill epithelium to a toxicant is sufficiently high, branchial uptake may be limited by the rate of blood flow through the gill lamellae. Chemical binding to plasma proteins or to cells in the blood would increase the capacity of blood to carry toxicant away from the gills. The uptake clearance when blood flow is the rate-limiting factor may be expressed as:

$$CL_b = Q_c P_{bw} \tag{3.25}$$

where Q_c is the total cardiac output, and P_{bw} is an equilibrium blood–water partition coefficient.

Because the value of P_{bw} can be very large, it is possible for water flow across the absorbing surface of the gills to control the rate of chemical uptake. In this case, the value of CL_b is equal to the effective respiratory volume (Q_w), which is the flow rate of inspired water that exchanges with blood:

$$CL_b = Q_w \tag{3.26}$$

To a first approximation, the potential rate limitations on branchial flux can treated as if they were resistances in series in an electrical circuit (Hayton and Barron, 1990):

$$CL_b = \left(h/DP_{mw}A + 1/Q_c P_{bw} + 1/Q_w\right)^{-1} \tag{3.27}$$

A more complex model based on the counter-current structure of fish gills was developed by Erickson and McKim (1990a,b) and is described below in the section on physiologically based toxicokinetic models; however, in the case where one resistance is the principal determinant of chemical flux (by virtue of being much greater than the other two), the two models reduce to a common description.

Compartmental Models for Fish

The use of compartmental models to characterize the kinetics of absorption, distribution, and elimination of exogenous and endogenous substances by a variety of species is well established. The foundations of this approach (Wagner, 1981) were developed by Haggard (1924), Widmark and Tandberg (1924), Dominquez and Pomerene (1934), and Teorell (1937). In the decades since this early work was published, there have been refinements in modeling concepts and in the techniques for data analysis. A number of textbooks on this topic are available (Gibaldi and Perrier, 1982; Rowland and Tozer, 1995; Wagner, 1993; Welling, 1986). Riggs (1963) defined the term *compartment* as follows:

> If a substance, S, is present in a biological system in several distinguishable forms or locations, and if S passes from one form or location to another form or location at a measurable rate, then each form or location constitutes a separate compartment for S.

In the context of toxicokinetics, a parent toxicant and its metabolites would be forms of substance S, and a location would be one or more tissues in which the forms had similar kinetic behavior. As an example, a tank of exposure water might be a compartment from which toxicant absorption occurs, the blood and highly perfused tissues might constitute a second compartment, the poorly perfused tissues would be a third compartment, and a metabolite might require specification of a fourth compartment (Figure 3.20A).

Compartments are assumed to behave like a tank that contains a well-stirred fluid; that is, toxicant that enters a compartment is assumed to distribute instantaneously and linearly, such that the concentration is everywhere proportional to the amount of chemical in the compartment. The number of compartments is generally small (1 to 5) to maintain mathematical simplicity and the capability to fit model-based equations to experimental data. Body compartments are usually arranged so chemical enters and exits from only one of the compartments, the so-called central compartment. With multiple-compartment models, the added peripheral compartments are usually attached to the central compartment so chemical exchanges between the central and each peripheral compartment; this configuration is termed *mammillary*, as opposed to the *catenary* configuration, which refers to a chain-like series of compartments.

Downloaded From Vet-eBooks.com

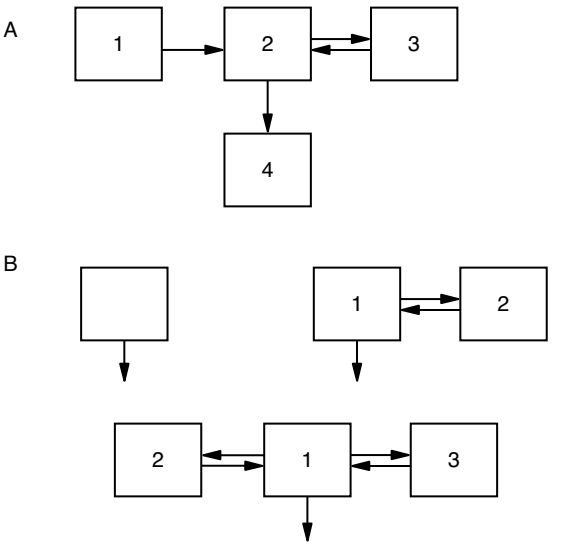

FIGURE 3.20 Examples of compartmental models. (A) A model appropriate for toxicant absorbed from the gastrointestinal tract (GIT) and eliminated by formation of a metabolite. Compartment 1, GIT; compartments 2 and 3, the body lumped into rapidly and slowly equilibrating tissues; compartment 4, the metabolite. Arrows represent first-order kinetic processes. (B) Mammillary models that represent the body as one, two, or three well-stirred compartments.

Typical mammillary configurations are shown in Figure 3.20B. Some considerations in the selection of the number of compartments include the purpose of the model, the frequency with which toxicant concentration is measured, and the number of sites from which samples are taken for determination of toxicant and metabolite concentrations.

Volume of Distribution

The size of a compartment is characterized by an apparent volume of distribution, V, that has units of volume or volume normalized to body size (weight or surface area). The apparent volume of distribution of the central compartment (compartment 1 in Figure 3.20B) is the amount of toxicant in the compartment divided by the toxicant concentration in a reference region. The reference region is the fluid or tissue in which the toxicant concentration is measured, commonly blood or plasma. In the case of plasma, for example, the value of V_1 would represent the volume of plasma that would be required to account for all toxicant in the central compartment. In studies with small fish, the exposure water is commonly used as the reference region. In this case, the value of V_1 represents the volume of water that would be required to account for all of toxicant in the central compartment under equilibrium conditions and in the absence of clearance from the central compartment. Under these conditions, the concentration in the exposure water equals the concentration of toxicant freely dissolved in plasma water.

The apparent volumes of distribution of the peripheral compartments are based on the same reference region as that of the central compartment, and the summed volume of all compartments is the apparent steady-state volume of distribution (V_{ss}). The magnitude of the V_{ss} is determined by the affinity of a toxicant for the reference region relative to that for other tissues and fluids. The fractional water content of most fish tissues is about 65 to 80% (Bertelsen et al., 1998). If plasma were used as the reference region, a V_{ss} of about 0.65 to 0.8 L/kg would be expected for a toxicant that distributed only into body water and did not bind to plasma proteins. Alternatively, if the toxicant reversibly bound to plasma proteins but had relatively little affinity for other tissues, the V_{ss} would be less than 0.65 L/kg. Conversely, if the toxicant had high affinity for one or more tissues (e.g., high lipid solubility resulting in high concentrations in fat), the V_{ss} would be much greater than 1 L/kg. A physiologically based model of apparent volume of distribution is described in Rowland and Tozer (1995). V_{ss} values measured in fish vary widely (Table 3.2).

Diethylhexylphthalate	23	Sheepshead minnow	Water	19,000	Karara and Hayton (1984)

[a] V_{ss} values referenced to plasma and blood were determined by collecting serial samples after intravascular administration of the chemical. Values referenced to water were determined from whole-body concentrations during waterborne exposures.

[b] V_{ss} was calculated using noncompartmental analysis as the product of mean residence time (MRT) and total body clearance (CL).

[c] β-Phase volume of distribution (V_β).

One-Compartment Model

Intravascular Administration

The simplest compartment model assumes that the fish body behaves like a single, well-stirred compartment. In this section, the one-compartment model is developed for a toxicant that is administered by intravascular injection. Intravascular administration is usually accomplished by injecting a solution of the toxicant via an indwelling catheter placed in the dorsal aorta. The dose may be administered as a rapid injection (bolus) or as a constant-rate infusion using an infusion pump. After the dose is administered, samples of plasma are removed at various times to measure the toxicant concentration (C_p).

Bolus Dose—For a toxicant administered as a bolus dose, its rate of elimination (dX/dt; mass/time) is:

$$-dX/dt = CLC_p \tag{3.28}$$

Division of both sides by V, followed by integration, yields an equation that predicts the time course of C_p:

Downloaded From Vet-eBooks.com

$$C_p = C_0 e^{-(CL/V)t} \tag{3.29}$$

where t is time and C_0 is the plasma concentration at t = 0 (i.e., the dose/V). This equation predicts that the plasma concentration will decline exponentially and a graph of log C_p vs. time should give a straight line. From the slope of the line, the ratio CL/V may be obtained, which is commonly referred to as the elimination rate constant (k_{el}):

$$k_{el} = -2.3 \cdot \text{slope} = CL/V \tag{3.30}$$

The elimination half-life ($t_{1/2}$) is calculated from k_{el}:

$$t_{1/2} = 0.693/k_{el} = 0.693V/CL \tag{3.31}$$

This relationship shows that a change in $t_{1/2}$ may result from a change in CL or V. Barron et al. (1987b) found that the $t_{1/2}$ for di-2-ethylhexylphthalate (DEHP) in rainbow trout increased with acclimation temperature and that this increase was primarily due to changes in V and not CL. The *y*-axis intercept of the semilog plot gives an estimate of C_0 that is used to calculate a value for V:

$$V = \text{dose}/C_0 \tag{3.32}$$

As a minimum, the number of plasma samples should be three times the number of parameters to be estimated (in this case, six samples to estimate the two parameters CL and V). These samples should be uniformly spaced and should be taken over a time span at least three times the $t_{1/2}$.

Infusion Dose—In some cases, it may be advantageous to administer the dose at a constant rate (R_0). This approach avoids the high transient plasma concentration associated with a bolus dose and provides a larger volume of solvent to dissolve the toxicant. The plasma concentration will increase exponentially during the infusion, followed by an exponential decline after the infusion is stopped. During the infusion, the predicted plasma concentration is:

$$C_p = \left(R_0/CL\right)\left(1 - e^{-k_{el}t}\right) \tag{3.33}$$

After three to four half-lives, the exponential approaches a value of zero, and a steady-state condition is achieved in which the rate of infusion equals the rate of elimination of the toxicant.

Plasma samples are generally obtained after the infusion has been stopped using the same cannula employed to infuse the toxicant. The value of k_{el} is obtained from the slope of a semilog plot of the post-infusion plasma data (Equation 3.30). If the infusion was sufficient to achieve a steady-state condition, CL can be calculated from:

$$CL = R_0/C_{ss} \tag{3.34}$$

where C_{ss} is the steady-state plasma concentration, estimated from the *y*-axis intercept of a semilog plot of the post-infusion C_p,t profile. The volume of distribution (V) can then be calculated as:

$$V = CL/k_{el} \tag{3.35}$$

If the infusion was stopped prior to steady state, k_{el} may still be estimated from the slope of the semilog plot, but estimation of CL and V is less straightforward because the amount of toxicant in the fish at the end of the infusion is unknown. Equation 3.33 may be rearranged to give the following expression for estimation of CL, which can then be used along with k_{el} to estimate V:

$$CL = \left(R_0/C_{end}\right)\left(1 - e^{-k_{el}t_{inf}}\right) \tag{3.36}$$

where C_{end} is the concentration in plasma at the end of the infusion, estimated from the semilog plot, and t_{inf} is the duration of the infusion.

Downloaded From Vet-eBooks.com

Waterborne Exposure

Kinetic studies with fish may be conducted by exposing small fish or juveniles of larger species to a chemical in water. Typically, the exposure is initiated with a fixed number of fish and at each sampling time a subset of animals is collected to determine whole-body chemical concentrations. The exposure may be conducted using a *flow-through* system that maintains a constant concentration of toxicant in the exposure water. Alternatively, fish may be exposed in a static system, which may or may not be renewed during the progress of a test. The aqueous concentration of toxicant in a static exposure system may decline over time due to absorption by the test organisms. Additional losses may occur due to adsorption to the test container, volatilization, photodegradation, and microbial metabolism.

Flow-Through Exposure—The rate of toxicant accumulation in fish dosed in a flow-through exposure (dX/dt; usually normalized to body weight) is proportional to the difference between the concentration of toxicant in the exposure water (C_w) and the concentration unbound in the plasma water ($C_{p,u}$):

$$dX / dt = \rho\left(C_w - C_{p,u}\right) \tag{3.37}$$

The C_w is constant during the exposure, and the $C_{p,u}$ can be replaced with X/V, where V is the apparent volume of distribution of the toxicant referenced to the exposure water. The units of V and ρ are usually normalized to body weight; for example, if X had units of ng/g, and C_w and $C_{p,u}$ had units of ng/mL, then V would have units of mL/g and ρ would have units of mL/hr/g. ρ is often the same as CL_b, as discussed on pages 95 to 96. Integration of Equation 3.37 gives an equation for X as a function of time:

$$X = VC_w\left(1 - e^{-(\rho/V)t}\right) \tag{3.38}$$

This equation can be fit to experimentally determined values of X at various times to determine values for ρ and V, and the elimination half-life can be calculated as:

$$t_{1/2} = 0.693V/\rho \tag{3.39}$$

Equation 3.38 predicts that X will exponentially approach a limiting value equal to VC_w. The value of V is equivalent to the bioconcentration factor (BCF), as described later in this chapter.

When a metabolite of the toxicant is formed during the exposure, this model may be extended to permit simultaneous characterization of its toxicokinetics. One approach is to determine the total amount of metabolite formed, including that in the fish and in the exposure water. Quantification of the amount eliminated to the exposure water is complicated by the need to measure metabolite in water flowing from the exposure vessel. The appropriate rate equations for this situation are:

$$dX / dt = \rho\left(C_w - C_{p,u}\right) - CL_m C_{p,u} \tag{3.40}$$

$$dM / dt = CL_m C_{p,u} \tag{3.41}$$

where CL_m is the metabolism clearance for metabolite formation. The integrated form of Equation 3.40 is (Benet, 1972):

$$X = X_{ss}\left(1 - e^{-k_{el}t}\right) \tag{3.42}$$

where

$$X_{ss} = \rho VC_w / \left(\rho + CL_m\right) \tag{3.43}$$

$$k_{el} = \left(\rho + CL_m / V\right) \tag{3.44}$$

The integrated form of Equation 3.41 is:

Downloaded From Vet-eBooks.com

$$M = \rho CL_m C_w t / (\rho + CL_m) - CL_m X_{ss} (1 - e^{-k_{el}t}) / (\rho + CL_m) \quad (3.45)$$

The dependent parameters ρ, V, and CL_m, can be estimated by fitting Equations 3.42 and 3.45 to measured values of X and M. Initial parameter estimates (required as inputs to the data-fitting software) can be obtained from a graph of $(X_{ss} - X)$ vs. time on semilogarithmic coordinates. The slope of this plot is equal to $k_{el}/-2.3$. The value of ρ can then be estimated from the relationship:

$$\rho = k_{el} X_{ss} / C_w \quad (3.46)$$

Importantly, the presence of a metabolic elimination pathway cannot be deduced from the X,t profile alone. The model-predicted M,t profile (Equation 3.45) indicates that M will increase linearly with time after a transient period (T_{lag}) that is determined by the half-life of the parent toxicant:

$$t_{1/2} = 0.693V(\rho + CL_m) = 0.693/k_{el} \quad (3.47)$$

By extrapolating the linear part of the M,t plot to the time axis, it is possible to obtain an estimate of T_{lag}, which can be shown to be equal to $1/k_{el}$ by solving Equation 3.45 when M = 0. Substituting, Equation 3.45 may now be written as:

$$M = [\rho CL_m C_w / (\rho + CL_m)][t - T_{lag}(1 - e^{-t/T_{lag}})] \quad (3.48)$$

The BCF for this case is:

$$BCF = X_{ss}/C_w = \rho V / (\rho + CL_m) \quad (3.49)$$

Rather than being equivalent to V (as in the model without metabolism), the BCF is now a fraction of V that is equal to the ratio $\rho/(\rho + CL_m)$ (Karara and Hayton, 1984).

Static Exposure—In a static exposure, the C_w may decline due to uptake of chemical by the exposed organisms. Under these circumstances, Equation 3.37 may be integrated to give:

$$X = \frac{VV_w C_{w,0}}{V_w + V}\left[1 - e^{-((1/V_w)+(1/V))\rho t}\right] \quad (3.50)$$

where $C_{w,0}$ is the initial concentration of chemical in the exposure water, and V_w is the volume of exposure water. The water concentration would decline according to the relationship:

$$-dC_w/dt = \rho(C_w - C_{p,u})/V_w \quad (3.51)$$

Integrating, one obtains:

$$C_w = C_{w,0}\left[1 - \frac{V}{V_w + V}\left(1 - e^{-((1/V_w)+(1/V))\rho t}\right)\right] \quad (3.52)$$

An examination of Equation 3.50 suggests that the time to achieve steady state is influenced by the value of V_w and that it is shorter than it would have been had C_w remained constant (as in a flow-through exposure). This influence of V_w on the time to steady state can be exploited to shorten the time required to characterize the X,t profile when the time to steady state would otherwise be very long. By making V_w relatively small compared with V, the time to steady state is minimized.

Downloaded From Vet-eBooks.com

Body Weight—A modification of the static exposure model is required when experiments are conducted using individual fish of different sizes. Larger fish will deplete the exposure solution faster, but the amount of toxicant absorbed per gram of body weight will be less than in smaller fish because the absorbed toxicant distributes into a larger body size. In this case, Equations 3.32 and 3.51 must be rewritten to explicitly consider fish body weight (W):

$$dX/dt = \rho W\left(C_w - C_{p,u}\right) \tag{3.53}$$

$$-dC_w/dt = \rho W\left(C_w - C_{p,u}\right)/V_w \tag{3.54}$$

Integrating, one obtains equations analogous to those given previously:

$$X = \frac{VV_wC_{w,0}}{WV_w + V}\left[1 - e^{-\left((W/V_w)+(1/V)\right)\rho t}\right] \tag{3.55}$$

$$C_w = C_{w,0}\left[1 - \frac{V}{WV_w + V}\left(1 - e^{-\left((W/V_w)+(1/V)\right)\rho t}\right)\right] \tag{3.56}$$

To fit Equation 3.55 and Equation 3.56 to experimental data, both time and fish weight are entered as independent variables, along with measured values of C_w and X.

Oral Administration

A single oral dose may be administered to a fish that has been prepared with an indwelling vascular catheter. If the absorption kinetics are first order and monoexponential, then the rate of appearance of chemical in the fish is:

$$dX/dt = k_{ab}X_g - CLC_p \tag{3.57}$$

where k_{ab} is the absorption rate constant, and X_g is the amount of toxicant remaining in the GIT. From this equation it is possible to derive the following relationship:

$$C_p = k_{ab}F \cdot dose\left(e^{-(CL/V)t} - e^{-k_{ab}t}\right)/V\left(k_{ab} - (CL/V)\right) \tag{3.58}$$

where F is the fraction of the dose that reaches the systemic circulation of the fish (oral bioavailability; see earlier section on hepatic clearance). The value of F may be estimated by comparison of the area under the C_p,t profile with the area determined after an intravascularly administered dose, where F is unity.

When the dietary exposure is continuous, the rate of change of the amount of chemical in the fish is:

$$dX/dt = FR_{in} - CLC_p \tag{3.59}$$

where R_{in} is the rate of chemical ingestion. In this case, the mass of chemical exponentially approaches a constant or steady-state value:

$$X_{ss} = \left(FR_{in}V/CL\right)\left(1 - e^{-k_{el}t}\right) \tag{3.60}$$

Two-Compartment Model

A one-compartment model assumes that a chemical distributes instantaneously throughout all tissues of the exposed animal. This assumption often fails because chemical distribution to each tissue is linked to blood perfusion rate, and tissue-specific perfusion rates vary considerably. When the kinetics of internal distribution affect the shape of the plasma concentration–time profile, a higher order compartment model is required. Perhaps the most common example of this phenomenon occurs when log-transformed plasma concentration data from an intravascular dosing study decrease in a *biphasic* manner (Figure 3.21). The

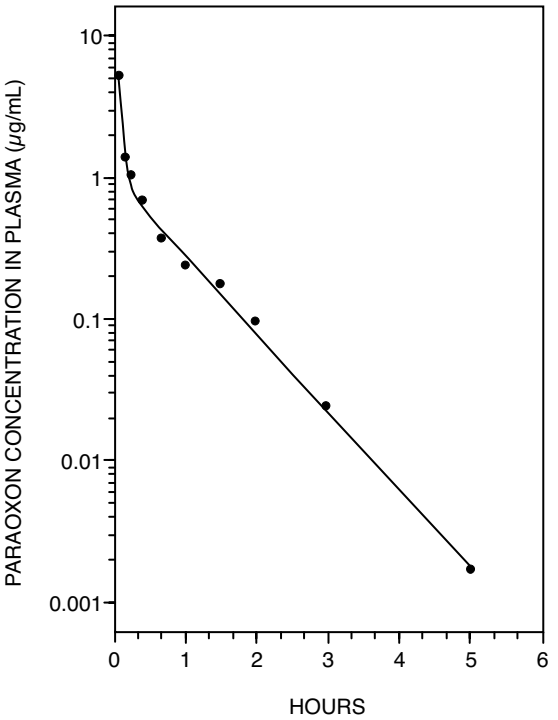

FIGURE 3.21 Paraoxon plasma concentration–time profile in rainbow trout after intraarterial injection. Symbols represent the experimentally determined concentrations, and the line represents the least-squares fit of a two-compartment-model-based biexponential equation. (Adapted from Abbas, R. et al., *Toxicol. Appl. Pharmacol.*, 136, 194–199, 1996.)

early and often rapid decline in plasma concentration is thought to be due primarily to a redistribution of the injected compound, while the later elimination or β phase is controlled by rate limitations on chemical elimination. A two-compartment model for intravascular administration of a bolus dose is described in the following section. Space does not permit the presentation of other multiple-compartment models; however, the principles illustrated by this relatively simple model apply generally to more complex models.

Intravascular Bolus Administration

This widely used model represents the body as two compartments (Figure 3.20B). Toxicant enters the central compartment, distributing instantaneously. Some of this toxicant moves from the central compartment into a peripheral compartment. Once it is in the peripheral compartment, the toxicant is again assumed to distribute instantaneously. The central compartment generally represents the blood and highly perfused tissues such as the liver, kidney, and GIT. The peripheral compartment usually represents poorly perfused tissues, including muscle and fat. The brain may be associated with either compartment, depending on whether the blood–brain barrier limits the rate of toxicant exchange between the blood and brain tissues.

Following the intravascular administration of a bolus dose (X_0), mass-balance equations that describe the rate of change of the amount of toxicant in compartments one and two may be written as follows:

$$dX_1/dt = k_{21}X_2 - k_{10}X_1 - k_{12}X_1 \tag{3.61}$$

$$dX_2/dt = k_{12}X_1 - k_{21}X_2 \tag{3.62}$$

where X_1 and X_2 are the amounts of toxicant in compartments 1 and 2, k_{12} and k_{21} are first-order intercompartmental transfer rate constants, and k_{10} is a first-order rate constant for chemical elimination

Downloaded From Vet-eBooks.com

from the central compartment. These equations may then be integrated to give X_1 and X_2 as functions of time:

$$X_1 = \left[X_0/(\alpha-\beta)\right]\left[(k_{21}-\beta)e^{-\beta t} - (k_{21}-\alpha)e^{-\alpha t}\right] \tag{3.63}$$

$$X_2 = \left[X_0 k_{12}/(\alpha-\beta)\right]\left(e^{-\beta t} - e^{-\alpha t}\right) \tag{3.64}$$

where α and β are rate constants that are comprised of the model rate constants:

$$\alpha = 0.5\left\{(k_{12}+k_{21}+k_{10}) + \left[(k_{12}+k_{21}+k_{10})^2 - 4k_{21}k_{10}\right]^{1/2}\right\} \tag{3.65}$$

$$\beta = 0.5\left\{(k_{12}+k_{21}+k_{10}) - \left[(k_{12}+k_{21}+k_{10})^2 - 4k_{21}k_{10}\right]^{1/2}\right\} \tag{3.66}$$

The total amount of toxicant in the body ($X = X_1 + X_2$) is:

$$X = \left[X_0/(\alpha-\beta)\right]\left[(k_{12}+k_{21}-\beta)e^{-\beta t} - (k_{12}+k_{21}-\alpha)e^{-\alpha t}\right] \tag{3.67}$$

The plasma concentration is X_1/V_1, or:

$$C_p = \left[X_0/V_1(\alpha-\beta)\right]\left[(k_{21}-\beta)e^{-\beta t} - (k_{21}-\alpha)e^{-\alpha t}\right] \tag{3.68}$$

which is an equation of the form:

$$C_p = Ae^{-\alpha t} + Be^{-\beta t} \tag{3.69}$$

This equation can be fit to the C_p,t profile by graphical or nonlinear least-squares methods to obtain estimates for A, α, B, and β. These values may then be used to calculate model parameters and other parameters of interest (Gibaldi and Perrier, 1982):

$$V_1 = X_0/(A+B) \tag{3.70}$$

$$k_{21} = (A_\alpha + B_\beta)/(A+B) \tag{3.71}$$

$$k_{10} = \alpha\beta/k_{21} \tag{3.72}$$

$$k_{12} = \alpha + \beta - k_{21} - k_{10} \tag{3.73}$$

$$V_2 = V_1(k_{12}/k_{21}) \tag{3.74}$$

$$V_{ss} = V_1 + V_2 \tag{3.75}$$

$$V_\beta = V_1(k_{12}+k_{21}-\beta)/(k_{21}-\beta) = V_1 k_{10}/\beta \tag{3.76}$$

$$CL = k_{10}V_1 = \beta V_\beta \tag{3.77}$$

$$t_{1/2,\alpha} = \ln 2/\alpha \tag{3.78}$$

$$t_{1/2,\beta} = \ln 2/\beta \tag{3.79}$$

V_{ss} and V_β are the steady-state and β-phase volumes of distribution. The former, when multiplied by C_p at steady state (e.g., in a continuous waterborne exposure), gives the amount of toxicant in the organism.

Downloaded From Vet-eBooks.com

The latter, when multiplied by C_p during the log-linear or β phase, gives the amount of toxicant in the organism. V_{ss} reflects only distribution, whereas V_β is, in addition, a function of the kinetics of distribution and elimination. $V_\beta \geq V_{ss}$ because during the β phase there is a positive chemical gradient from compartment 2 to compartment 1. For a given plasma concentration, this results in more toxicant in the organism during the β phase than during steady state. The $t_{1/2,\alpha}$ term is characteristic of the time required for distribution, and $t_{1/2,\beta}$ is the elimination half-life of the toxicant, which is similar to the half-life for a one-compartment model.

The CL parameter represents the total body clearance and may reflect elimination by several pathways (e.g., branchial elimination, renal excretion, and hepatic metabolism; see Equation 3.7). The amount of chemical eliminated by each pathway is directly proportional to the magnitude of the clearance for the pathway. To obtain a clearance value for each pathway, the amounts eliminated by each pathway must be determined. The individual clearances may then be calculated as follows:

$$CL_h = \left(M_\infty / X_0\right) CL \tag{3.80}$$

$$CL_r = \left(X_{r,\infty} / X_0\right) CL \tag{3.81}$$

$$CL_b = \left(X_{b,\infty} / X_0\right) CL \tag{3.82}$$

where M_∞ is the total amount of metabolite formed, and $X_{r,\infty}$ and $X_{b,\infty}$ are the amounts of chemical eliminated in urine and expired branchial water. Calculation of $X_{r,\infty}$ requires the use of urinary duct catheters to quantitatively collect the urine (Kleinow, 1991).

Utility of Compartmental Models for Fish

Compartmental models have the advantage of requiring limited data relative to physiologically based models and require only time-series data for the parent compound in a reference tissue, such as plasma, to infer chemical dynamics in other tissues and the whole fish (Barron et al., 1990). Compartmental modeling allows estimation of the key pharmacokinetic parameters characterizing chemical uptake from water (CL_b), distribution (V), and persistence (half-life). The modeled compartments generally do not have any physiological or anatomical reality, but clearance-based constants do allow a degree of physiological interpretation and realism. A common inference is that after intravascular administration of a chemical, the lower limit on the size of V is the blood or plasma volume, and a larger V indicates that the chemical is distributing outside of the vascular system. The magnitude of CL_b is directly interpretable as a proportion of ventilation volume and cannot exceed ventilation volume unless biotransformation occurs in the blood. Compartmental models are limited in their ability to extrapolate across species but have been used to assess the effects of body size and environmental factors such as temperature on toxicokinetics in fish and to discern presystemic biotransformation in the gill (Barron et al., 1987b, 1989; Schultz and Hayton, 1994).

Physiologically Based Toxicokinetic Models

Physiologically based toxicokinetic (PBTK) models are founded on the premise that chemical uptake and disposition can be described from anatomical, physiological, and biochemical attributes of the exposed organism and physicochemical characteristics of the compound. The compartments in a physiological model correspond to actual tissues and organs, and chemical transport within the animal is defined by blood flow relationships. This mechanistic foundation provides for the possibility of extrapolating kinetic information among species and chemicals by making appropriate adjustments of biological and chemical inputs.

Mass-balance differential equations that describe chemical kinetics in a tissue exchanging with blood were developed in the 1930s (Teorell, 1937). The computing power required to simultaneously solve equations for several tissues was not widely available, however, until the 1960s. Early use of the physiological modeling approach consisted primarily of describing the kinetics of chemotherapeutic

Downloaded From Vet-eBooks.com

agents (Gerlowski and Jain, 1983); subsequently, this approach was adopted by toxicologists interested in extrapolating data from laboratory test animals to humans. Much of the early work in this field was focused on modeling volatile organic compounds (Andersen, 1981; Ramsey and Andersen, 1984). Additional models have been developed for a variety of nonvolatile toxicants, including several metals (Medinsky and Klaassen, 1996). Increasingly, PBTK models are being linked with biologically based dose–response (BBDR) models to provide a complete (toxicokinetic and toxicodynamic) toxicological description (Connolly et al., 1988).

One early application of the PBTK modeling approach was to compare chemical distribution and elimination in fish and rodents. Models for methotrexate in stingrays (Zaharko et al., 1972) and phenol red in the dogfish shark (Bungay et al., 1976) were designed to simulate experiments in which compounds were injected intravascularly, and elimination was limited to urinary and fecal routes. The first PBTK model for fish that incorporated an environmentally relevant route of exposure (branchial) was developed by Nichols et al. (1990). Later models have incorporated both dermal and dietary routes of exposure (Nichols et al., 1996, 1998, 2004a). In this section, we review the principles of PBTK modeling with fish. Mathematical details pertaining to mass-balance tissue descriptions are deemphasized, as this information is available in several reviews (Gerlowski and Jain, 1983; Krishnan and Andersen, 2001; Rowland, 1985). This section focuses instead on route of exposure considerations as they relate to fish. An emphasis is placed on factors that distinguish fish and mammalian models, either in terms of model structure or the ways in which the models are used. In several instances, empirical data are reviewed to define the chemical kinetic behavior that successful models must simulate.

Model Structure

A PBTK model consists of several tissue compartments, connected in a manner that is consistent with the cardiovascular system of the exposed organism (Figure 3.22). Additional details follow from the type of exposure, characteristics of the test compound, and goals of the modeling exercise. Often, it is necessary to ignore known or suspected complexity to simplify the task of parameter estimation. In general, a modeler strives to create the simplest possible structure that will satisfactorily represent the behavior of the system under study. The number and identity of tissue compartments can vary greatly. An emphasis is usually placed on tissues that control the kinetics of uptake and elimination, as well as those that are important toxicologically.

Physiological and anatomical attributes of fish that influence chemical uptake and disposition were reviewed earlier in this chapter. Several attributes are singled out here because they tend to distinguish fish and mammalian PBTK models. First, chemical uptake by inhalation exposure can be adequately simulated in mammals by modeling the lungs as a mixed chemical reactor. Chemicals taken up across the lung travel first to the heart and then to the rest of the body. In contrast, the gills of many fish species are more appropriately modeled as a counter-current exchange system, and chemicals taken up across the gills travel throughout the body before reaching the heart. Second, the kidney in many fish is supplied by venous blood draining both the trunk musculature and skin. Although this portal blood does not appear to be available for glomerular filtration, it may contribute to urinary elimination of compounds that are actively secreted in the proximal tubule. Because fish are poikilothermic, physiological and metabolic parameters such as ventilation volume and cardiac output can vary greatly with ambient temperature, thereby having a large impact on chemical kinetics. Finally, it is important to recognize that important physiological differences exist among fish species because of differences in life history and reproductive strategy, dietary preferences, and the need to adapt to different environmental conditions. Incorporation of these differences into any given model depends on whether they influence the kinetics of the chemical.

The compartments in a PBTK model correspond to tissues and organs with similar kinetic characteristics. For a well-mixed compartment that receives only arterial blood, a mass-balance equation may be written as:

$$dX_i/dt = Q_i\left(C_a - C_{vi}\right) \tag{3.83}$$

Downloaded From Vet-eBooks.com

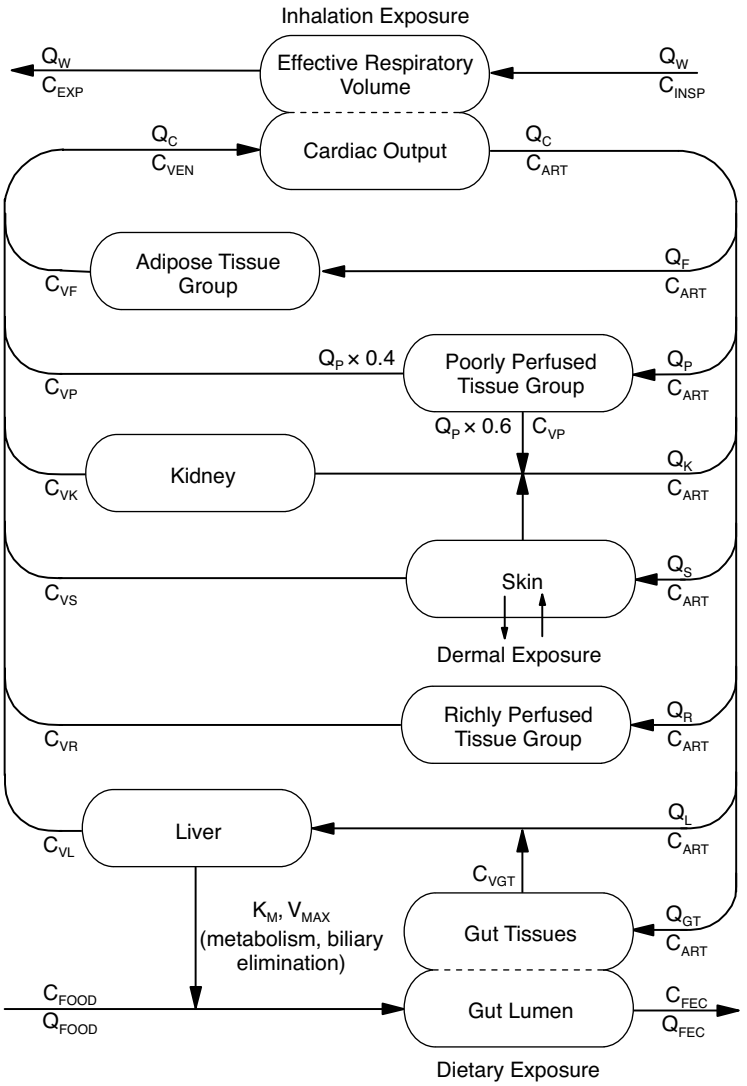

FIGURE 3.22 Schematic representation of a physiologically based toxicokinetic model for fish. Q_F, Q_P, Q_K, Q_S, Q_R, Q_L, and Q_{GT} refer to adipose tissue, poorly perfused tissue (white muscle, bone, and connective tissue), kidney, skin, richly perfused tissue (stomach, upper intestinal tract, spleen, and gonads), liver, and lower intestine blood flows as proportions of Q_C, the cardiac output. Q_W is the flow rate of inspired water that is available to exchange with blood at the gills, and C_{INSP} is the chemical concentration in this water. Q_{FOOD} and Q_{FEC} are the bulk flow rates of food and feces. C_{FOOD} and C_{FEC} are the chemical concentrations in food and feces. C_{VF}, C_{VP}, C_{VK}, C_{VS}, C_{VR}, C_{VL}, and C_{VGT} refer to chemical concentrations in venous blood draining these tissues, and C_{VEN} is the chemical concentration in mixed venous blood. K_M and V_{MAX} are kinetic rate and capacity parameters for saturable metabolism in the liver.

where X_i is the amount of chemical in the compartment, Q_i is the arterial blood flow rate, C_a is the chemical concentration in arterial blood and C_{vi} is the chemical concentration in venous blood draining the compartment. By definition, the rate of chemical accumulation by a tissue cannot exceed the product of blood flow rate and the chemical concentration in arterial blood. The actual rate of chemical accumulation at any point in time depends on both the prior exposure history (i.e., the extent to which chemical has already accumulated) and the rate of chemical exchange between blood and tissues, both of which have the potential to impact C_{vi}.

Downloaded From Vet-eBooks.com

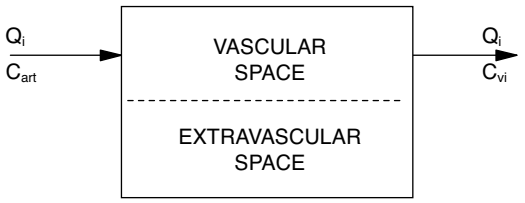

FIGURE 3.23 Schematic representation of a compartment exhibiting flow-limited kinetics. Symbols: Q_i, tissue blood flow rate; C_{art}, chemical concentration in arterial blood; C_{vi}, chemical concentration in venous blood draining the tissue.

A relatively simple tissue description can be developed if it is assumed that the rate of chemical exchange between blood and tissue is fast relative to the blood perfusion rate (Figure 3.23). Under these circumstances, chemical partitioning proceeds to equilibrium with the result that C_{vi} is determined by the chemical concentration in the tissue and the relative affinity of the compound for the tissue and for blood, denoted as P_i, the equilibrium tissue–blood partition coefficient:

$$C_{vi} = C_i / P_i \tag{3.84}$$

Substituting Equation 3.84 into Equation 3.83, one obtains:

$$dX_i/dt = Q_i\left(C_{art} - C_i/P_I\right) \tag{3.85}$$

or equivalently:

$$V_i dC_i/dt = Q_i\left(C_{art} - C_i/P_i\right) \tag{3.86}$$

where C_i is the chemical concentration in the tissue, and V_i is the tissue volume. This type of chemical distribution is said to be flow limited because the rate of chemical accumulation is controlled by the blood flow rate.

Chemical distribution is said to be diffusion limited when the rate of chemical diffusion across a biological membrane limits chemical flux between blood and tissues. Under these circumstances, the tissue must be divided into two subcompartments (Figure 3.24). Chemical flux between subcompartments is then modeled using the Fick relationship (see Equation 3.1). In practice, chemical permeability (i.e., DP_{mw}/h) and the surface area for diffusion are difficult to determine. The permeability-area (PA) product is therefore frequently treated as a first-order transport parameter (k_i), the value of which is determined from exposure data. If a diffusion limitation exists at the capillary endothelium, the relevant subcompartments are the vascular and extravascular tissue spaces. Alternatively, if the diffusion limitation exists at the cellular membrane, the relevant subcompartments are the extracellular and intracellular spaces. In either case, the mathematical treatment is identical, but different volumes must be assigned to represent each subcompartment.

For illustration, it is assumed here that the diffusion limitation exists at the capillary endothelium. Each subcompartment is considered to be a well-mixed phase; therefore, venous blood exiting the tissue has the same chemical concentration as that of the vascular subcompartment space. With these assumptions, a mass-balance equation for the extravascular space (ei) may written as:

$$V_{ei} dC_i/dt = k_i\left(C_{vi} - C_{ei}\right) \tag{3.87}$$

and for the vascular space (bi) may written as:

$$V_{bi} dC_{bi}/dt = Q_i\left(C_{art} - C_{vi}\right) - k_i\left(C_{vi} - C_{ei}\right) \tag{3.88}$$

The chemical concentration in the whole tissue may then be calculated from the volume-weighted contributions of the vascular and extravascular spaces:

Downloaded From Vet-eBooks.com

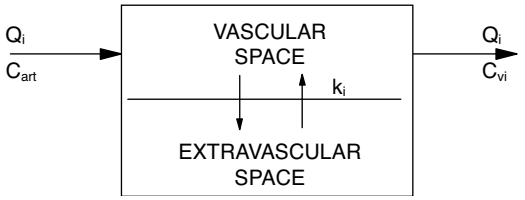

FIGURE 3.24 Schematic representation of a compartment exhibiting diffusion-limited kinetics. Symbols: Q_i, tissue blood flow rate; C_{art}, chemical concentration in arterial blood; C_{vi}, chemical concentration in venous blood draining the tissue; k_i, transport parameter used to model diffusive flux across the capillary endothelium.

$$C_i = \left(V_{bi}C_{bi} + V_{ei}C_{ei}\right)/V_i \tag{3.89}$$

In these equations, the terms C_a, C_{vi}, C_{bi}, C_{ei}, and C_i refer to *diffusible* chemical concentrations. Operationally, this includes both freely dissolved chemical and chemical that is loosely bound, such that the kinetics of desorption do not limit exchange. In some cases, it may be possible to estimate the concentration of diffusible chemical by using a static technique such as ultrafiltration to measure bound and free compound. If, however, desorption of bound chemical contributes to reestablishing the gradient for chemical flux, these data will underestimate the true concentration of diffusible chemical. One way to overcome this problem is to assume that the percentage of total chemical in both the vascular and extravascular spaces that is in a diffusible form is the same. The magnitude and direction of the concentration gradient for diffusion can then be calculated as the difference between chemical concentration in the vascular space and that in the extravascular space, divided by a tissue–blood equilibrium partition coefficient. Under these conditions, Equations 3.86 and 3.87 may be rewritten as:

$$V_{ei}dC_i/dt = k_i\left(C_{vi} - C_{ei}/P_i\right) \tag{3.90}$$

and

$$V_{bi}dC_{bi}/dt = Q_i\left(C_{art} - C_{vi}\right) - k_i\left(C_{vi} - C_{ei}/P_i\right) \tag{3.91}$$

where all concentration terms refer to total chemical concentrations.

Strong chemical binding interactions add complexity to these relatively simple formulations; for example, a number of specific binding proteins sequester metals in tissues, limiting their toxicity (Roesijadi and Robinson, 1994). Similarly, some organic compounds are highly bound by serum albumin while others form stable complexes with specific intracellular receptors. Low-capacity binding systems often follow a Langmuir-type isotherm, saturating at high substrate concentrations. Under these circumstances, the total concentration of chemical in the relevant compartment (C_j; here, denoting C_i, C_{ei}, or C_{bi}) can be expressed as the sum of free (C_j^*) and bound compound (expression in parentheses):

$$C_j = C_j^* + \left(\alpha_i C_j^* / \left(\varepsilon_j + C_j^*\right)\right) \tag{3.92}$$

where α_j is the binding capacity of the receptor and ε_j is the receptor dissociation constant. A first-order binding coefficient may be sufficient to describe the kinetics of a high-capacity binding system.

In view of these potential complexities, it is perhaps remarkable that the assumption of flow-limited chemical distribution has been shown to approximate the kinetic behavior of a large number of compounds in both fish and mammals. The principal advantage of this assumption is that it does not require the fitting of any kinetic parameters. For this reason, it is often used as a default assumption in model formulation. Exposure data are then examined for evidence of a diffusion limitation on chemical flux, generally presented as a slower than anticipated rate of accumulation. Such data would be insufficient to determine where the diffusion limitation existed and to what extent, if any, strong binding played a role in retarding uptake. It could be concluded, however, that additional studies are needed to guide model development. Factors that contribute to diffusion-limited chemical distribution include those generally associated with

Downloaded From Vet-eBooks.com

slow diffusion across biological membranes: large molecular volume, the existence of charged or highly polar substituent groups, and extreme hydrophobic character. The specific rate (per gram of tissue) of tissue blood perfusion may also be a factor. Low blood perfusion rates are associated with large intercapillary diffusion distances. Moreover, in a tissue with very low metabolic demand (e.g., the white muscle of a resting fish), only a fraction of the total tissue mass may be perfused at any point in time. In mammals, diffusion limitations have also been observed in highly perfused tissues, presumably because of reduced blood residence times. In modeling efforts with fish conducted to date, diffusion limitations have been employed to describe the uptake of pyrene into muscle tissue of rainbow trout (Law et al., 1991) and the accumulation of TCDD in adipose tissue of brook trout (Nichols et al., 1998). In the brook trout model, the PA product was calculated as a fraction of the estimated fat blood flow rate. The fitted value of the PA was then interpreted as the effective rate of blood flow to fat.

As the kidney and liver of fish receive both arterial and portal blood, a simple description of these organs can be developed by assuming that arterial and portal blood mix before exchanging with the tissue. Under these circumstances, total blood flow (Q_{mi}) equals the sum of arterial (Q_i) and portal inputs (Q_{pi}):

$$Q_{mi} = Q_i + Q_{pi} \tag{3.93}$$

where Q_{pi} is equal to all or a fraction of arterial flow to the upstream compartment. The chemical concentration in mixed blood (C_{mi}) can be calculated by summing the flow-weighted contributions of arterial and portal blood (C_{pi}):

$$C_{mi} = \left(Q_i C_{art} + Q_{pi} C_{pi}\right) / Q_{mi} \tag{3.94}$$

where C_{pi} is equal to the concentration in venous blood exiting the upstream compartment. Assuming further that chemical uptake by the tissue is flow limited, a mass balance for the compartment may then be written as:

$$dX_i/dt = Q_{mi}\left(C_{mi} - C_{vi}\right) \tag{3.95}$$

When the kinetic descriptions for all tissues have been defined, the concentration of chemical in mixed venous blood can be calculated from the flow-weighted contributions of venous blood draining each tissue compartment. In a model with chemical uptake at the gills, this mixed venous concentration provides one of the inputs to the branchial exchange description (see below). The complete model consists of a system of simultaneous mass-balance differential equations. Numerical integration procedures are then used to solve these equations at each time point.

Routes of Exposure

A critical part of any PBTK model is the route of exposure description. In experimental dosing studies, the investigator generally controls the route and timing of the exposure. Natural exposures may be more difficult to characterize and are more likely to be of a mixed type—that is, involving chemical flux at more than one exchange surface; for example, a compound that is present in water may also be present in prey items upon which a fish feeds. Environmental routes of uptake (branchial, dermal, dietary) can also function as routes of elimination. Indeed, it is possible for one exchange surface to function as a route of uptake (e.g., the gastrointestinal tract), while at the same time another operates as a route of elimination (e.g., the gills). In contrast, some experimental routes of exposure, such as intravascular infusion, function only as routes of uptake.

Branchial Uptake

The structure of fish gills reflects their primary function as a gas-exchange and osmoregulatory organ. A large surface area for exchange is achieved by an elaboration of plate-like structures termed *lamellae*, which form narrow channels above and below each gill filament. In most species, blood flows through

Downloaded From Vet-eBooks.com

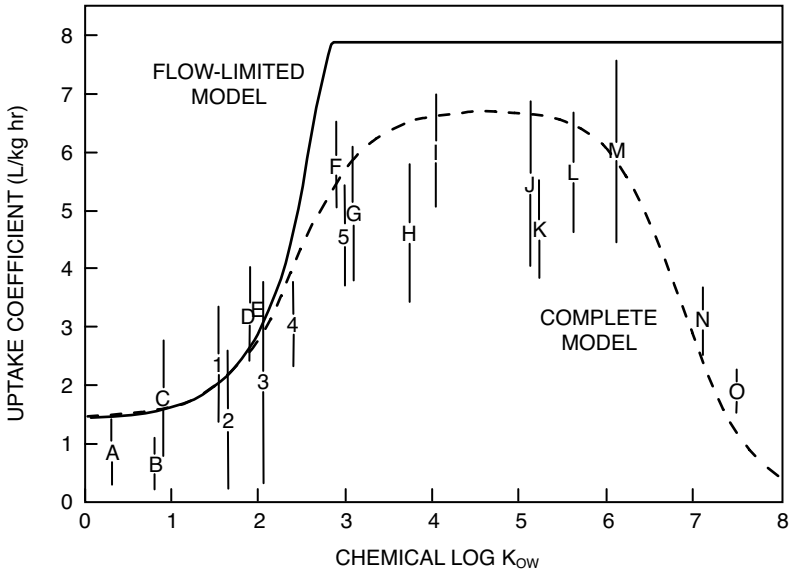

FIGURE 3.25 Observed and predicted uptake of chemicals across the gills of adult rainbow trout as a function of chemical log K_{ow}. Branchial uptake predicted by the flow-limited gill model is shown as a solid line; that predicted by the gill model with flow and diffusion limitations is shown as a dashed line. (Adapted from Erickson, R.J. and McKim, J.M., *Aquat. Toxicol.*, 18, 175–198, 1990.)

the lamellae in a posterior-to-anterior direction, providing for highly efficient counter-current exchange with inspired water.

The principal limitations on chemical uptake at fish gills were reviewed earlier in this chapter (see Compartmental Models for Fish and Branchial Clearance sections). If the permeability of the gill epithelium to a compound is low, diffusion can limit exchange, and uptake flux is controlled by the product of gill permeability and the surface area for diffusion. If, on the other hand, the permeability of the epithelium is high, uptake may be limited by the chemical capacities of blood and water flowing to the gills. A blood flow limitation exists if more chemical is delivered to the gills in respiratory water than can be carried away in blood. A water flow limitation exists if the capacity of blood to carry chemical away from the gills exceeds the chemical capacity of respiratory water.

Ignoring diffusion limitations on uptake, Erickson and McKim (1990a) developed a model for the branchial flux (F_g) of organic chemicals based on flow limitations and the behavior of counter-current exchange systems. The complete flow-limited model may be stated as:

$$F_g = \text{Min}\left[Q_w, Q_c P_{bw}\right]\left[C_w - \left(C_v / P_{bw}\right)\right] \tag{3.96}$$

where Q_w is the flow of inspired water that exchanges with blood, Q_c is the total cardiac output, P_{bw} is an equilibrium blood–water partition coefficient, and C_v is the chemical concentration in venous blood entering the gills. In this equation, F_g is calculated as the product of the concentration gradient between inspired water and venous blood entering the gills (second term in brackets) and the chemical capacity of blood or respiratory water (first term), whichever is less. When the flow-limited model was parameterized using data for rainbow trout it reproduced the well-known dependence of branchial uptake efficiency on chemical log K_{ow} for compounds of low to intermediate hydrophobicity but did not predict the observed decline in uptake for high log K_{ow} compounds (Figure 3.25). In addition, the model tended to overestimate the maximal rate of uptake by about 20%.

Subsequently, Erickson and McKim (1990b) published a more comprehensive gill model that included both flow and diffusion limitations, as well as binding of high log K_{ow} compounds to dissolved organic material. The full model, which included advective (direction of fluid flow) and diffusive (perpendicular

Downloaded From Vet-eBooks.com

to fluid flow) chemical transport in both blood and water, did not yield an analytical solution. An approximate analytical solution was obtained, however, by segregating the lamellar unit into layers in which only advective or diffusive transport predominates. This may be visualized as a diffusion barrier consisting of the gill epithelium and stagnant boundary layers in the adjacent water and blood channels. With these simplifications, branchial flux can be calculated as the product of the concentration gradient between inspired water and venous blood and an exchange coefficient (k_x):

$$F_g = k_x \left(C_w - C_v P_{bw}\right) \tag{3.97}$$

where

$$k_x = \frac{e^{-kd/kb} - e^{-kd/kw}}{\frac{e^{-kd/kb}}{k_w} - \frac{e^{-kd/kw}}{k_b}} \tag{3.98}$$

The terms k_w, k_b, and k_d in the equation for k_x represent the capacity of respiratory water, blood flowing through the gills, and chemical diffusion across the gills, respectively, to support branchial flux:

$$k_w = Q_w \tag{3.99}$$

$$k_b = Q_c P_{bw} \tag{3.100}$$

$$k_d = DA/h \tag{3.101}$$

where D, A, and h, respectively, refer to the chemical diffusivity in, the total area of, and the effective thickness of the gill diffusion barrier. Importantly, this model assumes that chemical diffusion in the aqueous phase of the gill epithelium limits flux. The model does not, therefore, incorporate the partition coefficient (P_{mw}), which appears in the model given by Hayton and Barron (1990) (Equation 3.27). A simulation for rainbow trout generated using the complete model (approximate analytical solution) is shown in Figure 3.25. This simulation accurately describes all of the observed trends in the data, including the reduction in uptake of high log K_{ow} compounds.

The complete gill model has been used to describe branchial uptake of waterborne chemicals by several fish species, requiring the collection of necessary physiological and gill morphometric information (Figure 3.26) (Lien et al., 2001; Nichols et al., 1993). For many compounds, however, a good approximation of branchial flux can be obtained using the simpler flow-limited model. Direct experimental evidence for the predominant influence of flow limitations on branchial uptake has been obtained by independently varying Q_w and Q_c for chemicals with different log K_{ow} values (Schmieder and Weber, 1992). Finally, it is important to understand that both the flow-limited and complete gill models separate the blood circulation into arterial and venous sides. In a PBTK model, chemical taken up across the gills (predicted by the gill description) is added to that already present in venous blood to provide a new value for the arterial blood concentration. The arterial blood concentration is then used as an input to each of the tissue descriptions (Figure 3.22).

Dermal Uptake

Dermal uptake represents a second possible route of exposure that may be important for small fish, juveniles of larger species, and fish that live in intimate contact with contaminated sediments. The structure and function of fish skin were addressed earlier in this chapter. Additional information is provided in a recent review (McKim and Lien, 2001). The general architecture of fish skin (epidermis, dermis, and hypodermis) is similar in most species, but the thickness of these layers varies widely. Additional differences exist with respect to the presence or absence of scales and the number and location of sensory organs, mucous glands, and other specialized structures.

A PBTK model for dermal uptake in small fish was developed by Lien and co-workers (Lien and McKim, 1993; Lien et al., 1994) from the gill model given in Equation 3.97 by assuming that water flow does not limit chemical transport across the skin. This model can be visualized as a parallel network

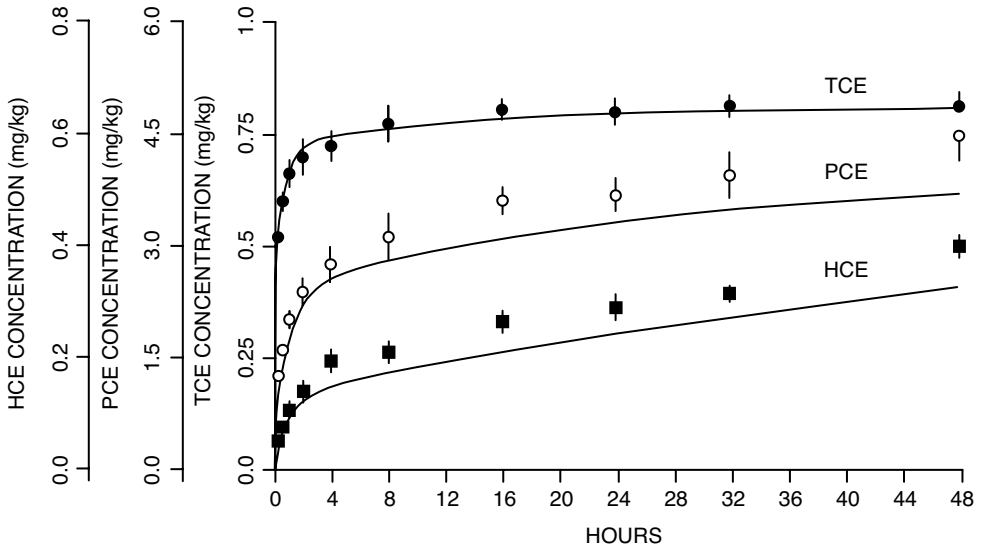

FIGURE 3.26 Concentration time course of tetrachloroethane (TCE), pentachloroethane (PCE), and hexachloroethane (HCE) in arterial blood of adult channel catfish. Catfish were simultaneously exposed to all three chloroethanes in water. Solid lines represent simulations generated using a PBTK model incorporating the branchial uptake description given by Erickson and McKim (1990b). Measured values are shown as individual points. (Adapted from Nichols, J.W. et al., *Aquat. Toxicol.*, 27, 83–112, 1993.)

of capillaries with chemical diffusion from water to blood perpendicular to the capillary axis. Given these assumptions Equation 3.97 simplifies to:

$$k_x = k_b\left(1 - e^{-kd/kb}\right) \tag{3.102}$$

This description suggests that dermal flux may be limited by the capacity of the skin surfaces to support chemical diffusion (k_d) and the capacity of blood flowing to the skin (k_b) to remove chemical once it has been absorbed. The terms k_b and k_d are analogous to those given in Equations 3.99 and 3.100, except that in this case diffusivity, area, and thickness refer to the skin diffusion barrier, and the relevant blood flow rate is that to skin. As in the gill model given by Erickson and McKim (1990b), diffusive flux was assumed to be limited by chemical diffusion in the aqueous phase of the diffusion barrier. Using this model, dermal flux (F_s) may be calculated as the product of k_x and the concentration gradient for uptake:

$$F_s = k_x\left(C_w - C_a/P_{bw}\right) \tag{3.103}$$

The chemical concentration in venous blood draining the skin is then calculated by adding this flux to the amount of chemical already present in arterial blood perfusing the skin.

This model was used to compare the capacities of gill and skin surfaces to support chemical uptake in small fish. Lien and McKim (1993) exposed fathead minnows and Japanese medaka to 2,2′,5,5′-tetrachlorobiphenyl (TCB), and Lien et al. (1994) exposed fathead minnows to a homologous series of three chlorinated ethanes. Model predictions (gill only and gill plus skin) were evaluated by comparison with measured whole-body chemical residues. Based on this analysis, approximately 50% of the total uptake of TCB was attributed to dermal absorption. The contribution of dermal absorption to the uptake of the three chloroethanes ranged from 20 to 30% and tended to increase with the degree of chlorine substitution.

A more complex description of dermal uptake is required if chemical accumulation by skin tissue impacts chemical flux between water and blood. Following the approach used by McDougal et al. (1990) to describe dermal flux of chemical vapors by rats, Nichols et al. (1996) developed a dermal uptake model for fish that incorporates a discrete skin compartment. The model structure was also changed somewhat

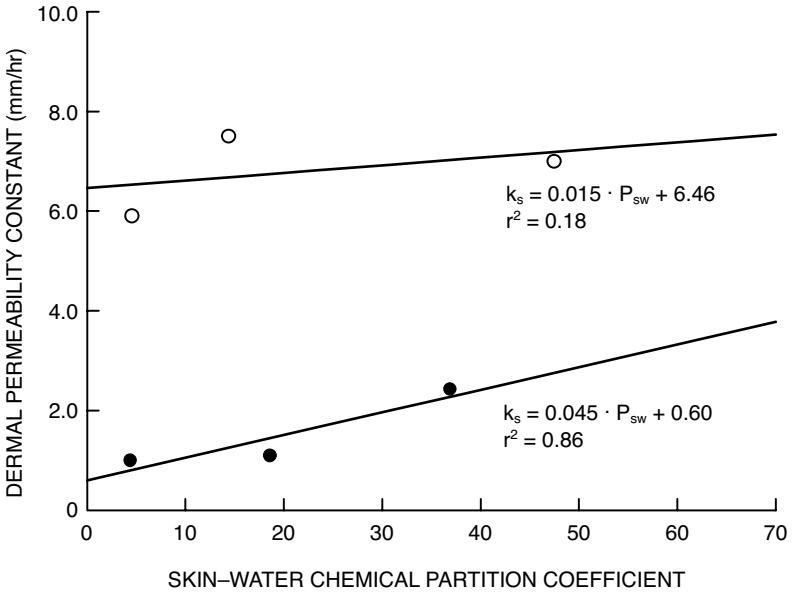

FIGURE 3.27 Dermal permeability of three chlorinated ethanes in rainbow trout and channel catfish as a function of skin–water chemical partitioning. Fitted permeability coefficients for rainbow trout are given as solid circles. Open circles represent fitted coefficients for channel catfish. Equations were generated for each species by simple linear regression. (Adapted from Nichols, J.W. et al., *Fundam. Appl. Toxicol.*, 31, 229–242, 1996.)

from that of Lien et al. (1994) to reflect more detailed aspects of vascular organization. Specifically, anatomical studies with fish suggest that, although a portion of venous blood draining the skin contributes directly to the mixed venous return, most of this blood flows to the caudal vein and from there to the kidney.

Assuming that chemical transfer between blood and skin is flow limited, a mass balance on the skin compartment may be written as:

$$V_s dC_s/dt = Q_s\left(C_a - C_s/P_s\right) + k_s A_s\left(C_w - C_s/P_{sw}\right) \tag{3.104}$$

where P_s and P_{sw} are skin–blood and skin–water equilibrium partition coefficients. The first term on the right-hand side of this equation is identical to that given previously for a flow-limited tissue (Equation 3.86), and the second term describes chemical diffusion across a membrane separating skin tissue from the external environment. In this formulation, k_s is the permeability coefficient defined as in Equation 3.1 (DP_{mw}/h), and A_s is the total skin surface area.

The dermal submodel was evaluated by exposing large trout and channel catfish to a series of chlorinated ethanes in a chambered exposure system (McKim et al., 1996). For these studies, only the trunk region of the fish was exposed. Chemical uptake across the skin then resulted in the accumulation of chemical in blood and tissues and elimination across the gills. By using compounds for which validated inhalation models already existed, it was possible to fit a set of apparent skin permeability coefficients (k_s) (Nichols et al., 1996). Figure 3.27 shows fitted permeability constants for three chloroethanes in both trout and channel catfish. Fitted permeability coefficients increased little if at all with increasing chemical affinity for skin. Based on this observation, the authors speculated that diffusion through tissue water limits dermal flux of moderately hydrophobic compounds.

Dietary Uptake

Chemical and physiological factors that control xenobiotic uptake from the diet were described earlier in this chapter. The dietary route of exposure may be important within an aquaculture setting as a means of dosing animals with antibiotics and other therapeutic agents. Oral bioavailability defined using AUC

Downloaded From Vet-eBooks.com

methods is often used to characterize uptake efficiency for these compounds. The diet also represents an important route of uptake for lipophilic environmental contaminants (log $K_{ow} > 5$) (Bruggeman et al., 1984). This is due in part to the fact that these compounds accumulate to high levels in prey items. High log K_{ow} compounds also tend to bind to dissolved and particulate organic material in water, reducing their availability for branchial uptake. Similar considerations may also apply to several metalloids and organometallic compounds, including selenium, cesium, methylmercury, and tributyltin.

Considerable effort has been expended to identify factors that control dietary uptake of hydrophobic compounds, and recent modeling work reflects this emphasis. Within the intestine, uptake of dietary lipid and a reduction of meal volume increase chemical activity in the gut contents above that of the meal, potentially resulting in chemical uptake by fish even when chemical concentrations in their prey are at or near equilibrium with those in water (see Mechanism of Biomagnification section below). It is important, however, to note that even low rates of metabolism could reduce the extent of chemical accumulation substantially (Clark et al., 1990; de Wolf et al., 1992; Endicott and Cook, 1994; Nichols et al., 2004b). Chemicals in the diet are particularly susceptible to metabolic clearance because of the potential for presystemic metabolism in tissues of both the gut and liver (Van Veld, 1990).

To date, very few PBTK models incorporating a dietary uptake description have been developed for mammals, and only two have been published for fish. Most of the mammalian models have treated dietary uptake as a first-order absorptive process. If absorption is assumed to be 100% efficient, the dose can be modeled as a mass of compound and it is not necessary to define a gut compartment. A second approach also employs a first-order absorptive rate constant but provides for the possibility that absorption is less than 100% efficient. In this second approach, a gut lumen compartment is defined and the consumption of food and egestion of feces are modeled as bulk flow rates or periodic events. In both of these approaches, the value of the first-order rate constant is generally obtained by fitting model simulations to measured (usually blood or plasma) chemical concentrations.

At the other end of the spectrum in terms of complexity, Bungay et al. (1981) developed a highly detailed model for dietary uptake of chlordecone in the rat. The gut portion of this model consists of six compartments corresponding to the stomach, small intestine (three compartments), cecum, and lower intestine. Diffusion limitations on chemical flux were assumed to exist at both the tissue–blood and tissue–gut lumen interfaces, and 12 different rate constants were fitted by modeling to measured residues in tissues and gut contents.

Nichols et al. (1998) used two approaches to model the accumulation of TCDD in feeding studies with brook trout. The first approach was based on the assumption that a chemical equilibrium is established between fecal material contained within the terminal colon (C_{fec}) and venous blood draining the GIT (C_{vgt}):

$$C_{fec} = C_{vgt}P_{fb} \tag{3.105}$$

where P_{fb} is the feces–blood equilibrium chemical partition coefficient. Termed the *fecal partitioning submodel*, this approach is similar to that proposed by Barber et al. (1991) to model PCB accumulation by lake trout, the principal difference being that an equilibrium is established with venous blood exiting the gut and not with the entire fish.

From mass-balance considerations, it follows that:

$$\left(Q_{food}C_{food}\right) - \left(Q_{fec}C_{fec}\right) = \left(Q_{gt}C_{vgt}\right) - \left(Q_{gt}C_{art}\right) \tag{3.106}$$

where Q_{food} is the feeding rate, C_{food} is the TCDD concentration in the diet, Q_{fec} is the fecal egestion rate, Q_{gt} is the blood flow rate to the lower intestines, and C_{art} is the chemical concentration in arterial blood. Substituting Equation 3.105 into Equation 3.106 and solving for C_{vgt} yields:

$$C_{vgt} = \left(Q_{gt}C_{art} + Q_{food}C_{food}\right) / \left(Q_{gt} + Q_{fec}P_{fb}\right) \tag{3.107}$$

Venous blood draining the tissues of the lower intestine was then assumed to mix with arterial blood flowing to the liver.

Downloaded From Vet-eBooks.com

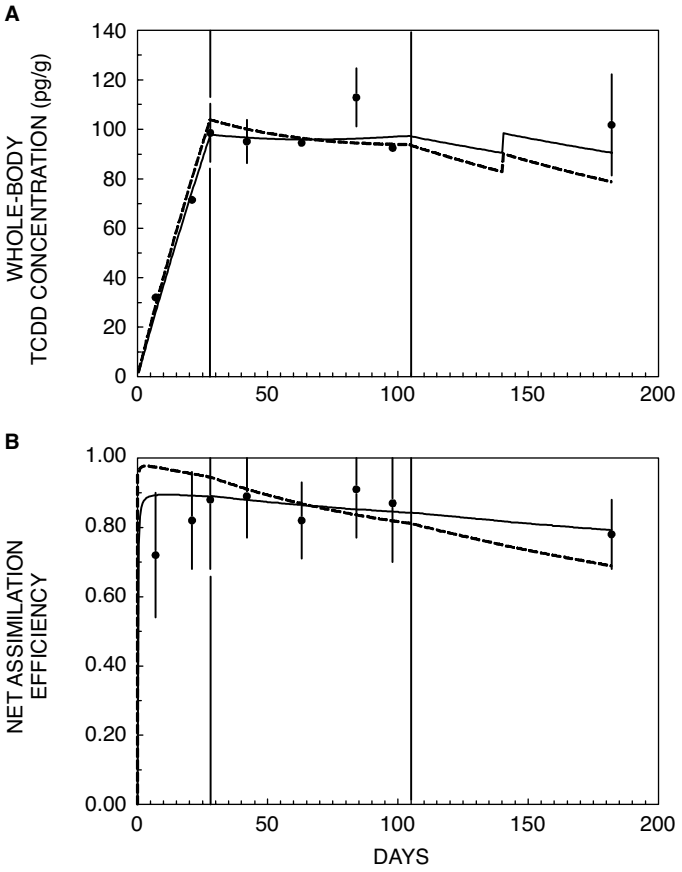

FIGURE 3.28 Accumulation of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) in brook trout. Measured whole-body concentrations (A) and calculated assimilation efficiencies (B) are shown as individual points. Simulations were obtained using a physiologically based toxicokinetic model for brook trout. Dashed lines were generated using a "fecal partitioning" gut submodel. Solid lines were obtained by imposing a "diffusion limitation" on dietary uptake. Vertical lines delineate the three phases of the study: loading (0 to 28 days), maintenance (29 to 105 days), and depuration (105 to 182 days). (Adapted from Nichols, J.W. et al., *Environ. Toxicol. Chem.*, 17, 2422–2434, 1998.)

The primary advantage of this simple gut description is that it is not necessary to fit the value of a first-order absorption rate constant. In a very simplistic way, the model also accounts for changes in chemical affinity that accompany digestion (through its impact on P_{fb}) and the concentrating effect of a reduction in meal volume (by specifying both Q_{food} and Q_{fec}). Moreover, because chemical is allowed to accumulate in blood flowing to the gut tissue compartment, the model provides for the possibility of decreased absorption efficiency due to a decline in the gradient for uptake. The disadvantage of this model is that it cannot account for kinetic limitations that may prevent an equilibrium from being established between feces and blood.

In the brook trout study, measured whole-body TCDD residues were lower than those predicted by the fecal partitioning model, suggesting the existence of a kinetic limitation on dietary uptake (Figure 3.28). A second model was therefore developed that incorporated a diffusion limitation on the chemical flux between feces and tissues of the intestinal tract. For the feces:

$$dA_{fec}/dt = \left(Q_{food}C_{food}\right) - \left(Q_{fec}C_{fec}\right) - k_{gt}\left(C_{fec} - C_{gt}P_{fgt}\right) \tag{3.108}$$

where A_{fec} is the amount of TCDD in feces, k_{gt} is a first-order rate constant, C_{gt} is the chemical concentration in gut tissues, and P_{fgt} is the feces–gut tissue equilibrium partition coefficient. For tissues of the intestinal tract:

Downloaded From Vet-eBooks.com

$$dA_{gt}/dt = Q_{gt}\left(C_{art} - Cv_{gt}\right) + k_{gt}\left(C_{fec} - C_{gt}P_{fgt}\right) \quad (3.109)$$

Chemical concentration in venous blood draining the gut was then determined from that of the gut tissues by assuming that chemical exchange between blood and tissues was flow limited.

The value of k_{gt} was determined by Nichols et al. (1998) by fitting model simulations to measured whole-body TCDD concentrations and calculated assimilation efficiencies. The model was then used to simulate TCDD kinetics in various tissues and organs, resulting in good correspondence between predicted and observed values. The disadvantage of this approach is that k_{gt} is difficult to interpret. The fitted value of k_{gt} (which has units of flow) was found to be about 5% of the estimated blood flow rate to the lower intestine. It could not be determined, however, whether this reduction in uptake was due to a limitation on diffusion, chemical binding in feces, or some other kinetic constraint.

Recently, Nichols et al. (2004a) developed a more detailed description of the fish GIT to describe dietary uptake of [^{14}C]-2,2′,5,5′-tetrachlorobiphenyl (TCB) by rainbow trout. The GIT was modeled using four compartments corresponding to the stomach, pyloric ceca, upper intestine, and lower intestine, and the luminal volume of each compartment was allowed to change in time as a function of bulk flow of ingesta and nutrient uptake. The model was developed using data from rainbow trout that were fed a meal of 60-day-old fathead minnows contaminated with TCB. Chemical partitioning coefficients were adjusted to account for changes in chemical affinity associated with the uptake of dietary lipid. Permeability coefficients for the absorbing gut segments were then fitted by modeling to measured TCB concentrations in gut contents and tissues.

As expected, most of the TCB was taken up within the upper intestine during the period of peak lipid absorption. It was concluded, however, that a kinetic limitation on chemical uptake acting along the entire length of the GIT resulted in a chemical disequilibrium between feces and tissues of the lower intestine. The mechanistic basis for this kinetic limitation remains unknown; however, a comparison of fitted gut permeability coefficients with the permeability coefficient for branchial uptake of TCB suggests that dietary uptake is unlikely to be limited by the rate of diffusion across the gastrointestinal epithelium.

The gut model was then used to simulate chronic exposures to TCB and a series of hypothetical high log K_{ow} compounds (Nichols et al., 2004b). Predicted steady-state biomagnification factors for TCB were very close to values measured in both laboratory and field studies; however, the incorporation of a log K_{ow}-dependent decrease in gut permeability was required to reproduce observed trends in biomagnification and dietary assimilation efficiency. Although not constituting proof as such, this finding suggests that dietary absorption of hydrophobic organic compounds by fish is controlled in part by factors that vary with chemical log K_{ow}.

Hepatic and Renal Elimination

The foregoing descriptions of chemical exposure routes in fish are bidirectional with respect to chemical flux and can function, therefore, as routes of elimination when activity gradients favor the movement of chemical out of the organism. Thus, blood and water flow limitations that define maximum rates of chemical uptake at the gills will also act to limit maximal rates of branchial elimination. Depending, however, on the way that a particular compound is handled, a complete PBTK model may also have to incorporate other routes of elimination, potentially including urinary and biliary elimination, as well as biotransformation.

The physiological and biochemical factors that dictate hepatic and renal handling of xenobiotic compounds were reviewed earlier in this chapter. Although limited, studies in fish suggest that hepatic and renal clearance contribute substantially to the elimination of many compounds, particularly if they are substrates for active systems that secrete chemicals to urine and bile. Currently, guidance on the kinetics of elimination by urinary and biliary routes comes largely from mammalian studies. For most compounds, the kinetics of renal clearance by glomerular filtration are first order with respect to the free chemical concentration in plasma. In contrast, clearance pathways involving active secretion to urine or bile often exhibit saturable, nonlinear kinetics. Biotransformation pathways in both mammals and fish may also exhibit nonlinear kinetics.

Downloaded From Vet-eBooks.com

The first step in modeling elimination is to specify the organs where it occurs and the chemical kinetics (e.g., first-order, saturable) over the concentration range to which the tissue is exposed. Elimination may then be modeled by incorporating a clearance expression (dA_{cl}/dt) into the mass-balance equation for the eliminating compartment:

$$dA_i/dt = Q_i\left(C_{art} - C_{vi}\right) - dA_{cl}/dt \tag{3.110}$$

Referenced to the chemical concentration in venous blood draining the tissue, the kinetics of first-order clearance can be written as:

$$dA_{cl}/dt = k_{fc}\, C_{vi} V_i \tag{3.111}$$

Saturable pathways can be described using a Michaelis–Menten type of equation where K_m and V_{max} are parameters that define an *in vivo* intrinsic clearance term:

$$CL_{int} = V_{max}/\left(K_m + C_{vi}\right) \tag{3.112}$$

$$dA_{cl}/dt = V_{max} C_{vi}/\left(K_m + C_{vi}\right) = CL_{int} C_{vi} \tag{3.113}$$

Although often localized to the liver as a matter of convenience, biotransformation can be incorporated into any one or more of the individual tissue descriptions. Ascribing metabolism to the tissue where it actually occurs may be critical to the modeling outcome when this activity limits chemical uptake across the gills or gut (Barron et al., 1989; Van Veld, 1990). In some cases, a modeler may be more interested in the kinetics of a metabolite than of the parent compound from which it was derived. Under these circumstances, the disappearance of parent compound (including both the rate of metabolism and the site where this metabolism occurs) is equated to the production of the metabolites) (Nichols, 1999). Additional information, including equilibrium partitioning, plasma binding, chemical reactivity (e.g., covalent binding to tissue macromolecules), and subsequent elimination, is then required to develop a description of metabolite kinetics.

Model Parameterization

Anatomical, physiological, and biochemical information required to develop PBTK models for fish is given throughout this text. Additional information is provided in numerous texts and hundreds of scientific papers. Although it is true that most of this information has been developed for a relatively few fish species, allometric and temperature relationships permit the extrapolation of these data to other, untested species. The goal of this section is to provide guidance on how existing data can be used in PBTK modeling efforts. An emphasis is placed on chemical elimination pathways, as these pathways are often found to be primarily responsible for differences in chemical disposition that exist among species.

Physiological Inputs

In the absence of measured values for a given fish species, it may be possible to estimate the values of critical physiological inputs using allometric scaling relationships. A review of allometric scaling techniques is given by Schmidt-Nielsen (1984). These principals have been applied to PBTK modeling efforts by several authors (Dedrick, 1973; Mordenti, 1986; Rowland, 1985; Travis et al., 1990). In mammals, physiological parameters linked to cellular metabolism (e.g., cardiac output, oxygen consumption rate) often scale to the 3/4 power of body weight (exponent of 0.75). Renal clearance and the capacity for hepatic metabolism (V_{max}) were reported by Travis et al. (1990) to scale to an exponent of 0.75. In a more recent review, Hu and Hayton (2001) found that renal clearance scales to the 2/3 power of body weight (exponent of 0.67). The Michaelis–Menten constant, K_m, which is a measure of the substrate affinity of an enzyme, is thought to remain relatively constant across species.

In studies with fish, it has been difficult to make comparisons among species because of differences in experimental design (e.g., temperature, light cycle) that affect metabolic rate. The strongest comparisons,

Downloaded From Vet-eBooks.com

therefore, have been made using different sized individuals of a single species held under otherwise identical conditions. Although highly variable among species, the average allometric exponent for oxygen consumption rate is about 0.8, or slightly higher than the average value for mammals (Schmidt-Nielsen, 1984). Within a single species, gill surface area also tends to scale to an exponent of about 0.8 (Hughes, 1984), as does the absorptive surface area of the intestinal mucosa (Buddington and Diamond, 1987). Skin surface area within a species scales to an exponent of about 0.67 in accordance with the surface law (Schmidt-Nielsen, 1984). Data presented by Wood and Shelton (1980) suggest that cardiac output in rainbow trout scales to an exponent of about 0.9. The dependence of cardiac output on acclimation temperature also has been characterized for rainbow trout (Barron et al., 1987a). Cardiac output in trout had a Q10 of 4.0 (i.e., a 10°C increase in temperature was associated with a fourfold increase in cardiac output). Q10 values reported for oxygen consumption in fish and other poikilotherms generally average around 2.0 (Ott et al., 1980).

Small fish present special challenges for PBTK modeling because direct measurements of many anatomical and physiological parameters are difficult or impossible to make. Lien and McKim (1993) addressed this problem in studies with Japanese medaka and fathead minnows by calculating effective respiratory volume (Q_w) and functional gill surface area as functions of oxygen consumption rate, which can be easily measured even in larval fishes. Cardiac output for these small fish species was estimated using a relationship given by Erickson and McKim (1990b) that accounts for the effect of both size and temperature.

Chemical Partitioning

Mass-balance equations that describe chemical flux between blood and tissues include a term that defines both the direction and magnitude of the concentration gradient. Generally, the blood is defined as the reference state. The concentration gradient is then calculated as the difference between the chemical concentration in blood and the concentration in the tissue, divided by an equilibrium tissue–blood partition coefficient. In the context of this description, it is assumed that chemical associations with blood and tissue constituents are low affinity. Operationally, this means that the kinetics of chemical dissociation from binding sites in blood and tissues are fast relative to the residence time of blood in tissues and do not, therefore, limit the overall kinetics of distribution. Partition coefficients are also required to develop physiological descriptions of chemical flux at the gills, skin, and gut.

Chemical partition coefficients can be obtained directly from chemical concentrations in blood and tissues of animals that have been exposed to near steady state, provided that metabolism or some other route of elimination does not reduce tissue concentrations below those expected from simple partitioning. The disadvantage of this approach is that it requires prior exposure of animals to generate model simulations. A number of *in vitro* systems have also been developed to generate partition coefficients. Gargas et al. (1989) used a vial headspace equilibration technique to determine partition coefficients for a large number of volatile hydrocarbons. This method was subsequently adapted for use with fish tissues (Hoffman et al., 1992). The vial equilibration method measures the depression in headspace concentration that occurs as a result of chemical partitioning to the sample. Samples generally consist of tissue homogenates diluted in saline, although the technique has also been adapted for use with intact samples of skin (Mattie et al., 1993). Other *in vitro* partitioning methods have been developed for nonvolatile compounds. Law et al. (1991) obtained partitioning estimates for pyrene in trout tissues using an equilibrium dialysis technique. Jepson et al. (1994) used a filtration method to evaluate the partitioning of lindane, parathion, paraoxon, perchloroethylene, and two haloacetic acids between rat tissues and saline. Murphy et al. (1995) measured the partitioning of TCDD and estradiol between rat tissues and propylene carbonate. Because this solvent is essentially immiscible with tissues, this method did not require a filtration step.

To a first approximation, hydrophobic organic compounds partition between tissues and blood in accordance with the lipid content of each phase (Van der Molen et al., 1996). *n*-Octanol is frequently used as a surrogate for biological lipid. By assuming a correspondence between *n*-octanol–water partitioning and lipid–water partitioning, Nichols et al. (1991) developed an algorithm to predict blood–water partitioning in rainbow trout. A similar approach, expanded to include partitioning to phospholipid, was used to predict tissue–blood partition coefficients in rats (Poulin and Krishnan, 1995).

Downloaded From Vet-eBooks.com

Chemical partitioning in a vegetable oil/water system has also been used as a basis for predicting tissue–blood partitioning (Poulin and Krishnan, 1995, 1996a). Alternatively, measured partitioning values can be used to fit the value of slope and intercept terms that relate the extent of partitioning to chemical log K_{ow} and tissue lipid content. Using this approach, tissue-specific equations have been developed for rats, humans, and fish (Bertelsen et al., 1998; DeJongh et al., 1997). An interesting feature of these studies is that fitted slope and intercept terms have suggested that nonlipid cellular constituents contribute substantially to chemical partitioning in lean tissues, including blood.

High-Affinity Binding

High-affinity binding can affect chemical disposition by reducing the fraction of a compound in blood or tissues that is free to diffuse across cellular membranes. An example of high-affinity binding is provided by mammalian PBTK models for TCDD. Although differing in detail, all such models feature some type of specific binding in the liver, generally including an inducible component (Leung et al., 1990). An important outcome of this binding is that TCDD can induce its own redistribution from fat to liver. Fish do not appear to possess these hepatic binding proteins in quantities sufficient to influence TCDD distribution (Nichols et al., 1998). A second example of high-affinity binding is that exhibited toward many heavy metals. Endogenous metal-binding proteins regulate internal concentrations of free metal, both as a means of limiting toxicity and because many metals perform vital biological functions as cofactors and components of enzymes and oxygen transport proteins (Roesijadi and Robinson, 1994). To date, no PBTK models have been developed for metals in fish, and only a few exist for mammals (Gray, 1995; O'Flaherty, 1991, 1996). It may be anticipated that knowledge of metal-binding systems will be required to develop PBTK models for uptake and disposition of most metals.

Urinary and Biliary Elimination

Radiolabeled microspheres have been used to estimate arterial blood flow to the kidneys of arctic grayling (Cameron, 1975), rainbow trout (Barron et al., 1987a), and channel catfish (Schultz et al., 1999). Arterial renal blood flow in the grayling was about 6% of cardiac output; in trout, arterial blood flow ranged from 6 to 10% of cardiac output, depending on the acclimation temperature. Added together, arterial blood flows to the head and trunk kidneys of channel catfish constituted about 9% of cardiac output. Renal portal blood flows in fish are poorly known and cannot be determined using the microsphere method. In most species, however, renal portal blood is supplied largely by the caudal vein, which drains both the skin and the trunk musculature (Satchell, 1992; Smith and Bell, 1975). An estimate of total blood flow to the kidney may therefore be determined by summing the arterial flow and the estimated flow in the caudal vein. In rainbow trout, this results in a total estimated flow equal to about 42% of cardiac output (Nichols et al., 1990). Reported urine flows in fish were summarized by Hickman and Trump (1969) and Hunn (1982). Urine flows in freshwater fish generally range from 1.0 to 10.0 mL hr^{-1} kg^{-1}, while those in saltwater fish range from 0.1 to 1.0 mL hr^{-1} kg^{-1}. Glomerular filtration rates in fish, summarized by Hickman and Trump (1969), usually exceed urine flow in a given species by a factor of about 1.5 to 5.0.

Measured bile flow rates in fish are generally quite low, ranging from 30 to 200 μL hr^{-1} kg^{-1} (Boyer et al., 1976a,b,c; Gingerich et al., 1977; Sanz et al., 1993; Schmidt and Weber, 1973); nevertheless, secretion into bile may represent an important route of elimination for some compounds. Zaharko et al. (1972) incorporated biliary elimination into a PBTK model for methotrexate in stingrays. Bungay et al. (1976) described the biliary elimination of phenol red and its glucuronide conjugate in a PBTK model for the dogfish shark. In both efforts, first-order rate constants were used to represent the sum of metabolic and secretory processes. The value of each rate constant was determined by modeling to measured amounts of chemical in gallbladder bile (because the animals were not fed, all of the bile produced was retained in the bladder). Time constants were incorporated into both models to simulate observed delays in chemical appearance due to the time required to transit the biliary tree. The model presented by Bungay et al. (1976) also incorporated a first-order renal clearance constant to describe the appearance of phenol red and its glucuronide conjugate in urine. Figure 3.29 shows model simulations and measured chemical concentrations in bile and urine given in this study.

Lines represent simulations generated using a physiologically based toxicokinetic model, and the symbols show measured values. (Adapted from Bungay, P.M. et al., *J. Pharmacokinet. Biopharmaceut.*, 4, 377–388, 1976.)

Biotransformation

Currently, there is considerable interest in using *in vitro* metabolism information to develop PBTK models for compounds that undergo biotransformation. Questions remain, however, concerning the ability of *in vitro* systems to predict *in vivo* metabolism. Due to its known importance as a metabolizing organ, most of the metabolism research conducted to date has focused on the liver. The preparations most commonly used for *in vitro* liver metabolism research are microsomes, freshly isolated hepatocytes, S9 fractions, and precision-cut liver slices. The activity of a microsomal or S9 preparation is commonly expressed as µmoles (of product) min^{-1} mg $protein^{-1}$; that of an isolated hepatocyte preparation is generally expressed as µmoles min^{-1} M $cells^{-1}$ (M = 10^6); and that of a liver slice may be expressed as µmoles min^{-1} $slice^{-1}$, µmoles min^{-1} mg $tissue^{-1}$, or µmoles min^{-1} M $cells^{-1}$.

An approach for incorporating *in vitro* metabolism data into PBTK models was presented by Houston and Carlile (1997a). Briefly, their approach is to: (1) estimate *in vitro* intrinsic clearance ($CL_{in\,vitro,int}$) from the ratio of V_{max}/K_m, determined under linear conditions with respect to time and the amount of enzyme present (i.e., mg of protein or number of cells) (Rane et al., 1977); (2) extrapolate $CL_{in\,vitro,int}$ to *in vivo* intrinsic clearance for the whole liver ($CL_{in\,vivo,int}$) using biologically based proportionality constants; (3) incorporate $CL_{in\,vivo,int}$ into an appropriate liver model that explicitly accounts for both blood-flow limitations and chemical binding relationships; and (4) account for any nonhepatic routes of chemical clearance. A conceptually similar approach was used by Ploemen et al. (1997) to incorporate human *in vitro* data into a PBTK model for ethylene dibromide.

In a review of earlier work involving several mammalian species, Wilkinson (1987) found that hepatic extraction ratios were generally well predicted by *in vitro* estimates of V_{max} and K_m, determined using microsomes, S9 fractions, and isolated hepatocytes. Houston and Carlile (1997b) compared $CL_{in\,vivo,int}$ estimates for 35 compounds, obtained by extrapolating data from rat microsomes, hepatocytes, and liver slices, to observed *in vivo* values. Clearance rates predicted by isolated hepatocytes and liver microsomes were highly correlated. In general, however, isolated hepatocytes provided the most accurate predictions of *in vivo* clearance. $CL_{in\,vitro,int}$ values measured using rat liver slices were lower than those obtained

Downloaded From Vet-eBooks.com

using isolated hepatocytes when expressed in comparable units (per 10^6 cells). Similarly, Worboys et al. (1996a,b) found that $CL_{in\ vitro,int}$ values for several compounds (expressed as V_{max}/K_m on a whole-liver basis) calculated using data from liver slices were lower than those obtained using isolated hepatocytes. Moreover, the extent of this difference increased with increasing metabolic activity. These studies suggest that slice metabolism rates are influenced by the rate of chemical diffusion from the culture medium into the center of the slice.

Working with rainbow trout, Cravedi et al. (1999) found that isolated hepatocytes were well suited for *in vitro* studies of biotransformation but in some cases failed to produce metabolites found *in vivo* in urine and bile. Research with mammals suggests that it is common for chemicals to be transformed by more than one metabolic reaction. Each of these reactions may exhibit saturable kinetics, characterized by a different set rate and affinity constants. Under these circumstances, it is possible for one pathway to predominate at one substrate concentration while another predominates at higher or lower concentrations.

In several studies with mammals, *in vitro* metabolic parameters have been evaluated by comparison with *in vivo* parameters determined using PBTK models. This approach is based on the assumption that a PBTK model is "correct" with respect to all nonmetabolic aspects of parent chemical disposition. The model can then be used to fit *in vivo* metabolism parameters by simulating the disappearance of parent compound or, less frequently, the appearance of metabolites. Depuration data are generally preferred for this purpose because of the absence of complications associated with chemical uptake and the rapid phase of internal distribution. Not surprisingly, the agreement between *in vitro* metabolism data and fitted *in vivo* parameters has been variable (Fiserova-Bergerova, 1995). In addition to limitations of the *in vitro* systems themselves, substantial metabolism may occur in tissues other than those to which the metabolism was ascribed in the model (and for which *in vitro* data are available). For this reason, fitted *in vivo* parameters are best thought of as *apparent* values representing the summed activities of all relevant enzyme systems and tissues. Law et al. (1991) used K_m and V_{max} data from a trout hepatocyte system to develop a PBTK model for pyrene. Total pyrene clearance greatly exceeded that predicted by *in vitro* metabolism, requiring the incorporation of a fitted clearance constant.

Metabolic parameters determined from *in vivo* studies can also be incorporated into PBTK models. Several authors have attempted to characterize *in vivo* metabolism by measuring products retained by fish or eliminated in bile, urine, feces, and exposure water (Bradbury et al., 1986, 1993; Cravedi et al., 1999; McKim et al., 1986; Stehly and Hayton, 1989a). In practice, however, these measurements are very difficult to make due to low metabolite concentrations and incomplete extraction of samples. One approach to dealing with these problems is to employ a technique called *microdialysis* to measure metabolite concentrations in blood and tissues. McKim et al. (1993) implanted a microdialysis probe into the dorsal aorta of rainbow trout and measured phenol and its major phase II metabolites (phenylglucuronide and phenylsulfate) in the blood of fish exposed to phenol in water. More recently, Solem et al. (2003) used a microdialysis probe to deliver a parent compound (phenol) to the liver in rainbow trout and measure the production of phase I metabolic products (hydroquinone and catechol). An important advantage of microdialysis sampling method is that dialysate samples are free of protein and can be analyzed without extraction. These experiments provide qualitative information about the identity and relative concentrations of metabolic products and can be performed without the need to expose whole fish. Improved *in vivo* calibration procedures and a knowledge of chemical concentration gradients around the microdialysis probe are required, however, before this information can be used to estimate metabolic rate constants.

Utility of Physiologically Based Fish Models

In the true sense of the word, a PBTK model cannot be said to be valid, only that it does or does not reproduce observed kinetics. Confidence in the specification of physiological parameters for a single species is gained if the same set of inputs provides acceptable simulations for several compounds exhibiting diverse partitioning behavior. Similarly, confidence in model structure derives from the ability to simulate the kinetic behavior of the one or more chemicals in several different species by making appropriate changes in physiological inputs.

Downloaded From Vet-eBooks.com

The principal advantage of a PBTK model is that it provides descriptions of the chemical concentration time course in specific tissues of interest. This provides a direct link to studies of toxic effect and in particular to observations for a specific site of action. As an example, numerous studies have suggested that TCDD is highly toxic to fish in early life stages. In wild fish, this exposure occurs following maternal transfer of accumulated residues to the developing ovaries. A PBTK model for the maternal transfer of TCDD was therefore developed to support studies of TCDD embryotoxicity in brook trout (Nichols et al., 1998). A second important use of PBTK models is to evaluate competing assumptions about factors that control chemical uptake and disposition. Nichols et al. (2004a,b), for example, used a PBTK model to investigate factors that control dietary uptake of hydrophobic organic compounds. Based on these studies, it was concluded that a log K_{ow}-dependent kinetic limitation prevents the gut tissues and contents from attaining an internal equilibrium. The nature of this limitation remains unknown, but it does not appear to be related to diffusion across the gastrointestinal epithelium. PBTK models can also be used to estimate important kinetic parameters that may be difficult or impossible to determine otherwise. Several examples of this approach appear in the preceding text, including the use of models to solve for biliary elimination rate constants (Bungay et al., 1976; Zaharko et al., 1972), dermal permeability constants (Nichols et al., 1996), and metabolic rate constants (Law et al., 1991).

The utility of PBTK models for fish was demonstrated particularly well by a linked toxicokinetic and toxicodynamic model for paraoxon in rainbow trout (Abbas and Hayton, 1997). Paraoxon is produced in mammals by oxidative metabolism of the insecticide parathion and is a potent inhibitor of acetylcholinesterase (AChE) and carboxylesterase (CaE). The activation of parathion to paraoxon is thought to be insignificant in trout; however, paraoxon can be formed in aquatic environments by nonenzymatic conversion of parathion and may be available for uptake by fish directly from water. The toxicokinetic portion of this model accurately simulated the uptake of paraoxon from water and its distribution to selected tissues. This information was then combined with experimentally determined rates of AChE and CaE synthesis and degradation, as well as biomolecular inhibition rate constants determined in previous studies with rodents. The linked model successfully reproduced the observed time course of AChE inhibition in each of the tissues examined and confirmed the role of CaE in detoxification of paraoxon by sequestration of active compound (Figure 3.30).

Another use of PBTK models is to evaluate the potential for variability among individuals of a single species to impact chemical uptake and disposition. A simple approach to this question was provided by Lien et al. (2001), who simulated the kinetics of three chlorinated ethanes in lake trout using physiological data from individual animals. Simulations for each animal were then plotted to represent the range of anticipated outcomes. Alternatively, statistical distributions for individual model inputs can be characterized and used in a repeated sampling (Monte Carlo) design to generate a distribution of predicted outcomes. The principal advantage of the former approach is that it explicitly treats the possible interdependence of model parameters. The Monte Carlo approach can be adapted to deal with parameter interdependence. In practice, however, this is difficult because the necessary information is generally lacking.

Mammalian PBTK modeling efforts are largely driven by the needs of human health risk assessment and in particular by the need to extrapolate data from laboratory test animals to humans. In this context, it is necessary to consider factors such as aging, health status, and dietary habits that could result in increased vulnerability among a subset of the human population. For fish and other ecological receptors, the principal driving force behind PBTK model development is the need to identify species that, for toxicokinetic or other reasons, may be particularly vulnerable. Simultaneous exposure by multiple routes is common in the environment. PBTK modeling is useful in this regard as it enables modeling of multiple chemical fluxes at all relevant exchange surfaces.

The principal disadvantage of using a PBTK modeling approach is that considerable effort is required to develop models for new species and chemicals. Future applications of the PBTK modeling approach will depend on the systematic collection of necessary biological and chemical information, as well as the development of methods for estimating critical parameters when data for a compound and species are limited or absent altogether. Quantitative structure–activity relationship (QSAR) approaches hold particular promise as a means of obtaining tissue partitioning estimates, and perhaps also metabolic rate predictions (McKim and Nichols, 1994; Parham and Portier, 1998; Parham et al., 1997; Poulin and Krishnan, 1996b; Verhaar et al., 1997).

Noncompartmental Analysis

Noncompartmental analysis can be used to estimate of the volume of distribution (V_{ss}), total body clearance (CL), and persistence of a chemical (mean residence time). Because it does not rely on curve-fitting techniques to fit model-based equations to experimental data, this approach avoids a number of statistical considerations such as choice of weighting function, multiple minima in the sum of squares fitting criterion, and large variance in parameter values. Although this approach does not characterize the kinetics of distribution of chemical, as do compartmental and PBTK modeling methods, it can be used to estimate basic pharmacokinetic parameters, even when the data are highly variable. Noncompartmental analysis was used by Barron et al. (1987b) to investigate the temperature dependence of di-2-ethylhexylphthalate kinetics in rainbow trout. Total body clearance values calculated in this manner were very close to those estimated using a compartmental model. Alavi et al. (1993) used noncompartmental analysis to estimate pharmacokinetic parameters for sulfachlorpyridazine in channel catfish. To date, however, very few researchers have used noncompartmental methods in kinetic studies with fish. The application of noncompartmental analysis to bolus dosing data is described below. Modifications of this approach are required to deal with more complex dosing regimens.

Intravascular Bolus Administration

No explicit model structure is used in noncompartmental analysis; however, the chemical must be measured in and exit the body from the pool or compartment of its introduction (Matis et al., 1985). The method is based on the concept of mean residence time (MRT) of the chemical in the body. The MRT is the average time that all the molecules of chemical spend in the body after their simultaneous administration; for example, if the dose consisted of 100 chemical molecules administered as a bolus, then the MRT would be the sum of the individual residence times of each chemical molecule divided by 100. Following bolus administration, the rate of chemical elimination at any time is:

Downloaded From Vet-eBooks.com

$$dX/dt = -CLC_p \tag{3.114}$$

where X represents the amount of chemical in the body, CL is the plasma clearance of the chemical, and C_p is the plasma concentration. From this relationship, the amount of chemical eliminated over a small time interval, dt, is:

$$dX = -CLC_p dt \tag{3.115}$$

At the time (t) that dX is eliminated, dX has spent t time in the body. The total time in residence for all the molecules that make up X is the sum of the products of all the dX multiplied by the corresponding residence times; that is, the integral of tdX:

$$\int_0^\infty -CLC_p t\,dt \tag{3.116}$$

The total amount introduced into the body is the total amount eliminated, which may be expressed as:

$$\int_0^\infty -CLC_p dt \tag{3.117}$$

The mean residence time is the total time in residence divided by the total amount introduced into the body:

$$MRT = \frac{\int_0^\infty -CLC_p t\,dt}{\int_0^\infty -CLC_p\,dt} = \frac{\int_0^\infty C_p t\,dt}{\int_0^\infty C_p dt} = \frac{AUMC}{AUC} \tag{3.118}$$

where AUC is the area under the plasma concentration–time profile, and AUMC is the area under the moment curve, which is the integral of the product of plasma concentration and time.

After intravascular bolus administration of chemical, the MRT can be used to calculate the V_{ss} using the relationship:

$$V_{ss} = MRT\ CL \tag{3.119}$$

where:

$$CL = dose/AUC \tag{3.120}$$

Even when the plasma concentration–time profile is complex and irregular, it is generally possible to calculate AUC and AUMC, provided the profile is completely characterized.

To obtain the total AUC, the area beyond the last measured plasma concentration must be estimated. This may be accomplished using the relationship:

$$AUC_{t,last-\infty} = C_{p,last}/\lambda_z \tag{3.121}$$

where λ_z is –2.3 times the slope of the log-linear portion. Although the plasma concentration–time profile can be highly irregular, it has to have a terminal log-linear phase to provide a λ_z value for the extrapolation. In the absence of a log-linear phase, it is necessary to have a sufficient number of samples so the measured concentrations fully outline the AUC. In that case, a CL value may be obtained but a value for V_{ss} cannot be determined.

Downloaded From Vet-eBooks.com

As a practical matter, it is important that the extrapolated portion of the AUC be relatively small (ideally, less than 10% of the total AUC). Due to the fact that the extrapolated part is just that, there is some uncertainty in its true value, as the log-linear phase may not continue on the extrapolated line.

Calculating the AUMC also involves determination of that part of the total area that lies beyond the last measured plasma concentration. If a log-linear phase is present:

$$AUMC_{t,last-\infty} = \frac{t_{last}C_{p,last}}{\lambda_z} + \frac{C_{p,last}}{\lambda_z^2} \tag{3.122}$$

and AUMC is then $AUMC_{0-t,last} + AUMC_{t,last-\infty}$. The problem of extrapolation is larger for AUMC than for AUC because much more of the C_p,t profile has been defined by the measured concentrations than has been defined by the C_{pt},t profile.

Bioconcentration, Bioaccumulation, and Biomagnification

In this section, chemical bioconcentration, bioaccumulation, and biomagnification in fish are treated as special topics because of their importance in the context of current regulatory approaches. By convention, the term *bioconcentration* refers to the accumulation of waterborne chemicals by aquatic animals through nondietary routes (Veith et al., 1979). The importance of bioconcentration as a measure of chemical accumulation by fish has been recognized since the 1960s (Hamelink et al., 1971). By the, 1970s, however, it had become apparent that uptake of very hydrophobic organic compounds by fish within an environmental setting was dominated by the dietary route of exposure (Bruggeman et al., 1981, 1984). The term *bioaccumulation* refers to the accumulation of chemicals by all possible routes of exposure. As described below, bioconcentration and bioaccumulation are expressed by referencing the chemical concentration in a fish to that in water or sediment. The term *biomagnification* refers to a stepwise increase in chemical concentration in organisms representing successively higher trophic levels, resulting from the ingestion of contaminated organisms at lower trophic levels. Biomagnification is expressed, therefore, by referencing the extent of chemical bioaccumulation in a predator to that of its prey.

Processes that control the rate and extent of chemical accumulation in fish were described in earlier sections of this chapter. Thus, uptake directly from water is dependent on factors that control chemical flux across the gills and skin, including the bioavailability of waterborne compounds, limitations on uptake imposed by water and blood flows, and the relative affinity of chemicals for blood, skin, and water. Similarly, the rate of uptake from dietary sources is dependent on the oral bioavailability of ingested compounds and the extent to which these compounds become concentrated in prey items. Elimination of parent compounds may occur at the gills, skin, and gut or by secretion into bile or urine.

Chemical accumulation may be substantially reduced by biotransformation. In controlled exposures with rainbow trout, Barron et al. (1989) found that measured concentrations of the phthalic acid ester di-2-ethylhexylphthalate were 100 to 1000 times lower than those predicted from chemical hydrophobicity. Similar findings have been reported for several azaarenes (Southworth et al., 1980) and polycyclic aromatic hydrocarbons (PAHs) (Jonsson et al., 2004). Experimental inhibition of metabolism resulted in an increase in bioconcentration of pentachlorophenol (Stehly and Hayton, 1989a).

In field sampling efforts, low levels of bioaccumulation in fish have been found for hydrophobic but easily metabolized PAHs (Varanasi et al., 1989). Lower than expected levels of bioaccumulation for some lower chlorinated dibenzo-*p*-dioxins and dibenzo-*p*-furans in field-caught fish were also attributed to metabolism (Opperhuizen and Sijm, 1990). Care is required, however, when interpreting field sampling data because metabolism may occur at multiple sites within a food web, altering the concentration of chemical to which a fish is exposed.

In Chapter 14, Mackay and Milford describe a chemical fate and transport model and show how this model can be used to predict chemical concentrations in a water–sediment system. Outputs from such models are often used as inputs to models of chemical bioconcentration and bioaccumulation in fish. Models of bioconcentration and bioaccumulation take different forms, depending on simplifying assumptions and the need to mechanistically describe controlling processes. In regulatory applications, it is

Downloaded From Vet-eBooks.com

common to start with the simplifying assumption that all elements of an ecosystem are at steady state. Non-steady-state models may be required, however, when chemical loadings to a system change over time or when other processes result in a substantial disequilibrium among water, sediment, and biotic components.

Techniques used to measure, express, model, and predict bioconcentration and bioaccumulation are described below. The concepts described in these sections are then combined in a simple food web. A brief description of the fugacity-based approach to chemical modeling is given to provide a basis for comparison with other modeling approaches. A more detailed description of the fugacity-based modeling approach is given in Chapter 14.

Bioconcentration

The term used to quantify the magnitude of bioconcentration in aquatic systems is the *bioconcentration factor* (BCF), which is defined as a proportionality constant relating the chemical concentration in a fish (or a portion thereof) to that in water under steady-state conditions. It is a measure of the propensity of a chemical to accumulate in fish, and BCF values fall between 0 and infinity (Veith et al., 1979). BCFs have units of water volume/tissue weight (e.g., mL/g) and can be viewed conceptually as the water volume containing the amount of chemical concentrated in 1 gram of animal tissue (Barron, 1990). BCFs can be measured directly by exposing fish in water until steady state is attained or estimated using simple kinetic models in conjunction with short-term uptake and elimination studies. Using these procedures, BCFs have been determined for a large number of nonionic organic compounds, as well as some metals, metalloids, and organometallics. Several authors have used these datasets to develop QSARs that relate the BCF of a compound to one or more physicochemical properties. These QSAR models are used extensively to estimate BCFs for untested chemicals and by extension to predict their behavior in aquatic systems.

As indicated previously, hydrophobic compounds tend to partition into tissue lipids. BCFs for such compounds may be interpreted, therefore, in terms of a chemical distribution between fish lipid and water. When making these interpretations, it is important to distinguish between a steady-state chemical distribution and true thermodynamic equilibrium. A steady-state condition is defined as an unchanging chemical concentration, and a thermodynamic equilibrium is a minimum energy state that reflects the relative affinity of a chemical for two partitioning phases. A system at steady state is unlikely to be in thermodynamic equilibrium in the presence of dynamic processes such as biotransformation and growth.

The lipid content of fish varies widely. Variability among BCFs for the same or similar compounds in more than one species or life stage can be reduced, therefore, by normalizing for differences in lipid content, although factors such as lipid composition may also be important (Ewald and Larsson, 1994; Vigano et al., 1992). The lipid-normalized BCF has units of mL/g lipid.

Steady-State Exposures

Steady-state exposures are conducted by exposing fish to a constant concentration of chemical in water for an extended period of time (U.S. EPA, 1996). Typically, these studies are conducted by exposing small fish in a flow-through system for 28 days. The fish are serially sampled, and whole-body concentrations of the chemical are quantified. This method may underestimate the true steady-state BCF if exposure times are too short. The length of time required to reach steady state depends on uptake and elimination rates; for example, specific PCB congeners with elimination half-lives of 100 days or longer may require 1 year to reach 90% of steady state (Barron et al., 1994). Steady-state exposures are species or site specific and allow for the incorporation of environmentally realistic exposure conditions.

Kinetic Modeling

Bioconcentration factors may also be estimated by applying simple kinetic models to uptake and elimination datasets (Barron et al., 1990; Branson et al., 1975; Landrum et al., 1992; U.S. EPA, 1996). Uptake from water is generally assumed to be first order with respect to the chemical concentration in

Downloaded From Vet-eBooks.com

water (C_w), and elimination is assumed to be first order with respect to chemical concentration in the fish (C_f). Assuming further that the fish can be adequately represented as a single compartment, a mass balance on this system may be written as:

$$dC_f/dt = k_1C_w - k_2C_f \tag{3.123}$$

where k_1 and k_2 are uptake and elimination rate constants, respectively, with units of inverse time. By assuming that the specific gravity of fish tissue is approximately 1.0, k_1 can also be expressed as a clearance rate, normalized for body weight (e.g., mL water per g tissue per day). The value of k_1 can then be interpreted by comparing it to physiological measures such as ventilation volume.

At steady state, $k_1C_w = k_2C_f$. Because, by definition, the BCF equals C_f/C_w, rearrangement of this equation gives the relationship used to estimate the BCF from kinetic data:

$$BCF = k_1/k_2 \tag{3.124}$$

Elimination rate constants are typically estimated from the slope of log-transformed depuration data. Uptake rate constants may then be estimated by fitting uptake data to Equation 3.123 using nonlinear regression methods. Kinetic models have the advantage of being chemical and species specific and do not require exposure to steady state. The BCF of a chemical may be unreliably estimated by this method if the duration or extent of sampling of the elimination phase is inadequate or if an inappropriate model is used (Stehly and Hayton, 1989b).

QSAR Models

Empirically based QSAR models are used to estimate BCFs for untested compounds based on their physicochemical properties. Most are linear regression models relating the log of the BCF of a compound to the log of its octanol–water partition coefficient (Lipnick, 1995). Veith et al. (1979), for example, developed the following relationship from BCFs in fish for chemicals with log K_{ow} values ranging from 1 to 7:

$$\log BCF = \left(0.85 \times \log K_{ow}\right) - 0.7 \tag{3.125}$$

QSAR models of this type have generally been developed using data for halogenated organic chemicals (Mackay, 1982). Implicit in this approach are the assumptions that: (1) an octanol–water system is an appropriate surrogate for a fish lipid–water system, and (2) bioconcentration results from thermodynamically driven partitioning between water and the lipid phase of the fish (Hansch et al., 1989). QSAR models can also be fit to lipid-normalized BCF data. Correspondence with the lipid-partitioning assumption is indicated when lipid-normalized log BCF values are approximately equal to log K_{ow} (Briggs, 1981). Additional QSAR models have been developed based on water solubility and molecular size descriptors (Hawker, 1990; Isnard and Lambert, 1988; Schuurmann and Klein, 1988).

Bioaccumulation

Bioaccumulation Referenced to Water

Bioaccumulation of contaminant residues in fish may be referenced to the chemical concentration in water using a bioaccumulation factor (BAF). BAFs are generally normalized to a fish's lipid content to permit comparisons among species and between predatory fish and their prey (to assess biomagnification; see below). For very hydrophobic compounds, adjustments to the total chemical concentration in water may be attempted as a means of accounting for reductions in bioavailability due to binding to dissolved and particulate organic carbon (Burkhard et al., 2003). Because the free chemical concentration in water may be difficult to measure, these adjustments are generally based on empirically derived relationships (Chin and Gschwend, 1992). The units obtained from this approach are ng/kg lipid divided by ng freely dissolved contaminant per liter of water.

Downloaded From Vet-eBooks.com

Mechanism of Biomagnification

Field sampling efforts suggest that in some cases measured BAFs in fish exceed the BCF that would have been expected from an equilibrium distribution of chemical between the fish and water. These observations have been attributed to processes that accompany the digestion of contaminated food items. According to the *digestion hypothesis*, absorption of dietary lipid and reductions in meal volume increase chemical activity in the gut contents above that of the ingested meal, resulting in an inwardly directed diffusion gradient and a potential for biomagnification of chemical residues (Connolly and Peterson, 1988; Gobas et al., 1993a,b, 1999). Under these circumstances, the gills become a route of net chemical elimination and not uptake, and the extent of bioaccumulation and biomagnification is determined by the balance between chemical uptake within the gut, branchial efflux, biotransformation, and growth.

The extent of biomagnification is defined using a biomagnification factor (BMF), which is the lipid-normalized chemical concentration in a predator divided by that of its prey. For a given trophic transfer step, a compound is said to *biomagnify* when the BMF is greater than 1. Within a simple food chain, BMFs for each trophic transfer step can be multiplied. Under these circumstances, the BAF for fish that occupy the highest trophic level will exceed the partitioning-based BCF prediction by an amount equal to the product of BMFs for all relevant trophic transfers.

Support for the digestion hypothesis has been obtained in studies with several fish species. In feeding studies with guppies and goldfish, the ratio of feces to food fugacity increased with chemical log K_{ow}, attaining a maximum value of 4.6 (in guppies) for the pesticide mirex (as described below, fugacity is a measure of chemical activity; see Gobas et al., 1993a). The ratio of intestinal contents to food fugacity in a natural population of white bass (*Morone chrysops*) also increased with chemical log K_{ow}, attaining a value of about 2.2 for 2,2′,3,4,4′,5,5′-heptachlorobiphenyl (Russell et al., 1995). In rainbow trout and rock bass (*Ambloplites rupestris*) exposed to 2,2′,4,4′,6,6′-hexachlorobiphenyl, the chemical fugacity in chyme following uptake of dietary lipid exceeded that of food by a factor of 7 to 8 under both laboratory and field conditions (Gobas et al., 1999).

Nichols et al. (2004a) developed a PBTK model for the dietary uptake of hydrophobic chemicals by fish that accounts for the absorption of dietary lipid and reductions in meal volume. The model was then used to simulate chronic exposures to a set of hypothetical high log K_{ow} compounds (Nichols et al., 2004b). The results of this effort showed that a log K_{ow}-dependent diffusion resistance acts along the entire length of the GIT to limit dietary uptake of high log K_{ow} compounds. This decrease in diffusive uptake appears to be responsible for a log K_{ow}-dependent decrease in absorption efficiencies, BAFs, and BMFs at log K_{ow} values greater than about 6 (Figure 3.9). Metabolism and growth were predicted by the model to result in lower BMFs at all log K_{ow} values. In either case, however, BMFs continued to increase with chemical log K_{ow} (assuming constant diffusion resistance). In field sampling efforts, BAFs for persistent organochlorines in fish have been shown to increase with log K_{ow} up to a log K_{ow} value of 6 or 7 and then level off or decline at higher log K_{ow} values (Burkhard, 1998; Thomann, 1989).

Bioaccumulation Referenced to Sediment

Aquatic sediments are formed from the deposition of particles and colloids and can act as both a sink and source of contaminants. Long-term contaminant input can lead to sediment concentrations that exceed the water concentration by several orders of magnitude. Both metals and hydrophobic organic compounds bind to sediments, but the nature of these interactions differs. Under reducing conditions, metals tend to form insoluble complexes with sulfide, and the acid volatile sulfide (AVS) content of sediment has been used to normalize for differences in apparent toxicity of some sediment-associated metals (Carlson et al., 1991; Di Toro et al., 1990). In oxic sediments, however, organic material may provide the major site for metal binding (Fu et al., 1992). Other factors that may influence metal bioaccumulation from sediment include: (1) speciation, (2) transformation to organic derivatives, (3) interactions of different metals, and (4) sediment chemistry (salinity, iron oxide content, redox potential, and pH) (Bryan and Langston, 1992).

The binding of organic contaminants to sediments has been related to the organic carbon content, clay type and content, cation exchange capacity, pH, and particle surface area of the sediment (Knezovich et al., 1987). In many systems, the organic carbon content of sediment (typically 0.5 to 3% of sediment mass) predicts contaminant toxicity (Bierman, 1990; Di Toro et al., 1991). Inferred by these observations

Downloaded From Vet-eBooks.com

is an association between toxicity and bioavailability. The source of this organic carbon (e.g., mud, plant material) may influence bioavailability and bioaccumulation (DeWitt et al., 1992). In some regions, soot carbon from the combustion of fossil fuels may also contribute to sediment binding of organic compounds (Accardi-Dey and Gschwend, 2003; Persson et al., 2002). Although generally present in small amounts (a few percentage points of total carbon), the affinity of soot carbon for some hydrophobic compounds may be considerably higher than that of organically derived carbon.

The extent of chemical bioaccumulation from sediment is typically expressed using either a bioaccumulation factor or a biota-to-sediment accumulation factor (BSAF) (Spacie et al., 1995). The sediment BAF is the ratio of the chemical concentration in fish to chemical concentration in sediment. Sediment BAFs have units of sediment mass per unit of tissue weight (wet weight/wet weight) and can be viewed conceptually as the sediment mass containing the amount of chemical concentrated in 1 gram of fish tissue. The BSAF is the ratio of the lipid-normalized chemical concentration (ng chemical per g lipid) in fish to the organic carbon normalized concentration in sediment (ng chemical per g organic carbon). Thorsen et al. (2004) adjusted this ratio further to account for chemical binding to soot carbon in sediments and determined that this binding was unlikely to have a major impact on BSAFs for PAHs in two freshwater bivalves. Additional work is required to determine whether such adjustments are needed for other compounds.

Biota-to-sediment accumulation factors are used to reduce variability in measured bioaccumulation due to variation in organism lipid content and sediment organic carbon concentrations. BSAFs in fish typically range from 0.1 to 10 (Bierman, 1990; Burkhard et al., 2004; Rubinstein et al., 1984; Schuytema et al., 1988). Values greater than 1 are often interpreted as evidence for biomagnification of chemical residues coupled with little or no biotransformation. Values less than 1 have been attributed to biotransformation, although other factors such as growth and low dietary assimilation efficiency may contribute.

Methods for estimating the bioaccumulation of sediment-associated contaminants include steady-state exposures, equilibrium partitioning (EqP) theory, and kinetic models. Each approach has been used extensively to estimate BSAFs for benthic invertebrates. Chemical accumulation by benthic invertebrates is important because consumption of these organisms by fish provides a route for translocation of sediment-associated contaminants to aquatic food webs. Direct exposures also have been employed to study the bioaccumulation of sediment contaminants by fish that live in intimate contact with these sediments (Hellou et al., 1995; Payne et al., 1995). BSAFs for high trophic level fish are generally predicted using a food web model that includes a benthic component (see below).

In each case, it should be noted that the BSAF definition makes no assumptions about a chemical equilibrium between the organism and sediment. Although it may be reasonable to assume that an equilibrium exists between sediments and benthic invertebrates, this assumption becomes more problematic for high-trophic-level fish. Field-derived BSAFs must be interpreted, therefore, in the context of changes in toxicant loadings to the environment, as well as other potential sources of disequilibrium.

Equilibrium Partitioning Theory of Bioaccumulation from Sediments

The equilibrium partitioning (EqP) theory of bioaccumulation from sediments is based on the assumption that chemicals partition between sediment, pore water, and aquatic organisms in accordance with thermodynamic principles (Di Toro et al., 1991). The theory predicts that the equilibrium concentration of a chemical in sediment pore water (C_w) is controlled by the concentration of the chemical in sediment (C_s), the organic carbon–water partition coefficient (K_{oc}) of the chemical, and the fraction of organic carbon (OC_s) in sediment according to:

$$C_w = C_s / \left(K_{oc} OC_s \right) \tag{3.126}$$

Bioaccumulation of contaminants by sediment-dwelling biota (C_{biota}) is determined by the lipid content of the organism (L_{biota}), C_s, and OC_s:

$$C_{biota} = L_{biota} \left(C_s / OC_s \right) \tag{3.127}$$

Substituting Equation 3.126 into Equation 3.127 and adopting the assumption that $K_{ow} = K_{oc}$ gives the relationship:

Downloaded From Vet-eBooks.com

$$C_{biota} = L_{biota} K_{ow} C_w \tag{3.128}$$

This equation suggests that the contaminant concentration in the organism can be estimated from the concentration freely dissolved in pore water. Hellou et al. (1995) suggested that K_{ow} and K_{oc} are not equal but are instead related by a proportionality constant. A modification of Equation 3.128 was derived by Hellou et al. (1995) by assuming that $K_{ow} = 0.4K_{oc}$ and that the density of sediment is 1.6 kg/L:

$$BSAF = L_{biota} / \left(OC_s \times 0.64\right) \tag{3.129}$$

Assumptions of the EqP theory include concentration-independent uptake and an absence of biotransformation or degradation of the contaminant. An implicit assumption of the EqP theory is that the bioavailable concentration in water is the freely dissolved portion; the presence of DOC does not, therefore, affect equilibrium partitioning. According to EqP theory, the equilibrium level accumulated by an organism is independent of the number and types of exposure routes (e.g., sediment ingestion or pore water exposure).

An extensive review of data supporting the EqP theory was given by Di Toro et al. (1991), who concluded that sediment-to-sediment variation in bioavailability (assessed by toxicity) can be reduced by a factor of two or three by application of EqP theory and that particle size effects are minimal. Using the principles of EqP theory, the U.S. Environmental Protection Agency has developed procedures to derive equilibrium partitioning sediment benchmarks (ESBs) for the protection of benthic organisms from adverse effects due to nonionic organic compounds (U.S. EPA, 2003).

Kinetic Models for Chemical Accumulation from Sediment

Kinetic models of contaminant bioaccumulation from sediment have been primarily developed for benthic invertebrates, including amphipods, insects, and mollusks (Lee, 1992). The simplest model is:

$$BAF = k_s / k_{el} \tag{3.130}$$

where k_s is the sediment uptake constant (g sediment/[g tissue × time]), expressed as a clearance term, and k_{el} is the elimination rate constant (1/time). This model is analogous to that given previously (Equation 3.124) to describe chemical bioconcentration from water. According to the model, sediment BAFs are independent of the chemical concentration in sediment but increase with any factor that increases the uptake rate constant or decreases the elimination rate constant.

Food Web Models of Bioaccumulation in a Sediment–Water System

Food web bioaccumulation models describe the contaminant mass balance in biota that comprise an aquatic food web (Thomann et al., 1992b). Contaminant concentrations in biota are calculated using mathematical equations that describe the dominant uptake and elimination processes. These processes may include equilibrium partitioning (e.g., sediments to benthos, water to plankton), chemical uptake from water, ingestion of contaminated food, growth, and excretion. Contaminant concentrations in source compartments (water and sediments) are generally assumed to have a homogeneous distribution and to be in steady-state equilibrium with biota comprising the lowest level of the food web.

Food web models are particularly useful for compounds that bioaccumulate in plankton and benthic invertebrates and then biomagnify in fish through successive trophic transfers. These models are used extensively to estimate BAFs, BSAFs, and BMFs and to determine the relative importance of benthic (sediment) and pelagic (water) contaminant sources. In a regulatory setting, these models can be used to characterize a contaminated site and evaluate various remedial options. The utility of this approach is limited, however, by the need to incorporate a large number of parameters, many with high levels of uncertainty. Model parameters typically include body size, temperature, feeding rate, prey selection, lipid content, and dietary bioavailability (absorption efficiency). The proportion of time each trophic group feeds within the contaminated food web may be an additional source of variability and uncertainty.

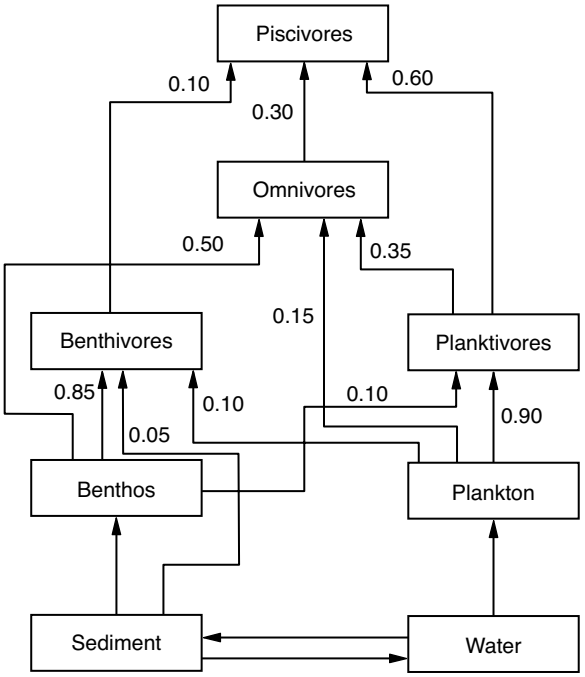

FIGURE 3.31 Schematic representation of a food wed bioaccumulation model. Numbers indicate the fractional contribution of each contaminant source to the diet of biota. Arrows without numbers designate equilibrium partitioning relationships.

The following section summarizes the model-based equations of a generalized food web model adapted from Thomann et al. (1992a) and Gobas (1993). This model can be viewed conceptually as a series of compartments linked by transport pathways (Figure 3.31). Compartments that correspond to biota are based on assumed feeding habits. Sediment and water compartments act as sources of chemical contamination. Generally, contaminant concentrations in sediment and water are specified as input parameters. These concentrations may be based on measured values for a site of interest or obtained as predictions from a fate and transport model (see Chapter 14). In addition to the pathways shown in Figure 3.31, the model also calculates chemical concentrations in fish tissues that result from exposure to a contaminant dissolved in the water column. More complex food web models are available, such as those based on species- and age-specific bioaccumulation (Connolly, 1991).

Plankton and Benthos

Contaminant concentrations in plankton and benthos are calculated from equilibrium partitioning relationships based on organism lipid content and the bioavailable chemical concentration in water and sediment pore water, respectively. For the simplified model in Figure 3.31, contaminant concentrations are assumed to be equal in phytoplankton and zooplankton. This simplification may be reasonable for chemicals such as PCBs that partition rapidly and exhibit little or no biomagnification between phytoplankton and zooplankton (Gobas, 1993; Oliver and Niimi, 1988). The assumption of equilibrium partitioning may depend on the rate of uptake relative to the rate of growth of biomass. Swackhamer and Skoglund (1993) concluded that the establishment of an equilibrium was unlikely under conditions of rapid phytoplankton growth.

Benthivores, Planktivores, Omnivores, and Piscivores

Predator trophic groups are defined by their prey selection. Contaminant concentrations in predator trophic groups (C_f) are calculated as the ratio of chemical intake (from water [k_{uw}] and food [k_{uf}]) to chemical elimination (due to excretion [k_{ex}] and egestion [k_{eg}]) and growth dilution (k_g):

Downloaded From Vet-eBooks.com

$$C_f = \frac{\left[\left(k_{uw}C_w\right) + \left(k_{uf}\Sigma P_i C_i\right)\right]}{k_{ex} + k_{eg} + k_g} \tag{3.131}$$

where dietary intake is the sum of the proportion of each prey trophic group selected (P_i) multiplied by the contaminant concentration in the dietary item (C_i). The uptake rate from water (k_{uw}) is dependent on the initial transfer of a chemical from water to the aqueous phase of the organism and then to the lipid phase of the organism:

$$k_{uw} = \frac{1}{\left[\left(W_v/Q_w\right) + \left(W_v/K_{ow}Q_l\right)\right]} \tag{3.132}$$

where W_v is the weight of the organism, and Q_w and Q_l are transport rates in the aqueous and lipid phases. Q_w is estimated from an empirical relationship that relates chemical transport to body weight:

$$Q_w = 88.3W_v^{0.6} \tag{3.133}$$

Q_l is less well known than Q_w but is thought to be about 100 times smaller than Q_w:

$$Q_l = Q_w/100 \tag{3.134}$$

The uptake rate from food (k_{uf}) is dependent on dietary absorption efficiency (α, the fraction of the dietary dose that is absorbed by the animal), feeding rate (FR), and W_v:

$$k_{uf} = \alpha FR/W_v \tag{3.135}$$

The FR depends on both allometric and bioenergetic considerations and may be estimated from an empirical relationship based on body weight and ambient temperature (T in °C; annual average):

$$FR = 0.022W_v^{0.85}e^{0.06T} \tag{3.136}$$

The excretion rate of a chemical across the gills (k_{ex}) is dependent on the transfer of chemical from lipid to the aqueous phase of the fish and then to ambient water:

$$k_{ex} = \frac{1}{\left[\left(W_vL_iK_{ow}/Q_w\right) + \left(W_vL_iQ_l\right)\right]} \tag{3.137}$$

The fecal egestion rate (k_{eg}) is calculated as 0.25 times the uptake rate from food:

$$k_{eg} = 0.25k_{uf} \tag{3.138}$$

The growth of a fish over time tends to reduce contaminant concentrations by increasing the tissue mass into which chemicals are distributed. This phenomenon is referred to a *growth dilution* and is accounted for by calculating k_g as a weight-dependent coefficient:

$$k_g = 0.000502W_v^{-0.2} \tag{3.139}$$

Food web models are typically calibrated using existing data on contaminants in an ecological system similar to that which is being modeled. Parameter inputs, including body size, temperature, prey selection, lipid content, and asorption efficiency, may be determined from literature values or site-specific measurements. As with compartmental and PBTK modeling, parameter values can be adjusted to obtain better agreement between observed and model-estimated concentrations of contaminants in biota. As

Downloaded From Vet-eBooks.com

noted by Thomann et al. (1992b) and others, equilibrium partitioning models can substantially underestimate the accumulation of PCBs, chlorinated pesticides, and other organochlorine compounds in upper trophic level fishes because trophic transfer is not considered.

Fugacity-Based Models

Fugacity-based models were initially developed from engineering principles (models of gas transfer) and have been applied extensively in environmental fate modeling to estimate chemical concentrations in different environmental compartments (phases), including air, water, sediment, and biota. Using a fugacity approach, the concentration of a contaminant is expressed in units of moles/volume (e.g., mol/m^3) rather than mass/mass (e.g., mg/kg body weight) or mass/volume (e.g., mg/L water) and is calculated as the product of chemical fugacity f (Pa) and the fugacity capacity Z (mol/Pa m^3). The fugacity of a compound is an expression of chemical activity that characterizes the escaping tendency from a particular phase, while *fugacity capacity* can be viewed as a kind of solubility (Mackay and Paterson, 1982). In general, fugacity-based models assume that a chemical achieves equilibrium between all of the environmental phases, although transfer resistances (model terms that limit transfer from phase to phase) can be incorporated to model retention of a chemical.

Fugacity-based models have been developed to describe chemical bioaccumulation in fish (Gobas et al., 1989) and trophic transfer in aquatic food webs (Campfens and Mackay, 1997). To illustrate this approach we can consider the one-compartment model for chemical bioconcentration given earlier as Equation 3.123:

$$dC_f/dt = k_1C_w - k_2C_f \tag{3.140}$$

When expressed in fugacity terms, this same equation takes the following form:

$$VZD_f/dt = D_f f_w - D_f f_f \tag{3.141}$$

where V is the volume of the fish (m^3) and D_f is a fish-to-water transport parameter (mol/Pa/hr). Importantly, this equation implies that at steady state chemical fugacities in the water (f_w) and fish (f_f) are equal.

Extending this approach further, steady-state bioaccumulation in fish exposed to contaminated food and water may be calculated from the relationship:

$$D_f f_w + D_a f_a = f_f\left(D_w + D_e + D_m + D_g\right) \tag{3.142}$$

where $D_f f_w$ is uptake from water, $D_a f_a$ is uptake from food, and the transport parameters in the parentheses account for elimination into water (D_w; due to branchial efflux) and feces (D_e), biotransformation (D_m), and growth dilution (D_g). Using this approach, Campfens and Mackay (1997) concluded that fecal egestion and growth dilution are the major loss processes for high log K_{ow} compounds and that there is a net loss of chemical through the gills.

The principal advantage of a fugacity-based modeling approach is that thermodynamic relationships among compartments can be assessed using a common (fugacity) metric. When used for fish bioaccumulation modeling, the main disadvantage of this approach is that model parameters are not directly interpretable in terms of physiological quantities such as clearance and water and blood flows.

Introduction

Biotransformation is a two-phase process catalyzed primarily through enzymatic reactions that often radically alter the chemistry of nonpolar lipophilic chemicals to polar water-soluble metabolites predominately leading to detoxification and elimination of the parent compounds. Unfortunately, the alteration of chemistry required for enhanced polarity often creates reactive intermediates through bioactivation, which can be more biologically hazardous than the initial parent compounds. The phase I process either adds or exposes polar atoms within a xeno- or endobiotic compound. Three general phase I reactions include oxidation, reduction, and hydrolysis (Table 4.1). When polarity has been enhanced through phase I reactions, phase II reactions generally attempt to further enhance polarity through conjugation of the phase I product with a bulky polar endogenous molecule. Alternatively, phase II reactions may protect against bioactivation by masking functional groups (i.e., amines) prone to reactive intermediate formation with groups that likely provide steric hindrance (i.e., methyl, acetyl) rather than augmented polarity (Table 4.1).

Phase I Reactions

Oxidation

Various enzymes are involved in the oxidation of xeno- and endobiotic compounds. Dehydrogenases oxidize substrates transferring electrons to an electron-deficient acceptor that is typically an essential cofactor for catalysis (e.g., NAD^+). Oxygenases catalyze the incorporation of molecular oxygen into molecules, and water is the source of oxygen for oxidases. Peroxidases derive oxygen from peroxide cofactors.

Cytochrome P450 Family of Drug Metabolizing Enzymes

Overview

The most dominant enzyme system responsible for oxidation processes in phase I biotransformation is the cytochrome P450 monooxygenases. The cytochrome P450s (CYPs) constitute a superfamily of heme-containing proteins that catalyze biological oxidation and reduction reactions. Klingenberg (1958) and Garfinkel (1958) first reported that hepatic microsomes contain a pigment that binds carbon monooxide with an unusual visible absorption maximum at 450 nm in its CO-reduced difference spectrum. Omura and Sato (1962) discovered that this pigment was a *b*-type cytochrome and called it cytochrome P450. The hepatic microsomal CYP system has broad substrate specificity and is responsible for oxidative metabolism of many structurally diverse endogenous and xenobiotic compounds. CYP enzymes are important for converting lipophilic foreign chemicals into more water-soluble products for excretion and, hence, detoxification. On the other hand, CYP enzymes catalyze the conversion of certain compounds such as polycyclic aromatic hydrocarbons (PAHs) and nitrosamines into more toxic intermediates. Constitutive CYP forms that appeared early in evolution are involved in biosynthesis (anabolism) of endogenous substances such as steroids, fatty acids, vitamins, bile acids, leukotrienes, thromboxanes,

TABLE 4.1

Phase I and Phase II Enzymatic Activities and Cofactors

Enzyme	Cofactors
Phase I	
Oxidation	
Cytochrome P450	Oxygen, NADPH, cytochrome b_5 (optional)
Flavin-containing monooxygenase	Oxygen, NADPH
Monoamine oxidase	H_2O
Aldehyde oxidase	NAD^+
Alcohol dehydrogenase	
Aldehyde dehydrogenase	
Cyclooxygenase	Arachidonic acid, oxygen
Peroxidase (PGH synthetase, lipoxygenase)	Peroxide (lipid-OOH or H_2O_2)
Reduction	
DT diaphorase	NAD(P)H
Hydrolysis	
Carboxylesterase	H_2O
Epoxide hydrolase	
Phase II	
UDP-glucuronosyl transferase	UDPGA
Sulfotransferase	PAPS
Amino acid conjugation	Amino acids (taurine, glycine, glutamine)
Glutathione *S*-transferase	Glutathione
Acetylation	Acetyl-coenzyme A
Methylation	*S*-Adenosylmethionine

and prostaglandins (Ryan and Levin, 1990). Inducible CYP forms (CYP1 through CYP4) emerged later in evolution and are primarily involved in the breakdown (catabolism) of endobiotics as well as xenobiotics. The following section attempts to update the phylogeny of each CYP family, addresses what is known regarding specific regulation, and then discusses what has been discovered regarding substrate specificities, catalytic function, and, when available, physiological role. Some families and isoforms have been better characterized than others. It is hoped that informational gaps are identified here that will stimulate further research in underrepresented CYP families and enhance our understanding of this important superfamily of enzymes.

The CYP superfamily is ancient, with the ancestral gene having existed more than 3.5 billion years ago (Nelson et al., 1993). Animals, plants, and microorganisms all contain CYP, and in mammals they have been identified in all tissues that have been examined. The emergence of new CYP genes results from a sequence of events, including speciation, gene duplication, divergence, and drift as a function of mutation and fixation all withstanding evolutionary pressures (Nebert et al., 1989; Nelsen, 1999). CYPs are generally most prevalent in the liver in association with the endoplasmic reticulum or mitochondria (Peter and Coon, 1991). As of 2004, the human genome has 57 putatively functional full-length *CYP* genes; *Fugu rubripes* (pufferfish) (Nelson, 2003) and *Danio rerio* (zebrafish) genomes have 54 and at least 81, respectively. CYP sequences that have been reported to the P450 nomenclature committee are listed on the cytochrome P450 homepage (http://drnelson.utmem.edu/CytochromeP450.html). The CYPs considered in the same family display more than 40% amino acid sequence similarity, and those within a subfamily are more than 55% similar (Nelson et al., 1993). Nomenclature has been standardized so *CYP* indicates the gene, followed by an Arabic numeral for the gene family, a capital letter for the subfamily, and an Arabic numeral for the specific subfamily member; for example *CYP*1A1 is responsible for the metabolic activation of benzo(*a*)pyrene (BaP) in most species, including mammals. The microsomal CYPs responsible for oxidation or metabolism of steroids and xenobiotic metabolism are located in families one through four.

The overall CYP-mediated reaction takes the form of:

$$RH + O_2 + NADPH + H^+ \rightarrow ROH + H_2O + NADP^+$$

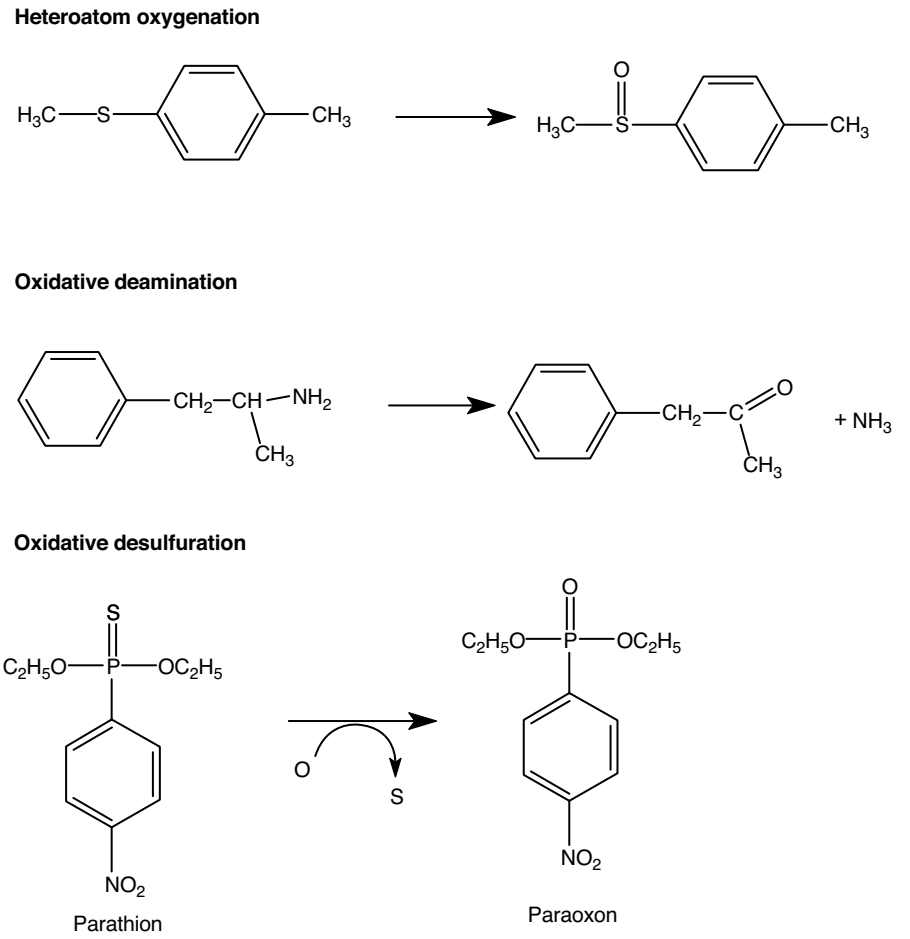

FIGURE 4.2B Examples of reactions catalyzed by cytochrome P450.

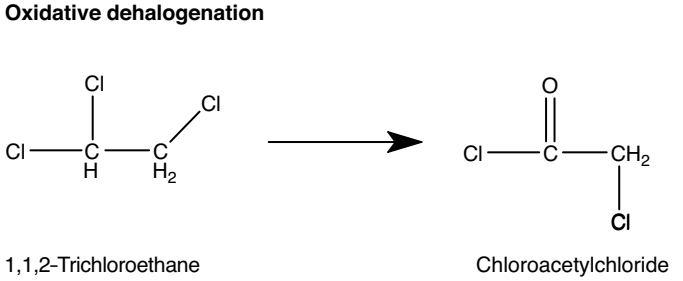

FIGURE 4.2C Examples of reactions catalyzed by cytochrome P450.

The reaction begins with the transfer of electrons from NAD(P)H to NADPH–cytochrome P450 reductase in the microsomal system (Figure 4.1). The active site of CYPs is generally a noncovalently bound heme iron in the form of protoporphyrin IX (Gonzalez and Gelboin, 1993; Henne et al., 1992). CYP-mediated reactions include aliphatic and aromatic carbon hydroxylation, epoxidation, heteroatom dealkylations, heteroatom oxygenation, deamination, desulfuration, and dehalogenation (Figure 4.2).

The reaction cycle is initiated when the substrate binds to the oxidized (Fe^{+3}) CYP complex and facilitates an electron transfer from NADPH to the complex. Oxygen then binds to the reduced CYP complex with coordination to iron *trans* to thiolate. The second electron is contributed by either

NADPH–cytochrome P450 reductase or NADH–cytochrome b_5 reductase. The next step involves cleavage of the oxygen–oxygen bond, uptake of two protons, and release of water. Oxygen is inserted into the substrate through generation of hydroxyl and carbon free radicals. Finally, dissociation of ROH restores the P450 to the initial ferric state (Parkinson, 2001). In addition, the peroxide shunt can allow a peroxy compound to substitute for oxygen in substrate oxidation.

Expression of CYP genes are regulated by diverse mechanisms. Basal levels of individual CYP mRNAs and proteins are regulated via transcriptional and post-transcriptional processes, including mRNA and protein stabilization or degradation. Induction of CYP gene expression of isozymes in families one through three has been extensively investigated in vertebrates, including fish, and is described in the next sections of this chapter. Table 4.2 summarizes many inducers, inhibitors, and substrates of CYP1, CYP2, and CYP3 which can be used to measure induction of specific CYP isozyme-dependent activities in fish research. As shown in the table, many inducers, such as PAHs, are substrates for the CYPs that they induce and therefore stimulate their own metabolism. CYP-mediated metabolism of some substrates can be highly complex and is dependent on both the species and tissue or organ investigated. Figure 4.3 illustrates many of the oxidative metabolites of BaP that are catalyzed by CYP isoenzymes. The metabolite profiles are variable and dependent on species differences in expression of CYP isoforms and their catalytic activities; for example, fish (such as the brown bullhead) treated with BaP preferentially metabolize the hydrocarbon to the more toxic 7,8- and 9,10-oxidation products (Willett et al., 2000). In contrast, mussels exposed to BaP preferentially (47% total metabolites) form 1–6, 3–6, and 6–12 BaP quinones (Michel et al., 1995).

CYP1

Phylogeny — CYP1 split from the CYP2 family approximately 450 million years ago (MYA) (Nelson et al., 1993) (Figure 4.4). The CYP1 gene family represents one of the most studied families of CYP in fish, primarily with regard to the role that CYP1A subfamily members (see below) play in the biotransformation of environmentally persistent aromatic hydrocarbons (e.g., TCDD, PAHs) and their relationship with disease processes resulting from exposure to compounds of this nature (Stegman and Hahn, 1994).

Regulation—Expression of CYP genes are regulated by diverse mechanisms. Basal levels of individual CYP mRNAs and proteins are regulated via transcriptional and post-transcriptional processes, including mRNA and protein stabilization or degradation. CYP1 gene expression is induced by structurally diverse aromatic hydrocarbons wherein the induction response requires initial binding to the aryl hydrocarbon receptor (AhR). The AhR is a basic helix–loop–helix DNA-binding protein that has been extensively characterized in laboratory animals and human cell lines. In mammals, the AhR controls the transcription of the genes CYP1A1, CYP1A2, CYP1B1, as well as phase II enzymes such as glutathione *S*-transferase, uridine diphosphate (UDP)-glucuronosyltransferase, and aldehyde-3-dehydrogenase (Safe, 1995). Agonists for the AhR include both synthetic and naturally occurring compounds. The best characterized ligands include certain PAHs and planar halogenated aromatic hydrocarbons (HAHs), including polychlorinated dibenzo-*p*-dioxins (PCDDs) and -furans (PCDFs), as well as polychlorinated biphenyls (PCBs). Planar HAHs bind to the AhR in predictable structure–activity relationships. 2,3,7,8-Tetrachlorodibenzo-*p*-dioxin (TCDD) has the highest AhR binding affinity among the HAHs and is also correlated with the high toxic potency of this congener (Safe, 1990). Structure–activity relationships are not as clear-cut for the PAHs because the toxic and genotoxic responses induced by these compounds are not all AhR mediated; however, Billiard and coworkers (2002) found a positive relationship between PAH binding to the teleost AhR and PAH potency for CYP1A induction. More recently, numerous naturally occurring dietary AhR ligands have been identified, including indole-3-carbinol, indolo-(3,2-*b*)-carbazole, dibenzoylmethanes, curcumin, and carotinoids (Denison and Nagy, 2003; Jeuken et al., 2003).

Studies with the $AhR^{-/-}$ knockout mouse have shown that this protein plays an important role in normal embryonic development (Abbott et al., 1995) and development of the liver and immune system (Fernandez-Salguero et al., 1995). The AhR was first identified in 1976 in hepatic cytosol from C57BL/6 mice (Poland et al., 1976). Apparent molecular masses of the photoaffinity-labeled cytosolic AhR are highly species dependent, ranging from 95 kDa for mouse to 124 kDa for hamster (Safe, 1995). The AhR has been identified by photoaffinity labeling in several species of teleosts and elasmobranchs (Hahn et al., 1994), as well as in the fish cell lines PLHC-1 and RTG-2 (Hahn et al., 1993). Nuclear AhR levels found in the killifish (*Fundulus heteroclitus*) were 203 fmol/mg, which was relatively high compared to most rodent species (Willett et al., 1995). Whereas mammals have a single AhR gene, two genes (AhR1 and AhR2) have been cloned in killifish (Karchner et al., 1999), zebrafish (Andreasen et al., 2002), and rainbow trout (*Oncorhynchus mykiss*) (Abnet et al., 1999). Four forms of the AhR (AhR1α, β; AhR2α, β) are found in Atlantic salmon (*Salmo salar* L.) (Hansson et al., 2004). The presence of AhR in fish indicates that this protein has been conserved for at least 450 million years. For more on AhR-mediated toxicities, refer to Chapter 5.

A simplified mechanism of AhR-mediated induction of CYP1A involves a ligand entering the cell where it associates with the cytosolic AhR, which exists as a multiprotein complex with two molecules of heat shock protein 90 (Hsp90), the X-associated protein 2 (XAP2), and a 23-kDa co-chaperone protein (p23) (Denison and Nagy, 2003). Binding of ligand causes a conformational change that facilitates nuclear translocation and association with the AhR nuclear translocator (ARNT). The AhR/ARNT heterodimer, in turn, associates with dioxin response elements (DREs; sometimes called AhR response elements, or AhREs) and with various coregulators (Carlson and Perdew, 2002) to initiate transcription and translation of AhR-responsive genes, including CYP1s. Induction of CYP1 protein can be determined at the transcriptional (mRNA) level using northern blot or quantitative reverse transcription polymerase chain reaction (RT-PCR) and at the protein level by using western blot, enzyme-linked immunosorbent assays (ELISAs), or immunohistochemistry. Finally, CYP1-dependent catalytic activities such as aryl hydrocarbon hydroxylase (AHH) or ethoxyresorufin-*O*-deethylase (EROD) can also be used to measure induction.

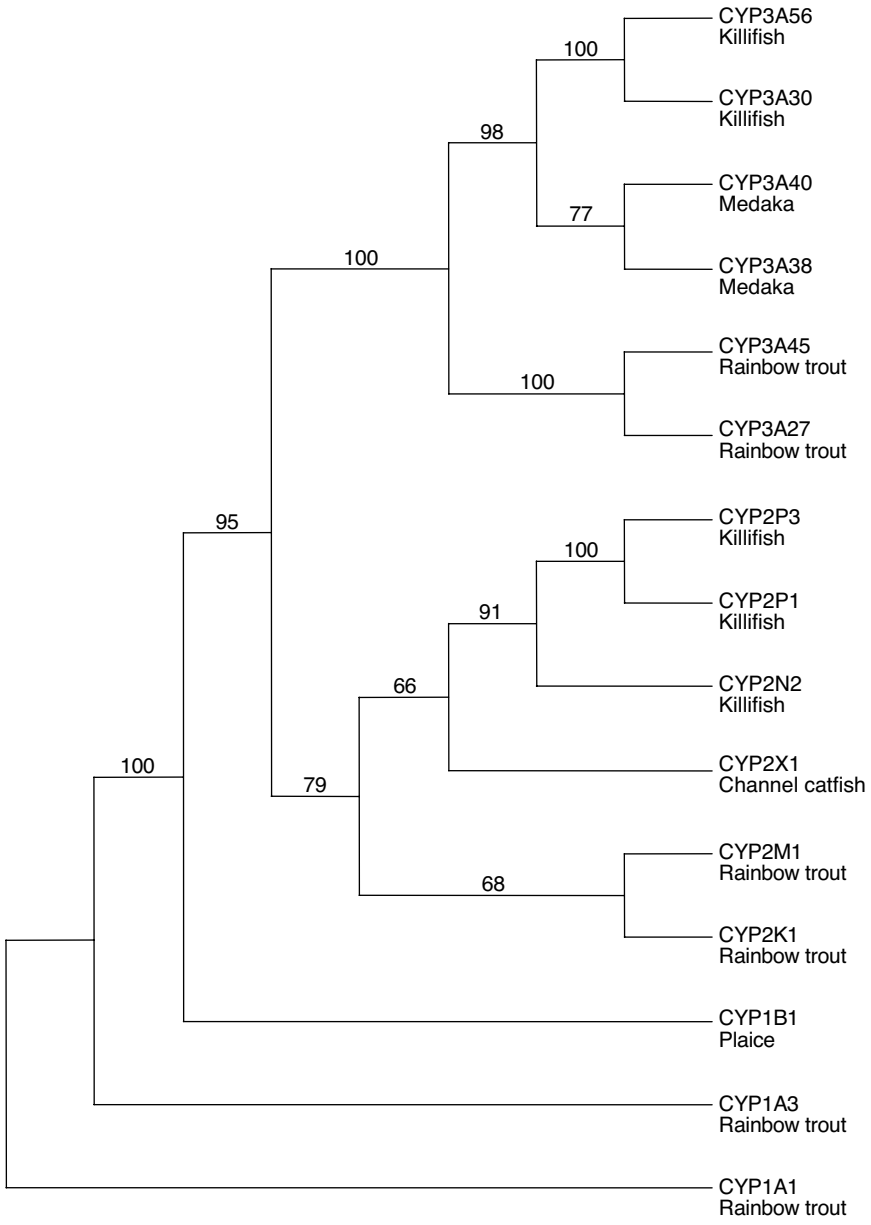

FIGURE 4.4 Phylogenic analyses of CYP in fish.

CYP1A—Research on CYPs in fish is more limited than that reported for mammals. Like mammals, fish CYPs catalyze oxidation of many of the same endogenous substrates and environmental chemicals. The most studied CYP form in fish is CYP1A. The first fish CYP1A cDNA was cloned by Heilmann et al. (1988), and sequence analysis showed 57 to 59% and 51 to 53% homology to mammalian CYP1A1 and CYP1A2 genes, respectively. This cDNA hybridized to a 2.8-kb mRNA that was induced 10-fold by 3-methylcholanthrene (3-MC) in rainbow trout. In fish, this form is generally recognized as CYP1A, and the terminology is supported because mammalian 1A1 and 1A2 are believed to have diverged 250 MYA by a gene-duplication event (Nebert and Gonzalez, 1987), whereas fish diverged from the mammalian line prior to that time. A hybrid CYP1A gene in fish is further suggested because some regions of the trout CYP1A sequence are identical to all mammalian CYP1A1 but not CYP1A2, while other

Downloaded From Vet-eBooks.com

regions are identical to all mammalian CYP1A2 but not CYP1A1 (Stegeman and Hahn, 1994). This homology pattern can be explained by a single CYP1A gene in fish that is ancestral to both mammalian CYP1A1 and CYP1A2.

More recently, CYP1A has been cloned from killifish (Morrison et al., 1998) and medaka (*Oryzias latipes*) (Kim et al., 2004; Ryu et al., 2004) and assembled from the pufferfish (*Fugu rubripes*) genome, although the pufferfish sequence is missing much of its *N*-terminal half (Nelson, 1999). Morrison and coworkers (1998) conducted a phylogenetic analysis of CYP1 genes (mammalian, avian, and fish) that highlighted the problem with CYP1 nomenclature, particularly with trout CYP1A. Following the isolation by Heilmann et al. (1988) of the trout CYP1A1 cDNA, Berndtson and Chen (1993) reported a CYP1A2 gene cloned in rainbow trout; however, the sequence of this clone was only 4% different from the CYP1A1 clone isolated from the same species. Furthermore, the fish CYP1A2 was not orthologous to the mammalian 1A2 and was coordinately induced with CYP1A1 in trout treated with 3-MC (Berndtson and Chen, 1993). Later, the "CYP1A1" was renamed "CYP1A3," and the original "CYP1A2" was renamed "CYP1A1." Until functional data are provided for these various forms (Cao et al., 2000; Carvan et al., 1999), the nomenclature remains confusing and somewhat arbitrary, and, accordingly, CYP1As are not being provided a number following the subfamily until this issue is resolved (see cytochrome P450 homepage).

Multiple CYP proteins have been purified. Those corresponding to CYP1A include P450LM4b in rainbow trout (*Oncorhynchus mykiss*) (Williams and Buhler, 1984); P450E in scup (*Stenotomus chrysops*) (Park et al., 1986), perch (*Perca fluviatilis*) (Forlin and Celander, 1993), and rainbow trout (Celander and Forlin, 1991); and P450c in the Atlantic cod (*Gadus morhua*) (Goksøyr, 1985). The activity of the monoclonal antibody (mAb) developed against scup CYP1A (mAb 1-12-3) supports the conservation of CYP1A through evolution because this antibody recognizes presumptive CYP1A proteins in mammals, birds, amphibians, reptiles, and nearly 100 different fish species (Stegeman and Hahn, 1994). A study by Goksøyr and coworkers (1991) investigated the immunochemical cross-reactivity of the three antibodies prepared against the β-naphthoflavone (BNF)-inducible CYP1A proteins from rainbow trout, cod, and scup. Microsomes from induced hagfish (*Myxine* sp.), herring (*Clupea harengus*), rainbow trout, perch, scup, plaice (*Pleuronectes platessa*), and rat were tested. Western blot results indicate that all three antibodies recognize the same antigens in the microsomes, and, as expected, the antibodies react most strongly with their conspecific microsomes. Of the microsomes tested, perch and hagfish were the only microsomes not recognized by all three antibodies. The molecular mass of the immunoreactive proteins ranged from 52 kDa for hagfish to 59 kDa in rainbow trout (Goksøyr et al., 1991).

Since the early reports on the effects of crude oil on brown trout (*Salmo trutta*) (Payne and Penrose, 1975), research correlating environmental pollution with induction of CYP1A-mediated activities in fish has been used as a biomarker. The induction of hepatic CYP1A mRNA, immunoreactive protein, and EROD or AHH enzyme activities in fish have been extensively studied in both controlled laboratory and field experiments. Some of these studies are summarized in a review by Bucheli and Fent (1995), which found that 93% of the field studies (68/76) showed that CYP1A induction in fish was related to contaminant levels in the environment. It should also be noted that fish adapted to living in highly contaminated habitats (e.g., Superfund sites with PAH or HAH contamination) are also refractory to CYP1A induction (Bello et al., 2001; Brammell et al., 2004; Meyer et al., 2002; Prince and Cooper, 1995). Prolonged exposure of rainbow trout to a PCB mixture resulted in unresponsiveness to 3-MC treatment and decreased CYP1A expression upon additional dosage of PCB (Celander and Forlin, 1995). The mechanisms of this inhibition are not entirely clear (Meyer et al., 2003; Powell et al., 2000). For more on the use of CYP1A as a biomarker, refer to Chapter 16.

Inhibitors—The type, time dependence, and degree of inhibition caused by various CYP inhibitors are also species dependent. Selective inhibitors of CYP isozymes have been used to characterize substrate specificity and modulation of toxicity and carcinogenicity of xenobiotics and in biochemical mechanistic studies of CYP enzymes. Both AHH activities and the mutagenicity of 3-MC are inhibited by ellipticine and its derivatives. Structural analysis of ellipticine derivatives reveled that methyl substitution in the 5 and 11 positions is essential for inhibitory responses (Lesca et al., 1980). Some environmental contaminants are also CYP1A inhibitors in fish; for example, 2-aminoanthracene (2-AA) caused a 67% inhibition

Downloaded From Vet-eBooks.com

of BNF-induced EROD activity in channel catfish (*Ictalurus punctatus*) (Watson et al., 1995). In both *in vitro* and *in vivo* experiments, 2-AA was a mechanism-based inhibitor of CYP1A. Similarly, 3,3′,4,4′-tetrachlorinated biphenyl (PCB 77) at high doses causes competitive inhibition of CYP1A enzyme activity and decreased induction of CYP1A protein (Gooch et al., 1989; White et al., 1997b). White and coworkers' (1997a) data suggested that, in scup, tetrachlorinated biphenyl (TCB) decreased CYP1A protein by enhancing protein degradation. TCB also initiated redox cycling through an uncoupling of CYP1A (Schlezinger and Stegeman, 2001). Finally, in killifish cotreated with BaP and the four-ring PAH fluoranthene (FL), both hepatic EROD activity and CYP1A immunoreactive protein levels were significantly inhibited (Willett et al., 2001). Although a covalent interaction between FL and CYP1A was not detected, the relative composition of DNA adducts changed in cotreated fish, suggesting that BaP metabolism is significantly affected when fish are co-exposed to PAH mixtures. Antifungal imidazoles (clotrimazole and ketoconazole) inhibit CYP1A-mediated EROD activities in gizzard shad (*Dorosoma cepedianum*), rainbow trout, and Atlantic cod (Hasselberg et al., 2004; Hegelund et al., 2004; Levine et al., 1997). Acrylamide, an environmental contaminant, is also an inhibitor of CYP1A and suggests feedback regulation on CYP1A mRNA transcription (Haasch et al., 1992; Petersen and Lech, 1987).

CYP1B—Until the mid-1990s, the CYP1 gene family was believed to contain a single subfamily with the well-known members CYP1A1 and CYP1A2; however, in 1994, the cDNA for CYP1B1 was isolated from TCDD-induced human keratinocyte cells (Sutter et al., 1994). Human CYP1B1 is a single-copy gene that is located on chromosome 2. It contains three exons and two introns and generates a 5.2-kb mRNA (Murray et al., 2001). In mammals, CYP1B1 expression is high in vascular endothelial cells, breast, prostate, uterus, epithelial lining of the head and neck, and the adrenal cortex (Nebert et al., 2004). CYP1B1 protein has also been reported in human breast, kidney, lung, brain, and testis tumors (McFadyen et al., 2001; Murray et al., 2001). Recombinant human CYP1B1 is highly active in oxidizing the potent PAHs BaP and dimethylbenzanthracene (DMBA) to their respective carcinogenic metabolites. Shimada and coworkers (1999) found that CYP1B1 was more active than CYP1A1 in metabolizing BaP to the proximate toxicant BaP-7,8-diol. Their study suggests that species or tissues with less CYP1B1 may be less likely to form DNA-reactive PAH metabolites and thereby may be more resistant to carcinogenesis. This finding is supported by studies with CYP1B1-null mice. Seventy percent of DMBA-treated wild-type mice developed highly malignant lymphomas, whereas the CYP1B1-null mice only had 7.5% cancer incidence (Buters et al., 1999). Likewise, metabolism of DMBA to toxic intermediates in MCF7 and T47D breast cancer cells is blocked by CYP1B1 antibodies (Angus et al., 1999; Christou et al., 1994).

A significant void in CYP1B1 research exists in nonmammalian species such as fish. There are only two published studies where CYP1B was studied in four fish species: scup, killifish, zebrafish (*Danio rerio*) (Godard et al., 2000), and plaice (Leaver and George, 2000). The plaice CYP1B has two protein-coding exons with similar exon–intron boundaries compared to the human CYP1B1. The amino acid sequence of the plaice has 54% identity with the human CYP1B1 sequence but only 39% identity with the plaice CYP1A (Leaver and George, 2000). CYP1B was detected in plaice gill by northern blot but did not appear to be induced by BNF. For carp (*Cyprinus carpio*), two partial CYP1B and two CYP1C sequences have been submitted to GenBank. Similarly, scup genes and the killifish partial sequence recently have been reclassified CYP1C1 and CYP1C2, suggesting that the genes have less than 55% amino acid identity with either the plaice or mammalian CYP1Bs. The cloned channel catfish and brown bullhead (*Ameiurus nebulosus*) CYP1B genes are 71, 61, and 55% similar, respectively, to carp, plaice, and human CYP1B1 (accession number DQ088663). Currently, none of the CYP1B-dependent metabolic studies has been done in fish or fish cells, yet fish are commonly used in toxicology and carcinogenicity testing. *In vivo* and *in vitro* data in catfish do indicate that CYP1B mRNA is induced in gill (but not liver) primary cultured cells and gill, kidney, blood, gonad, and liver following BaP exposure (Butala, unpublished data; Metzger, unpublished data).

In addition to its involvement in PAH metabolism, human CYP1B1 is an estradiol hydroxylase primarily at the C-4 position, whereas CYP1A1 and CYP1A2 have activity at the C-2, C-6α, and C-15α positions of estradiol (Hayes et al., 1996). Tumors have been reported in tissues where estradiol was converted to the 4-hydroxyestradiol metabolite, but tumors did not form where there was primarily

Downloaded From Vet-eBooks.com

2-hydroxylation. Similarly, an elevated ratio of 4-/2-hydroxyestradiol formation in human mammary microsomes has been used as a risk factor for malignant breast cancer (Liehr and Ricci, 1996). Catechol estrogens, such as 4-hydroxyestradiol, are capable of undergoing metabolic redox cycling between hydroquinone and quinone forms, generating potentially mutagenic free radicals and oxidative stress. In channel catfish the 4-/2-hydroxyestradiol ratio was statistically higher in microsomes from BaP-treated fish compared to controls (0.2 and 0.04, respectively) (Butala et al., 2004). The shift toward more 4-hydroxyestradiol production in exposed fish suggests induced production of the redox active estrogen metabolite. As with PAH metabolism, lower levels of CYP1B1 and less associated formation of 4-hydroxyestradiol may be indicative of lower genotoxicity. More studies are necessary to determine the physiological significance of CYP1B in fish.

CYP2

Phylogeny — CYP2 and CYP1 genes belong to the CYP2 clan (Figure 4.4). The CYP1 gene family is believed to have diverged from the CYP2 gene family more than 420 MYA (Nelson, 2003). CYP2 is the most diverse CYP gene family, with 13 known CYP2 subfamilies in fish: 2K, 2M, 2N, 2P, 2R, 2U, 2V, 2X, 2Y, 2Z, 2AA, 2AD, and 2AE (see cytochrome P450 homepage). Two of these, CYP2R and CYP2U, also have mammalian representatives; thus, these subfamilies probably represent more conserved CYP2 genes that emerged over 420 million years of evolution. No functional data are available on CYP2R and CYP2U isozymes, although it is proposed that these earlier emerging CYP2 forms are more likely involved in the metabolism of endobiotics than xenobiotics (Nelson, 2003).

Although mammalian and piscine CYP2 gene families have structurally diverged during vertebrate evolution, there are still some conserved structures as well as catalytic functions among certain CYP2 subfamilies; for example, fish CYP2N, CYP2P, CYP2V, and CYP2Z genes are related to mammalian CYP2D and CYP2J genes (Nelson, 2003). Furthermore, phylogenetic analyses suggest that the killifish CYP2P subfamily is more closely related to the mammalian CYP2J subfamily, compared to the CYP2K and CYP2N subfamilies in fish; thus, the piscine CYP2P and the mammalian CYP2J subfamilies may have arisen from a common ancestral gene (Oleksiak et al., 2003). The fish CYP2 genes and suggested pseudogenes reported to the P450 nomenclature committee are listed in Table 4.3.

Members of the CYP2 gene family in fish are involved in the metabolism of endobiotics, such as arachidonic acid, lauric acid, and sex steroid hormones, as well as xenobiotics such as aflatoxin, alkoxyresorufins, and benzphetamine (Buhler and Wang-Buhler, 1998; Oleksiak et al., 2003; Yang et al., 1998, 2000). The following paragraphs summarize highlights from functional studies of some of these CYP2 subfamilies.

CYP2B-Like Forms—Over the last decades, fish liver microsomes have been shown to metabolize prototypical mammalian CYP2B substrates, including aldrin, benzphetamine, ethylmorphine, aminopyrine, and alkoxyresorufins (Buhler and Williams, 1989; Eisele et al., 1984; Elskus and Stegeman, 1989; Goksøyr et al., 1987; Haasch et al., 1994; Kleinow et al., 1990; Stegeman, 1981). The existence of piscine CYP2B-like enzymes further was supported by protein purification and immuno-cross-reactivity studies; however, a piscine CYP2B gene ortholog has so far not been reported. In the scup, five different CYP isozymes (P450A to P450E) were isolated from liver microsomes. Reconstitution of scup P450B demonstrated oxidation of testosterone at the 15α-position (Klotz et al., 1986). *N*-terminal analysis of scup P450B showed 50% sequence identity with rat CYP2B1 and CYP2B2; furthermore, proteins from different taxa, including several fish species, show cross-reactivity with antibodies against both scup P450B and rat CYP2B1 (Stegeman and Hahn, 1994).

In rainbow trout, five different CYP isozymes (LMC1 to LMC5) were isolated from liver microsomes (Miranda et al., 1989). Reconstituted LMC1 was shown to catalyze lauric acid hydroxylase activity and to cross-react with rat CYP2B1 antibodies (Miranda et al., 1989, 1990). Rainbow trout LMC1 was later assigned as CYP2M1 (Yang et al., 1998). Further studies are needed to elucidate whether scup P450B and CYP2M1 are homolog genes and whether the mammalian CYP2B and the piscine CYP2M subfamilies have arisen from a common ancestral gene.

The presence of hepatic CYP2B immunoreactive proteins and comparatively high activities toward mammalian prototypical CYP2B substrates (i.e., aminopyrene and pentoxyresorufin) were observed in

Downloaded From Vet-eBooks.com

some tropical fishes from the Bermuda Archipelago; however, great differences were found in aminopyrene-*N*-demethylase and pentoxyresorufin-*O*-depentylase activities among species, with the Bermuda chub (*Kyphosous sectatrix*) and sergeant major (*Abudefduf saxatilis*) displaying the highest activities. In addition, polyclonal antibody (pAb) against rat CYP2B1 cross-reacted most strongly with hepatic microsomal proteins in tomtate (*Haemulon aurolineatum*), pinfish (*Lagodan rhomboides*), Bermuda chub, and sergeant major (Stegeman et al., 1997). The reason for the observed differences in CYP2B-like expression among species is not known. Earlier, it was suggested that natural dietary compounds may be causing these differences, as higher CYP2B-like protein levels were observed in butterfly fish (*Chaetodon capistratus*) that consumed gorgonians (containing high levels of allelochemicals) compared to butterfly fish that avoided gorgonians (Vrolijk et al., 1994). CYP2N mRNA expression in *Chaetodon xanthurus* (CYP2N7) was significantly higher than in the facultative coralline-feeding butterfly fish *C. kleini*, *C. auriga* (CYP2N6), or *C. vagabundus*, as well as an obligate coralline feeding species (*C. punctofasciatus*) from the Great Barrier Reef in Australia (DeBusk, 2001). When each species, including *C. xanthurus*, was gavaged with gorgonian extracts from *Sinnularia maxima* for 3 days, with the exception of *C. punctofasciatus*, CYP2N mRNA expression was diminished (DeBusk, 2001). In the Bermuda species investigated, herbivorous fish had higher CYP levels (including CYP2B-like proteins) compared to carnivorous fish (Stegeman et al., 1997). It remains to be shown if natural dietary chemicals may act as inducers of CYP2B-like forms in fish or if other mechanisms are involved.

Phenobarbital (PB) and 1,4-*bis*(2-[3,5-dichloropyridyloxy])benzene (TCPOBOP) are powerful PB-type inducers of CYP2B genes in mammals (Poland et al., 1981). In mammals, induction of CYP2B by PB-type inducers proceeds through activation of the constitutive androstane receptor (CAR) followed by nuclear translocation, dimerization with the retinoid X receptor (RXR), and binding to phenobarbital response elements (PBREMs) in the promoter region of the CYP2B genes (Honkakoski et al., 1997, 1998a,b).

In fish, however, an apparent lack of response to PB-type inducers has been observed (Buhler and Williams, 1989; Eisele et al., 1984; Goksøyr et al., 1987; Haasch et al., 1994; Iwata et al., 2002; Stegeman, 1981), although a CAR immunoreactive protein was detected in scup liver cytosol and nucleus using antibodies against human CAR. No induction of CYP protein levels, including scup P450B, or catalytic activities were seen in scup injected with TCPOBOB. In fact, TCPOBOB treatment had no effect on translocation of the cytosolic CAR-immunoreactive protein in scup liver (Iwata et al., 2002). This study points to functional differences, possibly in receptor activation or translocation, between fish and mammals. Recently, a single piscine CAR/PXR gene was identified (*fr078207*) when searching the pufferfish genome; however, this receptor was more related to PXR family members and hence a probable functional analog of PXR (Maglich et al., 2003). Thus, CAR may have diverged from the pregnane X receptor (PXR) at a later point in vertebrate evolution, or CAR may have been lost in some or all teleost lines (Maglich et al., 2003). The apparent lack of a piscine CAR receptor may be one explanation for the observed lack of PB-type as well as diminished CYP3A (see below) induction in fish.

CYP2E-Like Forms—The possible existence of a CYP2E form in fish (*Poeciliopsis monacha-lucida*) was proposed based on hybridization with a rat CYP2E1 49-base oligonucleotide, antibodies to rat CYP2E1, as well as responsiveness to ethanol treatment. This CYP form was suggested to be involved in the CYP-mediated dealkylation of the fish carcinogen diethylnitrosamine (Kaplan et al., 1991). Furthermore, hepatic microsomal metabolism of the mammalian CYP2E substrate chlorzoxazone in winter flounder (*Pleuronectes americanus*) and in viviparous *Poeciliopsis monacha* and *Poeciliopsis viriosa* is indicative of the presence of CYP2E-like enzymes (Kaplan et al., 2001; Wall and Crivello, 1998). A piscine CYP2E gene ortholog, however, has so far not been reported.

The CYP2K Subfamily—A CYP protein, denoted LMC2, was isolated from rainbow trout liver (Miranda et al., 1989). It was subsequently cloned and assigned as CYP2K1 (Buhler et al., 1994). CYP2K1 is one of the dominant CYP forms expressed in liver and trunk kidney, and it displays sexually dimorphic expression, with higher levels in sexually mature males compared to females (Buhler et al., 1994). In addition to liver and trunk kidney, CYP2K1 also is expressed, though at lower levels, in blood cells, upper intestine, head kidney, stomach, heart, gonads, and male muscle (Cok et al., 1998). Heterologous

Downloaded From Vet-eBooks.com

expression of CYP2K1, using baculovirus *Spodoptera frugiperda* (*Sf9*)-infected insect cells, showed that CYP2K1 catalyzed hydroxylation of lauric acid primarily at the (ω-1) position but also to a minor extent at the (ω-2) position. In addition, CYP2K1 catalyzes the conversion of the procarcinogen aflatoxin B_1 to aflatoxin B_1-8,9-epoxide (Yang et al., 2000). Treatment of rainbow trout with 17β-estradiol decreased CYP2K1 mRNA and protein levels as well as lauric acid hydroxylase activities and bioactivation of aflatoxin B_1. Treatment with testosterone resulted in slightly decreased CYP2K1 mRNA levels, whereas this treatment had no significant effect on CYP2K1 protein levels (Buhler et al., 2000). Thus, CYP2K1 is mainly expressed in the digestive tract and appears to be involved in metabolism of endobiotics such as lauric acid as well as xenobiotics such as aflatoxin B_1. In addition, CYP2K1 also is expressed in, for example, steroidogenic tissues; furthermore, hepatic CYP2K1 expression is affected by sex steroids, particularly 17β-estradiol (Buhler et al., 2000; Cok et al., 1998). This may have toxicological implications, as many natural fish populations are exposed to endocrine-disrupting chemicals (EDCs), including estrogenic compounds. In fact, treatment of rainbow trout with xenoestrogens (methoxychlor, diethylstilbestrol, 4-*tert*-octylphenol, and biochanin A) decreased hepatic acid hydroxylase activity and reduced CYP2K1 protein expression (Katchamart et al., 2002). CYP2K gene orthologs also have been cloned from killifish, pufferfish, and zebrafish (see Table 4.2 and Table 4.3).

The CYP2M Subfamily—As mentioned earlier, rainbow trout LMC1, previously isolated from rainbow trout liver (Miranda et al., 1989), was cloned and assigned as CYP2M1 (Yang et al., 1998). Highest expression of CYP2M1 was observed in liver, but also trunk kidney expresses CYP2M1. Interestingly, in trunk kidney a pronounced sexually dimorphic expression of CYP2M1 was seen, with juvenile females expressing 20-fold higher levels than juvenile males. Expression decreased in trunk kidney in sexually mature animals (Yang et al., 1998). In addition to liver and trunk kidney, CYP2M1 also is expressed, though at lower levels, in head kidney, stomach, heart, gonads, and brain (Cok et al., 1998). Recombinant CYP2M1, expressed in *p*SLV-transfected COS-7 and in baculovirus-infected *Sf9* cells, catalyzed hydroxylation of lauric acid primarily at the (ω-6) position (Yang et al., 1998). Although CYP2M1 appears to be involved in the metabolism of fatty acids and fatty acid derivatives, the physiological function is unknown. Treatment of rainbow trout with 17β-estradiol resulted in decreased CYP2M1 protein and mRNA levels, whereas treatment with testosterone had no effect on CYP2M1 (Buhler et al., 2000). In addition, treatment with xenoestrogens (methoxychlor, diethylstilbestrol, 4-*tert*-octylphenol, and biochanin A) also reduced CYP2M1 protein levels as well as lauric acid hydroxylase activity (Katchamart et al., 2002). It should be noted, however, that the lauric acid hydroxylase activity assay used could not distinguish between CYP2K1, CYP2M1, and possible other CYP activities. So far, no CYP2M ortholog genes have been reported in other species (Table 4.3); however, increased renal ω and ω-6 hydroxylation of lauric acid was observed in male channel catfish treated with ciprofibrate, whereas in male bluegill (*Lepomis macrochirus*) hepatic ω, ω-4, and ω-5 hydroxylation was induced by ciprofibrate (Haasch et al., 1998). Although sequence data are needed to verify the identity of the CYP enzymes induced, these data imply induction of CYP2M-like activities by peroxisome proliferators.

The CYP2N Subfamily—CYP2N1 and CYP2N2 were cloned from killifish liver and heart cDNA libraries (Oleksiak et al., 2000). CYP2N1 mRNA expression was detected at high levels in liver and intestine (mid gut) and at low levels in heart and brain. CYP2N2 mRNA levels were highest in heart and brain and present at lower levels in liver and intestine. Heterologous expression of CYP2N1 and CYP2N2 in *Sf9* insect cells revealed transformation of arachidonic acid to epoxyeicosatrienoic acids. CYP2N1 preferentially metabolized arachidonic acid at the 8,9- and 11,12-olefins and to a lesser degree at the 14,15-olefin, and CYP2N2 preferentially metabolized arachidonic acid at the 8,9-olefin and to a lesser degree at the 11,12- and 14,15-olefins. In addition to being arachidonic acid epoxygenases and hydrolases, the CYP2Ns also metabolize xenobiotics. Thus, both CYP2N1 and CYP2N2 isoforms metabolize benzphetamine and also exhibit minimal alkoxyresorufin-*O*-dealkylase activities (Oleksiak et al., 2000). Intestinal CYP2N1 mRNA levels were decreased in starved animals and in animals treated with 12-*O*-tetradecanoylphorbol-13-acetate (TPA) or starved and treated with TPA-treated killifish. Intestinal CYP2N2 mRNA levels were diminished in animals treated with TPA, whereas starvation had no significant effect on this response; however, increased CYP2N2 mRNA expression was observed in

Downloaded From Vet-eBooks.com

heart (but not in brain) in killifish treated with TPA (Oleksiak et al., 2000). Hepatic CYP2N2 mRNA levels were increased in killifish exposed to anthracene in the lab and in killifish collected from a PAH-contaminated site (Peterson and Bain, 2004); thus, CYP2N genes are expressed in hepatic and extrahepatic organs and appear to be regulated by environmental agents. CYP2N gene orthologs also have been cloned from scup, butterfly fish (*Chaetodon xanthurus*), pufferfish, and zebrafish (Table 4.3).

The CYP2P Subfamily—CYP2P1, CYP2P2, and CYP2P3 were cloned from a killifish genomic library (Oleksiak et al., 2003). CYP2P genes are predominantly expressed in liver and intestine. Recombinant CYP2P3 expressed in baculovirus-infected *Sf9* insect cells catalyzed benzphetamine *N*-dealkylation and arachidonic acid oxidation. Arachidonic acid was oxidized to 14,15-, 11,12-, and 8,9-epoxyeicosatrienoic acids and 19-hydroxyeicosatetraenoic acid. The regiospecificity was similar to human CYP2J2 and rat CYP2J3 isozymes. Similar to that observed for CYP2N1 and CYP2N2, decreased levels of intestinal CYP2P2 and CYP2P3 mRNA were observed in killifish treated with TPA. Prolonged starvation or fasting (20 days) resulted in decreased levels of CYP2P2 and CYP2P3. Neither TPA nor fasting had any significant impact on CYP2P1 mRNA levels; however, fasting followed by refeeding resulted in increased levels of CYP2P1 mRNA but not CYP2P2 and CYP2P3 transcription levels. In rat, fasting resulted in reduced intestinal CYP2J3 and CYP2J4 protein levels; thus, intestinal expression of killifish CYP2P2 and CYP2P3 genes and arachidonic acid regiospecificity of the recombinant CYP2P3 isozyme show great similarities to mammalian CYP2J forms. Relatedness to mammalian CYP2J genes was further confirmed by phylogenetic analysis, using the minimum evolution criterion. Killifish CYP2P genes clustered with mammalian CYP2J genes, separate from the piscine CYP2N and CYP2K subfamilies (Oleksiak et al., 2003). CYP2P gene orthologs also have been cloned from scup, butterfly fish, pufferfish, zebrafish, and largemouth bass (*Micropterus salmoides*) and as a partial sequence from Atlantic salmon (Table 4.3).

The CYP2X Subfamily—The presence of two CYP2-like isozymes in channel catfish was indicated based on immunoreactivity with antibodies against both rainbow trout CYP2K1 and CYP2M1. Furthermore, treatment with ethanol (Perkins and Schlenk, 1998) or the insecticide fenitrothion (Perkins, 1999) specifically decreased expression of the lower (47-kDa) protein. Clofibrate treatment specifically increased the upper (51-kDa) protein. Furthermore, female catfish displayed higher levels of the 47-kDa protein compared to males (Perkins, 1998). A CYP2-immunoreactive protein, denoted CM-HA3, was next isolated from channel catfish liver. *N*-Terminal amino acid analyses followed by a BLAST search revealed sequence identity to both CYP2K1 and CYP2M1 (Perkins et al., 2000). By using degenerate PCR primers designed against this *N*-terminal followed by RACE, a CYP clone was isolated from catfish liver and designated as CYP2X1 (Schlenk et al., 2002); however, the derived amino acid sequence was different from the *N*-terminus of CM-HA3. CYP2X1 expressed in *Sf9* cells demonstrated benzphetamine demethylase activity, but testosterone, fenthion, and *p*-nitrophenol metabolism was not observed. CYP2X gene orthologs also have been cloned from pufferfish and zebrafish (Table 4.3).

CYP3

Phylogeny — Analyses of the complete sequences of several teleost genomes indicate that fish species contain a complement of CYP gene families similar to those found in mammals. To date, however, tissue distribution, mechanisms of gene regulation, and the catalytic function of many of these enzymes remain unknown. The CYP3 gene family is believed to have diverged between 800 and 110 MYA (Maurel, 1996), and four subfamilies have been identified, including CYP3A to CYP3D (see CYP home page). To date, 13 teleost CYP3A genes have been identified by sequence homologies. Additional subfamilies (CYP3B to CYP3D) have been discovered by data mining of both the pufferfish and zebrafish genome databases (see Table 4.4). The CYP3 identity of these genes was based on gene sequence homologies of less than 55% when compared to members of the CYP3A family. Current nomenclature for the CYP3 gene family, however, does not reflect orthologous relationships between organisms due to the presence of multiple CYP3A-like sequences in individual species; thus, CYP3A diversity is thought to include both orthology (diversification due to speciation) and paralogy (diversification due to gene duplication) (McArthur et al., 2003; Nelson et al., 1996). In a previous study, orthologous relationships between

Downloaded From Vet-eBooks.com

mammalian and teleost CYP3A genes were suggested using nearest-neighbor and maximum parsimony methods (Celander and Stegeman, 1997). More recently, Bayesian analysis of 45 vertebrate CYP3A deduced amino acid sequences suggest that teleost, diapsid, and mammalian CYP3A genes have undergone independent diversification and that an ancestral vertebrate genome contained a single CYP3A gene (Hegelund and Celander, 2003; McArthur et al., 2003). Phylogenetic analyses suggest that the divergence of CYP3A paralogs and additional subfamily members is likely due to successive gene-duplication events. Whole genome duplications in teleosts have been suggested (Christoffels et al., 2004; Furutani-Seiki and Wittbrodt, 2004), and multiple CYP3A paralogs have been identified in several species, including medaka, rainbow trout, and killifish (Celander and Stegeman, 1997; Hegelund and Celander, 2003; Kullman and Hinton, 2001; Kullman et al., 2000; Lee and Buhler, 2003; Lee et al., 1998; Lemaire et al., 1996). Teleost CYP3A paralogs demonstrate high degrees of sequence similarity: 90% (CYP3A38 and CYP3A40), 94% (CYP3A27 and CYP3A45), and 98% (CYP3A30 and CYP3A56) for medaka, trout, and killifish, respectively. Each sequence conforms to the specific structural features associated with the cytochrome CYP gene superfamily and exhibits >40% sequence similarity to the CYP3A subfamily. It has been suggested that the topologies of all CYP enzymes are similar, especially regarding structurally conserved regions such as the heme-binding domain, oxygen-binding region, and specific sites associated with redox interactions (Szklarz and Halpert, 1997). Differences in CYP catalytic activities are suggested to be determined predominantly by amino acid composition in six substrate recognition sites (SRS1 to SRS6) (Gotoh, 1992). Recently homology models for CYP3A genes have been described (Harlow and Halpert, 1998; Yang et al., 1998). Key amino acids associated with CYP3A substrate specificity, binding, and regio-specific catalysis have been suggested by using molecular modeling and site-directed mutagenesis. Statistical comparisons using the DIVERGE program identified regions in SRS1, SRS5, and SRS6 that appear to be associated with a general conserved CYP3A function, whereas SRS2, SRS3, and SRS4 confer functional differences among different CYP3A enzymes (McArthur et al., 2003). Alignments of medaka CYP3A38 and CYP3A40 demonstrate that 12 of 49 amino acid differences occur in SRS regions. These differences are predominately observed in SRS1, SRS3, and SRS6. As noted below, it has been suggested that these amino acid substitutions are responsible for the differing kinetic and catalytic properties of these two teleost paralogs.

Multiple CYP3A-like teleost proteins have additionally been observed using immunochemical detection in numerous other species. Although gene sequences for these species have not been identified, cross-reactivity with antibodies specific for either mammalian or teleost CYP3A proteins suggests that multiple CYP3A-like proteins are present in the liver and intestine of several teleosts (Celander et al., 1996).

Function—Functionally, CYP3A enzymes are among the most versatile forms of CYPs as they have unusually broad substrate specificities for both endogenous and exogenous substrates, including steroids, bile acids, eicosanoids, retinoids, xenobiotics such as pharmaceuticals, and procarcinogens (Aoyama et al., 1990; Gillam et al., 1993; Li et al., 1995; Smith et al., 1996; Waxman et al., 1998). CYP3A-like proteins were initially purified from several teleost species, including scup, rainbow trout, and Atlantic cod (Celander et al., 1989; Klotz et al., 1986; Miranda et al., 1989). Identification of these proteins as CYP3A-like was based predominantly on steroid hydroxylase activity and cross-reactivity with CYP3A-specific antibodies. In some instances, antibodies were additionally used as catalytic inhibitors. Purified cytochrome P450A from scup and LMC5 from rainbow trout exhibited specific steroid hydroxylase activity, similar to that observed with mammalian CYP3A enzymes. Each enzyme additionally demonstrated minimal benzo(*a*)pyrene hydroxylase and ethoxycoumarin *O*-deethylase activities, suggesting a functional difference from the previously identified and inducible CYP1A form. Further characterization of purified teleost enzymes was undertaken by comparative reciprocal western blot analysis. Cross-reactivity between teleost and mammalian antibodies further supported a close structural as well as functional similarity between teleost and human CYP3A enzymes (Celander et al., 1996; Miranda et al., 1991). Functional characterization of recombinant CYP3A enzymes has been determined for CYP3A27, CYP3A45, CYP3A38, and CYP3A40 by heterologous expression in baculovirus systems. Recombinant rainbow trout CYP3A27 exhibited a maximum CO-reduced spectrum at 450 nm and comigrated with purified CYP3A27 (formerly denoted LMC5) on western blots. In reconstitution experiments, recombinant protein exhibited catalytic activities for the 6β-, 2β-, and 16β-hydroxylation of

testosterone at 1.48, 0.043, and 0.034 nmol/min/nmol, respectively, as well as dehydrogenation of nifedipine at 50 pmol/min/nmol (Lee and Buhler, 2002). Although turnover rates were significantly higher with the recombinant enzyme, hydroxylase profiles were similar to that observed with purified CYP3A27 enzyme. Heterologous expression of the rainbow trout paralog CYP3A45 additionally exhibits testosterone hydroxylase activity with 6β-hydroxytestosterone as the major metabolite. Activity was higher than that observed with CYP3A27 and was significantly enhanced by the addition of cytochrome b_5 to the reconstitution assays (Lee and Buhler, 2003).

Recombinant medaka CYP3A38 and CYP3A40 catalyzed hydroxylation of testosterone, as well as the *O*-debenzylation of benzyloxyresorufin (BR) and 7-benzyloxy-4-(trifluoromethyl)-coumarin (BFC); however, efficiencies and specificities were significantly different between the two isoforms. Thus, K_m and V_{max} activities based on BFC *O*-debenzyloxylase were estimated to be 0.116 and 0.363 μ*M* and 7.95 and 7.77 nmol/min/nmol P450 for CYP3A38 and CYP3A40, respectively. Medaka CYP3A38 preferentially catalyzed testosterone hydroxylation at the 6β- and 16β-positions, with minor hydroxylation at other positions within the steroid nucleus, whereas CYP3A40 catalysis was predominantly limited to the 6β- position (Kashiwada, unpublished data). Putative identification of CYP3A SRS1 to SRS6 indicated that 12 of the 49 amino acid differences between CYP3A38 and CYP3A40 occur in SRS1, SRS3, and SRS5, previously known to be associated with steroid hydroxylation (Kashiwada, unpublished data; Kullman and Hinton, 2001). Functional analysis of teleost and mammalian CYP3A paralogs has demonstrated that gene-duplication events are tied to acquisition of new function and that convergent evolution of CYP3A function may be frequent among independent gene copies (McArthur et al., 2003). The physiological role of CYP3A is yet to be determined. Given the robust steroid hydroxylase activity, there is speculation that CYP3A forms play an important part in steroid (hormones as well as bile acids) homeostasis. Although the physiological function of CYP3A is still unknown, the fact that these genes are expressed in tissues that act as barriers to the environment (i.e., digestive and respiratory tracts) together with the broad substrate specificities of CYP3A enzymes suggest that they evolved as biochemical defense to prevent bioaccumulation of xenobiotics. In addition, the presence of CYP3A enzymes in steroidogenic tissues implies a role in steroid biotransformation.

Regulation—CYP3A are the major constitutive CYP forms expressed in the liver and intestine of most mammals and other species, including fish (Celander et al., 1996, 1989; Hegelund and Celander, 2003; Hegelund et al., 2004; Husoy et al., 1994). Numerous studies have demonstrated, however, that constitutive expression of CYP3A genes between species, and paralogous CYP3A forms within species, are highly variable with age, gender, development, tissue localization, and between individuals. Variations in gene expression may be due to external environmental factors, including temperature, salinity, diet, or other environmental stressors; biological factors, such as circulating hormone levels; or tissue-specific factors associated with development or reproductive cycle. Depending on species, sexual dimorphic expression of CYP3A has been observed. Lee et al. (1998) reported higher levels of CYP3A expression in juvenile female rainbow trout intestine when compared to males. Gender differences were additionally observed in kidney and liver but to a lesser degree than in intestine. A similar trend was demonstrated in winter flounder (*Pleuronectes americanus*) hepatic microsomes and in Atlantic cod, where CYP3A expression was sevenfold higher in females than males (Gray et al., 1991; Hasselberg et al., 2004). In contrast, adult killifish males displayed up to 2.5-fold higher levels of hepatic and extrahepatic CYP3A30 and CYP3A56 mRNA and protein levels compared to females (Hegelund and Celander, 2003). This finding was in agreement with higher hepatic testosterone 6β-hydroxylase activities in male killifish (Gray et al., 1991; Stegeman and Woodin, 1984). Other species, including medaka and sexually mature rainbow trout, also exhibit a higher level of CYP3A expression in male liver microsomes compared to females (Aoyama et al., 1990; Celander et al., 1989, 1996; Gillam et al., 1993; Gotoh, 1992; Harlow and Halpert, 1998; Kullman and Hinton, 2001; Lee and Buhler, 2003; Li et al., 1995; Smith et al., 1996; Szklarz and Halpert, 1997; Waxman et al., 1998). Variations in CYP3A expression in Atlantic salmon and turbot (*Scophthalmus maximus*) during reproductive cycles have been reported, implying a regulatory role of sex steroids on CYP3A expression (Arukwe and Goksøyr, 1997; Larsen et al., 1992). Steroid reproductive hormones and plasma growth hormones have been shown to influence the sexual dimorphic expression of CYP3A in rodents (Park et al., 1999; Sakuma et al., 2002; Wang and Strobel, 1997).

In teleosts, the effects of exposure to reproductive hormones on CYP3A expression differ depending on species. Numerous studies with rainbow trout, brook trout, medaka, and other fish species have demonstrated that exposure to 17β-estradiol results in a suppression of total microsomal CYP content. This correlated with decreased CYP3A mRNA expression, CYP protein levels, or steroid hydroxylase activities (Buhler et al., 2000; Celander et al., 1989; Pajor et al., 1990). Treatment of male Atlantic cod with 17β-estradiol resulted in an increase in CYP3A protein expression (Hasselberg et al., 2004). The mechanisms of hormonal regulation of CYP genes in teleosts have yet to be determined; however, it is possible that circulating hormone levels (steroids or growth hormone) are associated with sexual dimorphic differences in CYP expression in fish.

Numerous pharmaceuticals and xenobiotics have been demonstrated to alter CYP3A gene transcription in mammals via binding and transactivation of members of the nuclear receptor family NR1, including the pregnane X receptor (PXR), the constitutive androstane receptor (CAR), and the vitamin D receptor (VDR) (Pascussi et al., 2003; Plant and Gibson, 2003). As mentioned above, although Maglich et al. (2003) did not find CAR in the pufferfish genome, they identified a single PXR/CAR gene that was more PXR like, indicating CAR may have evolved after divergence of fish or may have been lost in some or all teleosts. To date, PXR and VDR have been identified in few teleost species. Prototypical mammalian NR1 (PXR) receptor agonists, including dexamethasone (DEX), rifampicin (RIF), and pregnenolone-16α-carbonitrile (PCN), are seemingly less effective at altering teleost CYP3A gene transcription (Celander et al., 1989, 1996a,b; Kullman, unpublished data). In tilapia, PCN treatment resulted in twofold induction of CYP3A proteins (Pathiratne and George, 1996). The ligand-binding region of PXR was isolated from zebrafish (Kliewer et al., 2002). This region was shown to be activated by some prototypical mammalian PXR agonists, including nifedipine, phenobarbital, clotrimazole, and some steroids, but PCN, DEX, and RIF did not activate the fish receptor (Moore et al., 2002). Induction of hepatic CYP3A expression *in vivo* by ketoconazole was observed in juvenile rainbow trout and Atlantic cod (Hasselberg et al., 2004; Hegelund et al., 2004). As mentioned above, response to 17β-estradiol resulted in either enhanced or diminished CYP3A expression, depending on the species examined (Buhler and Wang-Buhler, 1998; Hasselberg et al., 2004; Husoy et al., 1994; Pajor et al., 1990). Furthermore, xenoestrogens also affect CYP3A expression. Male Atlantic cod exposed to alkylphenols showed enhanced hepatic CYP3A expression, whereas treatment with ethinylestradiol and nonylphenol suppressed CYP3A expression in Atlantic salmon and Atlantic cod (Arukwe et al., 1997; Hasselberg et al., 2004). Slight increases in hepatic CYP3A expression have been demonstrated in rainbow trout exposed to cortisol, whereas cortisol treatment had no effect on CYP3A protein levels in Arctic char (*Salvelinus alpinus*) (Celander et al., 1989; Jorgensen et al., 2001).

Although gene sequences for PXR and VDR have been identified in fish (Kliewer et al., 2002), few functional data exist regarding their role in transcriptional activation of CYP3 genes. Identification of cognate hormone response elements upstream of pufferfish and medaka CYP3A genes suggest that nuclear receptors may be involved in transcriptional regulation; however, this has yet to be determined (Kullman, pers. commun.). Cloning and analysis of lamprey VDR suggest that this nuclear receptor is capable of binding and transcriptional activation of the mammalian CYP3A4-DR3 hormone response element. These results demonstrate conservation in the DNA binding behavior of an early form of this receptor and a possible role in transcriptional activation of CYP genes in fish. (For more on nuclear receptors in teleosts, see Chapter 7). Modulation of teleost CYP3A expression following xenobiotic exposure is highly variable and species dependent.

Studies examining the binding behavior of mammalian PXR have demonstrated transactivation and CYP3A induction by xenoestrogens, including bisphenol A, nonylphenol, DDT, and other organochlorine pesticides (Courmoul et al., 2002; Masuyama et al., 2000; Takeshita et al., 2001; You, 2004). The response of aquatic species to these and other PXR, CAR, and VDR ligands has been minimal; thus, the overall induction of CYP3A in teleosts appears to be considerably weaker than that reported in mammals. Compared to mammalian species, this suggests that teleost CYP3A expression may be governed by alternative transcriptional mechanisms. Given the recent completion of several teleost genome projects, examination of promoter sequences will shed some light on regulatory elements and transcriptional control of theses genes. In several studies, discrepancies have been noted between changes in gene expression and changes in steroid hydroxylase activity. In a study by Hasselberg et al. (2005), exposure

Downloaded From Vet-eBooks.com

of juvenile Atlantic cod to ketoconazole resulted in slight increases in CYP3A expression but marked decreases in CYP3A-specific catalytic activity. Similar discrepancies have been noted in medaka, for which significant decreases in catalytic activity cannot be accounted for by corresponding reductions in CYP3A expression (Kashiwada, unpublished data). As noted in the section on CYP1A, these discrepancies between message level and catalytic activity necessitate determination of expression at several levels prior to making conclusions about regulatory mechanisms.

Localization—Localization of CYP3A expression is similar to that observed in mammalian species, with high levels of expression found in the liver and intestinal mucosa. Some differences are observed between specific CYP3A paralogs and may represent putative regulatory and functional differences that occurred during gene duplication events. Immunohistochemical and mRNA analysis of CYP3A27 has demonstrated strong responses in intestinal ceca, proximal descending intestine, and liver, with minor expression occurring in brain (Cok et al., 1998; Lee et al., 2001). The rainbow trout paralog CYP3A45 was predominantly expressed in the gastrointestinal tract, with weak expression occurring in the liver (Lee and Buhler, 2003). In killifish, CYP3A30 and CYP3A56 were coexpressed in intestine and liver, consistent with that observed for rainbow trout CYP3A27. In both species, CYP3A expression is prominent in the digestive tract (intestinal mucosa and liver), suggesting a role for these enzymes in first-pass metabolism of xenobiotics. Extrahepatic CYP3A expression is observed in gill, kidney, brain, spleen, and ovary, suggesting a possible role for CYP3A enzymes in the fine-tuning of endogenous substrates at the site of synthesis or action as well as metabolic defense against xenobiotics (Hegelund and Celander, 2004).

Development—Biotransformation systems for embryonic and fetal tissues of vertebrates are not as well characterized as those for adults. Embryogenesis is a dynamic process that presents a continuously changing metabolic profile as enzymes are induced and repressed (Miller et al., 1996). In general, developing organisms lack many CYP forms present in adults; however, in some instances, they contain certain forms that are only expressed during development. These differences in total CYP content may explain developmental processes and altered sensitivities to toxic exposures during development. Teleost embryos are often sensitive to xenobiotics, and prolonged exposures result in numerous developmental malformations, early mortality, and delayed hatch (Cooke and Hinton, 1999; Villalobos et al., 1996). The nonspecific onset of many of these aberrations may reflect an inability of embryos to sufficiently metabolize and detoxify many of these xenobiotics. CYP3A27 cDNA was cloned from both embryonic and adult hepatic mRNA, suggesting this gene is expressed early during rainbow trout development (Lee et al., 1998). Kullman and Hinton (2001) demonstrated that CYP3A38 and CYP3A40 genes are differentially regulated during embryonic development. Analysis of CYP3A38 and CYP3A40 mRNA and protein demonstrated the presence of a single CYP3A transcript for early and late embryonic stages and two CYP3A transcripts in larvae and adult liver in medaka. Using gene-specific probes, results demonstrated that CYP3A40 is expressed early in embryonic development and continues throughout adult stages. CYP3A38, however, is tightly suppressed during embryonic development and is only expressed post-hatch. Given the role of CYP enzymes in maintaining steady-state levels of morphogenic ligands, it is not surprising to find these enzymes in the earliest stages of life. Previous studies have provided strong evidence for the presence of multiple forms of CYP in the developing fish embryo (Buhler et al., 1997; Chen and Cooper, 1999). In general, fetal CYP forms are present in low levels and exhibit stringent temporal expression patterns that diminish following birth or hatching (Juchau et al., 1998). CYP3A40 mRNA expression was detected as early as stage 11, representing an early multicellular stage of development. Liver formation does not occur until stage 26, demonstrating that initial CYP3A40 expression occurs prior to organogenesis. Functionally, expression of CYP3A40 during early embryonic development may serve multiple purposes including xenobiotic metabolism, hydroxylation of steroid or other morphogenic ligands, and metabolism of yolk. As with human CYP3A7, CYP3A may be the only constitutively expressed cytochrome P450 during embryogenesis, although some adults do express CYP3A7.

Mechanisms of Stimulation and Inhibition—Mutation and docking studies have demonstrated that CYP3A proteins have a large substrate-binding pocket in comparison to other members of the CYP superfamily (Khan and Halpert, 2000). This large pocket is thought to enable CYP3A enzymes to bind

Downloaded From Vet-eBooks.com

multiple substrate molecules at any given time and results in unusual kinetic behaviors consistent with allosteric interaction. The atypical kinetic behavior of CYP3A enzymes results in either sigmoidal or convex rate–substrate concentration profiles indicative of positive or negative cooperativity (Houston and Kenworthy, 2000). With human CYP3A4, homotropic cooperativity (i.e., one substrate) has been observed with numerous chemicals and results in an initial lag in the rate–substrate concentration profile, thus generating sigmoidal profiles (Harlow and Halpert, 1997). Addition of secondary substrates such as α-naphthoflavone (ANF) can result in modification of testosterone hydroxylation activity, suggesting heterotropic (two or more substrates) cooperative interaction (Harlow and Halpert, 1997, 1998). Activation of BFC *O*-debenzyloxylase activity by ANF also was observed in rainbow trout liver microsomes (Hegelund and Celander, unpublished data). In studies with CYP3A38 and CYP3A40, addition of higher (>25 μ*M*) BFC concentrations resulted in a decrease of catalytic activity and a convex rate–substrate plot. This type of deviation from Michaelis–Menten kinetics is indicative of negative homotropic cooperativity and is due to an inability to maintain V_{max} at higher substrate concentrations. In separate experiments, nonylphenol was used as a heterotropic effector. Results were biphasic, suggesting that nonylphenol acts as a concentration-dependent cooperative activator and inhibitor of BFC catalysis. The rate substrate plot demonstrates a sigmoidal curve at low concentrations (below 100 n*M*), indicative of heterotropic activation; however, at higher concentrations, activity levels are decreased, resulting in a convex rate–substrate plot that is indicative of heterotropic inhibition (Kullman et al., 2004). Rainbow trout and killifish exposed to ketoconazole, a potent antifungal agent, additionally exhibited significant decreases in CYP3A-mediated BFC *O*-debenzyloxylase activity, suggesting that this pharmaceutical is a potent heterotropic inhibitor of CYP3A activity (Hegelund et al., 2004). Alkylphenol additionally inhibited CYP3A activity in Atlantic cod liver microsomes with an IC_{50} of 100 μ*M* compared to ketoconazole, which had an IC_{50} in a submicromolar range (Hasselberg et al., 2004). These studies demonstrate that teleost CYP3A enzymes exhibit unusual kinetic behaviors consistent with allosteric interaction and cannot be described by hyperbolic kinetic models. Homotropic cooperative inhibition of BFC at high concentrations suggests that the CYP3A protein is capable of binding multiple substrate molecules, which may result in autoactivation or inhibition of catalysis. Interestingly, the addition of nonylphenol, alkylphenol, or ketokonazole results in heterotropic cooperative inhibition at environmentally relevant concentrations (Hasselberg et al., 2004; Hegelund et al., 2004). Given the putative role of CYP3A in maintaining the homeostatic balance for numerous endobiotics, enzymatic activation and inhibition by xenobiotic compounds may represent a (nongenomic) mechanism of altered metabolism and subsequent toxicity.

Flavin-Containing Monooxygenases

Overview

Flavin-containing monooxygenases (FMOs) are a multigene family of enzymes involved in the monooxygenation of primarily soft-nucleophilic-heteroatom-containing compounds (see Table 4.5) and some inorganic compounds (Hines et al., 1994; Ziegler, 1988; Ziegler and Mitchell, 1972). Because FMOs are located in the smooth endoplasmic reticulum (microsomes) and require NADPH and oxygen as cofactors for catalysis, FMO-catalyzed reactions were thought at one time to merely be another mixed-function oxidase reaction. FMOs were finally identified as unique enzymatic entities following purification of the enzyme by Ziegler and Mitchell (1972). Through an elegant series of experiments, Poulsen and Ziegler (1979) showed that FMOs have a distinct reaction mechanism that is not dependent on a reductase coenzyme (such as CYP), but they are directly reduced by NADPH. The reduction of the flavin by NADPH then allows binding of molecular oxygen, creating a hydroperoxyflavin that is very susceptible to nucleophilic attack by soft-nucleophilic-heteroatom-containing compounds and various inorganic species; thus, compounds with non-delocalized electronic features, such as tertiary amine- and sulfur-containing compounds, are excellent substrates for FMOs (Ziegler, 1988; Ziegler and Mitchell, 1972). Numerous substrates have been identified in mammalian systems, but few have been examined in fish (Schlenk, 1993, 1998).

One of the most surveyed, but more difficult to measure, FMO-catalyzed reactions in fish is that of trimethylamine oxidase (or more accurately TMA oxygenase) (for reviews, see Baker et al., 1963; Schlenk, 1998). Although FMO has yet to be purified to homogeneity in fish, numerous inhibition and

TABLE 4.5

Putative Substrates for Flavin-Containing Monooxygenases in Fish

Substrate	Product
Nitrogen-containing	
Trimethylamine	Trimethylamine *N*-oxide
N,*N*-Dimethylaniline	*N*,*N*-Dimethylaniline *N*-oxide
2-Aminofluorene	2-Hydroxyaminofluorene[a]
Sulfur-containing	
Thiobencarb	Thiobencarb-*S*-oxide[a]
Thiourea	Thiourea-sulfonic acid[a]
Methimazole	Methimazole-sulfonic acid[a]
Aldicarb	Aldicarb sulfoxide[a]
Selenium-containing	
Dimethylselenide	Dimethylselenoxide[a]
Selenomethionine	Selenomethione-Se-oxide[a]

[a] More toxic metabolite than parent compound.

correlative studies have indicated that TMA oxidase is catalyzed by FMO (Agutsson and Strom, 1981; Goldstein and Dewitt-Harley, 1973; Peters et al., 1995; Schlenk, 1994; Schlenk and Li-Schlenk, 1994; Schlenk et al., 1995). A direct relationship also exists between TMA content in fish tissues and enzyme expression (Larsen and Schlenk, 2001; Raymond, 1998; Raymond and DeVries, 1998; Schlenk, 1998). Fish that possess high tissue (muscle, liver, blood) concentrations of TMA or TMA *N*-oxide have higher levels of expression and enzyme activity than fish that do not have either of these biomolecules; for example, TMA-lacking species, such as the channel catfish (*Ictalurus punctatus*), do not express FMO-like protein or enzymatic activity, whereas TMA-containing rainbow trout or various elasmobranchs possess relatively high levels of FMO activity and expression in various tissues (Schlenk and Buhler, 1991; Schlenk and Li-Schlenk, 1994; Schlenk et al., 1993). The relationship between TMA and FMO has several implications regarding the evolution and possible physiological functions of these enzymes which are discussed further below.

Xenobiotics that have been shown to be substrates of the enzyme in fish include tertiary amines such as *N*,*N*-dimethylanaline (DMA) and TMA, thioether pesticides (e.g., aldicarb), thiocarbamates (e.g., eptam, thiobencarb), thiocarbamides (e.g., methimizole, thiourea), and thioamides (e.g., thiobenzamide) (Table 4.5); for a review, see Schlenk (1998). Currently, the most characterized diagnostic substrates for FMO activity in fish are thiourea and DMA (Schlenk, 1993, 1998). Enzymatic activities in fish appear to be sensitive to temperature and have a relatively high pH optimum of 8.0 to 9.6 in various fishes (Schlenk, 1993, 1998). Each of these assays is a simple spectrophotometric method; however, other more elaborate high-performance liquid chromatography (HPLC) methods utilizing enantioselective oxygenations have been identified in mammals to differentiate activities catalyzed by specific isoforms (Rettie et al., 1995). Recent studies have indicated unique stereochemical sulfoxidation reactions in trout, which have not been observed with any previous isoforms of mammalian FMOs (Schlenk et al., 2004). Typically, to validate FMO activity for an uncharacterized xenobiotic, co-incubation of other FMO substrates or CYP inhibitors is necessary, because FMO and CYP share many substrates. It is imperative to note, however, that many putative inhibitors of mammalian enzymes are not as effective in fish and few have been well-characterized, so care should be taken when interpreting data regarding the use of enzyme inhibitors (especially CYP and FMO) in studies with fish.

Currently, 12 FMO genes have been identified in mammals (classified as FMO1 to FMO12), but none has been fully characterized in any fish species (Hines et al., 1994). A close examination of accessible genomic sequences of the pufferfish (*Fugu* sp.) has indicated a gene fragment that is 42% identical with FMO4 and 56% identical to FMO5 (Dolphin, pers. commun.). Conservation of the secondary structure of FMOs has been observed in fish using western blot analyses that employed antibodies raised against mammalian forms (El-Alfy and Schlenk, 1998; Peters et al., 1995; Schlenk, 1998; Schlenk and Buhler,

Downloaded From Vet-eBooks.com

1993; Schlenk and Li-Schlenk; Schlenk et al., 1995). At least two microsomal proteins in rainbow trout liver were recognized by antibodies raised against porcine FMO1 (Schlenk and Buhler, 1993). Subsequent studies with antibodies raised against human FMO1 only recognized one of the two bands (Schlenk et al., 2004). Although a faint band was noted in Japanese medaka liver microsomes with *anti*-FMO3, a stronger signal from *anti*-FMO1 was observed (El-Alfy and Schlenk, 2002); however, catalytic activities (stereochemical analyses) in trout and shark do not correspond to FMO1 or FMO3 but seem to resemble FMO4-like activities, which tends to support genetic observations in *Fugu* (Schlenk et al., 2004).

Regulation, Function, and Toxicological Relevance

Regulation of FMO expression appears to be extremely complex, with the enzyme often being expressed in a random manner (Baker et al., 1963). As mentioned earlier, FMO has been observed in all marine fish species, some euryhaline, and virtually no freshwater species. Strong correlations have been observed between FMO1-like proteins, enzymatic activity, and mRNA recognized by FMO1 cDNA in juvenile Atlantic flounder (*Platichthys flesus*) and turbot (*Scophthalmus maximus*) (Peters et al., 1995; Schlenk et al., 1996a,b), but catalytic activity did not correspond with mRNA expression in sexually mature adult flounder (Schlenk, unpublished data). In fact, although FMO1-like mRNA was observed in all sexually mature animals, hepatic FMO activity was lacking in more than 40% of the animals, with males having more frequent expression. Although evidence suggests that various hormones may modulate the expression of FMO (El-Alfy and Schlenk, 2002; El-Alfy et al., 2002; Schlenk et al., 1997), no consistent induction of enzyme expression has been observed following xenobiotic treatment. In medaka, estradiol downregulated the hepatic FMO3-like protein but induced the gill FMO1-like form (El-Alfy and Schlenk, 2002). Testosterone downregulated both forms of FMO and activity in medaka. Arterial infusion of cortisol induced expression of FMO1 in rainbow trout gill and liver (El-Alfy et al., 2002). However, infusion of growth hormone failed to alter FMO activity or expression (Schlenk, unpublished data).

As mentioned above, FMO activity and protein in several tissues, particularly the gill, appear to be directly correlated with serum osmolality or the salinity regime in which the fish resides (Daikoku and Sakaguchi, 1990; El-Alfy and Schlenk, 2002; Schlenk, 1998; Schlenk and El-Alfy, 1998; Schlenk et al., 1996a,b). Several hypotheses have been put forth to explain this relationship. Four possibilities are: (1) TMA *N*-oxide is produced as a cellular defense to prevent the enzyme inactivation by high cellular ion (Na, K) or urea that occurs in fish residing in subartic or subantarctic environments (Raymond, 1998; Raymond and DeVries, 1998); (2) TMA *N*-oxide is produced to counterbalance high tissue and serum levels of urea that are present regardless of temperature (e.g., in sharks) (Van Waarde, 1988; Yancey et al., 1982); (3) TMA *N*-oxide may be produced in muscle of deep-sea gadiform teleosts (which also produce urea) as an adaptive defense against high pressure (Gillett et al., 1997); and (4) TMA *N*-oxide may be formed by FMOs as a secondary organic osmolyte in response to shifts in salinity regimes (Schlenk, 1993). Each scenario is interrelated, with the common similarity being hyperosmolality. In some euryhaline fish, FMO activity and expression are directly related to the salinity regime in which the animal resides (Charest et al., 1988; Daikoku and Sakaguchi, 1990; Daikoku et al., 1988; El-Alfy and Schlenk, 2002; Lange and Fugelli, 1965; Schlenk and El-Alfy, 1998; Schlenk et al., 1996a,b). FMO activity and protein expression is higher in gills and kidneys than liver in several species of euryhaline fish such as the Atlantic flounder (*Platichthys flesus*), Japanese medaka (*Oryzias latipes*), and rainbow trout (Larsen and Schlenk, 2001; Schlenk, 1998; Schlenk and El-Alfy, 1998; Schlenk et al., 1995). In addition, FMO activity in trout and medaka is downregulated following steroid treatment, which also downregulates osmoregulatory function (i.e., Na^+/K^+-ATPase) (McCormick, 1995; Schlenk et al., 1997). FMO activity and expression in rapid osmoconformers such as striped bass and tilapia do not respond to changes in salinity (Wang et al., 2001), which is also consistent with mechanisms of Na^+/K^+-ATPase regulation in these species. Testing scenarios 1 and 3, recent studies in rainbow trout have indicated that urea infusion or reductions in temperature induce FMO activity and increase muscular TMA *N*-oxide concentrations (Larsen and Schlenk, 2001). Given induction following cortisol treatment, several factors may be involved in FMO regulation in rainbow trout, including stress resulting from alterations in cellular redox potential due to urea or hyperosmotic conditions (El-Alfy et al., 2002; Larsen and Schlenk, 2001). Clearly, more studies are necessary to better understand the regulation of this enzyme system given its role in xenobiotic biotransformation and toxicology.

Downloaded From Vet-eBooks.com

The toxicological significance of FMO-catalyzed biotransformation reactions has not been extensively examined in fish. Recent studies with organoselenides and FMO from sharks have indicated that FMO may be involved in the oxidation and initiation of redox cycling in these species (Schlenk et al., 2003); however, most studies examining the toxicological roles of FMO have examined pesticides. The oxygenation of the pesticides thiobencarb and eptam in striped bass (*Morone saxatilis*) by hepatic FMO was shown to lead to the formation of a reactive-intermediate that covalently bound protein sulfhydral groups (Cashman et al., 1990; Perkins et al., 1999); however, protein binding was not observed *in vivo* by thiobencarb. *S*-Oxygenation of aldicarb to the sulfoxide by FMO significantly increased the inhibition of acetylcholinesterase in rainbow trout (*Oncorhynchus mykiss*) (250-fold) and Japanese medaka (*Oryzias latipes*) (40-fold) (El-Alfy and Schlenk, 2002; Perkins et al., 1999). Elevated toxicity has been observed in FMO-containing fish which can activate aldicarb to the more potent sulfoxide compared to species that lack FMO and convert aldicarb to the less toxic sulfone or hydrolytic metabolites (Perkins and Schlenk, 2000; Schlenk, 1995).

Enhanced sulfoxidation may possibly explain the enhanced toxicity of aldicarb in higher salinity observed in medaka and trout, as FMO expression has been shown to be directly correlated to salinity in medaka (Larsen and Schlenk, 2001; Schlenk and El-Alfy, 1998). Studies comparing the effects of salinity on aldicarb toxicity in trout and striped bass indicate that salinity significantly enhances the toxicity of aldicarb in trout but not in striped bass (Wang et al., 2001). In striped bass, aldicarb sulfoxide formation and FMO expression were unchanged by salinity, whereas salinity increased aldicarb sulfoxide formation, cholinesterase inhibition, and FMO expression in rainbow trout. Consequently, understanding factors that affect the expression patterns of FMO is important when considering species-specific sensitivities to xenobiotics and differential responses of organisms to environmental factors such as salinity and temperature regimes.

Monoamine Oxidases

Monoamine oxidases catalyze the oxidation and eventual elimination of alpha carbon groups from secondary amines. Monoamine oxidases have been characterized in several fish species, with most occurring in trout. Given the critical importance in catecholamine metabolism, most studies have focused on its endogenous role in the neurophysiology of fish. In contrast to terrestrial vertebrates, which have two forms of the enzyme (MAO A and MAO B), fish appear to only have a single form that is genetically distinct from terrestrial vertebrates. Although no specific studies have examined the role of MAO in xenobiotic biotransformation in fish, the effects of various organic and inorganic pollutants on enzyme activity has been examined (Senatori et al., 2003).

Alcohol and Aldehyde Dehydrogenases

Alcohol dehydrogenase (ADH) catalyzes the oxidation of alcohols to aldehydes, which are subsequently converted to acids by aldehyde dehydrogenase (ALDH). NAD^+ is a cofactor for each enzyme. A class 3 ADH cDNA was first identified in sea bream, in which its expression was observed in all tissues as well as eggs and embryos. Expression decreased during early embryonic development but increased fourfold from day 1 to 21 after hatching, indicating that the maternal ADH mRNA is present in the eggs and embryos but diminishes as development occurs, allowing the larval tissue to express its own ADH (Funkenstein and Jakkowiew, 1996). An additional ADH3 cDNA was also identified by RT-PCR in zebrafish (*Danio rerio*) (Dasmahapatra et al., 2001). Expression of the gene in zebrafish embryos appeared to correspond with temporal variations in zebrafish susceptibility to ethanol toxicity. In cod, an ADH enzyme was purified that displayed structural similarities to ADH3, but functionally it was more like ADH1. Ethanol was an excellent substrate for the purified enzyme, and 4-methylpyrazole was a strong inhibitor ($K_i = 0.1\ \mu M$) (Danielsson et al., 1992). Allylic and acetylenic alcohols appear to be bioactivated through oxidation by trout liver ADH and may also act as inhibitors (Bradbury and Christensen, 1991). ALDH has been observed in all tissues of numerous fish species (Nagai et al., 1997). Similar to CYP1A, ALDH has been observed in mammals to be regulated by the Ah receptor. Studies in the dab (*Limanda limanda*), the sea bass (*Dicentrarchus labrax*), and the rainbow trout failed to observe increases in ALDH activities following 3-MC or BNF treatment (Le Maire et al., 1996); however, expression was significantly elevated in liver tumor tissues from adult rainbow trout treated with aflatoxin (Parker et al., 1993).

Downloaded From Vet-eBooks.com

Peroxidases

Lipoxygenases, cyclooxygenases, and peroxidases such as prostaglandin-H synthetase are typically involved in the oxidation of arachidonic acid to hydroxy and peroxyeicosatetraenoic acids, which are subsequently converted to prostaglandins, prostacylins, and thromboxanes. In mammals, each of these enzymes has been shown to activate various xenobiotics through cooxidation pathways requiring a hydroperoxide as a cofactor. Although the enzymes have been observed in fish, their contributions to xenobiotic biotransformation has not been examined. Examples of lipoxygenases observed in rainbow trout gills include the 15- and 12-lipoxygenase (German and Berger, 1990; Hsieh et al., 1988). PGH synthetase has also been observed in gills of freshwater fish (Christ and Van Dorp, 1972).

Aldehyde Oxidase

Aldehyde oxidase is a molybdozyme that is similar to xanthine oxidase located in the cytosols of liver in mammals and fish. Pyrroles, pyridines, pyrimidines, purines, and aromatic aldehydes derived from catecholamine metabolism tend to undergo oxidation reactions; however, under anaerobic conditions, 2-hydroxypyrimidine, N^1-methylnicotinamide, or butyraldehyde may act as electron donors in liver cytosols in fish, leading to substrate reduction under these conditions. Enzyme activity is inhibited by menadione, β-estradiol, and chlorpromazine. Recent studies in the goldfish (*Carassius auratus*) and the sea bream (*Pagrus major*) have demonstrated that aldehyde oxidase catalyzes the reduction of fenthion sulfoxide to the parent sulfide (Kitamura et al., 2003).

Reductases

One of the most common reductases involved in xenobiotic biotransformation is the cytochrome P450 reductase, which catalyzes single-electron reductions to substrates prone to accept single electrons (e.g., quinones, cyclic or aromatic amines). Often, this pathway activates heterocyclic compounds to redox cycling intermediates. Limited studies have evaluated the role of this enzyme in biotransformation in fish.

DT Diaphorase

DT diaphorase (NAD(P)H:[quinone acceptor] oxidoreductase) plays a significant role in one- and two-electron reduction reactions, particularly in the liver. 4-Nitroquinoline 1-oxide and nitrofurantoin were both reduced by DT diaphorase to genotoxic metabolites in a brown bullhead fibroblast cell line (Hasspieler et al., 1997). A novel dicoumarol-sensitive oxidoreductase that catalyzes the reduction of phenanthrenequinone was purified from gastric cytosol in the channel catfish (*Ictalurus punctatus*) (Hasspieler and Di Giulio, 1994). Due to its likely AhR-mediated regulation, the enzyme has shown promise as a biomarker in fish (see Chapter 16). Whether or not bifunctional regulation through ARE occurs (as in mammals) is uncertain.

Azo- and Nitroreductases

Catalyzing up to three sequential two-electron reductions, nitroreductases play a significant role in the biotransformation of primarily nitroaromatic compounds to corresponding amino aromatic compounds. When 2-nitrofluorene was incubated with liver microsomes or cytosol of sea bream (*Pagrus major*) in the presence of NADPH or 2-hydroxypyrimidine, 2-aminofluorene was formed (Ueda et al., 2002). Hepatic nitroreductases were also observed in catfish and catalyzed the formation of superoxide from nitrofurantoin, *p*-nitrobenzoic acid, and *m*-dinitrobenzene (Washburn and Di Giulio, 1988). Hepatic nitro- and azoreductases were observed in the marine teleosts barracuda (*Sphyraena barracuda*) and yellowtail snappers (*Ocyurus chrysurus*); however, only azoreductase activity was observed in elasmobranches, such as the lemon shark (*Negaprion brevirostris*) and stingray (*Dasyatis americana*) (Adamson et al., 1965). The lampricide 3-trifluoromethyl-4-nitrophenol was reduced by nitroreductases to 3-trifluoromethyl-4-aminophenol in rainbow trout (Lech and Costrini, 1972).

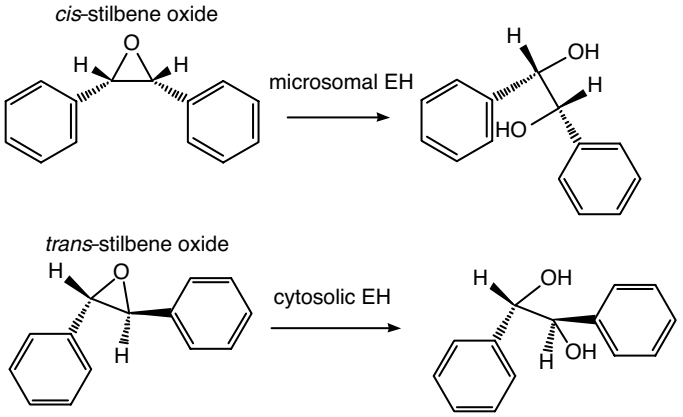

FIGURE 4.5 Reactions catalyzed by epoxide hydrolases.

Hydrolysis

Epoxide Hydrolase

Overview

Xenobiotic epoxides and arene oxides are usually formed by cytochrome P450-dependent oxygenation of a double bond or an aromatic ring. Due to the strain of the three-membered oxirane ring, they readily react with cellular nucleophiles such as water, glutathione, or nucleophilic centers in DNA bases. The function of the epoxide hydrolase (EH) group of enzymes is to catalyze the addition of water to an epoxide or arene oxide. Epoxide hydrolase enzymes are considered part of a larger class of hydrolytic enzymes, including esterases, proteases, dehalogenases, and lipases (Beetham et al., 1995). Studies with mammalian enzymes have shown that two major epoxide hydrolase enzymes utilize xenobiotic epoxides as substrates. These are the cytosolic enzyme that utilizes *trans*-epoxides as substrates and the microsomal enzyme that prefers *cis*-epoxides and arene oxides. In both cases, the products are *trans*-dihydrodiols (Hammock and Hasagawa, 1983) (see Figure 4.5). In a given animal, no evidence indicates multiple forms of the major microsomal or cytosolic epoxide hydrolase.

Microsomal epoxide hydrolase is of particular importance for arene oxides produced by the action of CYP on polycyclic aromatic hydrocarbons. For most arene oxides, conversion to the dihydrodiol results in detoxification of the PAHs. In some cases, however, epoxide hydrolase plays a role in the formation of reactive diol epoxide metabolites; for example, conversion of benzo(*a*)pyrene-7,8-oxide to the 7,8-dihydrodiol is part of the pathway leading to the ultimate carcinogen, (+)-*anti*-benzo(*a*)pyrene-7,8-dihydrodiol-9,10-oxide.

The preferred substrates for study of microsomal epoxide hydrolase activity are *cis*-stilbene oxide (shown in Figure 4.5) and benzo(*a*)pyrene-4,5-oxide, both of which are commercially available in radiolabeled form. The earliest studies of this enzyme were conducted with racemic styrene oxide, but this epoxide was thought to be less definitive in measuring microsomal epoxide hydrolase activity than a true *cis*-epoxide. Regardless of substrate, the method most commonly used to measure epoxide hydrolase activity was to incubate the radiolabeled epoxide or arene oxide with microsomes at pH 9 and then measure the amount of product formed. The pH optimum of microsomal EH activity in most species that have been examined was 8.5 to 9.5 (Balk et al., 1980; James et al., 1979). For some substrates (e.g., styrene oxide and *cis*-stilbene oxide), unreacted substrate was separated from product by extraction (Gill et al., 1983; James et al., 2004) and for others, such as benzo(*a*)pyrene-4,5-oxide, by chromatography (Jerina and Dansette, 1977). Other methods have also been developed, such as gas chromatography, spectrophotometric, and fluorimetric methods (Dansette et al., 1976; Westkaemper and Hanzlik, 1981), although these tend to be of lower sensitivity than the radiochemical methods. In all methods, an important consideration is to keep the reaction pH 6 or higher at all steps, as epoxides undergo spontaneous hydrolysis at acidic pH.

	Kidney	0.16	

[a] In units of nmol · min^{-1} · mg $protein^{-1}$.

In mammalian species, antibodies have been used to quantitate microsomal epoxide hydrolase enzyme in liver subcellular fractions (Bend et al., 1978). Such studies have not been conducted in fish. The cross-reactivity of fish epoxide hydrolases with mammalian microsomal or cytosolic epoxide hydrolases is not known, and no fish epoxide hydrolase protein or gene has yet been reported.

Enzyme Specificity, Regulation, and Inhibition

The first studies of epoxide hydrolase activity in fish were carried out with hepatic, branchial, gonadal, and intestinal microsomes from marine fish common to coastal Maine or Florida (Bend et al., 1978; Gill et al., 1982; James et al., 1974, 1976; Westkaemper and Hanzlik, 1981). These studies showed that, although epoxides were readily hydrolyzed in liver of most fish species, considerable variability exists between individuals as well as between species in the measured epoxide hydrolase activity. Gill, kidney, intestine, and gonads generally had lower epoxide hydrolase activity than liver. Freshwater fish also had readily measured epoxide hydrolase activity in liver and other organs (Parker et al., 1993; Perdudurand and Cravedi, 1989; Stott and Sinnhuber, 1978; Walker et al., 1978; Willett et al., 2000). Table 4.6 shows activities found in some representative marine and freshwater species in liver and other organs.

The importance of epoxide hydrolase activity in the biotransformation of polycyclic aromatic hydrocarbons was highlighted in a study of the *in vitro* metabolism of benzo(*a*)pyrene in scup hepatic microsomes (Stegeman and James, 1985). The ratio of BaP-9,10-dihydrodiol to 9-hydroxy-BaP was found to correlate well with the epoxide hydrolase activity of hepatic microsomes. Individual fish with low epoxide hydrolase

Downloaded From Vet-eBooks.com

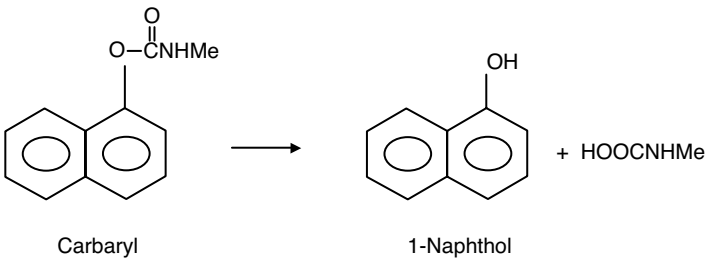

FIGURE 4.6 Reactions catalyzed by carboxylesterases.

activity formed proportionally more of the phenolic rearrangement product, 9-hydroxy-BaP, than BaP-9,10-dihydrodiol; individuals with high epoxide hydrolase activity formed proportionally more BaP-9,10-dihydrodiol and less of the phenolic rearrangement product. This relationship was not found for the ratio of BaP-7,8-dihydrodiol to 7-hydroxy-BaP. It was thought that this was because of differences in the chemical reactivity of the arene oxides of BaP. BaP-9,10-oxide, unlike BaP-7,8-oxide, was not readily hydrolyzed in the absence of epoxide hydrolase, making the presence of the epoxide hydrolase enzyme critical to determining if BaP-9,10-oxide would be hydrolyzed to the dihydrodiol or rearrange to the 9-hydroxy product. The presence of compounds that modulate enzyme activity was found to influence the metabolites of BaP formed in hepatic microsomes from control or 3-methylcholanthrene-induced sheepshead (Little et al., 1981). Incubation of BaP with hepatic microsomes in the presence of naphthoimidazole, a substance that inhibits CYP1A but stimulates epoxide hydrolase, gave a higher ratio of BaP-9,10-dihydrodiol to 9-hydroxy-BaP than incubations in the absence of the modulating agent, presumably by routing the BaP-9,10-oxide formed by CYP1A to BaP-9,10-dihydrodiol rather than to 9-hydroxy-BaP.

Modulation of epoxide hydrolase activity has been investigated following treatment with various xenobiotics. In mammalian species, several xenobiotics induce epoxide hydrolase activity, including phenobarbital, *trans*-stilbene oxide, and some aryl hydrocarbon receptor agonists, including PCBs (Bresnick et al., 1977; Gillette et al., 1987). In fish, however, induction of epoxide hydrolase activity following administration of these agents has not been demonstrated (James and Little, 1981; James et al., 1997). Indeed, in stingrays treated with 3-methylcholanthrene at a dose that induced AHH activity tenfold, epoxide hydrolase activity was significantly lower in hepatic microsomes from treated fish (4.54 ± 0.55 nmol/min/mg protein) relative to controls (5.81 ± 0.76) (James and Bend, 1980). A similar trend was observed in 3-MC-treated sheepshead. Flatfish exposed to PAH- and PCB-contaminated Puget Sound sediments showed no increase in epoxide hydrolase activity (Collier and Varanasi, 1991; Collier et al., 1986). Likewise, channel catfish and brown bullhead treated with 10 mg/kg benzo(*a*)pyrene showed no significant induction or species difference in liver microsomal *cis*-stilbene-oxide hydrolase activities (Willett et al., 2000). In the splake, treatment with the fish anesthetic tricaine methane sulfonate reduced epoxide hydrolase activity in liver and duodenum (Laitenen et al., 1981).

Carboxylesterases

Hydrolytic biotransformation of xenobiotics by various forms of carboxylesterases in fish plays a significant role in the detoxification of various pesticides (Glickman et al., 1982; Straus and Chambers, 1995; Wallace and Dargan, 1987) and plasticizers (Barron et al., 1989) (Figure 4.6). Most of the studies examining this pathway in fish have focused on postmitochondrial or cytosolic enzymes (Salamastrakis and Haritos, 1988), and some studies have examined the microsomal activities (Soldano et al., 1992; Vittozzi et al., 2001). No carboxylesterase genes have been characterized in fish, but studies with purified proteins (e.g., chlorpyrifos) have been carried out (Boone and Chambers, 1997). Differences in carboxylesterase activities among species have been hypothesized to be responsible for the acute toxicity of organophosphates (Keizer et al., 1991, 1993, 1995) and pyrethroids (Glickman et al., 1979, 1982). Carp were resistant to diazinon toxicity because of relatively high activity of hydrolyzing esterase activity, whereas trout was very sensitive to toxicity because of a lack of esterase activity and a sensitive acetylcholinesterase (Keizer et al., 1995). A similar relationship was observed in trout with permethrin (Glickman et al., 1979).

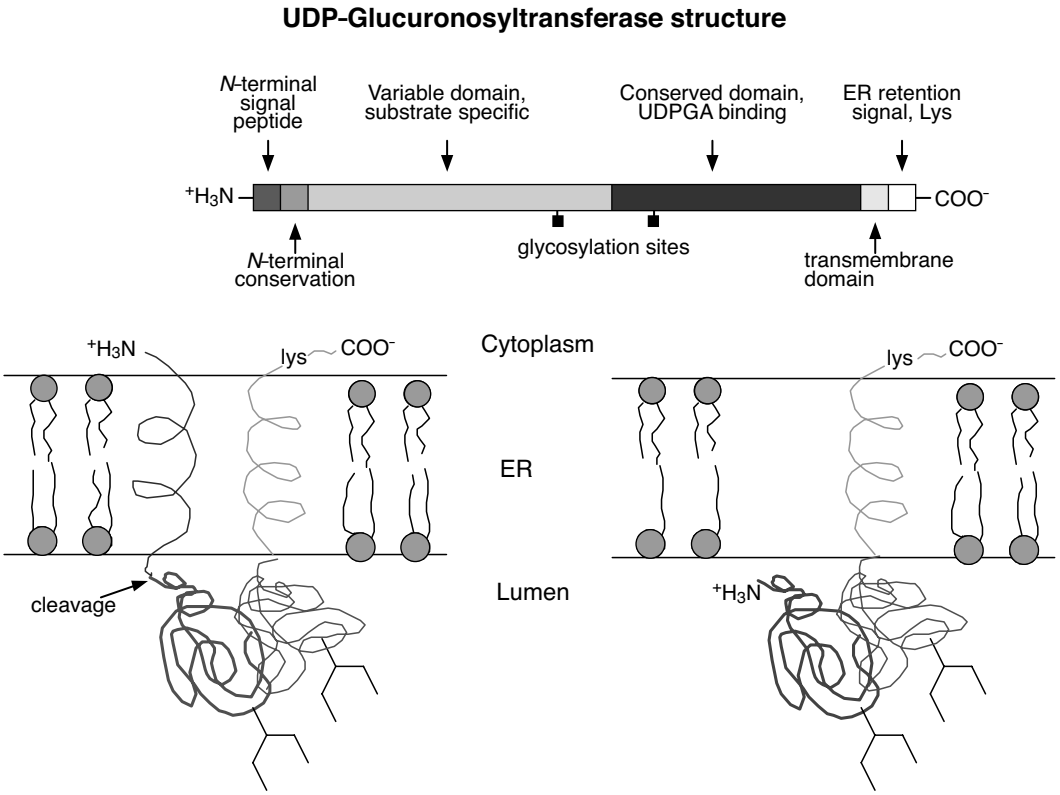

FIGURE 4.7 Structure and organization of UDP–glucuronosyltransferases.

Phase II Enzymes

UDP-Glucuronosyltransferases

Overview

The UDP-glucuronosyltransferases (UGTs) represent a major group of phase II conjugating enzymes. Glucuronidation is principally a characteristic feature of vertebrates; invertebrates tend to prefer to utilize glycosylation. Glucuronidation is the major pathway for the conversion (and inactivation) of both endogenous and exogenous compounds to polar, water-soluble compounds that are then excreted in the bile (compounds > 350 MW) or urine (compounds < 300 MW). The UGTs are active in the metabolism of endogenous compounds such as steroid hormones, thyroid hormones, and waste products such as bilirubin (Dutton, 1990). In addition, an important role is played in the biotransformation of natural toxins and anthropogenic toxicants that are absorbed into the organism. Because of their importance in the breakdown of therapeutic drugs, UGTs are extensively researched in the medical and pharmaceutical fields (Parkinson, 2001). This explains why so much is known about UGTs in mammalian systems, while research on UGTs in lower vertebrates and invertebrates is much more limited.

The glucuronosyltransferases are located in the endoplasmic reticulum (ER), with the active site facing inward into the lumen of the ER (Figure 4.7). The various isozymes have a common *C*-terminal, which anchors the enzyme in the membrane of the ER. This brings them in close proximity to phase I enzymes, such as CYP1A, which are also located on the ER; thus, phenolic phase I metabolites formed by CYPs can immediately be conjugated by the neighboring phenol-type UGT (UGT1A6). It has even been suggested that direct contact between CYP1A1 and UGT1A6 occurs and that these protein–protein interactions enhance the activity of the glucuronidation enzyme (Taura et al., 2004).

Downloaded From Vet-eBooks.com

Glucuronidation involves the transfer of an activated sugar group to the substrate. This process increases the water solubility and the molecular weight of the substrates, thus facilitating transport and excretion. The preferred cofactor for most UGT isoforms is uridine diphosphoglucuronic acid (UDPGA). However, a number of other nucleotide–sugar cofactors have been reported for these enzymes; therefore, the name *UDP-glycosyltransferase* has been proposed as a better name for this superfamily (Mackenzie et al., 1997). UDPGA is synthesized in the cytosol from uridine-triphosphate and glucose-1-phosphate. Contrary to many phase I reactions, glucuronidation does not require additional energy supply in the form of ATP or NADPH. The synthesis of UDPGA in the cytosol introduces an extra threshold for the glucuronidation reaction rate, as the water-soluble cofactor has to be actively transported through the ER membrane to reach the active site on the UGT enzyme. Mechanisms surrounding transport are still unknown.

UGT Gene Structure

Multiple UGT genes have been characterized in mammals (17 in humans) and are subdivided into two families. All UGT1 family members are encoded by a unique single locus gene, which in humans has 13 different first exons spanning some 300 kb. They encode the aglycone binding site, which is alternatively spliced onto identical exons 2 to 5, which encode the *C*-terminal half of the protein responsible for UDP-glucuronic acid binding. Each exon 1 appears to have its own promoter in the 5′ upstream region between its transcription start site and the preceding exon 1. Elaboration of the gene appears to have arisen from duplication into two clusters: (1) a *bilirubin cluster* (1A1 to 1A5 isoforms), primarily involved in the conjugation of amines, bilirubin, carboxylic acids, and thyroxine, and (2) a *phenol cluster*, which conjugates planar polyaromatic hydrocarbons (1A6) and bulky phenols (1A7 to 1A13). A similar although slightly less complex elaboration of the UGT1A family has been found in rodents and the rabbit. In humans and rats, at least one gene of the bilirubin cluster is a pseudogene resulting in reduced conjugation of planar phenols. In contrast, the genes of UGT2 family members, each comprised of six exons, are located at distinct loci on another chromosome. The UGT2A subfamily has postulated roles in olfaction, and the products of the UGT2B family genes appear to be particularly involved in bile acid and steroid hormone conjugation. Although many of the enzymes were successfully purified from rodents, the majority of the genes have been heterologously expressed for activity studies, and indeed most of the human enzymes are now commercially available.

The gene encoding the major phenol-conjugating isoform of plaice has been cloned (UGT1B1) and found to share an almost identical five-exon structure with mammalian UGT1 family members (George and Leaver, 2002; George, unpublished data). When heterologously expressed, it displays specificity for planar phenols such as 1-naphthol and 4-nitrophenol as aglycones but no demonstrable activity with bilirubin or steroids (Leaver et al., 2007).

Expressed sequence tags (ESTs) for UGTs have subsequently been cloned from flounder, plaice, and zebrafish. Analysis of the currently published zebrafish EST sequences and the latest assembly of the genome reveals that at least 14 distinct UGTs are expressed (George and Taylor, 2002; George, unpublished data, Leaver et al.., 2007). More putative genes can be identified in the genome; however, they are found on numerous chromosomes (in both mouse and humans, the UGT1 family occurs on one chromosome and the UGT2 family on another). The phylogenetic relationships between these expressed zebrafish UGT homologs and the human genes is shown in Figure 4.8. The zebrafish genes are divisible into three groups; the group with closest similarity to the characterized UGT1B1 gene comprises two alternatively spliced six-exon genes. Gene 6220 is comprised of six exon 1's, three of which are known to be expressed (Figure 4.9). The products arise by alternative splicing of the primary transcripts. Inspection of the nucleotide sequences of the intervening introns between the multiple exon 1's reveals the presence of peroxisomal proliferator response elements (PPREs) and xenobiotic response elements (XREs), which would support the plaice induction data. A further three zebrafish genes are comprised of six exons and divide with the mammalian UGT2 family, thus inferring the closest homology. Interestingly, gene 4649 also appears to exhibit alternative splicing. Intronless UGT genes can also be identified in zebrafish (four putative genes, two reported as ESTs) and in the pufferfish (two genes). These genes (family 3) have an unknown function and appear to be unique to fish.

The zebrafish protein sequences were translated from the genome sequence for which there are reported EST data (gene/protein numbers given [ZF]). (From George, S.G. and Taylor, A., *Mar. Environ. Res*., 54, 253, 2002. With permission.)

Reactions and Substrate Specificity

The spectrum of the acceptor substrates is very wide and, as with most enzymes that exhibit a broad specificity for structurally diverse compounds, multiple isoenzymes belonging to a number of multigene families are found (Mackenzie et al., 1997). The enzymes catalyze the transfer (conjugation) of glucuronic acid from the high-energy nucleotide UDP-glucuronic acid (UDPGA) to a wide variety of acceptor substrates (aglycones) to form β-glucuronides (Figure 4.10). The most common are the formation of *O*-glucuronides from alcohols, phenols, and carboxylic acids and *N*-glucuronides of carbamates, amides, and amines. *S*-Glucuronides of aryl mercaptans and thiocarbamates and *C*-glucuronides formed by conjugation of 1,3-dicarbonyls have also been identified in mammals but not so far in aquatic species. The endogenous roles of these enzymes are in the detoxification of toxic metabolites (e.g., bilirubin) formed from the degradation of heme, the secretion of bile acids (e.g., lithocholate), termination of hormone action (retinol, T_3, T_4, sex steroids), cessation of the action of olfactory stimulants, and, in the

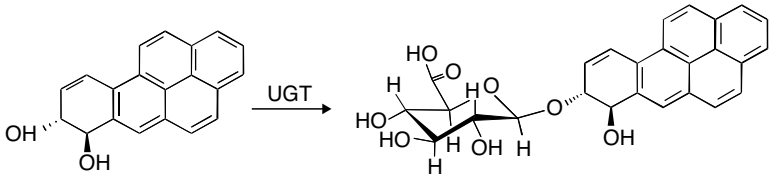

FIGURE 4.10 Glucuronidation of benzo(*a*)pyrene-7,8-dihydrodiol catalyzed by UGT.

case of fish, excretion of glucuronides of sex steroids as pheromones and spawning stimulants (Lambert and Resink, 1991). Many of the enzymes have a broad and overlapping substrate specificity, which gives them the ability to conjugate many xenobiotic compounds in addition to their preferred endobiotic substrates. This appears to be the case for those conjugating bilirubin and planar polyaromatic phenols, although several isoenzymes, particularly those metabolizing steroid hormones, appear to show a more restricted substrate specificity (Table 4.7).

Most investigations of fish have been *in vivo* studies concerned with the identification of the glucuronides of endobiotic and xenobiotic compounds. Glucuronide conjugates of bilirubin, 17β-estradiol, triiodothyronine (T_3), and thyroxine (T_4) have been identified in the bile of several fish species, whereas glucuronides of 3α-, 3β-, and 17β-hydroxy steroids and their metabolites have been identified in several tissues and body fluids, showing that the scope for endogenous compounds is the same as in mammals (George, 1994).

Quantitatively, glucuronidation is the most important pathway for detoxication and excretion of xenobiotic compounds in mammals, and studies to date indicate that this is also the case in fish. A recent listing of the wide and structurally diverse range of xenobiotic compounds whose glucuronides have been detected in bile, urine, and various tissues is given in Table 4.8. Compared with the large number of compounds shown to be glucuronidated *in vivo*, few studies have been reported on the scope of

TABLE 4.7

Substrate Specificities of Some Mammalian UGT Isoenzymes and Some Xenobiotics Conjugated

Endogenous Substrates	Xenobiotic Substrates
Bilirubin, thyroxine, 5-OH tryptamine	4-Nitrophenol (4NP)

TABLE 4.8

Compounds Glucuronidated in Fish

Chemical Class	Examples
Aromatic hydrocarbons	Benzene (metabolite phenol) Naphthalene (metabolite 1-naphthol)
Aliphatic hydrocarbons	Hexachlorocyclohexane (lindane)
Polyaromatic hydrocarbons (phenol and diol metabolites)	Phenanthrene, pyrene, chrysene, benzo(*a*)pyrene, retene (7-isopropyl-1-methylphenanthrene)
N-Heteroaromatics	Quinoline, dimethylquinoline, carbazole
Aromatic amines	Aniline, 2,4-dichloroaniline, naphthylamine
Thioazole	2-Amino-4-phenylthiazole (anesthetics, such as Piscaine™; the *N*-glucuronide)
O-Heteroaromatics (hydroxylated or dealkylated metabolites)	Dibenzofuran(s), tetrachlorodibenzofuran, 7-ethoxycoumarin
S-Heteroaromatics	Dibenzothiophene
Biphenyls (hydroxylated metabolites)	Biphenyl, tetrachlorobiphenyl
Resin acids	Abietic, hehydroabietic, hydroabietic, isopimaric, pimaric acids (present in wood pulps)
Phenolics	Phenol 1-naphthol, 4-amino phenol, 1-chlorophenol, *penta*-chlorophenol (wood preservatives), chlorophenolics formed during paper bleaching, 4-nitrophenol, 3-trifluoromethylnitrophenol (lampreycide), phenolphthalein, phenolsulfonphthalein (dyes, slow), aflatoxicol M (aflatoxin B_1 metabolite)
Phenolic xenoestrogens	Bisphenol A, diethylstilbesterol, 4-nonylphenol, nonylphenol diethoxylate, *tert*-octylphenol (degradation products of alkylphenoxylate detergents)
Phytoestrogens	Coumesterol, genistein, biochinin A
Antibiotics	Chloramphenicol, oxolinic acid, dimethylquinoline, miloxacin
Insecticides	Organophosphates (e.g., fenitrothion malathion, chloropyriphos); carbamates (e.g., 1-naphthyl-*N*-methylcarbamate, Sevin™); pyrethroids (e.g., pyrethrin)
Fungicides	Imidazole (e.g., Prochloraz™), pentachlorophenol
Plasticizers	*mono*-Ethylhexylphthalate, di-2-ethylhexylphthalate
Miscellaneous industrial chemicals, drugs	Picric acid, picramic acids, morphine, valproic acid, pristane, digoxigenin monodigitoxide
Endobiotics	Bilirubin, bilirubin glucuronide; cholic acids, cholate, deoxycholate, lithocholate; retinoic acid; triodothyronine (T3), thyroxine (T4); 3α-hydroxysteroids (androsterone); 3-hydroxysteroids (estradiol, estrone); 17β-hydroxysteroids (testosterone, 17-methyltestosterone)

glucuronidation in isolated microsomal preparations from fish. The liver is the most active tissue (see later section). Planar phenols such as 4-nitrophenol, 1-naphthol, and 4-methylumbelliferone are readily conjugated, although the rate may vary by as much as an order of magnitude between species. One difficulty in intercomparison is the well-known latency observed in microsomes due to the lumenal orientation of the enzyme and inaccessibility of UDPGA. In fish, this latency, which varies in a tissue-specific manner, does not appear to be so great as in mammals. Maximal activity in microsomes is only obtained in the presence of an optimized amount of detergent; indeed, an excess of detergent has an inhibitory effect (Burchell and Coughtrie, 1989; Clarke et al., 1992b). Many published results are not comparable because the species differences are remarkable, most notable being the much lower capacity for conjugation of phenols in trout than plaice (George, 1994).

Enzymology of Piscine UGTs

The UGTs are membrane-bound enzymes that are quite labile when isolated, requiring phospholipids to maintain activity; therefore, UGTs have proven to be notoriously difficult to purify and characterize. The only non-mammalian UGTs to be purified were from the plaice (Clarke et al., 1992c). At least six immunoreactive UGT peptides were visualized in plaice microsomes in western blots with mammalian

Downloaded From Vet-eBooks.com

antisera, indicating common structural epitopes (Clarke et al., 1992a). From purification studies, at least five UGTs have been identified in plaice liver (George, 1994), and the phenol-conjugating isoform that was purified to homogeneity displayed a very high activity toward planar phenols and no measurable activity toward bilirubin or steroids. The bilirubin-conjugating isoform appeared to exhibit both bilirubin- and phenol-conjugating activity as found in mammals. Reviews of earlier studies on glucuronidation in fish can be found in Clarke et al. (1991) and George (1994). The picture that emerges from these reviews is that UGT isoforms are found in a wide variety of fish species and that specific enzymatic activities are found for bilirubin, steroid and thyroid hormones, and phenolic compounds. As in mammalian systems, a diverse group of xenobiotic compounds has been identified as substrates for UGTs, among which are chlorinated phenols, aromatic hydrocarbon metabolites, phthalates, aflatoxin, pesticides, and antibiotics. Comparison of UGT activities among species was found to be a problematic task primarily due to the non-optimization of detergent concentrations in assays in most published studies. The enzymes also display maximal activity at 37°C (Clarke et al., 1992b); thus, corrections for temperature should be used for intercomparisons.

Tissue Distribution

In fish species, UGT activity is usually high in liver and intestine, but measurable activities have also been found in gill, kidney, and muscle tissue (Clarke et al., 1991; George et al., 1998; James et al., 1998; Singh et al., 1996). UGTs play an important role in gonadal tissues; in addition to the regulation of steroid hormones, UGTs play a role in the production of sex pheromones in fish (Lambert and Resink, 1991). Testosterone UGT activity is present in liver, testis, and intestine (Clarke et al., 1992b), and glucuronidation of pregnenolone and androstenedione has been demonstrated *in vitro* with testicular preparations (Andersson, 1992). Glucuronidation of bilirubin is confined to liver in both plaice and salmon.

Regulation of UGTs

Coregulation of both CYPs and UGTs occurs in mammals, and prototypical inducers such as clofibrate, PAHs, phenobarbital, and pregnenolone-16α-carbonitrile (PCN) differentially induce expression of both CYP and UGT isoforms. The degree of upregulation of UGT activity is generally some two- to threefold. UGT1A1 (bilirubin conjugation) is induced by the hyperlipidemic agent (and peroxisomal proliferator) clofibrate. In common with a number of phase I and II genes, UGT1A6 (planar phenol conjugation) is induced by interaction of the Ah receptor with an XRE in its promoter region. This coregulation of CYP1A and UGT1A6 in mammals and CYP1A and UGT1B1 in fish has been shown to facilitate detoxification of PAHs such as BaP. Mammalian CYP2B and CYP3A and UGT1A genes are also induced via a nuclear pregnane X receptor and a constitutive androstane receptor. Interestingly, these recognition motifs are also present in the zebrafish UGT6220 gene (George, unpublished data). Mammalian steroid UGTs are induced by PCN. Several reports indicate a modest induction of phenol UGT activity in fish from polluted environments and after experimental PAH exposure. To study the induction of AhR-activated enzymes, two PAHs are often used: 3-methylcholanthrene (3-MC) and β-naphthoflavone (BNF). Both compounds have been used as CYP1A and phenol UGT inducers in a number of fish species (Table 4.9). Maximal induction of CYP1A is usually found around 3 days after single treatment, but phenol UGT induction appears to be slower, with a maximum induction occurring around 8 days after treatment. In general, induction of EROD activity can be up to 250-fold, but UGT activity is never induced more than 3-to 6-fold. Two species, cod (*Gadus morhua*) and gilthead sea bream (*Sparus aurata*), displayed little or no response to AhR ligands as phenol UGT inducers (Goksøyr et al., 1987; Pretti et al., 2001). It must be noted, however, that multiple isoforms in mammals, including the constitutive steroid isoforms, also conjugate 4-nitrophenol. Immunoblot and northern blot analyses of xenobiotic-treated plaice have shown that induction of UGTs appears to be tissue specific (Clarke et al., 1992a). Treatment with the PAH (3-MC) increased phenol-conjugating activity and a 56-kDa immunoreactive peptide in liver by approximately 1.7-fold. The bifunctional PAH-type inducer BNF caused an induction (approximately three- to fourfold) of UGT1B1 mRNA only in intestine (Leaver et al., unpublished data). Although clofibrate did not appear to induce phenol- or bilirubin-conjugating activities (Clarke et al., 1992a),

treatment with the potent peroxisome proliferator-activated receptor γ (PPARγ)-mediated peroxisomal proliferator perfluorooctanoate (PFOA) has not been found to induce UGT1B1 mRNA levels in tissues other than kidney (Leaver et al., unpublished data). This pattern of induction by BNF and PFOA is identical to that observed for the glutathione *S*-transferase gene (GSTA), which contains peroxisomal proliferator response elements (PPREs) and antioxidant response elements (AREs) but not xenobiotic response elements (XREs) in the promoter region (Leaver et al., 1997). Exposure to PCBs generally induces UGT activity in fish species (Table 4.10). When tilapia (*Oreochromis niloticus*) were fed a diet amended with sewage sludge, tissue PCB concentrations were increased, together with an increase in UGT activity (Yang et al., 1993). Coplanar PCBs are AhR ligands; however, when coplanar PCBs are metabolized by CYP isozymes, the hydroxylated metabolites that are formed can be potent inhibitors of UGT and sulfotransferase (van den Hurk et al., 2002).

Inhibition of UGTs

Of great environmental concern is inhibition of the steroid-type UGT by environmental pollutants. Inhibition of these enzymes could cause an accumulation of active hormone that may lead to disturbed gonadal cycles and even tumor formation in the hormone secreting organs. Some xenoestrogens were indeed demonstrated to affect UGTs in fish species; for example, nonylphenol inhibited steroid-conjugating UGT activity in Atlantic salmon (Arukwe et al., 1997), and nonylphenol diethoxylate inhibited UGT activity in rainbow trout hepatocytes (Sturm et al., 2001). Growth hormone caused an inhibition of UGT with testosterone as substrate (Cravedi et al., 1995), indicating that there may be interactions between different UGT isoforms through their respective substrates. In addition, liver UGTs are important in the metabolism and excretion of thyroid hormones in fish; thyroid glucuronides have been measured in the bile of a variety of fish species (George, 1994). In rainbow trout (*Oncorhynchus mykiss*), injection

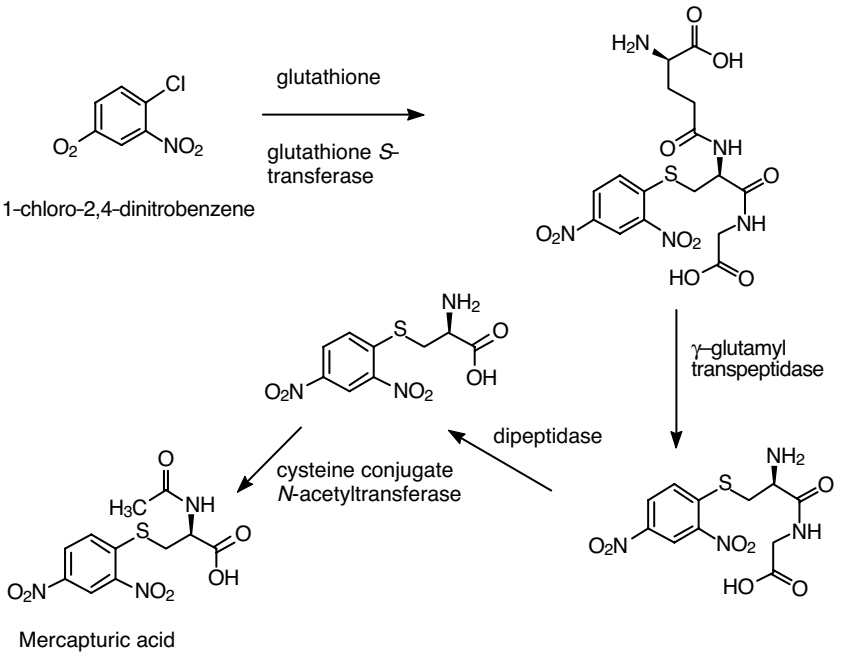

FIGURE 4.11 Glutathione conjugation of 1-chloro-2,4-dinitrobenzene. This compound is a substrate for several distinct glutathione *S*-transferase enzymes and is commonly used to measure glutathione transferase activity. The product has a strong ultraviolet absorbance at 344 nm, and its formation is readily followed spectrophotometrically. Following glutathione conjugation, the conjugate is converted in a three-step reaction to the *N*-acetylcysteine conjugate (mercapturic acid).

of thyroid hormones demonstrated that glucuronidation plays an important role in maintaining a homeostatic thyroid status (Finnson and Eales, 1999). Other environmental toxicants that inhibit UGTs are chlorinated hydrocarbons. Pentachlorophenol and other compounds in pulp mill effluents were shown to inhibit UGT activity in rainbow trout (Castren and Oikari, 1987). Hydroxylated PCBs form another group recognized as potent inhibitors of phenol-type UGT in channel catfish (van den Hurk et al., 2002). Inhibition of phenol-type UGT by PCB metabolites may hinder the detoxification of procarcinogens, as was demonstrated with benzo(*a*)pyrene-7,8-dihydrodiol in channel catfish (James et al., 1994).

Glutathione *S*-Transferases

Overview

The glutathione *S*-transferases (GSTs; EC 2.5.1.18) are a supergene family of phase II enzymes that provide cellular protection against the toxic effects of a variety of endogenous and environmental chemicals. These dimeric enzymes are ubiquitously distributed and comprise approximately 2 to 4% of total cytosolic proteins in liver. The most important reaction catalyzed by all isoforms is the conjugation of the tripeptide glutathione (gamma-glutamyl-cysteinyl-glycine) with an electrophilic center that can be a C, N, or S atom; these are present in arene oxides, aliphatic and aromatic halides, and α,β-unsaturated carbonyls. Following formation of the glutathione conjugate, the metabolite may undergo two separate amino acid cleavage reactions followed by *N*-acetylation to form mercapturic acid derivatives (Figure 4.11). The substrate specificity of the GSTs is extremely broad. Notable toxic xenobiotic electrophilic compounds that are conjugated and of toxicological interest include carcinogens and their metabolites, such as aflatoxin B_1, benzo(*a*)pyrene, 7,12-dimethylbenzanthracene, 5-methylchrysene, and pesticides (e.g., alachlor, atrazine, DDT, lindane, methylparathion). A number of GSTs also catalyze biosynthetic reactions of the leukotrienes and prostaglandins, and others act as organic peroxidases and steroid isomerases. A major role in endogenous metabolism is the detoxification of products of oxidative stress

arising from oxidation of lipids, nucleic acids, and proteins—for example, base propenals such as acrolein from DNA oxidation; cholesterol oxide, fatty acid hydroperoxides, and hydroxynonenals from lipid oxidation; and protein carbonyls from protein oxidation. Some isoforms can also exhibit a covalent binding rather than a catalytic role with some compounds. Reactive metabolites of carcinogens (e.g., PAHs) may bind covalently in a suicide reaction that prevents their reaction with DNA; however, many other neutral or lipophilic compounds that are not substrates, including steroid and thyroid hormones, bile acids, bilirubin, fatty acids, and heme, may bind noncovalently in a reversible manner. Functionally, the significance of this noncovalent binding is unknown, but, considering the high concentration of the enzyme proteins in the cytosol, roles in intracellular transport, as a buffer for these compounds, and as an efflux system (via the ATP-dependent glutathione conjugate efflux pumps GS-X, MOAT, and Mrp) have been postulated.

GST Gene Structure

Glutathione *S*-transferases are widely distributed in nature, and essentially all eukaryotic species contain multigene families, many of which contain further subfamilies of proteins. Both cytosolic and membrane-bound forms are present (Board et al., 1997, 2000; Hayes and Pulford, 1995). They are generally classified according to sequence homology and assigned to seven separate families of cytosolic enzymes (designated class alpha, mu, omega, pi, sigma, theta, and zeta) and to two membrane families—microsomal and mitochondrial (kappa). The native cytosolic enzymes are present as dimers of 24- to 26-kDa subunits, and a characteristic of the different families is that within each family the proteins contain conserved amino acid residues that enable formation of both homo- and heterodimers of enzyme subunits. The microsomal enzymes are trimers of approximately 15-kDa subunits and are integral membrane proteins.

In lower vertebrates and invertebrates, few GSTs have been fully characterized, although on the basis of the broad spectrum of catalytic activities found, immunochemical comparisons, and nucleotide sequence homologies, the presence of multiple isoforms from a number of gene families in all phyla is a certainty. On the basis of immunochemical cross-reactivity with antisera exhibiting family specificity, proteins of the alpha, mu, pi, and theta-like families have been identified in many fish species (Table 4.11), and in three mollusk species pi-class enzymes are the major isoforms.

The relative abundances of these isoforms differ between species. GSTs are most abundant in the liver. The predominant isoform in the cyprinids, salmonids, and gadoids is a pi-class homolog, and the

Downloaded From Vet-eBooks.com

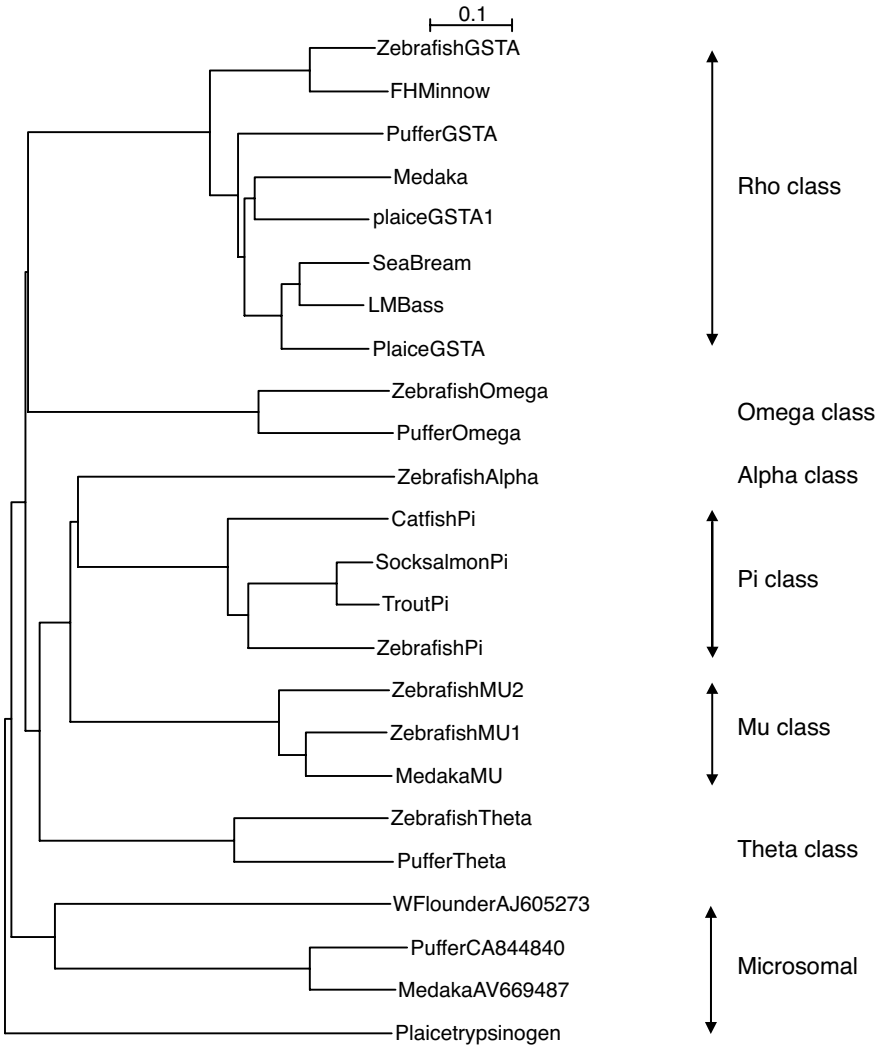

FIGURE 4.12 Phylogenetic relationships of cloned fish GSTs; derived from deduced amino acid sequences using Clustal W (zeta and mitochondrial kappa isoforms omitted).

major isoform in flatfish, mullet, and bass is now designated as Rho-class (Konishi et al., 2005). From nucleotide and protein sequence data, genes for all nine families have been identified in fish to date. A phylogenetic analysis of the sequenced fish genes is shown in Figure 4.12. Table 4.12 shows for each species the number of GST isoforms assigned to each family.

From purification studies, pi-class GSTs have been identified as the major hepatic and intestinal GSTs in the livers of salmonids, brown bullhead, channel catfish, and lamprey. These piscine pi-class enzymes display high activities with BaP epoxides and diol epoxides. The most highly characterized piscine GSTs are from the plaice, a pleuronectid flatfish, where purification and cloning studies identified a multigene cluster of enzymes originally designated as GSTA. These are most closely related to the mammalian, insect, and plant theta-class enzymes and have now been designated as a separate class, Rho. They appear to be unique to fish. Their genetic organization appears to be the same in plaice, flounder, sea bream, and largemouth bass. The primary role of these theta-like enzymes is in oxidative defense. GST-A is most active toward hydroxynonenals, and GSTA1 (or GSTR2) exhibits a high peroxidase activity with organic peroxides. They are the major isoforms in most tissues of flatfish. Homologs have been identified by cDNA sequencing, purification, or immunochemical cross-reactivity in a number of other fish species,

and quantitatively they also represent the major isoforms in bass and mullet livers (Gallagher et al., 2000; Martinez-Lara et al., 1997).

Reactions and Substrate Specificity

Before cloning studies and in the early days of purification, attempts were made to identify diagnostic substrates or reactions that may be diagnostic of the presence of certain isoenzymes in different tissues and species. Table 4.13 shows the preferred substrates (apart from 1-chloro-2,4-dinitrobenzene [CDNB]) of the different GST subunits in the rat on which this approach is based. It is important to note that a relatively small number of GST isozymes possess ketosteroid isomerase activity and catalyze the conversion of Δ5-3-ketosteroids to Δ4-3 ketosteroids.

It must be realized that great caution must be exercised when using catalytic activities (CDNB) to evaluate GST expression, as the activity toward any one substrate is a function of both the overlapping substrate specificities of the different isoforms and their different abundances within tissues; thus, such predictions may be unreliable. Consider, for example, the use of activity with ethacrynic acid (ETHA) which is diagnostic of pi-class GSTs but can also be conjugated by an alpha-class enzyme (GSTA4) in

TABLE 4.13

Downloaded From Vet-eBooks.com

three fish species, including cod, plaice, and trout. The relative hepatic activity ratios are 40 for trout, 4 for cod, and 1 for plaice. Although this would correctly indicate the predominance of a pi-class enzyme in trout and not in plaice (despite the presence of a significant amount of a GSTA4 homolog), it does not reflect immunological data showing that the concentration of GST pi in cod liver is very little lower than that of trout. Thus, the usefulness of diagnostic substrates is limited, and this approach is less reliable than immunochemical investigations.

In lower vertebrates, such as elasmobranchs and teleosts, both the covalent and noncovalent binding activities of the GSTs are very much lower as compared to rodents (Foureman et al., 1987; George and Buchanan, 1990). This may be attributed to the lower abundance of a GSTA1 homolog or an evolutionary adaptation of the enzyme in terrestrial vertebrates, as it has been postulated that terrestrial plant phytoalexins are bound by this protein. Teleost species contain stores of polyunsaturated fatty acids that are readily oxidized by free-radical attack, and this may explain the high constitutive levels of isoforms that detoxify lipid peroxidation products such as the alkenals and hydroxynonenals (e.g., GSTA class and GSTA4 homologs) as they will be better protected against xenobiotic-induced oxidative damage. This is particularly relevant in fish such as the cod and plaice where the fat is stored in droplets within the hepatocytes and not in adipose tissue as in the salmonids.

The substrate specificities, primarily with prototypical and endogenous substrates, have been determined with a number of highly purified preparations or recombinant GSTs from several fish species. In common with mammalian GSTs, they show greatest activity with CDNB as the substrate. The alpha-class enzyme from sea bass conjugates the alkenal *trans*-non-2-enal (N2E) at a higher rate than the prototypical xenobiotic substrates, and of these the highest rates were observed with ethacrynic acid (ETHA) and nitrobutyl chloride (NBC) (Angelucci et al., 2000). This is in agreement with an assignment of the sea bass enzyme as a GSTA4 homolog. The pi-class enzymes from salmon, trout, and catfish all exhibit relatively high rates of conjugation of ETHA, again following the pattern observed with a mammalian GST. The catfish enzyme has high activity with (±)-benzo(*a*)pyrene-4,5-oxide and *anti*-benzo(*a*)pyrene-7,8-dihydrodiol-9,10-epoxide as substrates, showing that it is an effective detoxicant of the active carcinogenic metabolite of BaP (Gallagher et al., 1996).

Fish GST and Oxidative Stress

As mentioned above, in addition to their protective activities toward electrophilic chemicals, certain GST isozymes can catalyze the reduction of cellular peroxides to their corresponding alcohols, as well as conjugate endogenous genotoxic unsaturated aldehydes formed during the peroxidation of membrane lipids (Alin et al., 1985; Hubatsch et al., 1998). Accordingly, the GST pathway in some species is an integral component of the cellular antioxidant defense system. Of the reactive intermediates produced during oxidative stress, 4-hydroxynonenal (4HNE) is a particularly reactive α,β-unsaturated aldehyde that is generated during lipid peroxidation as a result of the degradation of ω-6 polyunsaturated fatty acids (Esterbauer et al., 1991). 4HNE production is accelerated during exposure to a variety of prooxidant environmental pollutants (Figure 4.13). Because of its high reactivity, 4HNE rapidly forms covalent adducts with biomolecules containing nucleophilic sites, such as sulfhydryl groups of glutathione, cysteine, lysine, and histidine residues of proteins, and nucleophilic sites of nucleic acids. In rodents and humans, the alpha-class GSTA4 subclass displays uniquely high catalytic activity toward 4HNE and other α,β-unsaturated aldehydes, suggesting that these enzymes may have distinctively evolved as a secondary line of defense against oxidative injury (Hubatsch et al., 1998). As discussed previously, studies with the marine fish plaice (*Pleuronectes platessa*) have revealed the presence of a GST enzyme (GSTR1) that is a relatively efficient catalyst for the conjugation of a series of unsaturated alkenals and hydroxyalkenals, including 4HNE, but displaying little or no activity toward model substrates for mammalian GST. The recombinant Rho class of enzymes in plaice displays higher rates of conjugation of the natural substrates *trans*-oct-2-enal (O2E), N2E, and 4-hydroxy-2,3-*trans*-nonenal (4HNE) than prototypical substrates (apart from CDNB) (Leaver and George, 1998; Martinez-Lara et al., 2002). They also exhibit a high glutathione-dependent peroxidase activity with cumene hydroperoxide; substrate activity with phospholipid hydroperoxides has not been studied. Although both isoforms conjugate 4HNE at the same rate, GSTR1 displays a two- to tenfold higher activity toward O2E and N2E and also shows low but measurable activity with

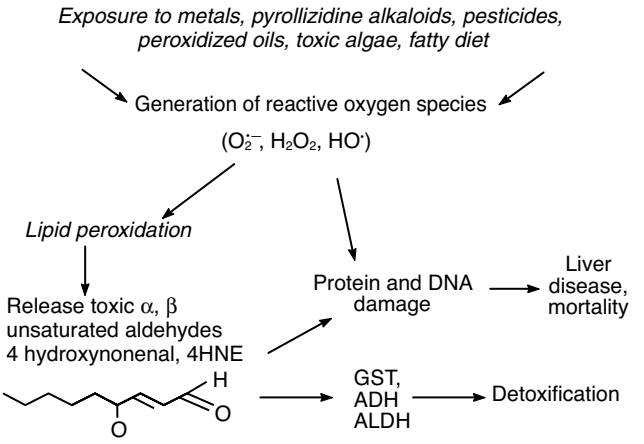

FIGURE 4.13 Pathway for the generation and detoxification of 4-hydroxynonenal (4HNE). In mammals and certain fish species, GST constitutes a protective pathway against 4HNE injury.

the prototypical xenobiotic substrates, with ETHA being the highest. GSTA1 has a fivefold higher peroxidase activity (25 μmol/min/mg protein). The purified GSTA homolog of sea bass displays the same characteristic profile of a high activity with N2E and relatively high activity with ETHA compared with other substrates.

Largemouth bass (*Micropterus salmoides*) expresses a liver GST that shares extensive sequence identity to the aforementioned 4HNE-metabolizing GSTA isolated from plaice that detoxifies 4HNE. Interestingly, the bass GST exhibits a catalytic activity toward 4HNE that exceeds that of several mammalian and aquatic species (Doi et al., 2004; Pham et al., 2002). Bass GSTA is also similar to a GST form found in two other fish species (European flounder and fathead minnow); however, similar genes may not be present in other aquatic species. Bass GSTA exhibits little sequence identity (21% or

less) to several mammalian GSTs, including the rat alpha-class GST form rGSTA4-4, which, as discussed, has a high catalytic efficiency toward conjugation of GSH with 4HNE. The presence of this interesting GST in several fish species suggests an important conservation of function that likely protects fish lipid membranes against the deleterious effects of oxidative injury.

Tissue Distribution

With the exception of the mammalian theta-class enzymes, all GSTs conjugate the prototypical substrate 1-chloro-2,4-dinitrobenzene (CDNB) with greatest activity (Figure 4.11). CDNB conjugating activity has been observed in all fish species examined to date (Table 4.14) and occurs in multiple tissues (George, 1994). Because CDNB is a general substrate and the rate of conjugation can vary between isoforms by up to two orders of magnitude, comparison of total CDNB conjugating activity in livers of different species, for example, is probably of little relevance in toxicological evaluation of environmentally relevant xenobiotics, as it will bear little relationship to the rate of metabolism of other compounds which may be isoform specific. Functional comparisons of activity toward individual toxicants is perhaps more meaningful from a toxicological viewpoint. Whereas kidney is the most active toward styrene-7,8-oxide and BaP-4,5-oxide relative to other tissues in the little skate (*Raja erinacea*) (Bend et al., 1978; Foureman et al., 1987; Gill et al., 1982), this finding must be placed in the context of relevance to the animal as compounds of this type may not be present systemically. They will more likely be taken up in the diet or generated by metabolism in the intestine or liver and conjugated in these tissues.

In general, most *in vitro* laboratory investigations of GST–CDNB conjugating activities in fish tissues use assay conditions and substrate concentrations similar to those proposed for mammals: 1 m*M* GSH and 1 m*M* CDNB) (Habig and Jakoby, 1981). Kinetic studies, however, have demonstrated that these substrate concentrations may not be at saturation with respect to initial rate kinetics for many isoforms because the K_m values differ by up to two orders of magnitude. Because the enzymes contain both electrophile and nucleophile binding sites, GST detoxification rates are determined by the concentration of electrophilic substrate and by the concentrations of nucleophilic cosubstrate (GSH). Kinetic studies in largemouth bass and brown bullheads in the presence of variable electrophile concentrations suggest that *in vitro* saturation of hepatic GST–CDNB conjugation occurs at higher electrophile concentrations in brown bullheads than in largemouth bass (Gallagher et al., 2000). Such an observation is consistent with a higher capacity for brown bullheads to detoxify electrophilic GST substrates under conditions of high environmental exposure. These observations are important under the prototypical conditions of environmental chemical exposure when the amount of chemical reaching the liver is relatively low and the rate of *in vivo* clearance is directly proportional to the amount of chemical concentrations *in vivo*. Also, as alluded to earlier, it is important to consider that the rate of GST–CDNB activity may not be reflective of rates of GST conjugation of environmentally relevant GST substrates, such as pesticides or epoxide carcinogens. For example, the rates of hepatic GST–CDNB conjugation by starry flounder and English sole are not correlated with the rates of hepatic GST conjugation of (+)-7β,8α-dihydroxy-9α,10α-oxy-7,8,9,10-tetrahydrobenzo(*a*)pyrene (BPDE) in those species. Specifically, starry flounder catalyze the rate of CDNB conjugation at initial rates threefold higher than is observed in English sole, whereas GST–BPDE activities are threefold higher in English sole as compared to starry flounder (Gallagher et al., 1998). Thus, specific GST conjugation of environmental chemicals in fish must be quantitated under assay conditions where the conjugation of the chemical can be monitored directly.

Although glutathione conjugation is generally associated with detoxification, small halogenated alkenes, such as dibromoethane, are activated by glutathione conjugation. In mammals, theta-class GSTs are particularly efficient in the conversion of dibromoethane to the carcinogenic sulfonium ion metabolite, as shown in Figure 4.14 (Thier et al., 1996). It was shown that a small fish species, the medaka, was quite susceptible to the development of liver cancer following exposure to ethylenedibromide and that a form of GST in liver was increased in the exposed fish, suggesting the presence of a theta-like GST in the medaka (Hawkins et al., 1998). This has been confirmed with cloning studies. Other fish species, such as the pleuronectid flatfish, bass, and mullet, have been shown to have theta-like GST in their livers (Gallagher et al., 2000; Leaver et al., 1993; Martinez-Lara, 1997). It is tempting to speculate that this may account for the high tumor incidence observed in flatfish from some polluted environments.

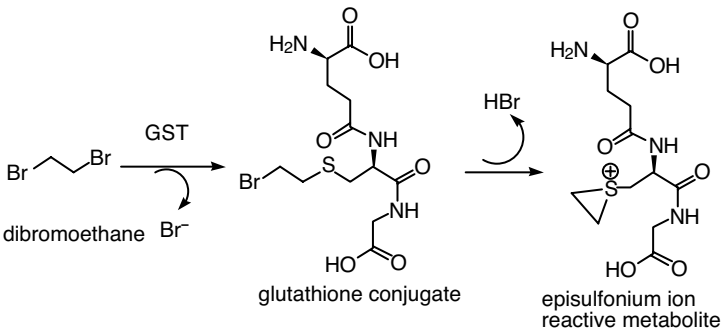

FIGURE 4.14 Formation of a reactive metabolite by glutathione conjugation. Halogenated alkanes such as dibromoethane can undergo glutathione conjugation then eliminate the second halogen to give a reactive episulfonium ion. This electrophilic metabolite can react with cellular nucleophiles.

Regulation of GSTs

Many of the mammalian GST isoforms are inducible; however, GST regulation is complex, and expression is both developmentally regulated and tissue specific (e.g., some are expressed in brain and testis only). Some GSTs are responsive to hormonal effects (growth hormone, thyroxine, insulin), and over 100 xenobiotic compounds have been shown to act as inducers (Hayes and Pulford, 1995). Moreover, in humans and the rat (but not in fish), GSTP1 is overexpressed in hepatocytes during the process of carcinogenesis. From structural and promoter analyses of GST genes (especially rGSTA2), various functional regulatory elements have been identified (Table 4.15). Interestingly, nucleotide sequences contributing to insulin responsiveness of GSTP and to specific expression of GSTs in liver and brain have been identified. Involvement of NF-κB and AP-1 sites, c-*fos*, and c-*jun* are also implicated in regulation. For a detailed discussion, the reader is referred to the review of Hayes and Pulford (1995).

An important facet of the GST pathway from an environmental perspective is the potential for induction of GST isozymes on exposure to certain dietary and environmental chemicals. Typically, a modest induction (twofold or less) of overall GST–CDNB activity is observed in fish exposed to prototypical GST-inducing agents in the laboratory. Studies of GST–CDNB activities in fish may be complicated by variations in diet, water temperature, gender, and reproductive cycling (Swain and Melius, 1984). Furthermore, as discussed, GST–CDNB activity represents an integration of the activity of multiple isoforms, and treatment effects on GST isoforms may not always be distinguishable by analysis of GST–CDNB activity. The importance in ascertaining effects of inducing agents on multiple fish GST isoforms is underscored by the fact that selective modulation of those GST isoforms with high specific activity toward environmental toxicants or their metabolites may be missed if GST–CDNB activity is the only endpoint. Ultimately, modulation of key GST isoforms that primarily contribute to the conjugation of environmental agents (or their metabolites) will be the critical determinants of chemical susceptibility.

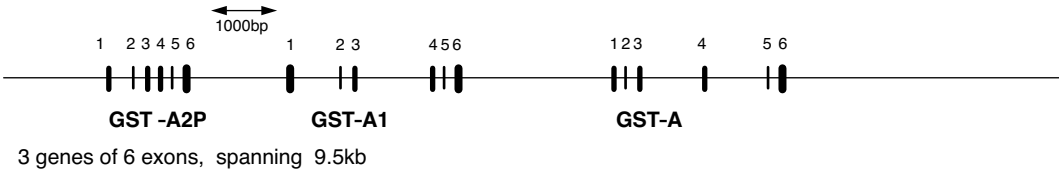

FIGURE 4.15 Structure of the plaice Rho-class gene complex.

Many laboratory studies of GST induction in fish have typically been conducted in conjunction with studies of CYP1A induction and have therefore involved AhR inducers, such as 3-methylcholanthrene (3-MC) and β-naphthoflavone (BNF) (George, 1994). Studies of GST induction in rodents indicate that antioxidant compounds such as ethoxyquin and butylated hydroxyanisole (BHA) are more effective inducers of GST expression than are AhR agonists (Buetler et al., 1995; Hayes and Pulford, 1995). This may not be the case in fish; for example, the level of induction in GST–CDNB activity in bullhead liver (1.6-fold) by ethoxyquin is consistent with previous studies of GST induction by other agents in other fish species. As an example, approximately twofold inductions of GST–CDNB activity have been reported in trout exposed to BNF (Celander et al., 1993) and in plaice (*Pleuronectes platessa*) exposed to BHA or *trans*-stilbene oxide (Leaver et al., 1992). Equivocable results have been obtained in studies on the induction of fish GSTs by xenobiotics, partially due to their high constitutive levels and large inter-animal variations in activities in wild populations, but primarily due to the use of substrates (e.g., HNE, ETHA) that are conjugated by several isoforms or the general substrate CDNB.

Promoter sequences targeted by prototypical GST antioxidant-inducing agents such as BHA not only include antioxidant response elements (AREs) but also electrophile response elements (EpREs), which confer inducibility by the monofunctional phenolic antioxidants to several rat GST and other phase II genes (Li and Jaiswal, 1993; Rushmore et al., 1991). The growing body of studies of GST induction in fish suggests that ARE-mediated GST gene induction may be conserved among many fish species. The GSTA1 gene (Figure 4.15) contains two peroxisomal proliferator response elements (PPREs) that coordinately upregulate expression of both GSTA and GSTA1 after exposure to peroxisomal proliferators (hyperlipidemic drugs, but potentially also environmental contaminants with binding ability such as synthetic lubricants, phthalate ester plasticizers, PCBs, certain pesticides, and alkylphenols). One of these PPREs is associated with an estrogen response element (ERE) that may produce cross-talk and thus explain the sex-dependent differences in expression that are observed. The GSTA gene contains four upstream antioxidant response elements that upregulate expression by compounds which *in vivo* include β-naphthoflavone (or probably a metabolite) and *trans*-stilbene oxide (Leaver et al., 1993). Two of these AREs are associated with CCAAT boxes, which may confer tissue specificity of response (Figure 4.16).

Attempts have been made to utilize GST induction in several invertebrates as biomarkers of xenobiotic exposure; indeed, the pi-class enzymes of Mollusca and Crustacea do show small (one- to twofold) increases in CDNB conjugating activity to many compounds, especially pesticides (Table 4.16). Several studies have also reported increased fish GST activities in fish inhabiting polluted environments (Armknecht et al., 1998; Otto and Moon, 1996). Accordingly, induction of GST activity has been proposed as a biomarker of exposure to environmental pollutants under field conditions. Again, careful characterization of the inducibility of individual fish GST isozymes under laboratory conditions and with respect to physiological status is necessary to interpret field data of GST expression.

TABLE 4.16

Induction of GSTs by Xenobiotics in Aquatic Organisms

	Inducers	Effect
PAHs	3-MC	No effect on activity in minnows and killifish, variable pattern (±1.5-fold in flounder and plaice)
	BNF	No effect on activity, induction of GSTmRNA in plaice, no effect on activity in trout.
	Petroleum/oil	Induced activity in scallop, mussel, and clam
PCBs	Tetrachlorobiphenyl	Induced activity in trout
	Arochlor®	Induced GSTA in flounder and plaice, activity in clams
	Clophen	Slight induction of activity in trout
Reactive epoxide	*trans*-Stilbene oxide	Induced GSTA in plaice and flounder
Antioxidants	BHA	Induced activity in plaice
	Ethoxyquin	Induced activity in salmon and possibly catfish
Pesticides	2,4-D	Induced activity in carp and tilapia
	Azinphosmethyl	Induced activity in carp and tilapia
	Carbaryl	Induced activity in prawns
	Endosulfan, *p,p′*-DDE, methoxychlor	Induced activity in clams
	Cypermethrin	Induced activity in crabs
Peroxisomal proliferators (PPRE-γ agonists)	Clofibrate, perflouroctanoic acid (PFOA)	Induced plaice GSTA and GSTA1
Cyanobacterial toxins	Microcystins	Induced activity in crabs

Inhibition of GSTs

Very little literature exists regarding the inhibition of GST activity; however, compounds that bind covalently (e.g., carcinogens) or noncovalently (e.g., heme degradation products, hematin itself, and bilirubin) will inhibit the activity of isoforms to which they are bound. Some xenobiotics may also be inhibitors of GST. Although the binding constants for bilirubin and hematin for plaice liver cytosolic GSTs are lower than those for mammalian GSTA1, these endobiotics do bind and act as inhibitors with I_{50} values of 320 and 10 m*M*, respectively (George and Buchanan, 1990). Binding constants of these compounds with purified GSTs from elasmobranchs were an order of magnitude lower than with plaice. Of particular note is the very high potency of organotin compounds (tributyltin, triphenyltin) for inhibition of plaice cytosolic GST activity *in vitro* (George and Buchanan, 1990).

Sulfotransferase

Overview

The sulfotransferase (SULT) family of enzymes catalyzes the transfer of the sulfonate group from 3′-phosphoadenosine-5′-phosphosulfate (PAPS) to hydroxyl (phenolic or alcoholic) and amine groups in a range of endogenous and exogenous substrates (Coughtrie, 2002; Mulder, 1981):

$$ROH + PAPS \rightarrow ROSO_3H + PAP$$

The cofactor for the sulfation reaction is 3′-phosphoadenosine-5′-phophosulfate and is synthesized from adenosine triphosphate (ATP) and inorganic sulfate. The reaction uses two molecules of ATP per molecule PAPS formed, which indicates the high-energy content of the cofactor (Falany, 1997). The rate of formation of PAPS is relatively slow, and cellular levels of PAPS are usually low. This results in the relatively low effectiveness of sulfation as a biotransformation pathway when organisms are exposed to sudden increase of potential substrates. In addition, the desulfated reaction product of PAPS is still able to bind to the active site of the enzyme and is therefore a potent inhibitor of the catalytic reaction.

Sulfate or sulfamate conjugates, once formed, are acidic molecules with pK_a values in the range of 2 to 4, and they exist largely as anions at physiological pH. Like other anions, they are readily excreted

Downloaded From Vet-eBooks.com

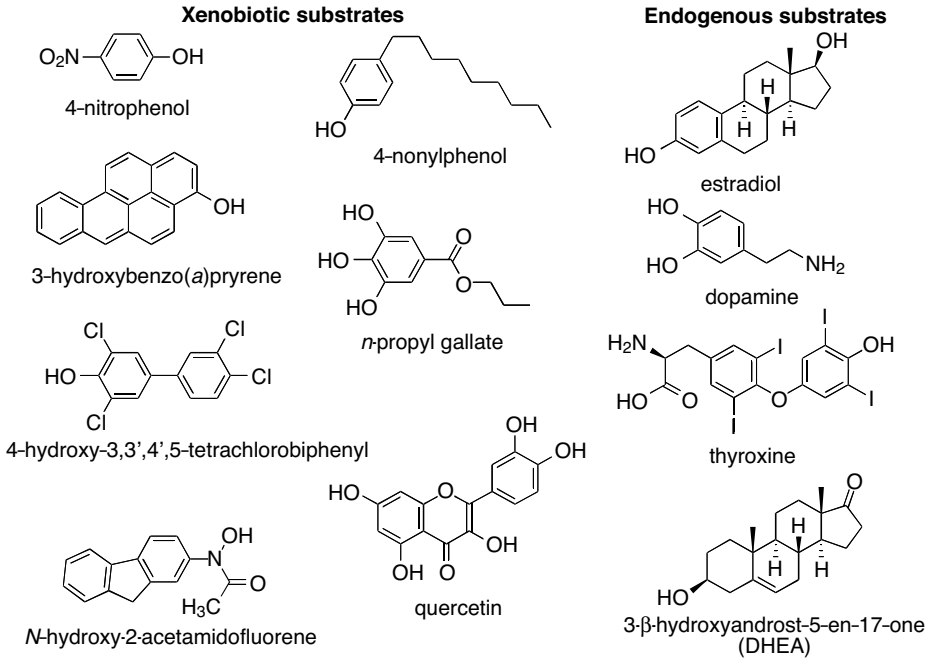

FIGURE 4.17 Selected xenobiotic and endogenous substrates for PAPS–sulfotransferase.

in bile and urine. Sulfate conjugates are also susceptible to hydrolysis by sulfatase, yielding back the parent substrate; for example, sulfate conjugates formed in liver may be excreted in part into the bile. The bile will be secreted into the intestine following a meal, where it may be hydrolyzed back to the starting compound by intestinal sulfatases. The parent compound may be reabsorbed and reconjugated in the liver (where it may undergo another round of biliary cycling) or may be conjugated by glucuronidation or sulfonation in the intestine and excreted.

Pollutant compounds that are potential substrates for SULTs include phenol and phenol derivatives, phase I hydroxylated metabolites of polycyclic aromatic hydrocarbons and polychlorinated biphenyls, aryl amines and their hydroxylated metabolites, and other xenobiotics and their metabolites with hydroxyl or amino groups in the molecular structure. Several physiologically important substrates such as steroids, bile acids, and neurotransmitters are also substrates for sulfation. Examples of xenobiotic and physiologically important substrates are shown in Figure 4.17.

In some cases, sulfonation is a detoxication pathway, but in other cases formation of the sulfate ester or the sulfamate leads to activation of the chemical to a reactive metabolite; for example, sulfonation of hydroxylated (phenolic) metabolites of PAHs is a detoxication pathway (Figure 4.18A). The conjugate is more water soluble and more readily excreted than the parent compound. Similarly, sulfonate conjugates of ring hydroxylated metabolites of *N*-acetylaminofluorene are relatively stable, water-soluble metabolites that are readily excreted. On the other hand, sulfonation of benzylic hydroxy groups, formed from hydroxylation of the methyl group in methylated PAHs (e.g., 6-hydroxymethyl-benzo(*a*)pyrene, 7-hydroxymethyl-12-methyl-benz(*a*,*h*)anthracene), may be an activation pathway (Watabe, 1983) (Figure 4.18B). This is because a sulfate group attached to an aliphatic carbon, especially a benzylic carbon, is a good leaving group and yields the carbocation that can alkylate DNA. In another example, sulfonation of *N*-hydroxyacetylaminofluorene gives an unstable product that decomposes to sulfate and the nitrenium ion, which can alkylate DNA (DeBaun et al., 1968) (Figure 4.19).

In addition to its importance in toxication and detoxication, sulfonation is an important pathway for transport and storage of several endogenous compounds. Estradiol, dehydroepiandrosterone (DHEA), and other hydroxylated steroids are readily sulfonated; they may be transported around the body as the sulfate conjugates and then hydrolyzed back to the active steroid at the target organ (Coughtrie et al.,

Downloaded From Vet-eBooks.com

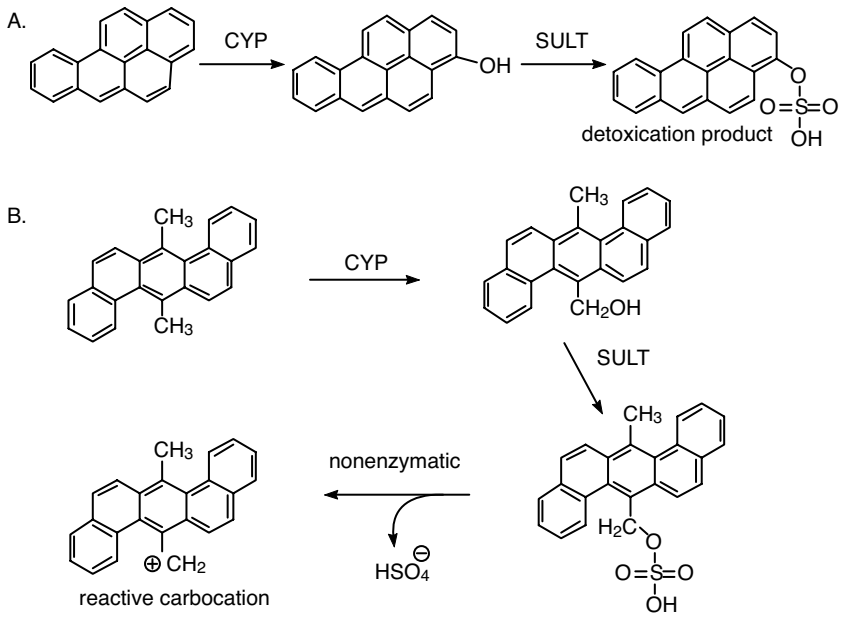

FIGURE 4.18 Sulfonation as a toxication or detoxication pathway. This figure shows examples of polycyclic aromatic hydrocarbons that are metabolized to nontoxic (A) or reactive (B) sulfate esters. The example in (A) shows the oxygenation of benzo(*a*)pyrene to 3-hydroxybenzo(*a*)pyrene, followed by sulfonation of the phenolic hydroxyl group to the nontoxic sulfate ester. The example in (B) shows the oxygenation of one of the methyl groups in 7,12-dimethyl-benz(*a*,*h*)anthracene to give 7-hydroxymethyl-12-methylbenz(*a*,*h*)anthracene, followed by sulfonation of the benzylic (alcohol-like) hydroxyl group to the unstable sulfate ester. This ester can spontaneously eliminate the sulfate group, leaving the reactive carbocation shown. The carbocation will react with cellular nucleophiles, possibly including DNA bases.

1998; Miki et al., 2002). The ability of the sulfonated steroid to cross cell membranes is sometimes superior to that of the unconjugated steroid. This is in part because the conjugates are substrates for several organic anion transporter proteins involved in the uptake as well as efflux of anions and in part because of more favorable solubility characteristics for diffusion conferred by the addition of a polar group to an otherwise poorly water-soluble molecule. The transport and hydrolysis of sulfonate conjugates of steroids have been described in mammals, but to date little direct evidence suggests this pathway in fish. Not only are steroid hormones readily sulfonated but also other physiologically important chemicals such as dopamine, related biogenic amines, and thyroid hormones. In the case of dopamine, the amino group and the ring hydroxyl groups are potential sites of sulfonation. In the shark, the sterol scymnol has been found as the sulfate ester, which appears to serve as a bile acid (Macrides et al., 1997). Rainbow trout liver contains SULT activity that is active with thyroid hormones, especially 3,3′,5-triiodothyronine (T_3) (Finnson and Eales, 1998).

Evidence for the sulfonation pathway in fish has been sought by examining bile, urine, and tank water of exposed fish for sulfonate conjugates, as well as by studying enzyme activity *in vitro* with the substrate of interest (Finnson and Eales, 1996; James, 1986; James et al., 1997, 1998). Studies that demonstrate sulfonation have also been conducted in hepatocytes and with *in situ* isolated preparations (Coldham et al., 1998; Cravedi et al., 1999).

Gene Structure of SULT

Several SULT enzymes with differing substrate selectivities are known to exist in the liver and other organs of humans (Coughtrie, 2002; Dooley, 1998). The nomenclature of the SULT enzymes was originally based on the enzymatic function of the isolated isoforms; however, because recombinant DNA techniques have become mainstream and additional SULT isoforms are being identified by their gene structure, the need for a widely accepted nomenclature was recognized. This has led to a proposed

Downloaded From Vet-eBooks.com

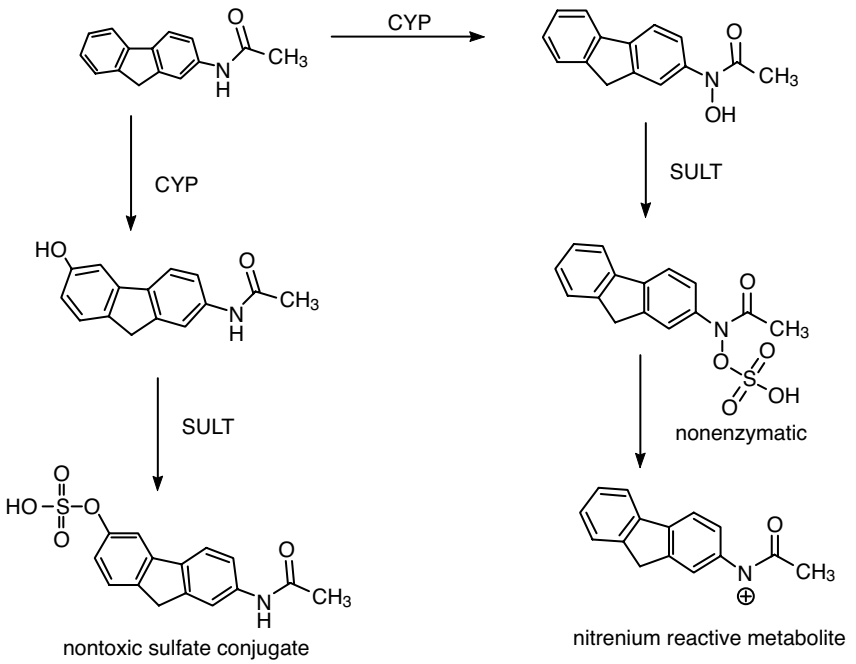

FIGURE 4.19 Sulfonation as a toxication or detoxication pathway. This figure shows two possible pathways of metabolism of the carcinogen *N*-acetamidofluorene. One pathway leads to the nontoxic and readily excreted sulfate conjugate of ring-hydroxylated *N*-acetamidofluorene. The other gives *N*-hydroxy-*N*-acetamidofluorene, which forms an unstable sulfate conjugate that nonenzymatically eliminates sulfate, leaving the reactive nitrenium metabolite. This can bind DNA bases and initiate carcinogenesis.

classification system consisting of a SULT superfamily for all cytosolic SULTs, with families and subfamilies for the individual isoforms being based on their amino acid sequence identity (Blanchard et al., 2004). Two major families comprise the phenol types (SULT1A1), the catecholamine type (SULT1A3), thyroid type (SULT1B), estrogen type (SULT1E1), and DHEA type (SULT2A). Other forms have been identified, but little is known about their biological function.

Recent elucidation of the entire zebrafish genome has allowed searching for DNA sequences that code for SULTs. Using primers based on the PAPS binding site in mammalian SULTs, up to seven different SULTs have been cloned and sequenced from zebrafish (Ohkimoto et al., 2003). Two of these have amino acid sequences that place them in the SULT1 gene family (Sugahara et al., 2003a), and another clone fits into the SULT2 family (Sugahara et al., 2003b). When compared to human and mouse SULT amino acid sequences, there was less than 60% identity, which prohibited classification into existing subfamilies.

The cloned, expressed, and purified zebrafish SULT1 isozymes had a molecular weight of around 35 kDa and demonstrated a strong activity toward 2-naphthol, similar to the mammalian SULTs from this family (Sugahara et al., 2003a). The SULT1 #1 form was more active on dopamine and T_3, while the #2 form was more active toward estrone and thyroxine. When tested for activity toward two coplanar hydroxylated PCBs, the #2 form had a relatively higher catalytic efficiency (V_{max}/K_m). The #2 form loses activity above 45°C, but the #1 form appears to be much more heat stable. Both forms were also analyzed for stability under heavy metal stress. Previous research with mammalian SULT had shown that heavy metal ions can have dramatic effects on SULT activity. The zebrafish SULTs were completely inhibited by 5-m*M* HgCl and CuCl; Co, Zn, Cd, and Pb had a less dramatic but still significant effect (Sugahara et al., 2003a,c). The cloned zebrafish SULT2 isozyme also had a molecular weight of 34 kDa and was active toward DHEA, T_3, and selected neurosteroids but not to any of the other phenolic substrates that were good substrates for the SULT1 isozymes (Sugahara et al., 2003c).

	Intestinal cytosol	9-Hydroxy-benzo(*a*)pyrene	930	Tong and James (2000)
		Benzo(*a*)pyrene-7,8-dihydrodiol	2	van den Hurk and James (2000)
Mummichog (*Fundulus heteroclitus*)	Liver cytosol	9-Hydroxy-benzo(*a*)pyrene	8	Gaworecki et al. (2004)
Lamprey (*Petromyzon marinus*)	Liver cytosol	Petromyzonol	232	Venkatachalam et al. (2004)
Rainbow trout (*Oncorhynchus mykiss*)	Liver cytosol	*N*-Hydroxy-2-acetylaminofluorene	0.2	Elmarakby et al. (1995)
	Liver cytosol	Thyroxine (T_4)	7.6	Finnson and Eales (1998)
	Liver cytosol	3,5,3′-triiodothyronine (T_3)	14	Finnson and Eales (1998)

Seven zebrafish SULT isozymes were bacterially expressed and purified and were investigated for activity toward 17β-estradiol and five environmental estrogens. Three of the isozymes did not show any activity, but the other four had various activities toward the substrates (Ohkimoto et al., 2003). The most active isoform (SULT1 ST 2) had a high activity toward 17β-estradiol that was competitively inhibited by bisphenol-A and 4-*n*-nonylphenol. Though the activity toward estrogenic compounds suggests that this isozyme is homologous to the mammalian estrogen form (SULT1E), the amino acid sequence is sufficiently different to exclude it from classification into this subfamily. This zebrafish isozyme also had a high activity toward polyphenolic plant compounds, such as genistein, daidzein, and quercetin. When these phytoestrogens were assayed together with 17β-estradiol, they clearly demonstrated competitive inhibition (Ohkimoto et al., 2004).

Piscine SULTs

Much less is known about these enzymes in fish (Table 4.17). A SULT with activity toward the endogenous substrate scymnol was found in shark liver, but no xenobiotic substrates were studied. The shark SULT had a higher molecular weight (40,000) than mammalian SULT (Macrides et al., 1994). SULT was purified from hepatic and intestinal cytosol of the channel catfish (Falany et al., 1990). Catalytically active fractions from liver and intestine contained proteins of 41,000 MW that cross-reacted with an antibody to the human phenol-sulfating form of phenol sulfotransferase (P-PST). Internal sequence from the liver enzyme indicated it was in the SULT1 family (Tong and James, 2000). The isolated intestinal and hepatic enzymes had nanomolar K_m values with 9-hydroxybenzo(*a*)pyrene as the substrate and were also active with several other substrates.

Reactions and Substrate Specificity

The specificity of sulfonation by substrate has been studied in a few fish species. Sulfonation of *N*-hydroxy-*N*-acetylaminofluorene and 3-hydroxyacetylaminofluorene (procarcinogenic and noncarcinogenic metabolites, respectively of acetamidofluorene) has been studied in small fish used in carcinogenicity testing (see Figure 4.19). As well as the acetamidofluorene metabolites, sulfonation of the model

Downloaded From Vet-eBooks.com

compound 4-methylumbelliferone was examined. Sulfonation of *N*-hydroxy-*N*-acetamidofluorene was demonstrated in control and 2-acetamidofluorene (AAF)-treated guppy, indicating that the pathway to the reactive ultimate carcinogen was intact (James et al., 2001). SULT activity was higher in guppy than medaka, suggesting a possible biochemical basis for the higher sensitivity of guppy to the carcinogenic effects of AAF. Rainbow trout, a species that is relatively insensitive to the carcinogenicity of AAF, formed very little *N*-hydroxy-2-acetylaminofluorene (N-OH-AAF) or N-OH-AAF sulfate (Steward et al., 1995).

Sulfonation of several xenobiotic substrates has been studied in the channel catfish. These include 3,7- and 9-hydroxybenzo(*a*)pyrene, benzo(*a*)pyrene-7,8-dihydrodiol, 2-naphthol, acetaminophen, 6-hydroxymethylbenzo(*a*)pyrene, 7-hydroxymethyl-12-methylbenz(*a*,*h*)anthracene, and *p*-nitrophenol. Higher activity was found with the phenolic substrates than the alcoholic substrates (Tong and James, 2000). In contrast to the benzo(*a*)pyrene phenols, the dihydrodiol procarcinogen BaP-7,8-dihydrodiol was a very poor substrate for sulfonation in the catfish intestine or liver (van den Hurk and James, 2000). Others have shown in mammalian systems that BaP-7,8-dihydrodiol inhibits SULT but is a poor substrate (Rap and Duffel, 1992). *In vivo* studies with the southern flounder, however, have shown that the sulfate conjugate of BaP-7,8-dihydrodiol was formed to some extent and was excreted more rapidly than the glucuronide (Pritchard and Bend, 1984).

The only other fish SULT that has been extensively studied for substrate selectivity is a recently cloned zebrafish enzyme. The expressed zebrafish SULT had high activity with flavonoids, isoflavonoids, and other phenolic natural products such as chlorogenic acid, catechin, epicatechin, and quercetin, as well as with phenolic xenobiotics such as nonylphenol and naphthol (Sugahara et al., 2003a). The zebrafish SULT was also active with dopamine, thyroxine, estrone, and dehydroepiandrosterone. Studies of catalytic efficiency (V_{max}/K_m) showed that the endogenous substrate dopamine was a relatively poor substrate for the expressed SULT enzyme compared with the natural product *n*-propyl gallate (Sugahara et al., 2003a).

Tissue Distribution

Most studies of sulfonation have focused on activity in the liver, but in the catfish the intestine was shown to be as active as liver in catalyzing the sulfonation of several substrates, including hydroxylated benzo(*a*)pyrenes, dopamine, and 6-hydroxymethylbenzo(*a*)pyrene (James et al., 1997; Tong and James, 2000). Demonstration of activity in the intestine is important in the context of first-pass metabolism of dietary carcinogens, which are often present at low levels. When low concentrations of substrate are present in ingested material, biotransformation in the intestine becomes more important. The capacity of the intestine for metabolism is fairly low, because the liver is a larger organ, but if only small amounts of xenobiotic are present, as is the case in many environmental samples, the intestine and other extrahepatic organs that are portals of entry, such as gills and skin, become important sites of first-pass metabolism.

Regulation of SULT

Not enough studies of SULT in fish have been conducted to have a good understanding of the number of SULTs present or their regulation by endogenous or exogenous factors. In mammalian species, SULTs are not induced by exposure to PAHs, and there are reports that AhR agonists such as PAHS repress SULT activity (Runge-Morris and Wilusz, 1994). The few studies that have been conducted in fish show no clear evidence of an effect of PAH-type inducing agents on SULT activity (James et al., 1997). In catfish exposed to β-naphthoflavone, there was a slight loss of activity with 7-hydroxybenzo(*a*)pyrene but no effect with the 3- and 9-hydroxy-BaP substrates. Evidence suggests that agents such as glucocorticoids and related substances cause a modest upregulation of SULT in mammals (Runge-Morris, 1998) and that tamoxifen upregulates SULT1A in intestine and liver of rats (Maiti and Chen, 2003), but this has not been demonstrated in fish.

Recent investigations into the expression of phenol-type SULT in mummichog (*Fundulus heteroclitus*) has revealed that this species has a remarkably low expression of this enzyme (Gaworecki et al., 2004). The activity toward 3-hydroxybenzo(*a*)pyrene was very low compared to a variety of other fish species

Downloaded From Vet-eBooks.com

(Gaworecki et al., unpublished data). In addition, a polyclonal antibody that was generated against channel catfish phenol-type SULT did not recognize any SULT protein in mummichog samples. Despite the low expression of phenol-type SULT in mummichog from clean reference sites, animals from the Atlantic Wood site in the Elizabeth River in Virginia, a site heavily contaminated with PAHs and other contaminants, showed significantly increased SULT activity (Gaworecki et al., 2004). Treatment with single doses of 3-methylcholanthrene or benzo(*a*)pyrene failed to induce the protein; thus, contrary to AhR-mediated CYP1A and UGT induction, SULT upregulation does not appear to be linked to AhR activation. This is not unusual, as GST induction also requires chronic exposure (James et al., 1979).

Inhibition of SULT

Sulfotransferase is subject to inhibition from a variety of sources. *In vitro*, PAP derived from the cosubstrate or sulfonate donor molecule PAPS inhibits SULT activity. Many bulky substrates inhibit their own sulfonation; for example, in catfish intestinal cytosol 3-hydroxybenzo(*a*)pyrene inhibited its own metabolism at concentrations above 0.5 μ*M* (Tong and James, 2000). The nonsubstrate β-naphthoflavone inhibited SULT activity with 3-, 7-, and 9-hydroxybenzo(*a*)pyrene in channel catfish intestinal and hepatic cytosol, with an IC_{50} of 48.0 ± 3.0 μ*M* (James et al., 1997). A natural flavonoid, quercetin, was a potent inhibitor of sulfation of 3-, 7-, and 9-hydroxybenzo(*a*)pyrene in channel catfish intestinal cytosol, with an IC_{50} of less than 1 μ*M* (van den Hurk and James, 2000). Although pentachlorophenol was reported to inhibit phenol sulfation in mammals, it was a poor inhibitor of the sulfonation of hydroxylated benzo(*a*)pyrenes in catfish and had an IC_{50} of about 100 μ*M* (van den Hurk and James, 2000). Recent studies showed that several hydroxylated PCBs inhibited estrogen SULT in mammalian systems with nanomolar IC_{50} values. Studies of the effects of hydroxylated PCB on the sulfonation of hydroxylated benzo(*a*)pyrenes in catfish intestinal cytosol showed that several of these PCB metabolites inhibited SULT, with low to high micromolar IC_{50} values (van den Hurk et al., 2002). Several metal cations, including mercury, cobalt, zinc, cadmium, copper, and lead, were shown to inhibit zebrafish SULT, although quite high concentrations (5 m*M*) were tested (Sugahara et al., 2003c).

Sulfonation of thyroid hormones was studied in liver cytosol from rainbow trout (*Oncorhynchus mykiss*) (Finnson and Eales, 1998). Based on optimum pH, thermal stability, and specific inhibitors, the investigators concluded that it is most likely that only one isozyme form is responsible for the sulfonation of thyroid hormones in trout, in contrast to the multiple isozyme forms found in mammals. No information is available yet on the inhibiting effects of hydroxylated PCBs on thyroid hormone sulfonation, as has been reported for mammalian systems (Schuur et al., 1998).

Activation of SULT

In vitro, SULT activity with some substrates can be increased by the addition of Mg^{2+} and others by incorporation of BSA into the assay vial. This phenomenon was also observed with the isolated catfish SULT (Tong and James, 2000) and zebrafish SULT (Sugahara et al., 2003a). The *in vivo* significance of this activation is unclear (Konishi-Imamura et al., 1995).

Amino Acid Conjugation

Overview

A relatively little studied pathway of phase II metabolism is the conjugation of carboxylic acids with amino acids. This pathway results in the formation of an amide bond between the carboxylate and the amino group of the amino acid (Figure 4.20). The resulting conjugate is an anion at physiological pH and is generally a better substrate for organic anion transporter proteins in kidney than the unconjugated xenobiotic; thus, amino acid conjugation facilitates the excretion of xenobiotic carboxylic acids (James and Pritchard, 1987). The amino acid utilized for this pathway in all fish species studied to date is taurine (James, 1976). It has been suggested that glycine conjugates (the major metabolites of benzoic acids in mammals) are metabolites of *p*-aminobenzoate in fish (James, 1986), but no solid evidence supports this pathway in fish. The enzymes responsible for amino acid conjugation are found in liver and kidney

Downloaded From Vet-eBooks.com

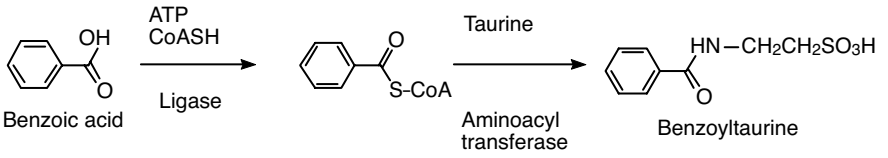

FIGURE 4.20 The pathway of conjugation of carboxylic acids in fish, illustrated with benzoic acid. The benzoic acid forms a coenzyme A thioester, in a reaction catalyzed by acyl–CoA ligase. The benzoyl–coenzyme A thioester then reacts with taurine, catalyzed by aminoacyl transferase, to give benzoyltaurine.

mitochondria. Two enzymes are involved, a carboligase that catalyzes the formation of an acyl-coenzyme A (CoA) intermediate and an aminoacyltransferase that catalyzes formation of the amide bond (Vessey, 1996). Figure 4.20 shows this pathway with benzoic acid as the substrate and benzoyltaurine as the product. Studies of the first step of this reaction—formation of the acyl-coenzyme A—have not been carried out in fish. The second step, catalyzed by acyl-CoA–taurine aminoacyltransferase, is located in the mitochondrial matrix in those fish that have been studied, and kidney had higher activity than liver (James, 1976). The activity has been studied with phenylacetyl-coenzyme A as the substrate and taurine as the cosubstrate. Even when the incubations were supplemented with glycine, no glycine conjugates were found.

Enzymes Specificity, Regulation, and Inhibition

Taurine conjugation is generally considered to be a detoxication pathway. Taurine conjugates are acidic and exist largely in the anionic form at physiological pH. It may be expected that they will therefore be readily excreted in urine. The taurine conjugate of benzoic acid was not, however, as good a substrate for the southern flounder renal organic acid transporter as hippuric acid (benzoylglycine), even though no hippurate was formed in flounder given benzoate (James and Pritchard, 1987). It was, nevertheless, excreted more readily than benzoic acid. Xenobiotic substrates for this pathway include 2,4-dichlorophenoxyacetic acid (2,4-D), 2,4,5-trichlorophenoxyacetic acid (2,4,5-T), the herbicide triclopyr, and *p*-aminobenzoic acid, a metabolite of the fish anesthetic tricaine methane sulfonate. Endogenous substrates include bile acids, benzoic acid, and phenylacetic acid, the latter being metabolites of aromatic amino acids. Southern flounder have been shown to excrete taurine conjugates of benzoic acid (James and Pritchard, 1987), 2,4-D, and 2,4,5-T (James, unpublished data). Dogfish shark excreted 2,4,5-trichlorophenoxyacetyltaurine in urine following a dose of 2,4,5-T (Guarino et al., 1977). Winter flounder excreted phenylacetyltaurine and 2,4-D-taurine after doses of phenylacetic acid and 2,4-D, respectively (James and Bend, 1976; Pritchard and James, 1979). Channel catfish excreted benzoyltaurine in urine after administration of benzoic acid (Plakas and James, 1990). Triclopyr has not been examined in fish, but a crustacean, the crayfish, retained triclopyr as the taurine conjugate in hepatopancreas and slowly excreted the conjugate (Barron et al., 1991). No studies have been performed on the regulation of this pathway in fish. Inhibitors and activators of the pathway are not known.

Acetylation

Overview

This pathway utilizes acetyl-CoA to donate an acetyl group to an amino group in a xenobiotic. Xenobiotic substrates include arylamines, aliphatic amines, and hydrazines. The reaction pathway with 2-aminofluorene as the substrate is shown in Figure 4.21. The enzymology of *N*-acetylation has been extensively studied in mammals, but few studies of acetylation in fish have been performed, beyond demonstration of the pathway with model substrates (de Wolf et al., 1993; Gregus et al., 1983). Acetylation is also an important terminal step in the formation of mercapturic acid metabolites from glutathione conjugates (Figure 4.11). It is thought, however, that the enzyme that acetylates cysteine conjugates is different from the *N*-acetyltransferase that acetylates xenobiotics containing amino groups that are not part of an amino acid.

Downloaded From Vet-eBooks.com

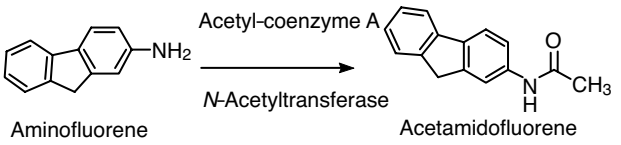

FIGURE 4.21 Acetylation of arylamines. The arylamine aminofluorene forms acetamidofluorene in a reaction catalyzed by *N*-acetyltransferase. The cosubstrate is acetyl–coenzyme A.

Enzyme Specificity, Regulation, and Inhibition

Acetylation has been shown to be a major pathway of metabolism in fish of a number of xenobiotics containing amino groups. These include therapeutic drugs such as sulfadimethoxine (Droy et al., 1989; Kleinow et al., 1992) and pollutants such as aniline, chloroaniline, and quinolines (Birkholz et al., 1989; Bradbury et al., 1993). Acetylation of the procarcinogen 2-aminofluorene leaves the molecule open for further metabolism by *N*-hydroxylation and sulfonation to a reactive nitrenium ion, as described in the section on sulfonation. Another pathway of activation of acetamidofluorene is *N*,*O*-acetyl transfer, leading to the unstable *N*,*O*-acetyl metabolite. This is readily deacetylated to yield a nitrenium ion active metabolite. Thus, although acetylation of amines may improve the water solubility and ease of excretion, it may in some cases lead to the formation of more reactive metabolites. In mammalian species, the *N*-acetyltransferase enzymes are not inducible but are expressed constitutively. The number of forms of *N*-acetyltransferase in fish and their regulation have not been studied.

Toxicological Relevance

The previous sections have addressed the occurrence, regulation, and catalytic activities of biotransformation systems in fish. The following section focuses on three model compounds and chemical classes and the contribution of biotransformation toward the toxicology of each compound. Benzo(*a*)pyrene was selected as being representative of the large class of polynuclear aromatic hydrocarbons (PAHs). Because of the use of the rainbow trout as a model organism for aflatoxin-induced hepatocarcinogenesis, significant work has been carried out characterizing the biotransformation of aflatoxin. Finally, due to the significant potential for exposure to fish, the biotransformation of organophosphates and carbamates is discussed.

Benzo(*a*)pyrene

The metabolic fate of PAHs in fish has been extensively studied because PAHs are common pollutants of the aquatic environment and are carcinogens in fish as well as higher vertebrates (for reviews in fish, see Buhler and Wang-Buhler, 1998; Buhler and Williams, 1989; Stegeman, 1981; Stegeman and Hahn, 1994). Benzo(*a*)pyrene (BaP), the model carcinogenic PAH, has received a great deal of attention and has served as a model to better understand PAH biotransformation. This compound is not in itself carcinogenic but becomes so upon biotransformation to reactive metabolites that form adducts to DNA bases and initiate the process of mutagenesis and carcinogenesis. BaP can also be metabolized to products that are not directly carcinogenic, such as quinones, phenols, and dihydrodiols (Figure 4.3). BaP possesses a structural "bay region" that impairs enzymatic detoxification of specific stereoisomer metabolites; for example, conversion of BaP to the (–)-7,8-dihydrodiol by consecutive reactions catalyzed by CYP1A and epoxide hydrolase (EH), respectively, may lead to an additional CYP1A oxygenation at the 9,10 position, producing the ultimate carcinogen, (+)-*anti*-BaP-7,8-dihydrodiol-9,10-epoxide (Jerina et al., 1984). These reactions are readily catalyzed by CYP1A and EH in fish liver (Buhler and Wang-Buhler, 1998; Buhler and Williams, 1989; Stegeman, 1981; Stegeman and Hahn, 1994). This particular metabolite is recalcitrant to a second EH hydrolytic reaction due to steric hindrance resulting from the "bay region" ring system; thus, the reactive intermediate is free to interact with DNA leading to potential mutagenesis and carcinogenesis.

Downloaded From Vet-eBooks.com

CYP1A is clearly the predominant enzyme responsible for each oxygenation of BaP, but other CYP isoforms are likely contributors. Studies with recombinant mammalian CYP isoforms indicate metabolic activation of several PAHs by CYP1B1 as well as CYP2C9, CYP2C19, and CYP3A4, albeit at slower rates than CYP1A and CYP1B enzymes (Shimada et al., 1999). CYP1A forms are readily inducible in fish by PAH and related planar polycyclic molecules, and this likely is a major factor in the sensitivity of fish to PAH-type carcinogens. In addition, other phase I enzymes may catalyze oxidation reactions (see above). Inhibition of cytotoxicity with indomethacin within trout cell lines that lack EROD activity suggests that prostaglandin-H synthase may contribute to the activation of BaP (Schirmer et al., 2000). Clearly cooxidative pathways should be explored in more detail, particularly in fish that possess significant quantities of unsaturated fatty acids which are prone to oxidation.

Other metabolites with potential biological activity include quinones, which have been suggested to be derived from initial phenolic metabolites. BaP has been shown to be converted to several quinone metabolites, including the 1,6- and 3,6-quinones derived from the 1-hydroxy and 3-hydroxybenzo(*a*)pyrene precursors (Stegeman, 1981). Although numerous biotransformation studies have identified quinones as BaP metabolites (Stegeman and Hahn, 1994; Willett et al., 2000; Yuan et al., 1997), few have explored the potential effects of these metabolites on cell function. Lemaire et al. (1994) reported that BaP quinones were capable of creating hydroxyl radical in hepatic microsomes of flounder and perch. Oxidative damage in larval turbot was observed following BaP treatment with parallel formation of BaP quinone metabolites.

Although quinones and the (–)-7,8-dihydrodiol can lead to greater toxicity of BaP, it should be noted that the majority of the metabolites of BaP are nontoxic. Examples include phenols (at the 1 and 3 positions) which are primarily conjugated as glucuronides and potentially sulfate derivatives (Buhler and Williams, 1989; Stegeman and Hahn, 1994). Glutathione conjugates presumably of the various arene oxides (4,5, 7,8, and 9,10) have also been reported in fish (Gallagher et al., 1996). The 4,5 and 9,10 dihydrodiols of BaP also do not appear to undergo bioactivation.

Tremendous species differences exist in the bioactivation of BaP in fish. Liver microsomes of channel catfish, which appear less susceptible to PAH-induced liver cancer, produce lower levels of (+)-7,8-expoxide (based on lower concentrations of (–)-7,8-dihydrodiol) than cancer-prone brown bullhead catfish (Pangrekar and Sikka, 1992; Yuan et al., 1997). *In vivo* studies by Willett et al. (2000) confirmed the species differences in (–)-7,8-dihydrodiol formation. However, hepatic EROD activities did not correlate with 7,8-BaP dihydrodiol formation, indicating that another enzyme system may be involved in BaP oxygenation (Willett et al., 2000). Ploch et al. (1998) also reported that, although *in vitro* DNA binding by BaP was directly related to hepatic EROD activity in the two species, *in vivo* DNA adducts were not related to hepatic EROD. These results are consistent with studies in carp, which have significantly higher rates of phase I metabolite formation compared to brown bullhead but are more resistant to PAH-induced cancers (Sikka et al., 1990).

The effects of other pollutants and environmental conditions on other metabolic pathways of PAHs, or all xenobiotics, are largely unknown. Dieldrin significantly enhances the biliary elimination of BaP but does not alter the metabolite profile (Barnhill et al., 2003). Tributyltin significantly inhibits BaP biotransformation in Arctic char (Padros et al., 2003). Rainbow trout acclimated to hypersaline conditions had a higher level of phase I metabolites and a shift from dihydrodiol to phenolic metabolites with 3-hydroxybenzo(*a*)pyrene predominant (Seubert and Kennedy, 2000).

In addition to phase I enzymes, species-dependent differences in phase II pathways may also contribute to differences in BaP-induced toxicities between species. Although significant epidemiological and biochemical evidence exists in humans and rodents (GSTM1), few studies have demonstrated a correlation between adverse effects and species-specific phase II metabolism in fish; for example, hepatic EH and GST activities in channel catfish were higher than in brown bullhead (Gallagher et al., 1996; Willett et al., 2000). When comparing overall biliary metabolite profiles in each species, significant differences were not observed in quantity or profile of conjugated BaP metabolites (Willett et al., 2000). Likewise, English sole from contaminated sites in Puget Sound appear to be more sensitive to liver lesions resulting from PAH exposure than starry flounder, but overall GST-catalyzed conjugation of BPDE is threefold higher in English sole (Gallagher et al., 1998). Although glucuronides represent the highest percentage of conjugated BaP metabolites in fish, few studies have identified specific metabolites or evaluated species differences in hepatic UGTs and whether this pathway contributes to species differences in BaP toxicity.

Downloaded From Vet-eBooks.com

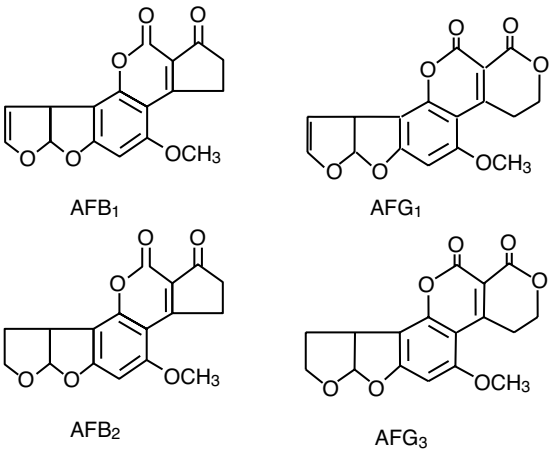

FIGURE 4.22 Structures of naturally occurring aflatoxins.

Although the liver is a major site of biotransformation of BaP, biotransformation to active metabolites in portals of entry, such as the intestine, gills, and skin, is also important. Studies in channel catfish intestine have shown that benzo(*a*)pyrene was metabolized to several metabolites, including BaP-7,8-dihydrodiol-9,10-epoxide, by intestinal microsomes and that metabolism was readily induced by exposure to the AhR agonist β-naphthoflavone (James et al., 1997; Kleinow et al., 1998). The major form of GST present in the intestine was a pi-class GST that had good activity with (+)-*anti*-BaP-7,8-diol-9,10-oxide (Gadagbui and James, 2000). Similar studies carried out with the channel catfish intestinal preparation in which (–)-BaP-7,8-dihydrodiol was infused showed that a major pathway for detoxification of the (–)-BaP-7,8-dihydrodiol was glucuronidation. In the catfish, (–)-BaP-7,8-dihydrodiol was more readily glucuronidated than sulfated, although the rate of glucuronidation of an environmentally relevant concentration of (–)-BaP-dihydrodiol was much lower than the rate of glucuronidation of a similar concentration of BaP phenols; the rate of conjugation of 2.5-μ*M* (–)-BaP-7,8-dihydrodiol in catfish intestinal microsomes was 0.025 ± 0.01 nmol/min/mg protein, whereas that of 1-μ*M* 7-hydroxybenzo(*a*)pyrene was 0.35 ± 0.07 nmol/min/mg protein (James et al., 1997; van den Hurk and James, 2000). In induced catfish, metabolism of (–)-BaP-7,8-dihydrodiol to the ultimate carcinogen (+)-*anti*-BaP-7,8-diol-9,10-oxide was increased, and the capacity of the intestine to detoxify the diol-epoxide by glutathione conjugation was apparently overwhelmed, as induced fish had considerably higher DNA adducts than controls (James et al., 1988). It is likely that species differences in the rate of conjugation of BaP-7,8-dihydrodiol relative to the rate of activation by CYP to BaP-7,8-dihydrodiol-9,10-oxide are factors in the species differences in sensitivity to this carcinogen.

Aflatoxin B_1

The aflatoxins represent a group of closely related difuranocoumarin compounds produced by the common fungal molds *Aspergillus flavus* and *Aspergillus parasiticus* (Figure 4.22). Although fish may be exposed to dietary aflatoxins by ingestion of contaminated feed, especially those with high levels of cottonseed meal, most of the work surrounding the effects of this compound in fish is due largely to its being an excellent model compound for hepatic carcinogenesis in rainbow trout. In the early 1960s, it was discovered that aflatoxin contamination was responsible for an outbreak of hepatocellular carcinomas in hatchery-reared rainbow trout (*Oncorhynchus mykiss*), a species for which background tumor rates are very low (Halver, 1969). Of the various aflatoxins, aflatoxin B_1 (AFB_1) (Figure 4.23) is considered to be the most potent hepatocarcinogen and hepatotoxin (Eaton and Gallagher, 1994). Although the carcinogenic potency of AFB_1 in rats is extremely high, rainbow trout exceed rats in sensitivity to AFB_1 hepatocarcinogenesis and are generally considered to be the most sensitive species to aflatoxin carcinogenicity (Hendricks, 1994). A dietary exposure to 20 ppb AFB_1 of the Shasta strain of rainbow trout for

Downloaded From Vet-eBooks.com

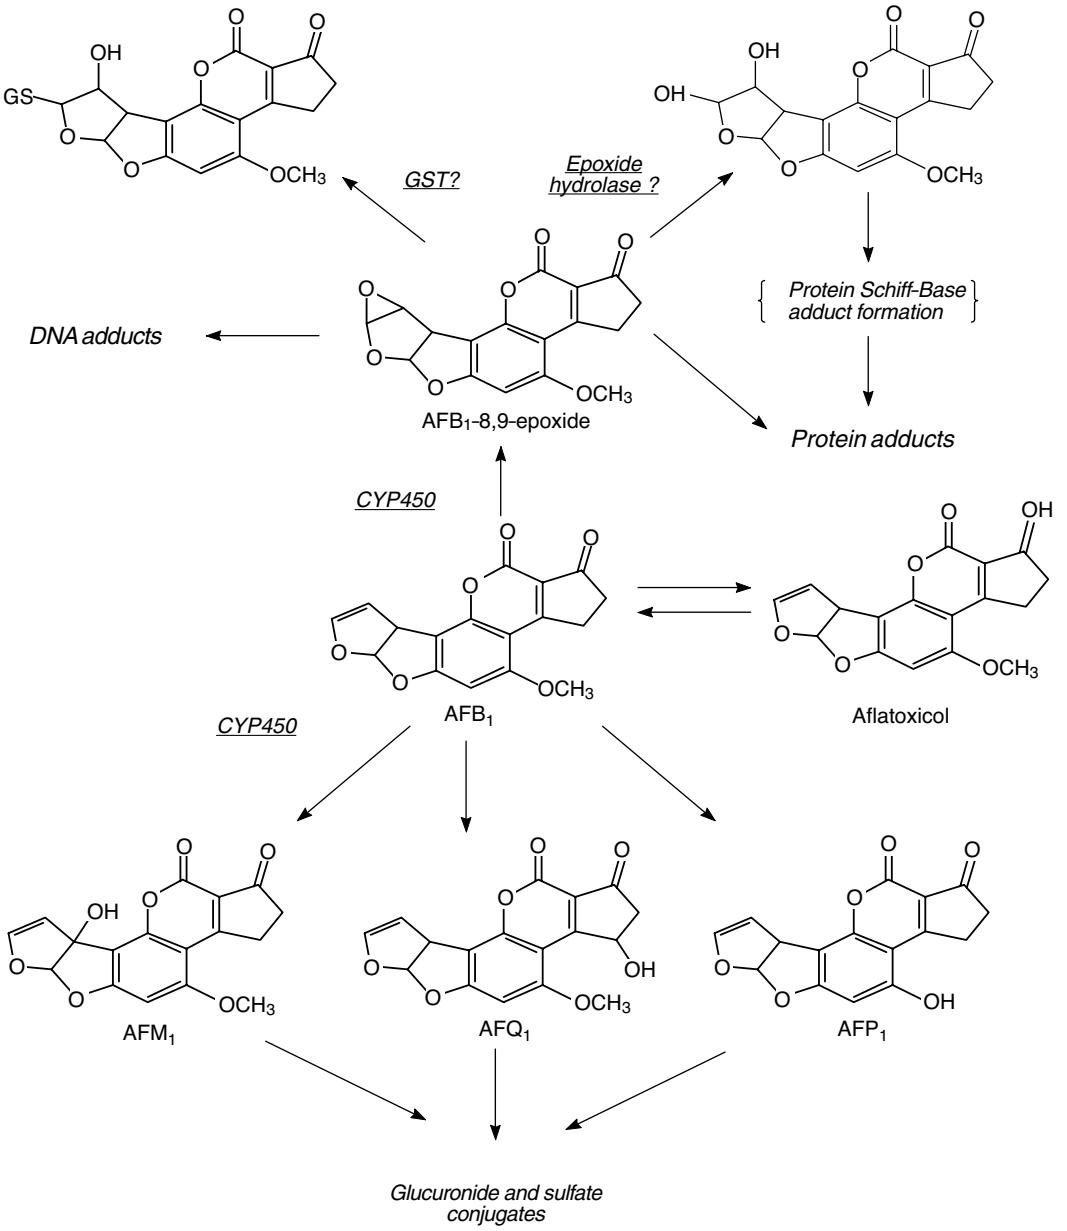

FIGURE 4.23 Biochemical pathways for aflatoxin (AFB_1) biotransformation.

only 4 weeks resulted in a tumor incidence of 62%. Remarkably, static renewal exposure of fertilized rainbow trout eggs (embryos) to 500 ppb (in the bathing medium) AFB_1 for 15 minutes resulted in 62% incidence of hepatic tumors 12 months after hatching (Hendricks, 1994).

Studies in several species have demonstrated that AFB_1 requires microsomal oxidation to the reactive AFB_1-*exo*-8,9-epoxide (AFBO) (Figure 4.23) to exert its hepatocarcinogenic effects. In addition to producing AFBO, chemical and enzymatic epoxidations of AFB_1 can also result in the formation of an *endo*-AFB_1 epoxide stereoisomer (Raney et al., 1992a). Although the *endo*-epoxide is less susceptible to hydrolysis compared to the *exo*-conformation, the *exo*-epoxide is much more efficient at forming DNA adducts and is much more mutagenic than the *endo*-epoxide (Raney et al., 1992b, 1993). AFB_1 carcinogenic potency is highly correlated with the extent of total AFBO–DNA adducts formed *in vivo*

Downloaded From Vet-eBooks.com

(for a review, see Eaton and Gallagher, 1994). When the administered AFB_1 dose is normalized to target dose (e.g., AFBO–DNA adducts per 10^8 nucleotides), a highly linear relationship between DNA adduct formation and tumor response is obtained, even when using combined data from both rats and rainbow trout (Buss et al., 1990). Furthermore, a large range of linearity exists among total administered dose and AFBO–DNA adduct levels in rainbow trout administered dietary AFB_1 (Dashwood et al., 1988). Collectively, these aforementioned studies demonstrating the linear relationship between AFB_1 dose and AFBO–DNA adducts are not supportive of a threshold hypothesis for aflatoxin genotoxicity at low doses, at least not in two highly sensitive yet diverse species (rats and rainbow trout).

Studies of AFB_1 metabolism and carcinogenesis have demonstrated that AFB_1 biotransformation is intimately linked with its toxic and carcinogenic effects. Accordingly, aquatic species differences among AFB_1 biotransformation pathways are a critical determinant underlying variations in species sensitivities of AFB_1-induced carcinogenesis. Although rainbow trout are extremely sensitive to the hepatocarcinogenic effects of AFB_1, Coho salmon (*Oncorhynchus kisutch*), a closely related salmonid, are resistant to AFB_1 carcinogenicity (Hendricks, 1994). The biochemical basis for this difference in AFB_1 sensitivity among salmonids may be due to less efficient CYP-mediated AFB_1 epoxidation in the Coho salmon relative to the trout. Specifically, AFB_1–DNA binding was reported to be 56-fold greater in rainbow trout liver than in Coho salmon after intraperitoneal (i.p.) AFB_1 administration and 18-fold greater after dietary AFB_1 exposure (Bailey et al., 1988). Other pathways, such as phase II metabolism and AFB_1 elimination, are relatively similar among the two species (Bailey et al., 1988), indicating that microsomal P450-mediated AFB_1 epoxidation and subsequent DNA binding accounts for differences in AFB_1–DNA binding among the two salmonids. Like Coho salmon, microsomes prepared from channel catfish (*Ictalurus punctatus*) liver are inefficient at catalyzing AFB_1 epoxidation (Gallagher and Eaton, 1995). Channel catfish injected with AFB_1 show no elevation in DNA damage as detected by the comet assay, as opposed to rainbow trout, which display extensive DNA damage in blood, liver, or kidney after exposure (Abd-Allah and el-Fayoumi, 1999). Thus, the evidence to date suggests that the resistance of some fish to AFB_1 carcinogenesis can be attributed to inefficient conversion of the procarcinogen to the DNA-reactive metabolite.

The microsomal CYP-dependent monooxygenases also oxidize AFB_1 to its hydroxylated metabolites, AFM_1, AFP_1, and AFQ_1 (Figure 4.23). AFQ_1 is formed via 3α-hydroxylation of AFB_1, whereas AFM_1 is produced by 9α-hydroxylation of AFB_1. *O*-Demethylation of AFB_1 results in the formation of AFP_1. The acute toxicities of the hydroxylated metabolites are generally lower than the parent compound (Hsieh et al., 1974; Stoloff et al., 1972), as are the mutagenic potencies (Coulombe et al., 1982, 1984; Hsieh et al., 1984). However, AFP_1 and AFQ_1 do not appear to be major oxidative metabolites of AFB_1 metabolism in fish. In contrast, significant amounts of AFM_1 are formed in fish (Ramsdell and Eaton, 1990; Ramsdell et al., 1991; Sinnhuber et al., 1974). Dietary AFM_1 is approximately 30% as carcinogenic as AFB_1 in trout (Sinnhuber et al., 1974), whereas the carcinogenic potency of AFQ_1 is approximately 1% that of AFB_1 (Hendricks et al., 1980). Although other aflatoxin metabolites, including the epoxides of AFM_1, AFP_1, and AFQ_1, may contribute to DNA binding, the evidence to date strongly indicates that such secondary oxidation products are of minor importance (Bailey, 1994; Raney et al., 1992b).

CYP2K1 is the major salmonid P450 isozyme that activates AFB_1 to AFBO (Williams and Buhler, 1983; Yang et al., 2000). Immunoquantitation studies of salmonid P450 isozymes indicate that Coho salmon microsomes express less CYP2K1 than rainbow trout, thus providing a mechanistic basis for the lack of AFB_1 oxidation by Coho salmon (Bailey et al., 1988). Juvenile trout injected with the estrogenic and androgen hormones 17β-estradiol and testosterone have lower mRNA and protein levels of CYP2K1 and reduced AFB_1–DNA binding relative to control animals, suggesting that hormonal status may affect the ability of rainbow trout to form the toxic AFBO (Buhler et al., 2000). A CYP2K1 ortholog is also present in zebrafish (*Danio rerio*) (Troxel et al., 1997), and it is likely that this or a related isoform is responsible for the activation of AFB_1 in this species. Like channel catfish, rainbow trout treated with BNF exhibit increased AFM_1 production (Goeger et al., 1988). In general, the capacity for AFBO stereoisomer production has not been measured in fish. It is reasonable to assume that species such as zebrafish and rainbow trout, which can catalyze AFB_1–DNA binding, can form *exo*-AFBO as a significant proportion of their microsomal AFBO. Furthermore, the fact that female zebrafish form more AFBO–DNA adducts than do males may be a reflection of a higher ratio of AFB_1-*exo*/-*endo* epoxide formation for females (Troxel et al., 1997). Interestingly, the level of AFBO–DNA adduct formation in

Downloaded From Vet-eBooks.com

zebrafish is fourfold lower than that observed for the sensitive rainbow trout but fivefold higher than for the rat. Despite the ability of zebrafish to activate AFB_1 and to form persistent AFBO–DNA adducts, zebrafish appear to be quite resistant to the carcinogenic effects of AFB_1 when administered by the dietary route (Troxel et al., 1997). Thus, the zebrafish studies suggest that mechanisms related to factors other than the inherent ability to bioactivate and detoxify AFB_1 may be involved; for example, it may be that the DNA-adducted cells do not go on to form initiated cells or that a lack of an initiation/promotion progression is present in zebrafish.

As opposed to rodents, fish can rapidly convert AFB_1 to a reductive metabolite, aflatoxicol (AFL) (Figure 4.23), by reducing the 1-keto-moiety via a cytosolic NADPH-dependent reductase (Salhab and Edwards, 1977). Aflatoxicol can be further metabolized by 9α-hydroxylation to form $AFLM_1$ (Figure 4.23) (Lovel et al., 1988). Aflatoxicol is a potent frameshift mutagen and also elicits unscheduled DNA synthesis in fibroblasts incubated with a rat liver postmitochondrial fraction (Stich and Laishes, 1975). Aflatoxicol is approximately 50% as carcinogenic as AFB_1 in trout (Schoenhard et al., 1981) and exhibits about 70% the mutagenicity of AFB_1 in an *in vitro* trout liver activating system (Coulombe et al., 1982). Accordingly, the formation of aflatoxicol does not appear to be an important detoxification pathway for AFB_1, especially as aflatoxicol may be rapidly converted back to AFB_1 by a microsomal dehydrogenase (Salhab and Edwards, 1977), thereby increasing the physiological half-life of AFB_1 (Loveland et al., 1977).

Several of the products of AFB_1 oxidative metabolism serve as substrates for phase II detoxification enzymes. As in the case of AFB_1 epoxidation, there is extensive interspecies variation in phase II conjugation of AFB_1 oxidative metabolites. In mammalian species, the primary pathway for AFB_1 detoxification is through GST-mediated conjugation of AFBO with reduced glutathione (GSH). The selectivity of GST isoenzymes toward AFBO serves as a critical determinant of differences among mammalian species in susceptibility to AFB_1 hepatocarcinogenesis (Degen and Neumann, 1981; Eaton and Gallagher, 1994; Eaton et al., 1990; Lotlikar et al., 1984; O'Brien et al., 1983; Roebuck and Maxuitenko, 1994). Mouse liver cytosolic fractions have 50- to 100-fold greater AFBO conjugating activity than rat even though both species have comparable amounts of GST activity toward 1-chloro-2,4-dinitrobenzene (CDNB) (Monroe and Eaton, 1987). Accordingly, mice are resistant to the hepatocarcinogenic effects of AFB_1 when compared to rats (Wogan and Newberne, 1967), a difference reflected by 50- to 100-fold less AFB_1–DNA adduct formation by mice after *in vivo* AFB_1 exposure (Monroe and Eaton, 1987). The high AFBO conjugating activity in mice is due to constitutive expression of an alpha GST isozyme (mGSTA3-3) that has unusually high conjugating activity toward AFBO.

In contrast to mammals, GST-mediated AFB_1 conjugation does not appear to be a significant route of AFB_1 detoxification in fish. Species such as rainbow trout (Valsta et al., 1988), Coho salmon (Valsta et al., 1988), or channel catfish (Gallagher and Eaton, 1995) do not form appreciable amounts of AFBO–GSH conjugates. The low capacity for AFBO–GSH conjugation in the presence of efficient AFB_1 epoxidation in the trout probably accounts for the high covalent binding index for AFB_1 in trout relative to mammals (Bailey et al., 1984). Detectable, albeit low, GST–AFBO activity has been measured in liver cytosolic fractions prepared from English sole (*Pleuronectes vetulus*) and starry flounder (*Platichthys stellatus*) (Gallagher et al., 1998), but the significance of this activity toward AFB_1 sensitivity has not been determined. English sole and starry flounder express a theta-class GST that shows relatively low homology to the mouse alpha-class GST with high AFBO conjugating activity (mGSTA3-3) (Gallagher et al., 1998). A similar form has also been cloned from largemouth bass, although its ability to conjugate AFBO has not been tested (Doi et al., 2004). There is no evidence for the presence of a GST orthologous to the mouse alpha-class GST form that rapidly conjugates AFBO in any fish species examined to date.

As in mammals, glucuronidation is an important pathway for the detoxification and excretion of xenobiotics in fish (for a review, see George, 1994). The production of AFL_1 represents a significant AFB_1 detoxification pathway when a glucuronide is produced and excreted. Biliary AFB_1 conjugates in rainbow trout, zebrafish, and Coho salmon are comprised mainly of AFM_1– and AFL_1–glucuronide conjugates (Loveland et al., 1984; Troxel et al., 1997). A similar metabolic profile appears to exist for channel catfish (Gallagher and Eaton, 1995). Although the rate of glucuronidation of AFB_1 metabolites by catfish liver has not been directly measured, channel catfish have high UDP–GT activities (Ankley and Agosin, 1987; Short et al., 1988) and produce polar biliary AFB_1 metabolites after oral AFB_1 administration (Plakas et al., 1991). Sulfate conjugates were not detected in rainbow trout exposed to

Downloaded From Vet-eBooks.com

AFB_1 (Loveland et al., 1984), which is consistent with other studies indicating that rainbow trout excrete xenobiotics as glucuronides, as opposed to sulfates (Bailey et al., 1984).

Rodent studies have demonstrated that a variety of dietary factors and synthetic antioxidants have been shown to influence the carcinogenicity of AFB_1. The inducibility of fish hepatic phase II enzymes by synthetic antioxidants has been demonstrated in several species, including plaice (George, 1994), channel catfish (Gallagher et al., 1992), largemouth bass (Hughes and Gallagher, 2004), and brown bullheads (Henson et al., 2001). In the case of the synthetic antioxidant ethoxyquin, juvenile brown bullheads fed a semipurified, antioxidant-free diet supplemented with ethoxyquin exhibited a significant increase in hepatic cytosolic GST activity toward 1-chloro-2,4-dinitrobenzene (CDNB) relative to control fish (Henson et al., 2001). Despite the ability of synthetic antioxidants to modulate GST and other phase II enzyme expression, there is little evidence for chemoprotection of AFB_1 carcinogenesis based on modulation of AFB_1 biotransformation in fish. The rainbow trout tumor model has been used extensively to study the mechanisms of a number of dietary anticarcinogens, including AFB_1.

Exposure to the natural product indole-3-carbinol (I3C) was effective as a chemoprotectant against AFB_1 tumorigenesis in rainbow trout (Takahashi et al., 1995). Although it was originally proposed that the mechanism of protection was mediated through the induction of CYP1A activity, studies concluded that the protection was largely due to the fact that I3C undergoes breakdown in the gastrointestinal tract to acid condensation products that act as blocking agents against AFBO–DNA adduct formation (Takahashi et al., 1995).

In summary, AFB_1 is an important dietary carcinogen that can serve as a model substrate for examining aquatic species' differences in biotransformation in relationship to susceptibility to carcinogenesis. The reader is directed to Chapters 5, 6, and 24 for additional information on the roles of biotransformations in the mechanisms of action of environmental procarcinogens in fish.

Organophosphate Esters and Carbamates

Acetylcholinesterases are common targets for a host of xenobiotics, including various classes of pesticides. Biotransformation often plays a critical role in facilitating or impeding the binding of these compounds to cholinesterases. One class of pesticides whose toxicology is significantly affected by biotransformation is the organophosphate ester insecticides. In general, organophosphate esters possess a phosphorothionate group bound to at least two alkyl ethers (see Figure 4.24). The phosphorothionate is usually activated through oxidative desulfuration to an oxon, which irreversibly binds to the serine residues of the anionic site of cholinesterase (see Figure 4.25). The inability of cholinesterase to regenerate because of this covalent interaction results in irreversible binding and inactivation of the enzyme. The classical example is that of parathion, which is activated to paraoxon which inactivates acetylcholinesterase (Figure 4.26). This monooxygenation is classically catalyzed by cytochrome P450 isoforms, but depending on the electronegativity of adjacent functional groups flavin-containing monooxygenases may also be involved in oxon formation (Levi and Hodgson, 1992). Alternatively, various hydrolytic processes (i.e., dearylation of parathion) may also occur which detoxify the compound, as each hydrolytic derivative does not inhibit cholinesterase. Hydrolysis may occur subsequent to or prior to desulfuration and is catalyzed by a host of carboxylesterases (Maxwell, 1992). An additional detoxification reaction involves the conjugation of certain compounds such as methyl parathion and methyl paraoxon with glutathione (Benke et al., 1974).

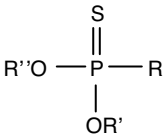

FIGURE 4.24 Structure of organophosphate ester.

Although the toxicity of a host of organophosphates have been examined in fish, the biotransformation of these compounds and elucidation of specific inhibitory metabolites have only been examined in a very few cases. As these organophosphates demonstrate acute toxicity, it is likely that all are converted to oxonic metabolites, even though few have been characterized chromatographically. The most studied organophosphate ester in fish species is parathion. Several studies have reported paraoxon formation in a range of fish species including channel catfish (*Ictalurus punctatus*) (Straus et al., 2000), bluegill sunfish (*Lepomis macrochirus*), bullheads (*Ictalurus melas*), white flounder (*Pseudopleuronectes americanus*) (Hitchcock and Murphy, 1971), sculpin (*Leptacottus armatus*) (Murphy, 1966), rainbow trout (Abbas et al., 1996; Wallace and Dargan, 1987), and mosquitofish (*Gambusia affinis*) (Boone and Chambers, 1997).

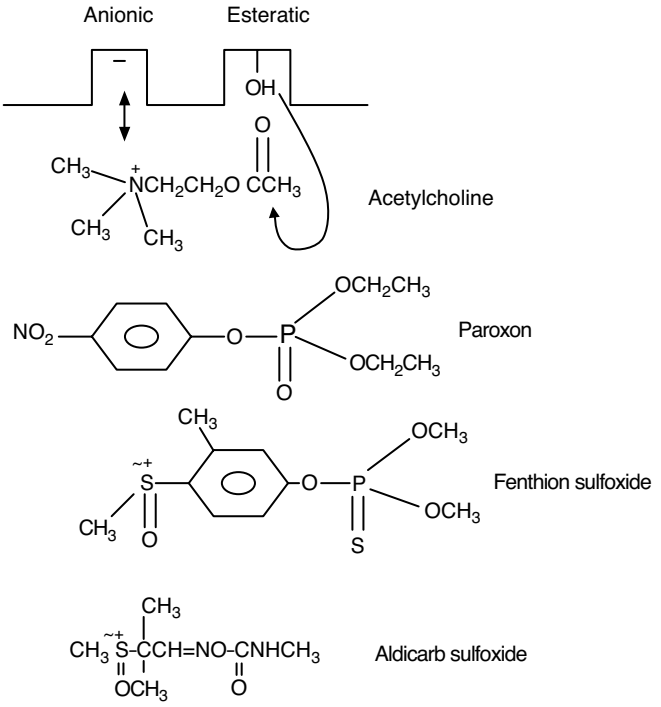

FIGURE 4.25 Inhibition of acetylcholinesterase by aldicarb sulfoxide demonstrating partial positive-charge interactions with enzyme.

Studies in channel catfish have examined the relative differences between dearylation and desulfuration of parathion as well as chlorpyrifos and the role of specific CYP isoforms in these processes (Straus et al., 2000). Pretreatment of fish with Arochlor® 1254 failed to alter either reaction in chlorpyrifos or parathion, indicating CYP1A was not involved in dearylation or desulfuration of either compound. Diazinon is another insecticide in which *in vitro* and *in vivo* biotransformations have been well documented in fish (Keizer et al., 1991, 1993). In fact, differences in oxidative desulfuration have been shown to be responsible for toxicity differences between fish species and developmental stages (Hamm et al., 1998).

Oxidative desulfuration is not the only transformation enhancing the inhibitory potency of cholinesterase-inhibiting xenobiotics. Sulfoxidation of xenobiotics anterior to the phosphorothionate moiety has also been shown to enhance the binding of the xenobiotic to the cationic site of cholinesterase (Figure 4.25). Recent studies in goldfish have shown that fenthion undergoes transformation to the sulfoxide and separately desulfuration to the oxon *in vivo* (Kitamura et al., 2000). *In vitro* studies using hepatopancreas microsomes from goldfish demonstrated conversion of fenthion to the sulfoxide, which was inhibited by SKF-525A and partially by alpha-naphthylthiourea, thus suggesting roles of CYP and FMO in the transformation (Kitamura et al., 1999). Studies with hepatopancreas cytosol indicated reduction of the sulfoxide to the sulfide through aldehyde oxidase (Kitamura et al., 1999). Fenthion sulfoxide was also observed in bioaccumulation studies using medaka treated with fenthion, but neither the sulfone nor oxon was observed (Tsuda et al., 1996).

Although aldicarb is a carbamate insecticide, oxygenation of the sulfur anterior to the carbamyl moiety significantly elevates the toxicity of this compound 40 to 150 times depending on the species (El-Alfy and Schlenk, 2002; El-Alfy et al., 2001; Perkins et al., 1999). *S*-Oxygenation of aldicarb has been observed in rainbow trout, Japanese medaka (*Oryzias latipes*), hybrid striped bass (*Morone saxatilis* × *chrysops*), channel catfish (*Ictalurus punctatus*), and rainbow trout (*Oncorhynchus mykiss*) (El-Alfy and Schlenk, 1998; Perkins and Schlenk, 2000; Perkins et al., 1999; Schlenk and Buhler, 1991; Wang et al., 2001). In each species except catfish, FMOs contributed to the *S*-oxygenation. As channel catfish and other predominantly freshwater fish do not have active FMOs (Schlenk et al., 1993), cytochrome P450

Downloaded From Vet-eBooks.com

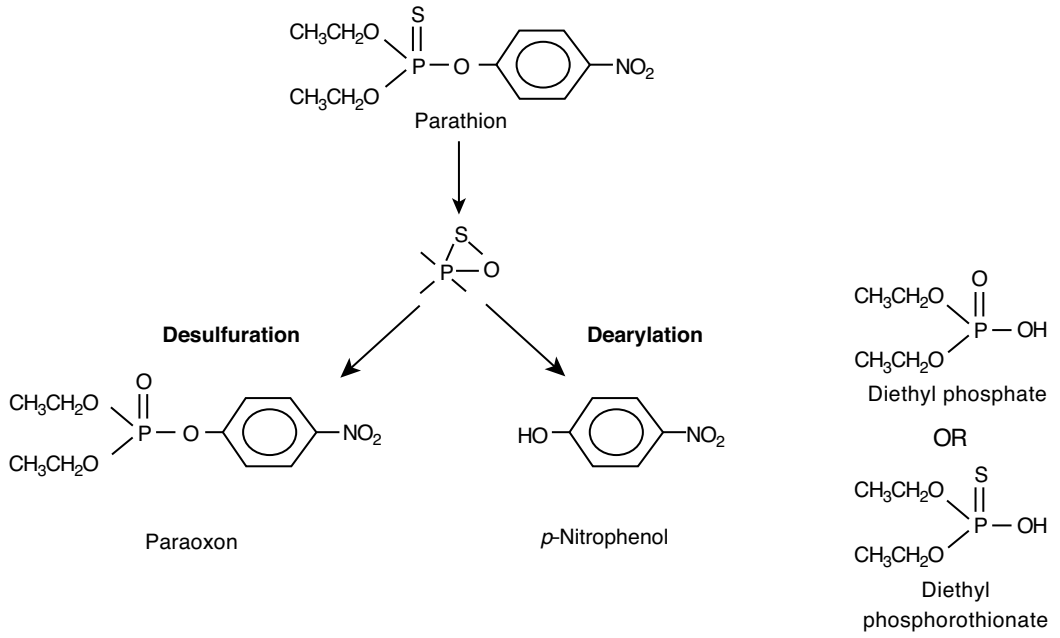

FIGURE 4.26 Metabolic pathway of parathion in channel catfish. (From Straus, D.L. et al., *Aquat. Toxicol.*, 50, 141, 2000. With permission.)

is exclusively responsible for this reaction (Perkins et al., 1999); however, no single CYP isoform appears to predominate in the sulfoxidation of aldicarb. Rather, it is likely that several isoforms participate in the reaction (Perkins et al., 1999). The reduced *S*-oxygenation of aldicarb in channel catfish relative to rainbow trout may explain its resistance against aldicarb toxicity compared to rainbow trout, which readily convert aldicarb to aldicarb sulfoxide (Perkins and Schlenk, 2000).

In summary, fish are capable of activating organophosphate esters to more potent cholinesterase inhibitors. Species differences in the bioactivation and esterase-mediated cleavage of organophosphates have been shown to greatly contribute to species differences in toxicity to these compounds. These data argue for more studies to better characterize specific enzymes responsible for these transformations to help identify sensitive populations of species that may be severely impacted by these compounds.

Conclusions

Biotransformation can be a very important process in the disposition and mechanistic determinations of the mode of action of xenobiotics. Alterations in enzyme expression can dramatically affect the sensitivity of an organism to the toxic insult of a xenobiotic or the disposition of endogenous substrates. Alteration may occur as a result of genetics, diet, gender, environmental influences, or other xenobiotics. Understanding the latter is critical in risk evaluations of chemical mixtures. Very little is known regarding the substrate specificities or the regulation of biotransformation enzymes in fish. Through advances in genomic technologies and the use of fish models in human health research (e.g., zebrafish, medaka), numerous genotypic discoveries have recently occurred. It is likely that phenotypic functionality studies with heterologously expressed enzymes resulting from genomic examinations will help in better understanding biotransformation pathways in fish. In addition, more studies are needed with whole-animal systems to better characterize *in vivo* pathways of chemical biotransformation in species other than classic fish models. Such studies are imperative for physiologically based toxicokinetic (PBTK) models, which may help better estimate dose and aid regulators in reducing uncertainty between species, thus leading to more accurate evaluations of chemical risk.

Introduction

Chemicals cause toxicity by interfering with the structure and function of cellular macromolecules such as proteins (e.g., enzyme inhibition and inactivation), lipids (e.g., lipid peroxidation), and nucleic acids (e.g., formation of DNA adducts). Chemicals or their metabolites also may act through interference with physiological signaling pathways, often by altering gene expression. In some cases, biotransformation of the original chemical modifies toxicity, either enhancing it through bioactivation to more reactive derivatives or reducing it through inactivation and enhanced excretion.

This general description of mechanisms of toxicity is as true for fish as it is for humans and other animals. In fact, most mechanisms of toxicity are not specific to fish. Thus, to understand mechanisms of toxicity in fish it is necessary first to obtain a strong foundation in mammalian toxicology, where

Downloaded From Vet-eBooks.com

much of the research and many of the major advances in mechanistic understanding have occurred. A discussion of mechanistic toxicology in fish is in part a question of extrapolation of knowledge obtained in rodent and human systems to fish. How do biochemical systems and mechanisms of toxicity in fish compare to what has been established in mammals? Are there differences in diversity or function of receptors and biotransformation enzymes involved in these mechanisms? Fish also have many unique features as compared to mammals, including distinct tissues (gill), routes of exposure (aqueous), and life history (externally developing eggs, metamorphosis). How do these influence the ability to extrapolate from rodents, or provide opportunities for novel mechanisms to be discovered? In addition, how can fish be used to study mechanisms involved in the effects of long-term exposure in natural setting—effects such as environmental carcinogenicity or evolved chemical resistance?

This chapter builds on a foundation in mammalian mechanistic toxicology (Gregus and Klaassen, 2001), as well as previous general descriptions of mechanistic toxicology in aquatic systems (Di Giulio et al., 1996; Mommsen and Moon, 2005; Schlenk and Benson, 2001) and other chapters in this book that deal with mechanism-related topics such as biotransformation (Chapter 4), oxidative stress (Chapter 6), target-organ toxicity (Chapter 11), and biomarkers (Chapter 16). We focus on mechanisms involving receptors and other ligand-activated transcription factors that regulate gene expression in response to chemical exposure.

Receptors are important in mechanisms of toxicity for several reasons: (1) Numerous receptors have been identified as targets of chemicals or are potential targets based on known ligands (Table 5.1). Chemicals can act as receptor agonists, partial agonists, or antagonists (defined below). Although toxicants may "mimic" the natural ligands in activating the receptor, they may do so at an inappropriate time, in an inappropriate cell type, or in a sustained way rather than the transient stimulus that characterizes most physiological ligands. (2) Receptors are involved in highly coordinated signaling pathways with key roles in embryonic development or adult homeostasis; thus, perturbation of receptor function can have serious and wide-ranging effects on the organism. (3) Receptors often can be activated or inhibited by very low concentrations of chemicals (nanomolar to micromolar) and thus can be sensitive to trace amounts of chemicals in the environment. (4) The effects of receptor activation often include amplification of the stimulus; for example, receptors that act as transcription factors typically control the expression of several genes, and a single activated receptor can stimulate the synthesis of multiple transcript copies from each gene. Other receptors control ion channels or initiate kinase cascades that similarly involve signal amplification.

To illustrate some general principles of receptor-mediated toxicity as they apply to fish, we concentrate on the well-known mechanisms involving dioxin-like compounds acting through aryl hydrocarbon receptors (AhRs); where appropriate, we also discuss other receptors that are targets for environmental contaminants. Important themes in this chapter include the value of fish both as targets and models, ligand–receptor pharmacology and its relevance to mechanisms of toxicity, and the presence in fish of additional diversity of toxicologically relevant genes—the result of a fish-specific whole-genome duplication in a teleost ancestor.

Fish as Targets and Models

The study of mechanisms of toxicity in fish involves two distinct rationales, with fish serving both as targets and as models. Clearly, fish are *targets* for environmental contaminants; some fish populations are highly exposed to chemicals, especially in urban, industrial, or coastal sites. These fish are studied because of concern for population-level effects (Cook et al., 2003; Nacci et al., 2002) or as sentinels for the health of the environment. In addition, they may be subjects of research to investigate the mechanisms involved in physiological or evolutionary adaptation to chemical exposure (Wirgin and Waldman, 2004) (see Chapter 13). Fish also are widely (and increasingly) used as animal *models* in toxicological research, with the ultimate goal of extrapolating the results to inform questions concerning the potential human health effects of chemical exposure. Thus, research in fish toxicology involves a two-way extrapolation, with human (and rodent) results being used to establish mechanisms of relevance to fish as targets, and fish being used as models to address specific mechanistic questions with application to human health.

Downloaded From Vet-eBooks.com

Several features of fish make them valuable as models in toxicology (Ballatori and Villalobos, 2002; Hinton et al., 2005; Kelly et al., 1998). As vertebrates, fish have a close evolutionary relationship to humans, with shared genes and biochemical pathways that have become even more apparent as a result of recent whole-genome analyses (Aparicio et al., 2002; Jaillon et al., 2004). Most of the fish species used in toxicological research are small, develop rapidly with a short generation time, and have transparent, externally developing embryos that facilitate experiments in developmental toxicology. For some species, such as zebrafish, methods for transgenesis (Linney and Udvadia, 2004; Udvadia and Linney, 2003) and gene knock-down (Nasevicius et al., 2000) are well developed and serve as powerful tools for mechanistic research. These and other advantages of small fish models have been described in detail elsewhere for zebrafish (*Danio rerio*) (Carvan et al., 2005; Hill et al., 2005; Linney et al., 2004b), medaka (*Oryzias latipes*) (Oxendine et al., 2006), Atlantic killifish (*Fundulus heteroclitus*) (Burnett et al., 2007), and rainbow trout (*Oncorhynchus mykiss*) (Bailey et al., 1996).

Comparative Toxicology: Complications and Opportunities

The use of fish as models for human health requires careful consideration of the similarities and differences between fish and mammals. First, it is important to keep in mind that "fish" as a group encompasses an estimated 29,000 species (compared to approximately 5500 for mammals), including bony, cartilaginous, and jawless fishes and representing an enormous range of genetic, biochemical, and physiological diversity. Second, although as vertebrates fish share with humans and other mammals most features of key biochemical pathways involved in mechanisms of toxicity, important differences between fish and mammals in the details of these pathways have emerged in recent years (Table 5.1). Most notable is the finding that a whole-genome duplication occurred in the teleost fish lineage approximately 350 million years ago (MYA), after its divergence from the lineage that would become tetrapods (including humans) (Amores et al., 1998; Christoffels et al., 2004; Crow et al., 2006; Hoegg et al., 2004; Postlethwait et al., 2004; Taylor et al., 2001). The result of this is that many fish species have retained extra copies (paralogs*) of some genes as compared to humans. Although only approximately 15 to 30% of the duplicated genes have been retained (Brunet et al., 2006), many of these encode transcription factors (Brunet et al., 2006; Steinke et al., 2006). Examples of toxicologically relevant genes for which fish have additional paralogs include CYP19 (Kishida and Callard, 2001; Tchoudakova and Callard, 1998), estrogen receptors (ERs) (Bardet et al., 2002; Hawkins et al., 2000), and aryl hydrocarbon receptors (see below). Other differences in genetic diversity have arisen from independent expansion of some gene families in mammals and fishes (e.g., the CYP2 family) as well as from lineage-specific gene losses in these groups. The resulting differences in the toxicological toolkit raise important questions about the extrapolation of findings between fish and mammals. The existence of differences in receptor diversity among species highlights the need to understand the nature of homologous relationships among these genes; interpretations and extrapolation will depend on whether the genes under consideration are related as orthologs or paralogs (Sanetra et al., 2005).

The presence of extra copies of fish genes as a result of the fish-specific whole-genome duplication is more than just an annoying complication. It also provides an opportunity for mechanistic insights, because duplicated fish genes might be exploited to obtain new information about the function of their single mammalian counterpart (Amores et al., 1998; Force et al., 1999; Lynch and Force, 2000; Postlethwait et al., 2004; Taylor et al., 2001); for example, the duplication, degeneration, complementation (DDC) model of gene evolution (Force et al., 1999; Lynch and Force, 2000) predicts that the multiple functions of a mammalian gene may be partitioned between its fish "co-orthologs" (referred to as *subfunction partitioning*) (Postlethwait et al., 2004). Most of the evidence in support of this model comes

* Distinct types of homologous genes occur within and among species, and specialized terms are used to distinguish among them. Genes in two different species are *orthologous* (Fitch, 1970) if they are descended from the same gene in the most recent common ancestor of the two species (i.e., the two genes are separated only by a speciation event). *Paralogous* genes (Fitch, 1970) are homologs that resulted from a gene duplication event such as a tandem duplication or a whole-genome duplication. If a gene duplication has occurred in one lineage but not another, the term *co-ortholog* (Gates et al., 1999; Taylor et al., 2001) is used to describe the relationship between each of the two duplicated genes in one species and their single ortholog in the other species. Other types of homology have also been described (Meyer and Mindell, 2001).

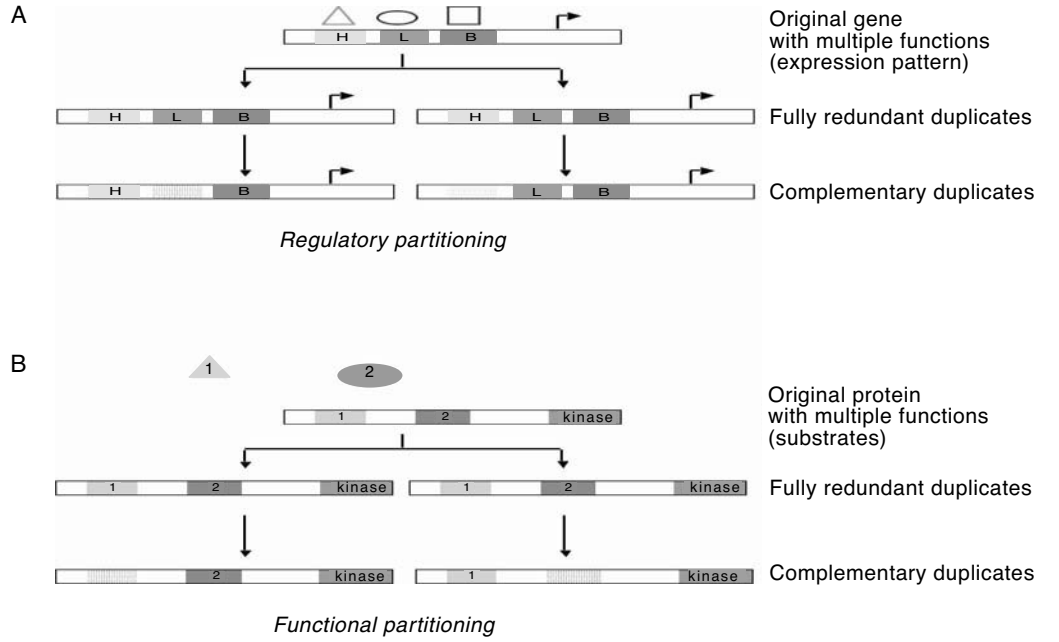

FIGURE 5.1 The duplication, degeneration, complementation (DDC) model of gene evolution. (A) *Regulatory partitioning:* The original gene is expressed in multiple cell types or tissues, such as heart (H), liver (L), and brain (B), controlled by tissue-specific transcription factors (colored shapes). After duplication, each gene copy loses regulatory sequences targeted by different transcription factors, resulting in complementary expression patterns. (B) *Functional partitioning:* The original gene encodes a protein with multiple functions, such as an enzyme that can act on different substrates (shapes 1 and 2). After duplication, residues required for substrate-specific recognition are differentially mutated, resulting in complementary loss of substrate binding. Schemes are based on the model proposed by Force, Lynch, and colleagues (Force et al., 1999; Lynch and Force, 2000). (A color version of this figure is available from the first author [mhahn@whoi.edu] upon request.)

from studies of zebrafish paralogs that have distinct patterns of expression that together sum to the expression pattern of their mammalian ortholog (reviewed by Postlethwait et al., 2004). We refer to this as *regulatory partitioning* (Figure 5.1A). For other genes, rather than (or in addition to) the partitioning of expression patterns, the fish genes may diverge with regard to specific functions—for example, differential loss of certain functional domains or specialization for subsets of ligands (*functional partitioning*; Figure 5.1B) (de Souza et al., 2005; Hawkins and Thomas, 2004; Hawkins et al., 2005). In either case, paralog-specific studies involving knock-down or other approaches applied to fish paralogs may reveal novel functional aspects of their mammalian ortholog. The possibility that fish paralogs may evolve new functions (*neofunctionalization*) must also be considered (Brunet et al., 2006; He and Zhang, 2005).

An understanding of receptor function and whether it is highly conserved, partitioned, or novel requires the application of quantitative biochemical methods that reveal the toxicologically important properties of the receptors. In the next two sections, we discuss the general principles governing ligand–receptor interactions and describe some useful experimental approaches to studying them.

Ligand–Receptor Interactions: General Principles

In physiological terms, a receptor has two properties: It recognizes a change in the environment, and it produces a response. Most cellular receptors (and nearly all of the receptors of toxicological interest) are proteins that interact with small molecule ligands. For these receptors, ligand concentration is the environmental change that must be monitored and responded to. The interaction of the receptor protein with the ligand leads to a conformational change in the protein that produces a cellular response; however, ligand binding does not automatically lead to a response, as different ligands for the same receptor may

Downloaded From Vet-eBooks.com

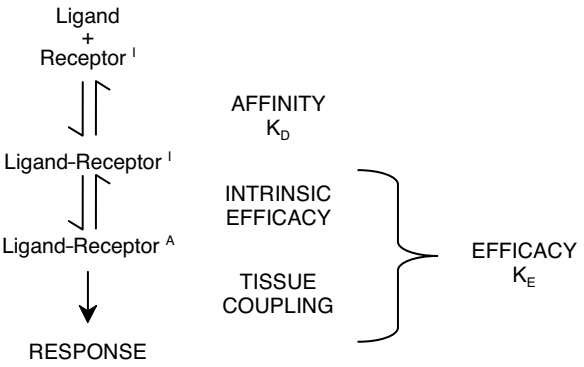

FIGURE 5.2 The pathway to receptor-mediated response. The ligand interacts with an inactive receptor ($Receptor^I$) to form a stable complex. The strength of this interaction is termed *affinity* and is typically represented by the equilibrium dissociation constant (K_D). The ability of the ligand to then convert the receptor to an active form ($Receptor^A$) is termed *intrinsic efficacy*. The magnitude of the response produced by the active receptor also depends on concentrations of other factors in the particular cell type, collectively termed *tissue coupling*. Intrinsic efficacy and tissue coupling together form the efficacy of the ligand–receptor complex, which is represented by the constant K_E in the operational model of receptor action.

differ in their ability to activate the receptor. The ligand–receptor interaction, therefore, may be thought of as a two-step process leading to activation (Figure 5.2): (1) the interaction of the ligand and the receptor (governed by a property termed *affinity*), and (2) the conversion of the receptor to an active form (a property termed *efficacy*).

Affinity

Ligand "binding" by a receptor is typically the result of several noncovalent interactions. The strength of this binding is termed *affinity*. The interaction of receptor and ligand is reversible, with rate constants for the association and dissociation of the ligand with the receptor:

$$L + R \underset{k_2}{\overset{k_1}{\rightleftharpoons}} LR \tag{5.1}$$

where L, R, and LR are the ligand, receptor, and ligand–receptor complex, respectively, and k_1 and k_2 are the association and dissociation rate constants. Typically association (or "on") rates are several orders of magnitude greater than dissociation (or "off") rates. At equilibrium, association and dissociation occur at an equal rate. If a single equilibrium dissociation constant (K_D) is defined to replace the rate constants:

$$K_D = \frac{k_2}{k_1} \tag{5.2}$$

then we can derive the following expression relating ligand concentration and the fraction of receptor that is occupied by ligand:

$$\frac{[LR]}{[R_T]} = \frac{[L]}{[L] + K_D} \tag{5.3}$$

where R_T is the total amount of receptor in the cell. This relationship is a variation of the Langmuir binding isotherm (Langmuir, 1916).

From Equation 5.3, it is evident that K_D is equivalent to the ligand concentration at which half the receptor is in a complex with ligand. At lower values of K_D, less ligand is needed to occupy the receptor, indicating a stronger affinity of the receptor for the ligand. Because on rates are much faster than off rates, the value for K_D is typically in the micromolar to picomolar range.

Downloaded From Vet-eBooks.com

The relationship expressed by Equation 5.3 involves several assumptions about the nature of the association. The most important assumptions for the experimental measurement of binding affinity are:

- The system must have reached equilibrium; that is, association and dissociation are occurring at equal rates when binding is measured, and the fraction of ligand bound has reached a steady state. Generally, this must be determined empirically by measuring binding at a single ligand concentration over several time points.
- Binding of one ligand molecule does not effect binding of another, which includes two major components: (1) Removal of a ligand molecule from the available pool by binding does not alter the concentration of free ligand; that is, the fraction of total ligand that is bound to the receptor is relatively small. (2) Binding is not cooperative, an assumption that is likely to be violated in instances where multiple ligand molecules bind to a single receptor or where receptor proteins form complexes and will often result in nonlinear Scatchard plots (see below).

Deviation from these assumptions can be accommodated by modifications of Equation 5.3 which fall outside the scope of this chapter but are described elsewhere (Kenakin, 1999; Kenakin et al., 1992).

Measurement of Affinity

Although binding assays utilizing fluorescence techniques are seeing increased use in pharmacological research (Hovius et al., 2000), binding affinity is most commonly measured in prepared cells or tissues of interest using radiolabeled ligands. The goal of such ligand binding assays is twofold. First, free ligand must be separated from bound ligand. Second, ligand bound to the receptor must be separated from that bound to nonspecific binding sites within the cell or tissue. Several procedures to achieve the first goal are discussed in the next section. To achieve the second goal, binding assays assume that nonspecific binding is of lower affinity and cannot be saturated in the range of ligand concentrations used. In contrast, the specific receptor binds ligand with much higher affinity but is present in vastly smaller quantities, which can be saturated at relatively low ligand concentrations. Labeled ligand can be displaced from high-affinity, low-capacity receptors but not from low-affinity, high-capacity nonspecific binding sites by an excess of unlabeled ligand; therefore, the definition of high-affinity (specific) binding sites (i.e., receptors) is binding sites that can be saturated within the concentrations of ligand used. High-affinity binding is determined by subtracting the amount of ligand bound in the presence of unlabeled competitor from the amount of ligand bound in the absence of competitor.

This means that the actual data collected from an experiment consist of two binding plots, a *total binding* curve measuring binding at several ligand concentrations in the absence of competitor and a *nonspecific binding* curve determined in the presence of competitor. The *specific binding* curve is simply the difference between these two. It is important to note that specific binding in radioligand experiments is not a directly determined value, but a derived one.

Possessing both a method to determine specific binding and a theoretical relationship to describe it (Equation 5.3), it should be possible to fit data to the relationship. By measuring the amount of receptor occupied at several different free ligand concentrations, the values of R_T and K_D can be determined. First, it is necessary to determine whether sufficient data have been collected to perform a proper binding analysis. The data should include several points at concentrations of free ligand above the K_D. This can be assessed visually by plotting specific binding vs. free ligand concentration on a semilog plot but not with a linear scale of free ligand, which can be misleading (Munson and Rodbard, 1983). Figure 5.3 shows two plots of the same idealized specific binding curve. The data on the left are plotted with a linear *x*-axis and seem to indicate that the last few points are beyond the inflection point (i.e., K_D) of the curve and that a saturating ligand concentration is being approached; however, the semilog plot on the right reveals that the inflection point has not been reached, and R_T and K_D (hereafter collectively called the *binding constants*) cannot be estimated properly. The experiment must be repeated with additional treatments using higher concentrations of ligand.

When sufficient data have been collected, the binding constants can be determined. The classic method for estimating these values, and one still in use, is the Scatchard plot (Scatchard, 1949). Because Equation

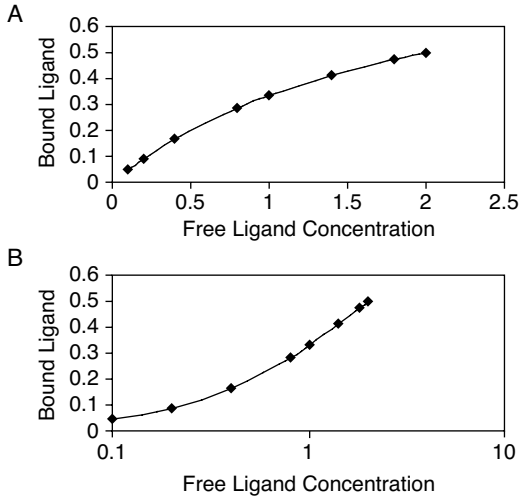

FIGURE 5.3 Achieving saturating concentrations of labeled ligand. The same values of ligand bound to receptor are represented in linear (A) and semilog (B) plots of ligand concentration. Although the receptor appears to be nearly saturated in A, the semilog plot shows that that insufficient data have been collected.

5.3 describes a nonlinear function of ligand concentration, a transformation that yields a linear relationship would be both visually satisfying and simpler to fit. By cross-multiplying the terms of Equation 5.6 and dividing throughout by [L]*K_D, such a linear relationship is established:

$$\frac{[LR]}{[L]} = -\frac{[LR]}{K_D} + \frac{[R_T]}{K_D} \tag{5.4}$$

A plot of bound ligand (or receptor) concentration divided by free ligand concentration on the *y*-axis and bound ligand concentration on the *x*-axis yields a line with a slope of $-1/K_D$ and an *x*-intercept of R_T (Figure 5.4). An obviously nonlinear relationship for data plotted in this fashion is a sign that one of the assumptions listed for Equation 5.3 is false.

Although the Scatchard plot is a useful tool for visually assessing the nature of the binding interaction and easily computing R_T and K_D, it does have its drawbacks. The transformation necessary to achieve the linear relationship includes both independent (ligand concentration) and dependent (binding) variables in the *y*-axis; therefore, data points from different ligand concentrations are weighted unequally, with points at higher ligand concentrations receiving greater relative weight in the determination of the binding constants. This typically leads to overestimation of both R_T and K_D.

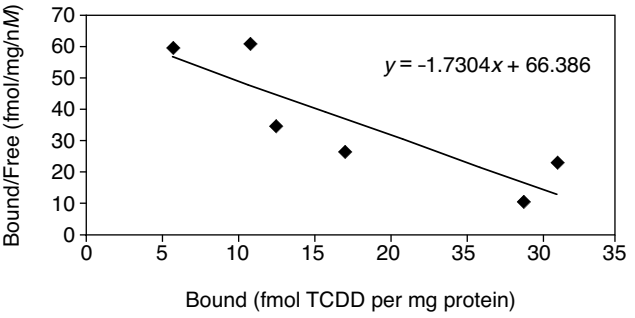

FIGURE 5.4 Scatchard plot of ligand binding. The linear fit of binding data is shown, producing estimates of 0.58 n*M* for K_D and 38 fmol TCDD per mg protein for R_T.

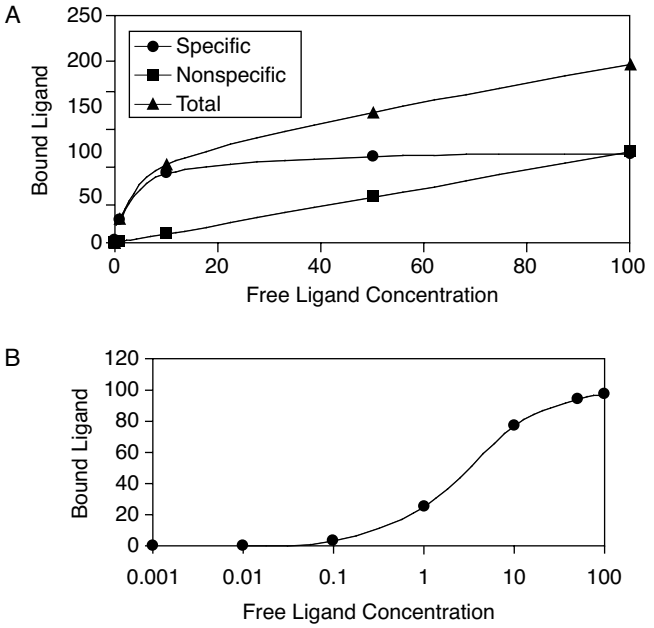

FIGURE 5.5 Idealized ligand binding data. (A) A typical plot of concentration-dependent total and nonspecific binding. Specific binding is calculated as the difference between total binding and nonspecific binding. (B) Specific binding from A is shown on a semilog plot to demonstrate that saturating concentrations of ligand are being approached.

Using computer software for performing nonlinear curve fits, it is possible to fit data directly to the Langmuir isotherm (Equation 5.3) without transformation. This produces more accurate estimates of the binding constants. The specific binding values are not measured directly, however, so this approach is still somewhat removed from the ideal of determining binding directly from measured quantities.

Nonspecific binding is by definition unsaturable within the range of ligand concentrations used, and it typically increases as a linear function of ligand concentration:

$$NSB = m[L] \tag{5.5}$$

where NSB is nonspecific binding and m is the slope of the line fit to the data. Total binding (TB) should simply be the sum of the specific and nonspecific binding:

$$TB = \frac{[L][R_T]}{[L] + K_D} + m[L] \tag{5.6}$$

Therefore, the data collected for the total binding curve can be fit to Equation 5.6 to determine the binding constants and the slope of the nonspecific binding line. Theoretically, even more accurate estimates of the binding constants can be achieved by simultaneously fitting the total binding data to Equation 5.6 and the nonspecific binding data to Equation 5.5. Idealized data showing the typical relationship among total, specific, and nonspecific binding are shown in Figure 5.5.

The method used to fit the binding data is critical when data are of relatively poor quality, which may be due to factors beyond the experimenter's control (e.g., unstable receptor or ligand, difficult tissue preparations). When the collected data closely fit Equations 5.3, 5.5, and 5.6, the binding constants estimated by the different methods are nearly identical. This is illustrated in Figure 5.6, where the data in panel A were collected from binding of [^{3}H]-2,3,7,8-tetrachlorodibenzo-*p*-dioxin ([^{3}H]-TCDD) to hepatoma cells from the fish *Poeciliopsis lucida* (PLHC-1), which have a relatively unstable aryl hydrocarbon receptor; the data in panel B were collected using the same technique from dolphin kidney cells (CDKs), which have a relatively stable receptor. Fitting the data to Equations 5.3, 5.4, or 5.5 and 5.6 (simultaneously)

Downloaded From Vet-eBooks.com

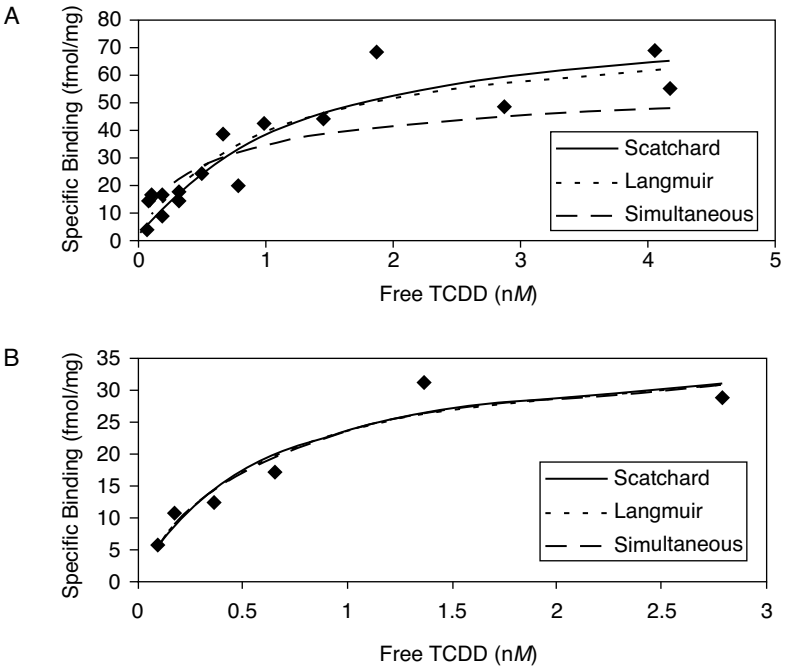

FIGURE 5.6 Effect of data quality on curve fits. Specific binding of [^{3}H]-TCDD was measured in PLHC-1 fish hepatoma cells (A) and CDK dolphin kidney cells (B), and the data were fit using the Scatchard method (Equation 5.7), directly fit to the Langmuir binding isotherm (Equation 5.6), or by simultaneous fitting of the total and nonspecific binding data (Equations 5.9 and 5.10). Binding curves predicted using the constants determined from the fits (Table 5.2) are plotted. The CDK cells were generously provided by Dr. Michael Carvan, and the data are shown with his permission.

yielded quite different estimates of K_D and R_T for PLHC-1 cells but nearly identical estimates for CDK cells (Table 5.2). Notice that as the theoretical appropriateness of the fits increases (moving down the table), the K_D and R_T decrease. Overestimation of the R_T is common when a few points with higher specific binding skew the fit, as the two points near 70 fmol/mg of specific binding do for the PLHC-1 data.

Efficacy

Interaction with a ligand is only the first step in the physiological role of the receptor. Ligand binding leads to a change in protein conformation that may activate the receptor (often referred to as receptor *activation* or receptor *transformation*). Depending on the specific receptor involved, activation may involve enzyme (e.g., protein kinase) or transport (e.g., ion channel) activity by the receptor protein itself, interaction with DNA response elements, or (most frequently) interaction with other proteins that help transduce the receptor signal. The structure of the ligand–receptor complex will vary depending on

Downloaded From Vet-eBooks.com

the ligand bound, which produces differences in the activity of the receptor. The relative ability of the ligand–receptor complex to produce a downstream response is termed *efficacy*.

Measurement of efficacy is complicated by the fact that it depends not only on the ligand and receptor but also on the presence of other factors in the cell; for example, the same ligand for a G-protein-coupled receptor may produce varying responses in different tissues depending on the identity and concentration of G proteins present. Even within a single tissue type, efficacy varies among responses. Perhaps the best-studied example of differential efficacy among tissues and responses is the effects of the hormone estrogen and synthetic estrogen receptor ligands, termed *selective estrogen receptor modulators* (SERMs), which recapitulate different subsets of estrogenic responses (MacGregor and Jordan, 1998). The mechanism of differential efficacy has been established for the SERM tamoxifen, which induces a receptor conformation that does not facilitate interaction with transcriptional coactivator proteins (Shiau et al., 1998).

The response produced by the ligand also varies among cell types due to differences in receptor concentration. Some cells may possess receptor reserve (i.e., "spare" receptors), such that only a fraction of the receptors must be occupied to produce a maximal response, while other cells contain just sufficient receptors to produce a maximal response, and others so few that a maximal response is never produced, regardless of ligand concentration.

All of these factors contribute to the observed efficacy of a ligand, which is determined by dose–response studies. Ligands can be classified based on the responses they produce as full agonists (which produce the maximal response possible), partial agonists (which produce a less-than-maximal response, even at high ligand concentrations), and antagonists (which interact with the receptor but produce no response). Because of tissue-specific differences in the concentration of receptors and other necessary factors, the same ligand could be a full agonist in one tissue, a partial agonist in another, and an antagonist in a third. Also, partial agonists can vary widely in the amount of response they produce. For these reasons, it can be useful to compare a set of ligands in terms of their relative efficacies rather than applying conditional (i.e., tissue-dependent) labels such as "full agonist" or "partial agonist."

Several models have been advanced to describe the contribution of efficacy to response. The operational model of Black and Leff (1983) has the advantage of representing efficacy in a single term, K_E, analogous to the representation of affinity with K_D. The operational model assumes a hyperbolic relationship between the amount of ligand-occupied receptor and response:

$$\frac{E}{E_{max}} = \frac{[LR]}{[LR] + K_E} \tag{5.7}$$

where E and E_{max} are the response produced and maximal response. Substituting Equation 5.3 into Equation 5.7 produces:

$$\frac{E}{E_{max}} = \frac{[L]\left[R_T\right]}{K_D K_E + \left(\left[R_T\right] + K_E\right)[L]} \tag{5.8}$$

If the binding affinity of the ligand and the concentration of receptors is known for the system, K_E can be determined by fitting dose–response data to Equation 5.8. Equation 5.8 can be solved for the conditions when response is half maximal (i.e., the EC_{50} for the system and ligand):

$$EC_{50} = \frac{K_D}{1 + \left(\left[R_T\right]/K_E\right)} \tag{5.9}$$

It is important to note that K_E depends both on the properties of the ligand–receptor complex and on properties of the tissue; however, if response is measured for a series of compounds in a single cell type, then differences among K_E values are due solely to the interaction of the ligand and receptor (Hestermann et al., 2000). Also, K_E is a useful value because it carries the same units as $[R_T]$, so $K_E/[R_T]$ is the fraction of receptors that must be occupied for a half-maximal response, giving a ready estimate of receptor reserve.

Downloaded From Vet-eBooks.com

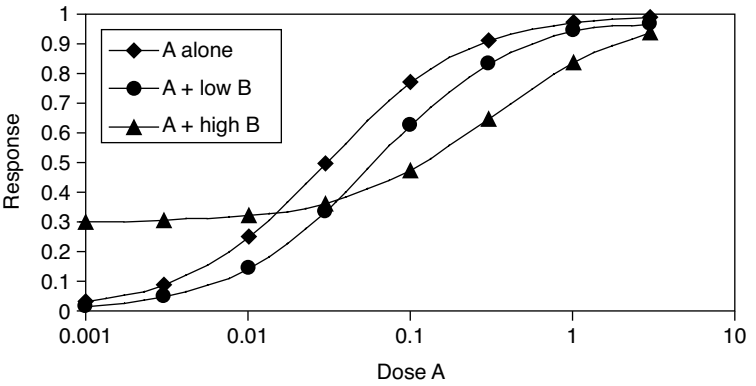

FIGURE 5.7 Effect of a low-efficacy ligand on the dose–response relationship for a high-efficacy ligand. Dose–response curves are shown for ligand A alone or with ligand B. The amount of ligand B added is the same at all doses of A within a single curve. At a low concentration of B, B alone evokes no response but antagonizes the action of A. At a higher concentration of B, B alone produces a small response and further antagonizes the action of A.

Equations 5.8 and 5.9 make clear that response depends on the concentrations of ligand and receptor as well as the affinity and efficacy constants. This takes us back to the concept expressed in Figure 5.2, that the ability of a compound to produce a response depends both on affinity and efficacy. If several compounds vary in their EC_{50} values for a response mediated by the same receptor, it is impossible to know without further information whether the compounds vary in their affinity or efficacy, or both.

Ligand-binding experiments are typically more difficult to perform than dose–response studies. Fortunately, it is possible to determine the relative efficacies of two ligands without knowing their receptor binding affinities by treating with combinations of the two. If ligand B has significantly lower efficacy than ligand A, then in combination ligand B would be expected to reduce the effect of ligand A (because it is occupying receptors without activating them). Sample data from this type of experiment are shown in Figure 5.7. A low dose of B, insufficient to elicit a response on its own, nevertheless occupies receptors, thereby requiring more A to produce a response and shifting the dose–response curve to the right. At a higher dose of B, the compound can cause a response on its own, but it also produces a greater inhibition of the response to compound A. If A and B had similar efficacies, the doses would produce additive effects, and adding B would not shift the dose–response curve to the right.

This example illustrates the importance of understanding efficacy for effective toxicological risk assessment. Because chemicals usually occur in the environment in complex mixtures, the presence of low-efficacy ligands can actually reduce the risk associated with high-efficacy ligands. Measuring the toxicity of these ligands separately and then summing to estimate the toxicity of the mixture will result in overestimation of the potential toxicity (Walker et al., 1996; Zabel et al., 1995). Thus, mixtures including low-efficacy ligands will violate the additivity assumption in the toxic equivalency factor approach (see Chapter 21). An example of the application of these principles concerning ligand affinity and efficacy and their application in the context of fish toxicology can be found in Hestermann et al. (2000).

A special case in which the concepts of affinity, efficacy, and potency are relevant to assessing the risk of mixtures involves the situation in which each of the individual compounds in the mixture is present at a concentration less than that which causes a significant biological effect on its own. Under what conditions might one expect to see a response ("something from nothing") from such a mixture (Silva et al., 2002)? The concept of concentration addition has been used to predict the effects of such mixtures (Brian et al., 2005; Thorpe et al., 2006). Clearly, however, the response will be influenced by differences in the relative intrinsic efficacies of the compounds. Understanding the interactions of compounds with different intrinsic efficacies remains incomplete; this is an important area of ongoing research.

Ligand–Receptor Interactions and Receptor Function: Approaches and Methods

The theoretical principles presented in the preceding section provide a foundation for considering practical aspects of assessing receptor function in fishes. To understand the role of receptors in mechanisms of toxicity, it is necessary to determine: (1) the biochemical characteristics of the receptors themselves; (2) the levels, location, and timing of their expression; (3) their interaction with other proteins and DNA; and (4) the genes or processes they regulate. A variety of experimental approaches and techniques that were developed originally for use in mammalian systems also have utility in fish. Often, however, modifications are required to account for physiological and other differences between fish and mammals (e.g., poikilothermy vs. endothermy). In addition, some methods are especially suited for fish, such as those that take advantage of the externally developing, transparent embryos. In this section, we summarize a few of the key approaches and techniques that are used to investigate receptor-mediated mechanisms of toxicity in fish, with examples from the well-studied AhR system.

Ligand-Binding Assays

The objective of investigating ligand–receptor interactions is to determine the physicochemical constants that govern those interactions—principally, ligand-specific kinetic constants such as on and off rates (association and dissociation rate constants), the equilibrium dissociation constant (K_D, a measure of binding affinity), and binding capacity (R_T, also called B_{max}). The theoretical aspects of these ligand–receptor interactions have been described earlier. To perform ligand-binding assays, one needs a ligand labeled with a radioactive or fluorescent tag, a method to separate ligand free in solution from that bound to proteins, and—because pure preparations of receptor are rarely available—a way to distinguish binding of ligand to the receptor (specific binding) from its binding to other proteins (nonspecific binding). Tritium ([^{3}H])-labeled or [^{125}I]-labeled ligands are commonly used, whereas [^{14}C]-labeled compounds usually do not have sufficiently high specific activity for binding assays.

Among the several ways to separate bound from free ligand is a classical method that uses *dextran-coated charcoal* (Poland et al., 1976); the charcoal adsorbs free ligand while the dextran coating minimizes the effect of charcoal on the proteins. The amount of charcoal must be determined empirically, and for some receptors species-specific sensitivity to charcoal complicates the use of this technique (Manchester et al., 1987; Nakai and Bunce, 1995). Rather than adsorb free ligand with charcoal, other methods use *hydroxylapatite* (HAP) (Gasiewicz and Neal, 1982) or *protamine sulfate* (Denison et al., 1984) to adsorb the proteins so free ligand can be washed away. Similarly, *filter-binding assays* collect solvent-aggregated proteins on glass-fiber membranes and remove free ligand by several washes (Dold and Greenlee, 1990). The latter can be performed either with cytosols prepared by differential centrifugation or with whole cells that have been incubated with radioligand. Another classical method involves *velocity sedimentation* on sucrose gradients (Okey et al., 1979; Tsui and Okey, 1981), which separates ligand–receptor complexes based on their sedimentation coefficient; the latter is a function of the size and shape of the protein complexes. Two types of centrifuge rotors can be used for this technique. Swinging-bucket rotors allow separation along the length of the centrifuge tube but require long spins (typically >18 hours). Vertical tube rotors permit much shorter spins (~2 hours) and thus facilitate analysis of labile ligand–receptor interactions (Tsui and Okey, 1981). Finally, free and bound ligand can be separated by denaturing gel electrophoresis, but only if the ligand has been covalently linked to the receptor—for example, through use of a *photoaffinity ligand* (Poland et al., 1986).

All of the approaches described above have been used to investigate fish AhRs (Hahn, 1998), as well as a variety of other receptors such as estrogen receptors (Hawkins and Thomas, 2004; Menuet et al., 2002), androgen receptors (Wells and Van Der Kraak, 2000), and retinoid receptors (Alsop et al., 2001). In some cases, multiple methods are used together to provide complementary information. Velocity sedimentation using vertical tube rotors (Figure 5.8A–D) has been useful because it is the gentlest procedure and provides ancillary information about receptor size; however, it is quite labor intensive and thus not suitable for large numbers of samples, such as are required for generating competitive

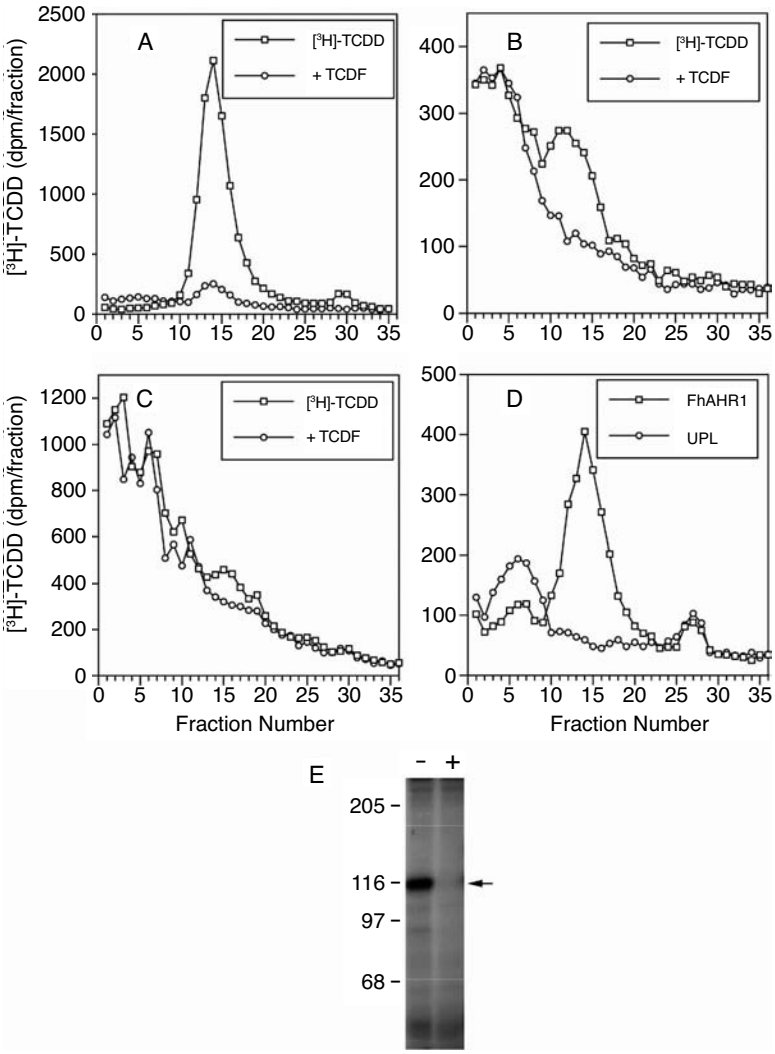

FIGURE 5.8 Data illustrating the specific binding of radioligands to AhR as measured using velocity sedimentation (A–D) and photoaffinity labeling (E). Specific binding of [^{3}H]-TCDD (~1 n*M*) to AhRs in cytosol from mouse Hepa-1 cells (A), cytosol from fish PLHC-1 cells (B), cytosol from killifish liver (C), and killifish AhR1 expressed from an AhR1 expression construct by *in vitro* transcription and translation using rabbit reticulocyte lysate (D). Samples were incubated with [^{3}H]-TCDD in the absence or presence of excess unlabeled TCDF (A–C) to determine total and nonspecific binding. In D, lysate lacking the AhR1 cDNA (unprogrammed lysate [UPL]) was used to determining nonspecific binding. (E) Photoaffinity labeling of AhRs in killifish hepatic cytosol using 2-azido-3-[^{125}I]iodo-7,8-dibromodibenzo-*p*-dioxin in the absence (–) or presence (+) of excess TCDF (for details, see Hahn et al., 1994). Numbers represent molecular weight standards. Data in C were generously provided by Dr. Susan M. Bello (Bello, 1999).

binding curves. Despite the gentleness of this procedure, specific binding of [^{3}H]-TCDD to fish AhRs in cell lysates or tissue cytosol is difficult to measure as compared to mammalian AhRs (Figure 5.8A–C). In contrast, expression of fish AhRs by *in vitro* transcription and translation from cloned cDNAs produces robust peaks of specific binding in velocity sedimentation assays (Figure 5.8D); thus, this procedure has been very useful for the initial characterization of cloned fish AhR cDNAs (Abnet et al., 1999a; Andreasen et al., 2002; Karchner et al., 1999, 2005). Photoaffinity labeling (Figure 5.8E) is very sensitive and provides an estimate of receptor molecular mass but cannot be used for determining binding constants. The batch assays, such as filter-binding, hydroxylapatite, and dextran-coated charcoal, are best for

Downloaded From Vet-eBooks.com

saturation binding analysis (see Figure 5.6); of these, the filter-binding assay has been most useful for studies of fish AhRs (Hestermann et al., 2000).

The assays described above are typically done using cell lysates or the soluble fraction of tissues or cells (cytosols); however, as noted above, they can also be performed on receptor proteins expressed from cloned cDNAs in bacteria, in mammalian cells, or by *in vitro* transcription and translation. An advantage of expression from cloned cDNAs is the ability to perform parallel assays in the same system but in the absence of receptor (Figure 5.8D); this provides a much more realistic assessment of nonspecific binding than that obtained by using an excess of unlabeled ligand.

Cell Culture

Cultured cells have shown great utility in characterizing receptors and receptor-dependent processes in fish, as they have in mammals. Fish cells or cell lines have been used for the direct assessment of ligand–receptor binding interactions (Hestermann et al., 2000; Lorenzen and Okey, 1990; Pollenz and Necela, 1998; Swanson and Perdew, 1991), for assessing reporter gene activation by ligand-activated transcription factors (Carvan et al., 2000), and for determining relative potencies of chemicals acting through receptor-dependent mechanisms by measuring the expression of endogenous target genes such as CYP1A (AhRs) (Clemons et al., 1996; Henry et al., 2001) or vitellogenin (ERs) (Petit et al., 1997; Smeets et al., 1999). An alternative way to characterize fish receptors is to express them in heterologous systems, such as bacteria, yeast, or mammalian cells. Cloned receptor cDNAs are inserted into an appropriate expression vector (sometimes as a fusion protein) and then are used to transform bacteria or transfect mammalian cells. Receptors expressed in this way can be characterized by the ligand-binding methods described above, as well as by reporter gene assays in which the ability of the receptor to activate transcription is assessed in the presence of different ligands. One advantage of expressing receptors in heterologous cells is that it facilitates comparative studies by providing a common cellular background on which receptors from different species can be examined (see, for example, Abnet et al., 1999b; Matthews et al., 2000).

In Vivo Assays

One of the great advantages of using fish to study mechanisms of toxicity is the ability to carry out *in vivo* experiments to assess receptor functions, especially those involved in developmental toxicity. Two of the most powerful approaches involve: (1) targeted gene knock-down to reduce or eliminate specific gene products, and (2) gene expression or overexpression by transgenesis. Currently, these are used primarily in zebrafish and other small fish models, although their use is expanding to other species as well.

Gene Knock-Down

The ability to perform targeted inactivation of mouse genes by homologous recombination (gene knock-out) has been a valuable tool in toxicological research, permitting an assessment of gene function through observation of the phenotype of animals lacking specific gene products. Gene knock-outs are not yet possible in fish. Analogous to gene knock-out, but with key differences, an anti-sense approach using morpholino-modified oligonucleotides (MOs) has been developed for producing targeted gene knock-downs in developing zebrafish (Anon., 2000; Ekker, 2004; Nasevicius and Ekker, 2000; Sumanas and Larson, 2002). Morpholino-modified oligonucleotides inhibit protein synthesis either by blocking the translational start sites of mature mRNAs (Figure 5.9A) or by altering pre-mRNA splicing (Figure 5.9B). MOs targeted to the 5′-UTR inhibit translation of maternal and zygotic transcripts by binding to mRNA between the 5′ cap and the start codon (Ekker and Larson, 2001; Summerton, 1999; Summerton and Weller, 1997); MOs targeted to exon–intron splice sites block the processing of zygotic (but not maternal) RNA (Draper et al., 2001; Ekker and Larson, 2001). By targeting the splice donor or splice acceptor site (or both), one can obtain mis-spliced mRNAs that have skipped exons or retained introns or reveal cryptic splice sites. If these modified splice products cause a frameshift or deletion of a critical part of the encoded protein, the product is inactive and the embryos are deficient for this protein. Incorrectly

Downloaded From Vet-eBooks.com

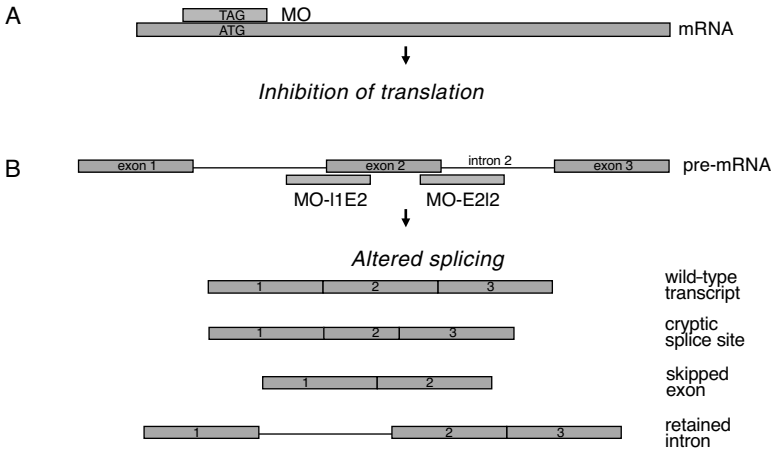

FIGURE 5.9 Two mechanisms of gene knock-down by morpholino oligonucleotides (MOs). (A) Inhibition of mRNA by MO targeted to translational start site. (B) Inhibition of pre-mRNA splicing by MOs targeted to splice donor or splice acceptor sites. For details, see text and Draper et al. (2001), Ekker (2004), and Nasevicius and Ekker (2000). (A color version of this figure is available from the first author [mhahn@whoi.edu] upon request.)

spliced transcripts can also be targeted for rapid degradation prior to translation (nonsense-mediated decay) (Baker and Parker, 2004).

Morpholino-modified oligonucleotides are injected at the one- to eight-cell stage and are distributed and retained in all cells (Ekker and Larson, 2001). They eliminate or greatly reduce the expression of the targeted protein, as indicated by expression analysis and by the fact that the phenotype of injected embryos (*morphants*) (Ekker, 2000) is in most cases indistinguishable from that of zebrafish null mutants at that locus (Lele et al., 2001; Nasevicius and Ekker, 2000) or mice bearing a null allele at the orthologous locus (Topczewska et al., 2001). MO-treated zebrafish have been shown to replicate several human genetic diseases (Nasevicius and Ekker, 2000). MOs function through at least the first 48 to 96 hours of zebrafish development, during which somitogenesis and organogenesis occur, and knock-downs lasting longer have been reported (Nasevicius and Ekker, 2000). Although used primarily in zebrafish, MOs have also been used successfully in other fish, including trout (Boonanuntanasarn et al., 2002) and lamprey (McCauley and Bronner-Fraser, 2006). The morpholino approach is proving extremely useful for identifying gene function during development, and it can be accomplished more quickly and with less cost than targeted disruption of murine loci. Similarly, gene knock-downs are finding application in developmental toxicology (Carney et al., 2004; Incardona et al., 2005, 2006; Linney et al., 2004b; Prasch et al., 2003). For example, studies using MOs have shown that AhR2 but not AhR1A and ARNT1 but not ARNT2 are required for TCDD developmental toxicity in zebrafish (Prasch et al., 2003, 2004, 2006).

Another approach for gene targeting in zebrafish is target-selected inactivation, in which zebrafish generated using mutagenized sperm are screened for point mutations that result in null alleles at specific loci. In contrast to mouse knock-outs, in which genes are targeted for homologous recombination, target-selected inactivation involves random mutagenesis followed by screening a large number of individuals for the desired mutation. The screening process is accomplished by high-throughput resequencing or by a method known as *TILLING* (Amsterdam and Hopkins, 2006; Wienholds et al., 2002, 2003) that facilitates the identification of mutated alleles. Although the use of target-selected inactivation in toxicological research has not yet been reported, this method holds great promise as a complement to MO-based knock-down approaches.

Gene knock-outs in zebrafish also have been generated by insertional mutagenesis, in which a retrovirus is used to disrupt genes at random (Amsterdam et al., 1999). The mutated gene is easily identified using viral sequences as probes. A good example of how such mutants might be used was provided by recent studies. By taking advantage of an ARNT2 mutant that was one of many mutants generated by random insertional mutagenesis (Golling et al., 2002), Prasch et al. (2004) were able to establish that ARNT2 is not required for the developmental toxicity of TCDD in zebrafish.

Downloaded From Vet-eBooks.com

Transgenics

Transgenic technologies are well developed in zebrafish (Udvadia and Linney, 2003) and well suited for studying receptor-mediated mechanisms of toxicity. Transient and stable (germline) expression of transgenes can be used to screen for chemical effects on gene expression (Blechinger et al., 2002; Perz-Edwards et al., 2001), test promoter function (Jessen et al., 1998; Long et al., 1997), and map regulatory elements (Barton et al., 2001; Meng et al., 1997, 1999), all *in vivo*. Heterologous promoters and proteins have been shown to function faithfully in zebrafish, recapitulating native expression patterns (Barton et al., 2001) or rescuing mutant phenotypes (Porcher et al., 1999). The coupling of green fluorescent protein (GFP)-based reporters (Amsterdam et al., 1995; Finley et al., 2001; Gibbs and Schmale, 2000) and transparent zebrafish embryos provides a powerful system for visualizing *in vivo* gene expression. Transgenic fish also can be used to investigate gene function by assessing the phenotype of fish in which specific proteins have been overexpressed through injection of mRNA or DNA. Such gain-of-function experiments provide a valuable complement to loss-of-function approaches such as MO-based gene knock-downs (Malicki et al., 2002). One advantage of overexpression is its flexibility to test the function of heterologous proteins (i.e., from other species) and the ability to test the effect of specific mutations on protein function. Gain-of-function experiments have been used to examine the effects of overexpressing hypoxia-inducible factor-1α (HIF-1α) (Kajimura et al., 2006), estrogen receptor-related receptor α (ERRα) (Bardet et al., 2005), CYP26D1 (Gu et al., 2006), and ARNT2X (Hsu et al., 2001).

Chromatin Immunoprecipitation

Chromatin immunoprecipitation (ChIP) has found widespread utility as a method for measuring the ability of receptors, other transcription factors, and associated protein complexes (including coactivators and chromatin-modifying enzymes) to occupy gene promoter and enhancer sequences *in vivo*. ChIP is replacing gel mobility shift assays as the preferred method for measuring protein–DNA interactions. ChIP has been applied most widely in mammalian cell culture, but it also has been used with fish cells (Dann et al., 2004; Hirayama et al., 2005) and embryos (Havis et al., 2006).

Genomics and Gene Expression Profiling

The emergence of genome-scale approaches and techniques has provided new opportunities for progress in a variety of fields, including comparative toxicology. Genomic approaches can be classified in a variety of ways; one useful distinction is between structural genomics and functional genomics, which provide distinct yet complementary information of relevance to mechanistic toxicology.

Structural Genomics

Structural genomics concerns gene sequences (coding and noncoding), gene structure, and gene organization—information that is usually obtained through whole-genome sequencing efforts. Genome sequences permit the description of the complete set of genes in a particular gene family, illuminating phylogenetic aspects of gene family diversity and providing information to help distinguish orthologous and paralogous genes among species. As an example, the genome sequences of the pufferfish *Takifugu rubripes* (Aparicio et al., 2002) and *Tetraodon nigroviridis* (Jaillon et al., 2004) have been useful in defining the complete sets of cytochrome P450s (Nelson, 2003) and nuclear receptors (Maglich et al., 2003) in fishes. The identification of several AhR genes in the *Fugu* genome helped resolve the orthologous and paralogous relationships between fish AhR1 and AhR2 forms (Karchner and Hahn, 2004; Karchner et al., 2005). In addition, sequenced genomes allow the identification of conserved noncoding sequences involved in regulating gene expression (Dickmeis et al., 2004). This latter approach has not yet been widely applied in fish toxicology but has great potential for understanding the regulation of toxicologically important genes.

Functional Genomics and Proteomics

The term *functional genomics* refers primarily to genome-scale assessment of gene and protein expression and interactions. There are several approaches for this; each has its own advantages and disadvantages.

Downloaded From Vet-eBooks.com

A detailed description of these can be found elsewhere (Ankley et al., 2006; Cossins and Crawford, 2005; Denslow et al., 2005; Ju et al., 2007; Larkin et al., 2003b); here, we briefly describe some of these approaches and discuss their application to fish toxicology.

Several polymerase chain reaction (PCR)-based methods are available to assess differential gene expression—for example, between control and chemically treated fish. Methods such as differential display PCR (ddPCR), suppressive subtractive hybridization (SSH), and representational difference analysis (RDA) are considered unbiased in that they involve no *a priori* selection of target genes and therefore can be used for gene discovery. These methods can identify genes that are either induced (upregulated) or repressed (downregulated), but all three have high rates of false positives; thus, genes identified as differentially expressed by these methods must be confirmed by more robust assays such as real-time reverse transcription PCR (RT-PCR). In some cases, genes identified by ddPCR, SSH, or RDA are used to construct a macroarray or microarray for subsequent use in evaluating gene expression in a larger number of samples (see below). Both ddPCR and SSH have been used to reveal differential gene expression in fish exposed to toxicants (Table 5.3).

Other methods for unbiased discovery of differentially expressed genes involve high-throughput analysis of transcript abundances in two different samples. Two powerful techniques are serial analysis of gene expression (SAGE) (Velculescu et al., 1995) and massively parallel signature sequencing (MPSS) (Brenner et al., 2000), both of which provide short sequence tags of 20 to 21 bp that are usually unique and can be mapped to genome sequences to determine the genes from which they came. Both SAGE and MPSS are quantitative in that tag abundances (the number of times each tag appears) are directly related to transcript abundances in the original samples. Although there is one report of SAGE applied to fish (Knoll-Gellida et al., 2006), neither SAGE nor MPSS has yet been used in the context of fish toxicology. In addition to SAGE and MPSS, the recently developed 454 parallel sequencing technology (Emrich et al., 2007; Margulies et al., 2005; Sogin et al., 2006) is likely to be even more powerful for transcriptional profiling in a variety of applications, including fish toxicology.

The first use of microarrays (DNA chips) in fish was by Gracey et al. (2001), who created custom cDNA microarrays to measure the transcriptional response of the goby (*Gillichthys mirabilis*) to hypoxia. Microarrays (cDNA and oligonucleotide) and macroarrays are now widely used in fish biology, including toxicology. Most of the available microarray resources are targeted to zebrafish (Handley-Goldstone et al., 2005; Linney et al., 2004a; Mathavan et al., 2005; Ton et al., 2002), salmonids (Rise et al., 2004; von Schalburg et al., 2005; Vuori et al., 2006), flounder (Williams et al., 2003), carp (Cossins et al., 2006; Gracey et al., 2004), or *Fundulus* (Oleksiak et al., 2001, 2002).

Several recent reports illustrate the power of microarray-based transcriptional profiling in fish to provide insight into mechanisms of toxicity or to identify candidate biomarkers of exposure or effect (Table 5.3). In one study, the mechanism of valproic acid (VPA) teratogenesis was investigated in zebrafish embryos. Gene expression profiles after VPA exposure were similar to those observed after exposure to inhibitors of histone deacetylase (HDAC), suggesting that HDAC inhibition plays a role in VPA teratogenesis (Gurvich et al., 2005). Several groups have used microarrays to investigate the effects of TCDD. Handley-Goldstone et al. (2005) found that CYP1A was the gene most strongly induced in whole zebrafish embryos exposed to TCDD early in development, confirming the dominance of this widely studied response to TCDD and other AhR agonists. More interestingly, these authors also measured altered expression of genes encoding components of cardiac muscle sarcomeres, including myosin and troponin T2; these changes suggest an explanation for cardiomyopathy seen in fish and other vertebrates (Handley-Goldstone et al., 2005). Altered gene expression has also been measured directly in hearts of larval zebrafish exposed to TCDD, demonstrating distinct responses in heart as compared to the rest of the larvae (Carney et al., 2006). Among the changes in cardiac gene expression occurring prior to signs of cardiovascular toxicity were increases in genes encoding xenobiotic-metabolizing enzymes (CYP1A, CYP1B1, CYP1C1, sulfotransferase) and those involved in cell signaling. Organ-specific changes in gene expression also were seen in medaka exposed to TCDD (Volz et al., 2005, 2006). Dramatic differences in the direction of change were seen between liver (changes dominated by induction) and testis (many genes repressed). This study also demonstrated how gene expression profiling can be fruitfully combined with histopathological analysis, an example of "phenotypic anchoring" of microarray data (see also Luo et al., 2005; Moggs, 2005; Moggs et al., 2004; Paules, 2003). Gene

Downloaded From Vet-eBooks.com

expression profiling has also provided clues to the mechanism by which TCDD inhibits fin regeneration in zebrafish. In addition to induction of genes encoding xenobiotic-metabolizing enzymes, regenerating fins of zebrafish exposed to TCDD displayed dramatically reduced expression of genes encoding extracellular matrix components and of *sox9b*, which may be an important regulator of the initial stages of regeneration (Andreasen et al., 2006). Together, these examples illustrate the emerging value of gene expression profiling in mechanistic toxicology.

In contrast to the rapidly increasing application of microarrays in fish toxicology, the use of proteomic techniques has lagged until recently (Bosworth et al., 2005; Denslow et al., 2005; Knoll-Gellida et al., 2006; Link et al., 2006a,b; Walker et al., 2007). As with DNA microarrays, proteomic studies have the power to illuminate mechanisms as well as to identify markers of exposure or effect in a way that complements RNA- and DNA-based methods. Proteomics and metabolomics also can be used to complement histopathological analyses, in a phenotypic anchoring approach that parallels that described above for microarrays (Stentiford et al., 2005; Ward et al., 2006).

The Aryl Hydrocarbon Receptor Signaling Pathway

Of all the receptors that are known as targets of environmental chemicals in fishes, two have been studied in greatest detail: aryl hydrocarbon receptors and estrogen receptors. Here, to illustrate the role of receptors in fish toxicology, we provide an overview of the AhR signaling pathway, AhR diversity, and studies demonstrating the mechanistic role of AhRs in the toxicity of planar halogenated aromatic hydrocarbons (PHAHs, or dioxin-like compounds) and polynuclear aromatic hydrocarbons (PAHs) in fishes. Additional details can be found in recent reviews of the AhR pathway in mammals (Ma, 2001; Nebert et al., 2004; Puga et al., 2005; Schmidt and Bradfield, 1996) and fishes (Hahn, 2002; Hahn et al., 2005, 2006a; Tanguay et al., 2003).

Much of what we know about the AhR and its associated signal transduction pathway has come from studies in mammalian systems—primarily murine and human cells and tissues. Although not as extensive, studies in fishes have shown that the essential features of AhR signaling in mammals are conserved (Pollenz and Necela, 1998; Pollenz et al., 2002; Wentworth et al., 2004). AhR proteins are localized primarily in the cytoplasm of cells, in association with Hsp90 and other proteins. Upon binding of ligands, AhR proteins are preferentially translocated to (or retained in) the nucleus, where they form dimers with AhR nuclear translocator (ARNT) proteins. The ligand–AhR–ARNT complex interacts with AhR response elements (AhREs; also known as XREs or DREs) to activate or repress gene expression from target genes. Diagrams of the AhR pathway can be found in recent publications (Hahn et al., 2005, 2006a).

Fish AhRs appear to have ligand structure–activity relationships similar (but not identical) to those of mammalian receptors, with high-affinity binding of TCDD, non-*ortho*-substituted PCBs, and some PAHs and lower affinity binding of other halogenated and nonhalogenated ligands such as indoles (Abnet et al., 1999b; Hestermann et al., 2000, unpublished results). Similarly, the AhR recognition sequence (AhRE) in fish is similar to that of mammals, as suggested by the ability of fish AhRs to recognize mammalian AhREs. Overlap also occurs in the identity of at least some AhR target genes in fish and mammals. CYP1A, CYP1B, and certain other genes encoding xenobiotic-metabolizing enzymes are inducible by TCDD in both groups (Stegeman and Hahn, 1994). Also inducible in mammals and fish is the AhR repressor (AhRR) gene, which encodes a repressor of AhR function (Evans et al., 2005; Karchner et al., 2002; Mimura et al., 1999; Roy et al., 2006).

Despite the mechanistic similarities, the piscine AhR pathway differs from that of mammals in some fundamental ways. One key distinction is in the number of AhR isoforms. Mammals have a single AhR, whereas most fish possess multiple (two to six) distinct AhR genes (Hahn, 2002; Hahn et al., 2006a). Phylogenetic analysis of teleost AhRs shows that there are two types, AhR1 and AhR2, which arose by a gene duplication occurring early in vertebrate evolution, prior to the divergence of fish and mammalian lineages (Hahn et al., 1997; Karchner et al., 1999). Fish AhR1 forms are orthologous (or co-orthologous) to mammalian AhRs, whereas AhR2 forms are found in fish (and birds) but not in mammals. Fish AhR1 and AhR2 have different tissue-specific patterns of expression, suggesting different functional roles. This

TABLE 5.3

Examples of Studies Investigating Differential Gene Expression in Fish Exposed Experimentally or Environmentally to Toxicants

Species and Stage	Toxicant or Comparison	Method (Number of Genes Represented)	Examples of Genes or Trends Identified	Refs.
Sheepshead minnows (*Cyprinodon variegatus*)	17β-Estradiol, 17α-ethynyl estradiol, diethylstilbestrol, methoxychlor, *p*-nonylphenol, endosulfan	ddPCR, macroarray (30–250)	Estrogens and xenoestrogens induce similar profile of altered gene expression; vitellogenin (+), choriogenin (+), zona radiata proteins (+), ERα (+), transferrin (–)	Knoebl et al. (2006), Larkin et al. (2003a)
Largemouth bass (*Micropterus salmoides*)	17β-Estradiol (E2), 4-nonylphenol (NP), 1,1-dichloro-2,2-*bis* (*p*-chlorophenyl) ethylene (*p*,*p*′-DDE)	ddPCR, macroarray (132)	E2 and NP cause similar but not identical gene expression profiles; *p*,*p*′-DDE causes sex-specific changes; vitellogenin (+), choriogenin (+), aspartic protease (+), transferrin (–)	Larkin et al. (2002, 2003c)
European flounder (*Platichthys flesus*) adults	Tyne estuary vs. Alde estuary	SSH, microarray (160)	CYP1A (+), UDPGT (+), elongation factor 1 (–)	Williams et al. (2003)
European flounder adults	Cadmium	SSH, microarray (500)	Induction of oxidative stress response; Cu/Zn SOD (+), thioredoxin (+), peroxiredoxin (+), GST (+), CYP1A (–)	Sheader et al. (2006)
Atlantic killifish (*Fundulus heteroclitus*) adults	Pyrene	SSH, ddPCR	CYP1A (+), retrotransposon (+), hepatocyte growth factor activator (+)	Roling et al. (2004)
Atlantic killifish adults	Anthracene	ddPCR, macroarray	CYP2N2 (+)	Peterson and Bain (2004)
Atlantic killifish adults	Chromium (III)	ddPCR	FABP (+), CYP2N2 (+)	Maples and Bain (2004)
Atlantic killifish juveniles	Arsenic	SSH, macroarray (96)	Myosin light chain (+), keratin II (+), tropomysin (+), parvalbumin (+)	Gonzalez et al. (2006)
Atlantic killifish adults	Elizabeth River, VA, vs. King's Creek, VA	ddPCR, macroarray	Factor XI (–), UDP-glucose pyrophosphorylase (–), complement components (–), glucose-6-phosphatase (+)	Meyer et al. (2005)

appears to be the case in zebrafish, in which AhR2 has been implicated as the form responsible for nearly all of the developmental toxicity of TCDD (see below). Thus, although in mammals the single AhR (AhR1 ortholog) is required for TCDD toxicity during development (Mimura et al., 1997), in zebrafish it is the AhR paralog (AhR2) that plays this role. Whether this is specific to zebrafish or is true generally in fish remains to be determined. In addition to AhR1 and AhR2, cartilaginous fishes possess a novel form of AhR designated AhR3 (Merson and Hahn, 2002). The functional characteristics of elasmobranch AhRs have not yet been established.

Some fish possess multiple forms of ARNT. Zebrafish share with mammals the presence of two ARNT genes—ARNT1 and ARNT2—and in both cases ARNT1 appears to be the toxicologically most relevant partner for AhR (Prasch et al., 2004, 2006; Sekine et al., 2006; Walisser et al., 2004). In other species of fish, only ARNT2 has been identified (Pollenz et al., 1996; Powell et al., 1999).

Recent studies using targeted knock-down of gene expression to study the toxicity of AhR ligands illustrate the power of the zebrafish model in mechanistic research. Using morpholino antisense oligonucleotides (MOs), AhR2 was shown to play a key role in the developmental toxicity of TCDD (Antkiewicz et al., 2006; Bello et al., 2004; Dong et al., 2004; Prasch et al., 2003; Teraoka et al., 2003) and in the ability of TCDD to inhibit fin regeneration (Mathew et al., 2006). The role of AhRs in the toxicity of PAHs and other nonhalogenated ligands is more complex, with both AhR2-dependent and AhR2-independent effects (Billiard et al., 2006; Incardona et al., 2004, 2005, 2006). MO-based knock-down has also helped illuminate the role of CYP1A in the toxicity of PHAHs and PAHs. Because CYP1A induction is the most well-known and most striking (in terms of magnitude) result of AhR activation, an important role for CYP1A in TCDD toxicity has been hypothesized, possibly involving the generation of reactive oxygen species (ROS) (Schlezinger et al., 1999; Teraoka et al., 2003); however, zebrafish embryos in which CYP1A expression and induction are prevented or reduced by injection of a CYP1A-MO are just as sensitive as uninjected fish to the developmental effects of TCDD (Carney et al., 2004). In contrast, CYP1A knock-down enhances the developmental toxicity of the PAH-like AhR agonist β-naphthoflavone (BNF) and PAH-containing mixtures (weathered crude oil) but provides partial protection against the toxicity of the PAH pyrene (Billiard et al., 2006; Incardona et al., 2005). CYP1A, then, appears to have a protective role with respect to some nonhalogenated compounds but is involved in the bioactivation of others.

The possible involvement of CYP induction in the toxicity of AhR ligands is complicated by the existence of other AhR-regulated CYP1 enzymes in fishes: CYP1B1, CYP1B2, CYP1C1, and CYP1C2 (Godard et al., 2005; Leaver and George, 2000; Wang et al., 2006). The role, if any, of these enzymes in PHAH and PAH toxicity has not yet been investigated.

Other Receptors and Ligand-Activated Transcription Factors

Aryl hydrocarbon receptors have been studied extensively in fishes and serve as an example of how receptors—and the genes they regulate—participate in mechanisms of toxicity and how this may be investigated using the approaches and tools available in fish biology. A variety of other receptors and other types of transcription factors activated by xenobiotics are also involved in fish toxicology (Table 5.1), although in many cases a molecular understanding is just beginning to emerge. We briefly mention a few of these other transcription factors and some key features with regard to their presence and function in fishes.

Nuclear Receptors

Aryl hydrocarbon receptors are not unique among receptors in displaying diversity among taxa. Other receptors that are targets of endocrine-disrupting compounds, such as estrogen receptors and other members of the nuclear receptor (NR) superfamily, exhibit such diversity (Baker, 2005; Bardet et al., 2002; Hawkins et al., 2000, 2005; Thornton, 2001). Although mammals possess two estrogen receptors (ERα and ERβ), fish possess an ERα and two ERβ forms (ERβa and ERβb), the result of the fish-specific genome duplication mentioned above (Hawkins et al., 2000; Menuet et al., 2002). Similarly, although mammals

Downloaded From Vet-eBooks.com

possess three estrogen receptor-related receptors (ERRs), fish possess up to six ERR genes (Bardet et al., 2004; Maglich et al., 2003; Tarrant et al., 2006). The role of nuclear steroid receptors in fish endocrine toxicology is detailed in Chapters 10 and 25. In addition, recent studies have identified membrane steroid receptors that are not related to the nuclear receptors but rather are G-protein-coupled receptors that mediate rapid nongenomic actions for estrogens, androgens, and progestins (Zhu et al., 2003a,b). These receptors, which may also be targets for environmental chemicals, are also described in Chapter 10.

Other nuclear receptors of importance in toxicology include the constitutive androstane receptor (CAR) and pregnane X receptor (PXR). The discovery of these receptors in mammals and their initial characterization in fishes have illuminated a long-standing mystery in toxicology. Early studies of CYP induction in mammals had suggested the existence of two types of responses: *3-MC type* and *PB type*, named after the model inducers 3-methylcholanthrene (3-MC) and phenobarbital (PB), which induce primarily CYP1A and CYP2B, respectively. Induction of CYP1A by 3-MC was well known to occur through the AhR, but the mechanism of PB-type induction remained elusive for many years. Interestingly, fish display 3-MC-type but not PB-type induction (Addison et al., 1987; Ankley et al., 1987; Elskus and Stegeman, 1989; Kleinow et al., 1990), but it was not known whether this was caused by lack of orthologous CYP2 genes or lack of the induction mechanism (reviewed in Stegeman and Hahn, 1994). Studies in mammals identified CAR as the transcription factor regulating CYP2 induction and PXR as the regulator of CYP3A induction (although some functional overlap occurs between the gene targets of these two receptors) (Handschin and Meyer, 2003). Searches of fish genome sequences and homology cloning efforts reveal that fish possess a homolog of mammalian PXR, but CAR appears to be absent (Maglich et al., 2003; Moore et al., 2002; Bainy and Stegeman, 2004). Evolutionary studies in a variety of vertebrates suggest that mammalian CAR and PXR arose by a gene duplication in the mammalian lineage (Handschin et al., 2004; Reschly and Krasowski, 2006); thus, nonmammalian PXR homologs are related to both PXR and CAR. The zebrafish PXR has been cloned; like other vertebrate PXRs, it has a broad ligand specificity, and it is activated by many of the known activators of mammalian PXRs (Bainy and Stegeman, 2004; Moore et al., 2002). Currently, the role of PXR in fish toxicology is not well understood beyond its probable function in regulating CYP3 expression. Recent studies have shown that several compounds, including some xenoestrogens, can induce PXR expression in fish (Bresolin et al., 2005; Meucci and Arukwe, 2006; Mortensen and Arukwe, 2006).

Peroxisome proliferator-activated receptors (PPARs) are nuclear receptors with a variety of roles in regulating lipid metabolism. PPARs have been studied extensively in mammalian systems; mammals have three PPAR isoforms that act as heterodimers with the retinoid X receptor (RXR). PPAR ligands include fatty acids (natural ligands), fibrate drugs, phthalate ester plasticizers, and herbicides (Grun and Blumberg, 2006; Peraza et al., 2006). Some fish species may possess additional PPAR forms as compared to mammals (Escriva et al., 2002; Hahn et al., 2005; Leaver et al., 2005; Maglich et al., 2003; Robinson-Rechavi et al., 2001). As compared to mammalian PPARs, fish PPARs have added complexity in terms of their diversity, expression patterns, and ligand specificity (M. J. Leaver, pers. commun.).

Corticosteroid receptors regulate responses to stress and salt balance, including seawater adaptation. Fish have two glucocorticoid receptors (GRs) and a mineralocorticoid receptor, whereas mammals have one of each (Bury et al., 2003; Greenwood et al., 2003; Maglich et al., 2003; Prunet et al., 2006; Stolte et al., 2006). Studies in mammals suggest that GR could be directly affected by xenobiotics (Johansson et al., 1998), but the role of fish GRs in mechanisms of toxicity is not well understood (Knudsen and Pottinger, 1999; Vijayan et al., 2005). Evidence in fish suggests interactions between GR signaling and other receptor-dependent signaling pathways, such as the AhR pathway (Celander et al., 1996, 1997; DeVault et al., 1989). For a detailed description of fish corticosteroid receptors as targets for xenobiotics, see Vijayan et al. (2005).

Other fish nuclear receptors also are potential targets for xenobiotics; these include thyroid hormone receptors (TRs), androgen receptors (ARs), and retinoid receptors (RXRs, RORs, RARs). Thyroid hormone receptors have important roles in metamorphosis and other developmental processes in fish (Power et al., 2001) and thus are likely to be important targets of contaminants, through direct or indirect mechanisms (Brown et al., 2004; Crane et al., 2005; Elsalini and Rohr, 2003; van der Ven et al., 2006). Retinoid and androgen receptors have also been examined as targets for environmental chemicals in fishes (Alsop et al., 2003; Hewitt et al., 2003; Makynen et al., 2000; Wells and Van Der Kraak, 2000).

Downloaded From Vet-eBooks.com

Neurotransmitter Receptors

Fish, like other vertebrates, possess a large variety of receptors for neurotransmitters such as GABA, glutamate, acetylcholine, and serotonin, as well as other receptors such as ryanodine receptors. All of these may be targets for environmental chemicals, as described in Chapters 9 and 20 and elsewhere (Baraban et al., 2005; Carr et al., 1999; Linney et al., 2004b; Stehr et al., 2006).

Olfactory Receptors

Another group of receptors that are potential targets for xenobiotic chemicals are the chemosensory receptors used by fish to detect small molecules (amino acids, steroids, fatty acids) in their aquatic environment. These receptors include the classical odorant receptors (Alioto and Ngai, 2005), vomeronasal receptors (Hashiguchi and Nishida, 2005), and the newly identified trace amine-associated receptors (TAARs) (Gloriam et al., 2005; Liberles and Buck, 2006). Odorant receptor gene expression changes during the parr–smolt transformation in Atlantic salmon (Dukes et al., 2004). These receptors have been suggested to be important in homing behavior, through imprinting on natal odor cues (Barinaga, 1999; Dittman et al., 1997; Nevitt et al., 1994); thus, interference with olfactory function in fishes could have long-term reproductive consequences. Few studies, however, have addressed the effect of toxicants on olfactory receptor function. One study showed that exposure of salmon to copper interfered with the neurophysiological response to natural odorants (Baldwin et al., 2003), illustrating the potential toxicological significance of the olfactory system.

Other Xenobiotic-Activated Transcription Factors

Other ligand-activated transcription factors play important roles in mechanisms of toxicity in fish. Some of these do not function as classically defined receptors, in that they do not exhibit high-affinity specific binding of ligands; rather, they are activated by other types of interactions with xenobiotics. One example of such transcription factors are those in the Cap'n'Collar basic leucine zipper (CnC-bZIP) family, including NRF2 (nuclear factor erythroid-derived-2 [NFE2]-related factor 2).* NRF2 and related proteins are activated by oxidative stress and upregulate the expression of genes that are part of the antioxidant response, including several phase II biotransformation enzymes (Nguyen et al., 2003).

Fish possess an antioxidant response that is similar, although not identical, to that of mammals, as described in Chapter 6 and elsewhere (Carvan et al., 2001; Hahn et al., 2005). A fish NRF2 ortholog has been identified and shown to regulate the induction of glutathione *S*-transferase π (GSTP), NQO1, and gamma-glutamylcysteine synthetase (γ-GCS) after exposure of zebrafish embryos and larvae to *tert*-butylhydroquinone (tBHQ) (Kobayashi et al., 2002; Suzuki et al., 2005); thus, the function and target genes of NRF2 appear to be conserved in mammals and fishes. As with many other transcription factors, however, the diversity of NRF2-like genes appears to be greater in fish than in mammals (Hahn et al., 2005). Understanding the different roles of these NRF genes in the response to xenobiotic exposure is an important goal of future research. Details concerning the mechanisms of response to oxidative stress can be found in Chapter 6.

Another example of a nonreceptor, ligand-activated transcription factor is the metal-responsive transcription factor (MTF-1). MTFs are zinc finger proteins that are activated (either directly or indirectly) by heavy metals such as Zn^{2+} and Cd^{2+}, and they regulate transcription through binding to metal-responsive elements (MREs) in the 5′-regulatory region of genes such as those encoding metallothioneins (MTs) (Giedroc et al., 2001; Samson and Gedamu, 1998). MTF-1 can also be activated by oxidative stress (Dalton et al., 1996). MTF-1 has been characterized in several fish species, and it appears to function similarly in fish and mammals (Auf der Maur et al., 1999; Chen et al., 2002; Dalton et al., 2000).

* NRF2 is also known as NFE2L2 (NFE2-like-2).

Conclusions and Future Directions

Our current understanding of receptor-mediated mechanisms of toxicity in fishes is only modest, but recent technical developments and the availability of genome-scale information have greatly accelerated the rate at which progress is being made. During the next 10 years, we anticipate substantial advances in our understanding of the impact of chemicals on fishes (fish as targets) as well as new mechanistic insights of more fundamental significance (fish as models). These advances are most likely to occur in the area of developmental toxicology, especially neurotoxicology, and will be facilitated by a more complete understanding of differences between mammals and fishes in the number and diversity of receptors that are targets for chemicals.

In the next few years, genome-scale profiling (functional genomics, proteomics, metabolomics) will contribute to the description of complex regulatory networks and an understanding of how they are perturbed by chemicals. These networks will include not only receptor-dependent signaling pathways, which we currently depict essentially as linear sequences of events, but also the various cross-talk and positive/negative feedback loops that are associated with them. Understanding such interactions will be essential to assessing risks to populations exposed to multiple toxicants and other environmental stressors.

With regard to receptor-dependent mechanisms of toxicity in fishes, many important questions remain; for example, what is the role of receptors in determining sensitivity to chemicals and in explaining species- and population-specific differences in susceptibility? What is the relative importance of differences in receptor diversity (number of paralogs), protein sequence, or receptor expression? What is the role of receptor polymorphisms in differential susceptibility observed among individuals and populations (Greytak and Callard, 2007; Hahn et al., 2004; Roy and Wirgin, 1997)? What are the target genes that are regulated by receptors, and which ones are directly involved in mechanisms of toxicity? These and many other questions will continue to provide interesting challenges and opportunities to researchers interested in understanding the impact of chemicals on fishes, whether for their own sake or as models for humans.

Acknowledgments

Preparation of this chapter was supported in part by National Institutes of Health grants R01ES006272, P42ES007381 (Superfund Basic Research Program at Boston University), R15CA115405, and P20RR016461 (South Carolina INBRE). We thank Dr. Susan Bello (Jackson Laboratories) and Dr. Michael Carvan (University of Wisconsin–Milwaukee) for permission to use unpublished data, and two anonymous reviewers for helpful suggestions.

Introduction

Mechanisms underlying the toxicity of numerous environmental pollutants are discussed throughout this book. The purpose of this chapter is to describe a particular set of phenomena that collectively comprise an important mechanism of chemical toxicity and cellular defense. These phenomena, referred to as *oxidative stress*, apply to a diverse array of chemicals and result in a diverse array of ultimate health outcomes. The study of oxidative stress broadly includes biological phenomena associated with the generation of reactive oxygen species (ROS), molecular systems designed to protect cells from ROS (often referred to as *antioxidant defense systems*), and the deleterious impacts of ROS. An excellent detailed monograph on this subject is Halliwell and Gutteridge (1999).

As in many areas of mechanistic toxicology, understanding of oxidative stress in fishes has lagged behind understanding in mammals and, indeed, has depended to a large degree on studies in other biological systems for the development of methodologies and concepts; however, the study of oxidative stress in fishes is currently an active area of investigation that is revealing a number of important similarities and differences with other organisms. Moreover, the multitude of chemicals entering freshwater and marine systems that can contribute to oxidative stress underlies the need for information on this phenomenon in fishes. In this chapter, we describe fundamental aspects of ROS chemistry and generation, antioxidant defense systems, cellular and organismal impacts, and specific mechanisms by which pollutants play roles in these processes. We also describe the current state of understanding of oxidative stress in fishes, including comparisons with other organisms.

Reactive Oxygen Species and Free Radicals

Oxygen (as dioxygen, O_2) currently accounts for about 21% of the Earth's atmosphere, and oxygen is the most abundant element in the planet's crust (at 54%); however, life first evolved under essentially anaerobic conditions, and O_2 is believed to have first appeared as a byproduct of photosynthesis by blue-green algae (cyanobacteria) beginning about 2.5 billion years ago (Harman, 1986). As atmospheric O_2 gradually rose over the ensuing millennia, several notable developments occurred:

1. Organisms remaining anaerobic either retreated to anaerobic microenvironments or perished due to the effects of O_2 such as oxidation of metabolic intermediates (such as thiols, iron, and pteridines), enzyme inhibition (such as occurs with nitrogenases), and effects of ROS generated during oxidations.
2. Aerobic organisms evolved that took advantage of the electron-accepting capacity of O_2. The energetic efficiency of O_2 as an electron acceptor over those employed by anaerobes (iron and sulfur, for example) enhanced the evolution of more advanced life forms (i.e., eukaryotic organisms). This switch required the concomitant development of mechanisms to protect these organisms from the toxic effects of O_2.
3. Ozone (O_3) levels in the atmosphere rose, giving organisms protection from intense solar ultraviolet radiation; this also enhanced eukaryotic evolution.

Downloaded From Vet-eBooks.com

Although the focus of this chapter is on toxicities associated with oxygen species, the critical role played by O_2 in shaping and promoting advanced life forms as we know them is of fundamental importance.

The primary basis for the toxicity of oxygen lies in its propensity to undergo electron transfers that yield reactive intermediates, here termed *ROS*. On the other hand, the ability of O_2 to accept electrons underlies its utility to aerobic organisms; for example, a key function of O_2 is to serve as the terminal electron acceptor in mitochondrial electron transport, which drives the production of high-energy adenosine triphosphate (ATP). In this process, O_2 is reduced to H_2O; this is a four-electron reductive process that proceeds sequentially through the one-, two-, and three-electron products. These univalent reductions of O_2 to water are shown in Equation 6.1 to Equation 6.4:

$$O_2 + e^- \rightarrow O_2^{\bullet -} \tag{6.1}$$

$$O_2^{\bullet -} + e^- \xrightarrow{2H^+} H_2O_2 \tag{6.2}$$

$$H_2O_2 + e^- \xrightarrow{H^+} \cdot OH + H_2O \tag{6.3}$$

$$\cdot OH + e^- \xrightarrow{H^+} H_2O \tag{6.4}$$

$$\text{Sum: } O_2 + 4e^- \rightarrow H_2O \tag{6.5}$$

The one-, two-, and three-electron products shown in Equations 6.1, 6.2, and 6.3, respectively, are the *superoxide anion radical*, *hydrogen peroxide*, and the *hydroxyl radical*, respectively. The two radical species are free radicals; as defined by Halliwell and Gutteridge (1999), a free radical "is any species capable of independent existence that contains one or more unpaired electrons." The existence of unpaired electrons tends to make free radicals reactive, although the range of reactivity among free radicals is extensive. $O_2^{\bullet -}$, for example, is relatively weakly reactive, while ·OH is extremely reactive and is among the most potentially deleterious compounds among radicals and ROS encountered in cells. Thus, ·OH reacts indiscriminately with cellular constituents such as membrane lipids, proteins, and DNA. Due to its reactivity, it has an *in vivo* lifetime measured in nanoseconds (Pryor, 1986). Interestingly, O_2 itself is by definition a free radical; it contains two unpaired electrons, each in a different π orbital and having parallel spins. This last feature impedes the ability of O_2 to act as an oxidant via accepting electron pairs from typical molecules containing electron pairs with opposite spins. If it were not for this spin restriction, O_2 would qualify as an extremely potent ROS, and aerobic life undoubtedly would have a very different nature.

Although H_2O_2 is not a radical, it is an important ROS. It is a weak reducing and oxidizing agent, which lends to its use as a safe disinfectant at high concentrations. Its uncharged nature permits it to cross cell membranes; however, its ability to serve as a precursor to ·OH at physiologically meaningful levels underlies its significance to cellular oxidative stress. This ability of H_2O_2 to generate ·OH via reaction with $O_2^{\bullet -}$ was first postulated by Haber and Weiss (1934), who proposed the following reaction:

$$O_2^{\bullet -} + H_2O_2 \rightarrow \cdot OH + OH^- + O_2 \tag{6.6}$$

Reaction 6.6 is termed the *Haber-Weiss reaction*, and reaction rates in aqueous solution, although thermodynamically favorable, are very low; however, as noted by Weiss in 1935 (Halliwell and Gutteridge, 1999), this reaction can be effectively catalyzed by transition metals such as iron, as shown in Equations 6.7 and 6.8:

$$Fe^{3+} + O_2^{\bullet -} \rightarrow Fe^{2+} + O_2 \tag{6.7}$$

$$Fe^{2+} + H_2O_2 \rightarrow \cdot OH + OH^- + Fe^{3+} \tag{6.8}$$

$$\text{Net: } O_2^{\bullet -} + H_2O_2 \rightarrow \cdot OH + OH^- + O_2 \tag{6.9}$$

Downloaded From Vet-eBooks.com

The net reaction, Equation 6.9, is the Haber-Weiss reaction. Equation 6.8 is referred to as the *Fenton reaction* (Walling, 1975). Other transition metals present in cells, particularly copper, also can participate in Fenton-like reactions. The abilities of iron and copper to participate in cellular ·OH generation, in addition to their roles as essential nutrients, may underlie the existence of proteins (such as ferritin for iron and ceruloplasmin and metallothionein for copper) that tightly regulate their cellular transport and fate.

In addition to these three O_2 reduction products, several other ROS and related chemicals can play important roles in oxidative stress. These include singlet oxygen, ozone, alkoxyl and peroxyl radicals, and reactive nitrogen species, such as nitric oxide and peroxynitrite (Halliwell and Gutteridge, 1999). Additionally, carbon- and sulfur-centered free radicals occur and affect cellular function. Singlet oxygen (commonly denoted as $^1O_2$) is an excited state of O_2 at 22.4 kcal above ground state. In this form, the outer π electrons are paired and in antiparallel spins; thus, $^1O_2$ is not a free radical, but the spin restriction of ground-state O_2 is removed, making $^1O_2$ more reactive than O_2. A major source of $^1O_2$ in the environment is through excitation of ultraviolet-absorbing chemicals, including many polycyclic aromatic hydrocarbons (PAHs). This phenomenon has important ramifications in aquatic toxicology and is discussed later in this chapter.

Ozone (O_3) also is not a free radical but is a much more powerful oxidizing agent than O_2. Ozone is produced in the stratosphere by the photodissociation of O_2 into oxygen atoms, which then react with O_2 to produce O_3. Tropospheric (ground-level) O_3 is produced by sunlight-enhanced reactions between nitric oxides and volatile organic compounds (VOCs); warmer temperatures and fossil-fuel combustion produce nitric oxides, which enhance this process. While stratospheric O_3 provides protection to organisms by reducing the solar ultraviolet radiation that reaches the Earth's surface, ground-level O_3 can be toxic, particularly to animal respiratory systems and plant photosynthesis.

Alkoxyl (RO·) and peroxyl (ROO·) radicals are potent oxidants that often arise in cells subsequent to ·OH attack of organic chemicals. Oftentimes, such attack initially produces carbon-based radicals, which under aerobic conditions react with O_2 to produce RO· and ROO·. This process underlies membrane lipid peroxidation, a hallmark cellular toxicity associated with ROS that is described below.

Although not the focus of this chapter, reactive nitrogen species (RNS) also play important roles in cellular physiology and toxicity and interact with ROS. Nitric oxide (NO·) is synthesized in many organisms by an enzyme group known as the *nitric oxide synthases* (NOSs); these enzymes catalyze the oxidation of arginine to produce NO· and citrulline (Muriel, 2000). Three forms of NOS have been identified in mammals, referred to as type 1, constitutive, or neuronal NOS (cNOS, nNOS); type 2 or inducible NOS (iNOS); and type 3 or endothelial NOS (eNOS). There is good evidence for conservation of genes coding NOSs in other organisms, including fishes (Cox et al., 2001).

NO· has been studied predominantly from the standpoint of the normal physiological roles it plays. These include acting as mediators of phagocytosis by macrophages and neutrophils and functioning as a neurotransmitter to relax smooth muscle and thereby produce vasodilation (Ignarro, 2002; Neumann et al., 2001; Toda and Okamura, 2003). NO· is not particularly reactive with nonradicals but is highly reactive with other radicals (Halliwell and Gutteridge, 1999). Toxicities associated with NO·, observed in some instances, are thought in large part to be due to its facile reaction with $O_2^{\bullet-}$. This reaction has at least two potentially deleterious consequences: (1) the loss of functional NO·, thereby interfering with vasodilation (and potentially leading to hypertension, for example), and (2) the production of peroxynitrite via the reaction:

$$O_2^{\bullet-} + NO\cdot \rightarrow ONOO^- \tag{6.10}$$

Peroxynitrite is a very powerful oxidizing species that can elicit cytotoxicity through several mechanisms, including those described below for ROS as well as by nitration of DNA bases and aromatic amino acids (Beckman and Koppenol, 1996).

Endogenous Cellular Sources of Reactive Oxygen Species

Before describing mechanisms by which chemical pollutants can generate ROS and enhance oxidative stress, it is important to discuss mechanisms by which these species arise normally. As alluded to earlier,

Downloaded From Vet-eBooks.com

the cellular generation of ROS is an unavoidable cost of aerobic life—the price exacted for making use of the energetic efficiency of O_2 as an electron acceptor.

Perhaps quantitatively the most important sources of ROS during normal cellular metabolism are the electron transport chains of mitochondria, the endoplasmic reticulum, and chloroplasts. Photosynthesis within chloroplasts poses unique problems for plants in terms of oxidative damage, which can be exacerbated by many common air pollutants (Hippeli and Ernstner, 1996). In animals, mitochondrial respiration is likely the most important source of ROS *in vivo*. It is estimated that under normal cellular levels of O_2 consumption, about 0.1% of the O_2 utilized by mitochondria forms $O_2^{\bullet-}$ (Beckman and Ames, 1998; Fridovich, 2004). Although the precise location of this leakage is not completely resolved and may depend on conditions, complex I and III constituents are often involved (Finkel and Holbrook, 2000; Turrens, 1997). Endoplasmic reticula (*microsomes* in subcellular fractions) are another important source of ROS production. Oxidative metabolism of endogenous compounds and xenobiotics by the cytochrome P450 enzyme systems that function in this fraction were discussed in detail in Chapter 4. As described, P450s catalyze oxidations by cleaving O_2, with one oxygen atom ultimately added to the substrate and the other ultimately giving rise to H_2O. In this process, two electrons provided by NADPH–P450 reductase or cytochrome b_5 are sequentially added to drive catalysis. This cycle can be uncoupled, resulting in the diversion of electrons to give rise to $O_2^{\bullet-}$ and H_2O_2 (Goeptar et al., 1995). Some xenobiotics can greatly enhance this uncoupling, as described later in this chapter.

Several oxidative enzymes can also generate ROS during catalysis, including xanthine oxidase, tryptophan dioxygenase, diamine oxidase, guanyl cyclase, and glucose oxidase (Fridovich, 1978; Halliwell and Gutteridge, 1999). Additionally, a number of molecules with key roles in cellular function can auto-oxidize in the presence of O_2, yielding $O_2^{\bullet-}$; these include glyceraldehyde, $FMNH_2$, $FADH_2$, epinephrine and norepinephrine, dopamine, tetrahydropteridines, and thiols such as cysteine (Halliwell and Gutteridge, 1999). These autoxidations are oftentimes substantially accelerated in the presence of transition metal ions such as iron and copper. The O_2-carrying proteins hemoglobin and myoglobin can also be sources of $O_2^{\bullet-}$ (Balagopalakrishna et al., 1996; Brantley et al., 1993). In these proteins, O_2 binding requires the reduced state of iron, Fe(II), in the heme group. Occasionally, oxygen will release as $O_2^{\bullet-}$ and concomitantly yield Fe(III) in the heme. These forms of hemoglobin and myoglobin are referred to as *methemoglobin* and *metmyoglobin*, respectively, and are unable to bind O_2. Approximately 3% of human hemoglobin is thought to undergo conversion to methemoglobin every day, suggesting a substantial basal flux of ROS in erythrocytes (Winterbourn, 1985). As discussed later, many chemicals can significantly increase methemoglobin formation.

In the context of oxidative stress, ROS are cast as bad actors, but it is important to note that ROS play positive roles as well. An important example of this is the production of ROS by neutrophils and macrophages by many vertebrates wherein ROS are employed in the phagocytic activity of these cells (Babior, 2000). Upon stimulation, these cells increase O_2 consumption up to 20 times resting levels; this phenomenon is referred to as the *respiratory burst*, a misnomer because it is unrelated to mitochondrial respiration. Stimulants for this burst include opsonized bacteria and zymosan (from yeast cell walls), bacterial peptides such as *N*-formylmethionylleucylphenylalanine (FMet-Leu-Phe), the lectin concanavalin A, and phorbol esters, such as phorbol myristate acetate (derived from oil of the seeds of *Croton tiglium*, a plant native to southeastern Asia). During the respiratory burst, NADPH provided by the pentose phosphate pathway is oxidized to NADP+ by NADPH oxidase, an enzyme complex associated with the plasma membrane (Henderson and Chappell, 1996); the two electrons abstracted from each NADPH are transferred to O_2, yielding $O_2^{\bullet-}$ as indicated in Equation 6.11:

$$\mathrm{NADPH} + 2\mathrm{O_2} \rightarrow \mathrm{NADP^+} + \mathrm{H^+} + 2\mathrm{O_2^{\bullet-}} \tag{6.11}$$

Because $O_2^{\bullet-}$ is not highly reactive in aqueous solution, it is considered unlikely that $O_2^{\bullet-}$ itself is the ultimate phagocytic agent employed by neutrophils and macrophages (Halliwell and Gutteridge, 1999); however, $O_2^{\bullet-}$ can readily react with itself and dismutate into hydrogen peroxide (Equation 6.12) or react with NO·, which is sometimes produced by these cells, to produce peroxynitrite (see Equation 6.10). Both products are bactericidal.

$$2\mathrm{O_2^{\bullet-}} + 2\mathrm{H^+} \rightarrow \mathrm{H_2O_2} + \mathrm{O_2} \tag{6.12}$$

Downloaded From Vet-eBooks.com

Additionally, H_2O_2 in the presence of iron within the bacterium may produce cytotoxic ·OH via the Fenton reaction (see Equation 6.8). The enzyme myeloperoxidase occurs in neutrophils but not macrophages (Hampton et al., 1998). This enzyme, first isolated from human pus, is a nonspecific heme-containing peroxidase that in the presence of H_2O_2 catalyzes the oxidation of chloride ion (Cl^-) to hypochlorous acid (HOCl), a potent bactericidal oxidant.

Although the generation of ROS by these phagocytic cells is generally beneficial (to the host organism, anyway!), chronic inflammation can produce damage in local tissues and can contribute to diseases associated with oxidative stress, including arthritis and some cancers.

Antioxidant Defenses

As described above, the generation of ROS is an inescapable part of aerobic life. To flourish, all aerobic organisms have evolved a diverse array of mechanisms to minimize impacts due to ROS, and healthy organisms generally can cope well with the normal flux of ROS associated with respiration, certain enzyme activities, autooxidations, phagocytosis, and so forth. These mechanisms include enzyme systems that act to remove ROS, low-molecular-weight compounds that directly scavenge ROS (in animals, some produced endogenously and others obtained from the diet), and proteins that act to sequester prooxidants, particularly iron and copper. A number of these mechanisms, particularly some antioxidant enzymes, have been highly conserved in the course of evolution. Among vertebrates, most mechanisms are very similar, with differences among phyla generally being more quantitative than qualitative in nature; thus, extensive research in this area with mammalian models has greatly informed work with fishes. The following discussion of antioxidant defenses is condensed from studies with various models; a later section describes fish-specific studies.

Antioxidant Enzyme Systems

Superoxide Dismutases

A superoxide dismutase (SOD) was first isolated from bovine blood by McCord and Fridovich (1969); since that time, several forms of this enzyme have been identified and characterized (Fridovich, 1995). These enzymes accelerate the dismutation of $O_2^{\bullet-}$ by accepting an electron from one $O_2^{\bullet-}$ and passing it to another, yielding the following net reaction:

$$O_2^{\bullet-} + O_2^{\bullet-} \rightarrow H_2O_2 + O_2 \tag{6.13}$$

The observations that practically all aerobic organisms contain SOD, that many organisms including vertebrates produce several distinct SOD proteins, and that these enzymes enhance a reaction that occurs rapidly nonenzymatically support the theory that $O_2^{\bullet-}$ plays an important role in oxidative stress, despite its low reactivity vs. some other ROS (notably, ·OH).

Vertebrates contain three distinct forms of SOD: copper/zinc (CuZnSOD), manganese (MnSOD), and extracellular (ECSOD). CuZnSOD occurs predominantly in the cytosol, with some present in lysosomes and the nucleus. Eukaryotic CuZnSODs have a molecular mass of about 32,000 and contain two protein subunits, each containing one Cu and one Zn ion. At physiological pH, the uncatalyzed dismutation of $O_2^{\bullet-}$ has a rate constant on the order of 5×10^5 $M^{-1}s^{-1}$; bovine erythrocyte CuZnSOD accelerates this reaction to about 1.6×10^9 $M^{-1}s^{-1}$, effectively reducing the half-life of cellular $O_2^{\bullet-}$ by several orders of magnitude. CuZnSOD is highly sensitive to inhibition by cyanide, a characteristic useful in distinguishing its activity from MnSOD in analytical assays. Diethyldithiocarbamate is also a potent inhibitor of CuZnSOD.

Manganese SOD in animals is highly associated with mitochondria; it also occurs in bacteria and plants. Amino acid sequences of MnSODs across these phyla are quite similar (and distinct from those of CuZnSODs), consistent with the endosymbiotic theory that proposes that mitochondria evolved from a symbiosis between an early CuZnSOD-containing eukaryote and a MnSOD-containing prokaryote

Downloaded From Vet-eBooks.com

(Fridovich, 1995). Interestingly, the blue crab (*Callinectes sapidus*) and other marine crustaceans that rely on Cu-dependent hemocyanins for O_2 transport contain no CuZnSOD, but have MnSOD in both mitochondria and cytosol (Brouwer et al., 1997). Vertebrate MnSODs have a molecular mass of about 92,000, and they usually contain four protein subunits and 2 or 4 Mn ions per enzyme. MnSODs are insensitive to inhibition by both cyanide and diethyldithiocarbamate. Despite these differences between MnSOD and CuZnSOD, both catalyze essentially the same reaction (Equation 6.13).

Extracellular SOD is also a CuZnSOD present in mammals (unknown for other vertebrates), but it has a far higher molecular weight than cytosolic CuZnSOD (135,000 vs. 32,000). ECSOD is a tetrameric glycoprotein in which each subunit contains one Cu and one Zn ion. It is particularly abundant in the extracellular space of blood vessels, bound to heparin sulfate, the glycosaminoglycan component of heparin sulfate proteoglycans that interact with various proteins on cell surfaces (Fukai et al., 2002). The large mass of this tetrameric protein and its affinity for cell surfaces prevents filtration by the kidneys (Fridovich, 1998). In blood vessels, ECSOD appears to play a critical role in protecting NO· from $O_2^{\bullet-}$. NO· produced by endothelial cells stimulates smooth muscle relaxation; thus, diminished ECSOD expression or activity may play a role in cardiovascular diseases (Fukai et al., 2002).

Another SOD found in bacteria, algae, and higher plants (but not observed in animal tissues) contains iron; hence, it is termed FeSOD. Most FeSODs contain two subunits, and each enzyme molecule has one or two iron ions. The bacterium *Escherichia coli* also contains a hybrid dimeric SOD, with one subunit from MnSOD and the other from FeSOD; this hybridization is facilitated by the similar amino acid sequences shared by the two forms (Fridovich, 1995).

Catalases

Although SODs very effectively reduce cellular $O_2^{\bullet-}$ concentrations, the downside of this activity is that one of the two products produced is H_2O_2. Hydrogen peroxide can be damaging in its own right, and in the presence of transition metals such as copper and iron it can also serve as the precursor to highly reactive ·OH. Most aerobic organisms and all vertebrates possess two enzyme systems that metabolize H_2O_2: the catalases and peroxidases (including glutathione peroxidases found in vertebrates, discussed below). Peroxidases generally can act on a variety of organic peroxides as well as H_2O_2, whereas catalases are largely restricted to H_2O_2.

Vertebrate catalases are large proteins with a molecular mass of 120,000 and consisting of four subunits, each containing a ferric heme group at its active site (Reid et al., 1981). The heme groups are deep within the subunits and accessed by narrow channels, which accounts for the substrate specificity of catalase. They catalyze a reaction conceptually similar to that catalyzed by SOD, a dismutation reaction (Equation 6.14). Aminotriazole is an effective catalase inhibitor (Darr and Fridovich, 1986).

$$2H_2O_2 \rightarrow O_2 + 2H_2O \tag{6.14}$$

The major cellular location of vertebrate catalase is in an organelle known as the *peroxisome*. Peroxisomes function in the β-oxidation of fatty acids, and H_2O_2 is produced as a byproduct of this process; thus, catalase prevents damage to peroxisomes and also impedes the movement of H_2O_2 to other locations in the cell (due to its uncharged nature, H_2O_2 traverses organelle membranes more readily than other ROS). The role that catalases play in the metabolism of H_2O_2 produced outside of peroxisomes appears to vary among tissues. The next enzyme discussed, glutathione peroxidase, has a broader distribution within cells and likely plays a more important role in clearing hydrogen (and other) peroxides produced in some tissues, such as liver; however, under conditions elevating H_2O_2 production in some tissues including erythrocytes (that do not contain peroxisomes), lung, and eye, catalase activity may be particularly important (Halliwell and Gutteridge, 1999).

Glutathione Peroxidases and Transferases

Glutathione peroxidases (GPXs) provide another mechanism by which animals can detoxify H_2O_2 (Arthur, 2000); moreover, they can also reduce fatty acid peroxides (LOOH), an important manifestation of oxidative stress described later. Four selenium-dependent GPXs have been identified in mammals:

Downloaded From Vet-eBooks.com

classical GPX (GPX1), gastrointestinal GPX (GPX2), plasma GPX (GPX3), and phospholipid hydroperoxide GPX (GPX4 or PHGPX). All contain selenocysteine at the active site. Selenocysteine is an amino acid analogous to cysteine in which the sulfur atom has been replaced by selenium. It is inserted by a specific tRNA into selenoproteins, including GPXs. Most GPXs characterized in vertebrates contain four subunits, each containing one selenium residue; PHGPX, however, is monomeric.

Little work has been done verifying the nature of GPXs in fish, although based on tissues examined and substrates used, it is likely that most selenium-dependent GPX activity measured in fish thus far corresponds to GPX1. Kryukov and Gladyshev (2000) detected 18 genes in zebrafish that contained selenocysteine. Two appeared very similar to one another and resembled both human GPX1 and GPX2; the other two were also very similar to one another and resembled human GPX4. The occurrence of highly matched pairs probably arose from a gene duplication event in many fishes, including zebrafish.

The reactions catalyzed by GPXs involve the reduction of a peroxide substrate to its corresponding alcohol, coupled with the oxidation of reduced glutathione (GSH) to glutathione disulfide (GSSG) (Chance et al., 1979). In the case of H_2O_2, the corresponding alcohol is water (Equation 6.15); with lipid peroxides, it is the corresponding lipid alcohol (LOH, Equation 6.16):

$$H_2O_2 + 2GSH \rightarrow GSSG + H_2O \tag{6.15}$$

$$LOOH \rightarrow 2GSH \rightarrow GSSG + LOH \tag{6.16}$$

An important distinction between catalase and GPX is the ability of only the latter to reduce lipid peroxides; however, most GPXs, including classical GPX, cannot metabolize lipid peroxides that are esterified to lipid molecules in membranes, for example. Such peroxides must first be released by lipase activity. An exception to this is PHGPX, which can directly reduce lipid peroxides associated with membranes (and also free LOOH), as well as thymine hydroperoxide, a form of oxidative DNA damage (Bao and Williamson, 2000).

Some glutathione *S*-transferases (GSTs; extensively discussed in Chapter 4) exhibit peroxidase activity, which is specific for LOOH (they are unable to act on H_2O_2). This activity is sometimes referred to as *selenium-independent* or *non-selenium* GPX activity, as GSTs contain no selenium. Although it can account for an appreciable portion of total GPX activity measured in tissue preparations with standard substrates such as cumene hydroperoxide, its significance *in vivo* is unclear (Halliwell and Gutteridge, 1999). Quantification of real GPX activity using H_2O_2 as substrate is sometimes preferred. Some GSTs play another role in antioxidant defense by conjugating breakdown products from lipid peroxidation such as 4-hydroxynonenal (Hayes et al., 2005).

Glutathione: Synthesis and Maintenance

As should be clear from earlier discussions of GSTs (Chapter 4) and discussions in this chapter, glutathione (GSH) plays critical roles in the protection of cells from chemical insult. It is also plays additional roles in metabolism, biosynthesis, transport, and cellular communication; thus, a brief description of this molecule with particular reference to oxidative stress is warranted at this juncture. GSH is the tripeptide γ-glutamyl-cysteinyl-glycine (Figure 6.1); concentrations vary widely among species and tissue but are generally far higher in mammals than amino acid concentrations, typically occurring in the low millimolar range (Griffith and Mulcahy, 1999); similar levels have been reported in fishes (see below). GSH is synthesized through two reactions, the first catalyzed by glutamate cysteine ligase (GCL; previously termed γ-glutamylcysteine synthase, or GCS) and the second by GSH synthetase (Equation 6.17 and Equation 6.18, respectively):

$$\text{L-glutamate} + \text{L-cysteine} + ATP \rightarrow \text{L-}\gamma\text{-glutamylcysteine} + ADP + P_i \tag{6.17}$$

$$\text{L-}\gamma\text{-glutamyl-L-cysteine} + \text{L-glycine} + ATP \rightarrow GSH + ADP + P_i \tag{6.18}$$

Downloaded From Vet-eBooks.com

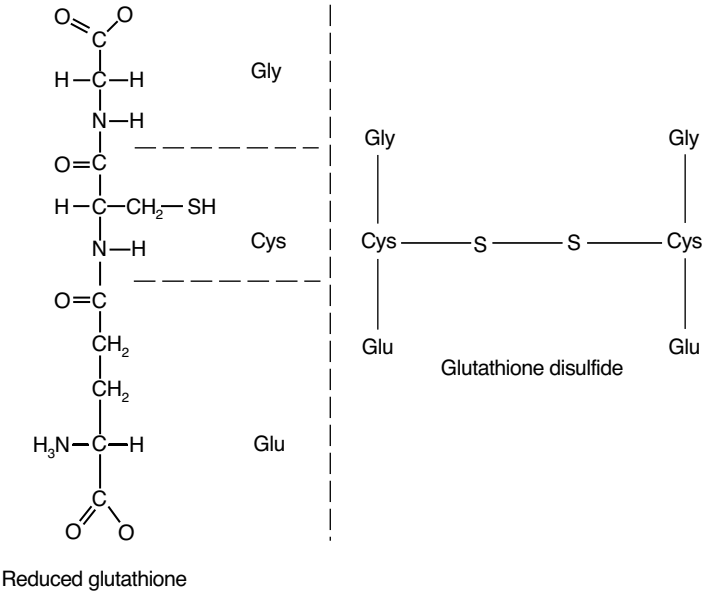

FIGURE 6.1 Structures of reduced glutathione (GSH) and glutathione disulfide (GSSG).

Glutamate cysteine ligase is the rate-limiting enzyme of GSH synthesis; it is sensitive to inhibition by buthionine sulfoximine (BSO), which can be used experimentally to deplete cellular GSH (Meister, 1995). GCL has been purified from a number of eukaryotes, and all are heterodimers composed of a heavy and a light subunit (molecular weights of about 73,000 and 31,000, respectively) (Griffith, 1999; Griffith and Mulcahy, 1999). The heavy subunit (GCL_h or GCLC, where C stands for "catalytic") is responsible for catalytic activity; the light subunit (GCL_l or GCLM, where M stands for "modifier") plays a regulatory function. In mammals, genes for the two are on separate chromosomes, and their transcription does not appear to be highly coordinated, although both have an antioxidant response element (ARE) in the promoter region (discussed below). Factors affecting GCL activity include availability of substrates (glutamate and cysteine) and feedback inhibition by GSH. GCLM modulates activity of the complete enzyme essentially by reducing K_m values for substrate concentrations and increasing the K_i for GSH.

As described above, GPX couples the reduction of H_2O_2 and LOOH to corresponding alcohols with the oxidation of GSH to GSSG. GSH can also directly scavenge ROS, including $O_2^{\bullet-}$, ·OH, RO·, ROO·, and $ONOO^-$ (Griffith, 1999; Halliwell and Gutteridge, 1999), with the thiol (–SH) group provided by cysteine as the active moiety that undergoes oxidation. In these cases as well, GSSG arises from GSH oxidation as a consequence. GSSG contains the backbones of two GSH molecules, covalently linked through a disulfide bond (Figure 6.1). Normal healthy cells not experiencing undue oxidative pressure typically exhibit GSH:GSSG ratios approaching or greater than 100:1, and declines in this ratio have been used as a marker of oxidative stress. This glutathione redox balance is maintained by GSH synthesis, export of oxidized and conjugated glutathione, and activity of glutathione reductase (GR), which catalyzes the reduction of GSSG to GSH:

$$GSSG + NADPH + H^+ \rightarrow 2GSH + NADP^+ \tag{6.19}$$

Glutathione reductase contains two subunits, each with fatty acid desaturase (FAD) at its active site (Thienne et al., 1981). Electrons provided by NADPH (produced by the pentose phosphate pathway) are apparently passed through FAD en route to their reduction of GSSG. In addition to the direct effects of ROS described below, the energetic costs of antioxidant defense activity are significant, as illustrated by the energy required to produce, maintain, and utilize GSH for this role.

Downloaded From Vet-eBooks.com

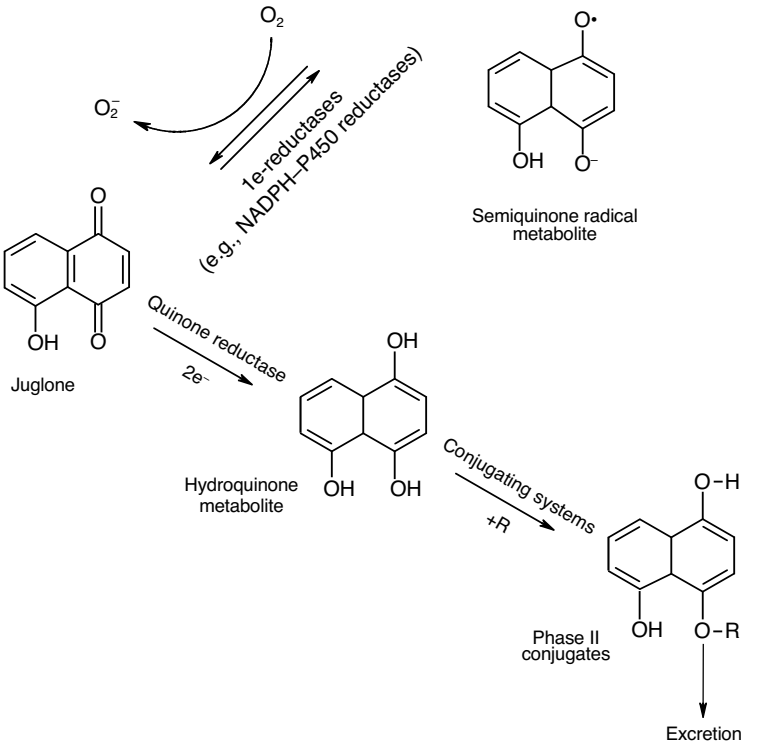

FIGURE 6.2 Metabolism of the plant-derived quinone juglone. Upper right portion depicts redox cycling through the semiquinone radical intermediate, a one-electron reduction product. The lower pathway depicts the two electron reduction pathway, which can be catalyzed by DT diaphorase (NAD(P)H:quinone oxidoreductase). This pathway yields phenolic compounds that are readily detoxified by phase II pathways (see Chapter 4).

Quinone Reductases

Quinone reductases do not directly act on ROS; however, by reducing quinones they can diminish ROS that are generated by quinones during the process of redox cycling, described below. Because quinones comprise an important group of environmental contaminants (as well as natural products), the inclusion of quinone reductase here is warranted (although it is also grouped with phase II enzymes, described in Chapter 4). Quinones, such as the natural product juglone (Figure 6.2), can exert toxicity via two mechanisms: reactions with –SH groups of GSH and proteins, leading to GSH depletion and enzyme inactivation, for example, and through generation of ROS via redox cycling (Bolton et al., 2000; Dinkova-Kostova and Talalay, 2000).

In the process of redox cycling, quinones can gain an electron from a reduced source, such as NADPH–cytochrome P450 reductase (see Chapter 4), yielding a semiquinone radical (Figure 6.2). Under aerobic conditions, this radical can donate its unshared electron to O_2, producing $O_2^{\bullet-}$. Quinone reductases circumvent this process by catalyzing a two-electron reduction of the quinone to its corresponding hydroquinone. In addition to quenching ROS formation, the hydroquinone products thus formed are oftentimes excellent substrates for phase II enzymes, particularly sulfotransferases (ST) and UDP-glucuronosyltransferase (UGT) (see Chapter 4); thus, quinone reductase activity also enhances elimination.

In mammals, two distinct quinone reductases have been identified; both are primarily cytosolic and both contain FAD (Foster et al., 2000). Until recently, only one had been recognized; it is formally termed NAD(P)H:quinone oxidoreductase and is also referred to as DT diaphorase. Zhao et al (1997), through comparisons with a cDNA clone isolated by Jaiswal (1994a), demonstrated that a previously ignored protein with quinone reductase activity (described by Liao and Williams-Ashman, 1961) had close sequence homology to DT diaphorase. This "rediscovered" protein structurally resembles a truncated version of DT diaphorase but is a separate gene product. These enzymes are now oftentimes

Downloaded From Vet-eBooks.com

referred to as *quinone reductase type 1* (QR1), which is DT diaphorase, and *quinone reductase type 2* (QR2). Major differences between QR1 and QR2 include functional electron donors (QR1 employs NADH and NADPH, but QR2 employs nonphosphorylated nicotinamides), inhibition (QR1 but not QR2 is very sensitive to dicoumarol), and regulation. QR1 is highly inducible through both xenobiotic response elements and antioxidant response elements (described below), but QR2 is apparently not inducible. Fish clearly express QR1 (see below), but we are unaware of reports concerning QR2 in this vertebrate class.

The proteins discussed here are generally considered major players as antioxidant enzymes; however, they do not include all enzymes known to have some antioxidant function. Peroxiredoxin (Georgiou and Masip, 2003), thioredoxin and glutaredoxin (Holmgren, 2000; Watson et al., 2004), heme oxygenase (Kvam et al., 1999), and other enzymes may play important roles at well, at least under some circumstances. For additional information, see Halliwell and Gutteridge (1999).

Low-Molecular-Weight Antioxidants

A number of biomolecules can directly scavenge ROS nonenzymatically. GSH, discussed above, is a very important component of this group, although it is also essential to GPX activity. Several other prominent antioxidants are vitamin related and are obtained through the diet by most animals. These include ascorbic acid (vitamin C), tocopherols (vitamin E components), and carotenoids (vitamin A, or retinol, precursors). A number of other compounds synthesized by animals exhibit antioxidant capacity *in vitro*, but their antioxidant functions *in vivo* generally remain unclear.

Ascorbic Acid (Vitamin C)

Plants and many animals can synthesize ascorbic acid from glucose, although humans and other primates, bats, and passerine birds cannot (Moreau and Dabrowski, 2003; Nishikimi and Yagi, 1996). Among fishes, teleosts cannot perform this synthesis, but those retaining more ancestral characteristics such as lampreys, sharks, rays, lungfishes, sturgeons, paddlefishes, and bowfin can (Moreau and Dabrowski, 1998). Those animals that cannot synthesize ascorbic acid lack the enzyme that catalyzes the terminal step in biosynthesis, gulonolactone oxidase. A DNA sequence resembling the gene for this enzyme in other animals has been identified in humans and guinea pigs, but it is extensively mutated and inactive (Nishikimi and Yagi, 1996).

At physiological pH, ascorbic acid exists largely as ascorbate (Figure 6.3) and is highly water soluble. Ascorbate serves as a cofactor for a number of enzymes, including proline hydroxylase and lysine hydroxylase, that are involved in collagen synthesis, as well as for dopamine-β-hydroxylase, which catalyzes the conversion of dopamine into norepinephrine (Nishikimi and Yagi, 1996). The hallmark human disease associated with vitamin C deficiency is scurvy, a common disease among sailors in earlier times (before the importance of fresh fruit was recognized); it is characterized by muscle weakness, blood vessel fragility, and bleeding from gums and other mucous membranes.

Ascorbate is a powerful reducing agent and has been shown with numerous *in vitro* studies to scavenge a number of ROS, including $O_2^{\bullet-}$, ·OH, ROO·, and HOCl (Halliwell, 1996). Although unequivocally proving the significance of these reactions *in vivo* is difficult, the function of ascorbate as an antioxidant is widely accepted based on considerations of its *in vitro* reactivity, concentrations in tissues, experimental manipulations of its levels in animals and accompanying markers of oxidative stress, and related consequences in human deficiencies (Halliwell and Gutteridge, 1999).

Upon reduction of an oxygen radical, ascorbate is oxidized to the ascorbyl radical (also known as semidehydroascorbate) (Bendich et al., 1986). This radical is relatively stable and unreactive, a feature central to its antioxidant function; that is, a much more reactive free radical reacts with ascorbate, yielding a less reactive and hence more innocuous ascorbyl radical. The ascorbyl radical is readily oxidized again, yielding dehydroascorbate (DHA, the two-electron oxidation metabolite of ascorbate). DHA has little antioxidant activity and can break down to several products (notably oxalic acid and threonic acid) or be reduced back to ascorbate by an apparently nonspecific GSH-dependent reductase (Wells et al., 1990).

Vitamin E

Vitamin E is a highly effective lipid soluble scavenger of peroxyl radicals and hence a key protectant against membrane damage via lipid peroxidation (Niki and Matsuo, 1993). It appears to be a dietary requirement of all animals. Vitamin E is actually a mixture of several tocopherols and tocotrienols; the major component acting in animal cells is α-tocopherol (Figure 6.3) (Diplock, 1985). α-Tocopherol (in addition to other tocopherols and tocotrienols) is effective at protecting membranes from oxidative attack by lipid peroxyl radicals ($LOO\cdot$) because it is more reactive with these radicals than are membrane lipids and proteins. Vitamin E components are also effective scavengers of $O_2^{\bullet-}$, $\cdot OH$, and $^1O_2$. As with ascorbate, α-tocopherol itself becomes a radical species upon reacting with an oxygen radical (Figure 6.3). α-Tocopherol can be regenerated from its radical form by mechanisms including reduction of the tocopherol radical by ascorbate; this reaction appears to represent an important cooperation between these vitamins to maintain active α-tocopherol within membranes (Traber, 1994).

Carotenoids

Carotenoids are a large group (over 600 described) of plant pigments, some of which are absorbed from the diet in many animals (Krinsky, 1993). Carotenoid structure generally includes about 40 carbons, most of which occur in alternating single and double bonds, a feature that allows for electron delocalization and absorbance of light in the visible range (Britton, 1995). Either or both ends of this carbon chain are often modified into cyclic rings, which may also contain oxygen groups; several carotenoids are illustrated in Figure 6.3. Carotenoids are very lipophilic and virtually insoluble in water. Many, including the most abundant carotenoid observed in humans, β-carotene (Figure 6.3), serve as precursors for vitamin A (retinol) and retinoic acid, which play important roles in cell growth, differentiation, and development. Some, such as astaxanthin (Figure 6.3), contribute to the red coloration of some fishes, including male sticklebacks, for which this coloration plays a role in sexual preference by female sticklebacks (Barber et al., 2000).

In terms of antioxidant function, the best established role for carotenoids is that of a scavenger of singlet oxygen in plant chloroplasts (Telfer et al., 1994); $^1O_2$ is generated at high rates during photosynthesis. The ability of carotenoids to scavenge a variety of oxygen radicals has been demonstrated *in vitro* (Liebler and McClure, 1996). Although it is generally believed that they also a serve a significant antioxidant function in animals *in vivo*, this has not been firmly established.

Other Antioxidants

A number of endogenous compounds with various well-characterized functions other than acting as an antioxidant have been shown to be also capable of scavenging ROS in various *in vitro* systems. These include bilirubin, estradiol, lipoic acid, coenzyme Q (ubiquinol), and uric acid (Halliwell and Gutteridge, 1999); however, the significance of *in vitro* studies suggesting an antioxidant function to the *in vivo* situation is oftentimes difficult to gauge.

Another potentially important function of some compounds, other than direct ROS scavenging, is regulation of metals that catalyze ROS production (via Fenton-like chemistry, for example). Iron and copper are the two essential transition metals that naturally occur in vertebrates at relatively high concentrations, and if they are free in cells they can readily enhance ROS generation, lipid peroxidation, and other manifestations of oxidative stress. Consequently, cells have mechanisms to carefully regulate them, keeping them available for incorporation into appropriate metalloproteins, for example, while preventing them from participating in destructive oxidative reactions, such as Fenton reactions and autooxidations.

For iron, perhaps the most important regulatory protein is ferritin (Harrison and Arosio, 1996; Orino et al., 2001). Most intracellular iron is bound to ferritin, which forms a large shell-like structure comprised in mammals of 24 subunits each of about 20,000 molecular weight and distinguished into two types: H and L. Up to 4500 iron ions can be stored in the core of a protein. H subunits are involved in iron detoxification by virtue of ferroxidase activity that oxidizes Fe^{2+} to Fe^{3+}. L subunits facilitate nucleation of Fe^{3+} within the core of ferritin for long-term storage. A similarly structured ferritin has been purified from the marine fish *Dasyatis akajei* (Kong et al., 2003).

Downloaded From Vet-eBooks.com

Ceruloplasmin serves an analogous function for copper (Harris, 1995). Dietary copper entering the bloodstream largely binds to albumin; this complex is taken up by the liver, where the copper is incorporated into ceruloplasmin. Ceruloplasmin has a molecular weight of about 132,000 and tightly binds six copper ions. The copper–ceruloplasmin complex is secreted by the liver into the plasma and can contribute copper to cells requiring it following binding to cell surface receptors. Ceruloplasmin has been found in several fish species, including carp, plaice, mullet, tilapia, and European eel (Grosell et al., 1998).

Metallothioneins (MTs) are low-molecular-weight (about 6500) proteins, the primary role of which is unclear, although evidence suggests that antioxidant activity may be at least an ancillary function (Coyle et al., 2002). Most research has focused on their roles in metal metabolism and homeostasis, including metal detoxification (Klaassen et al., 1999). They are very cysteine rich (about 30% of amino acid residues), which underlies their high binding affinities for a number of metals, including copper, cadmium, zinc, silver, bismuth, and mercury. Two isoforms, MT-1 and MT-2, appear to occur in all animal tissues and are the most-studied MTs. They typically bind five to seven metal ions per molecule and are inducible by some metals (including those mentioned above), stress hormones (such as glucocorticoids), oxidants, and inflammation. Considerable debate currently exists regarding whether their primary role is regulation of essential metals, particularly copper and zinc, for use in metalloenzymes vs. protection against metal toxicity, particularly from cadmium. Additionally, several lines of experimental evidence support an antioxidant function for MTs, including inducibility by prooxidants such as hydrogen peroxide and paraquat, protection against such chemicals in MT-enriched vs. MT-depleted cells (via transfections and gene knock-out models, for example), and the ability of MT to scavenge ROS and spare GSH (Klaassen et al., 1999). Whether or not these results have significant *in vivo* ramifications remains unclear.

Reactive Oxygen Species and Gene Expression

Antioxidant defenses can be altered in response to exposure to oxidative stress in a variety of ways, and the mechanisms by which such regulation occurs have been extensively studied in prokaryotic and mammalian systems. Expression and activity of antioxidant, as well as prooxidant, gene products are up- or downregulated at the levels of mRNA transcription, mRNA stabilization, and protein activation; however, the mechanisms by which these alterations occur, as well as the genes involved, are much more complex in eukaryotes than in prokaryotes.

ROS-Mediated Modulation of Gene Expression in Prokaryotes

In prokaryotes, well-defined redox-sensitive transcription factors first recognize ROS and then activate the transcription of antioxidant genes (Bauer et al., 1999). For example, the OxyR protein is specifically oxidized by (recognizes) hydrogen peroxide; the oxidized form of the protein, in which a disulfide bond has been created, drives transcription of genes, including MnSOD, catalase, glutathione reductase, hydroperoxidase, heat shock proteins, and glutaredoxin (Bauer et al., 1999; Zheng and Storz, 2000). Similarly, a [2Fe–2S] cluster in the SoxR protein is oxidized in the presence of superoxide-generating chemicals, at which point SoxR drives the transcription of the *soxS* gene. The SoxS protein, a transcription factor, acts to increase expression of genes including MnSOD, glucose-6-phosphate dehydrogenase, NADPH:flavodoxin oxidoreductase, aconitase, and endonuclease IV (Zheng and Storz, 2000). Interestingly, in some cases the proteins induced play an indirect rather than direct role in conferring resistance to oxidative stress. For example, fumarase C is induced via SoxS under conditions of oxidative stress, although fumarase, a citric acid cycle enzyme, is not itself an antioxidant. Fumarase C induction is essential under conditions of oxidative stress because the other forms of this enzyme, fumarases A and B, are inactivated by high oxygen conditions (Liochev and Fridovich, 1992).

Overview of ROS-Mediated Modulation of Gene Expression in Eukaryotes

Although an understanding of ROS-driven gene regulation in prokaryotes can be useful in developing hypotheses regarding responses to ROS in eukaryotic organisms, significant differences exist between the prokaryotes and eukaryotes thus far studied (Crawford, 1999; McCord, 2000). One major difference is that transcription factors that are responsive exclusively to ROS have not been identified in eukaryotes; rather, signaling molecules also involved in responses to other stimuli are used. Another major difference is that a different array of proteins is induced in eukaryotes, including many that are not thought of as classical antioxidants and sometimes not including proteins that typically are thought of as classical antioxidants. A third major difference is the presence in some mammalian species of an enhancer element known as the antioxidant response element (ARE), which regulates the expression of certain antioxidants and other proteins. Some of these differences may be attributable to the large differences that exist between single-cell and multicellular organisms in terms of their dependence on oxygen and the desirability of maximizing rates of cell division (McCord, 2000). These differences are discussed at greater length below.

The expression of many genes is affected by ROS; however, it is important to bear in mind that not all such changes necessarily represent adaptive, antioxidant responses. Some changes in gene expression simply result from oxidative damage; for example, low levels of damage may alter the activity of transcription factors (Gutteridge and Halliwell, 1999). Additionally, ROS are generated purposefully not only as physiological effector molecules (such as $O_2^{\bullet-}$ generated by phagocytes, discussed previously) but also as signaling molecules in pathways not necessarily related to oxidative stress *per se* (Finkel, 2000; Morel and Barouki, 1999; Palmer and Paulson, 1997; Sauer et al., 2001). Thus, ROS may be generated by enzymes such as NADPH oxidase or in the mitochondria as part of normally functioning signaling pathways (Palmer and Paulson, 1997; Sauer et al., 2001). It may be useful to conceptualize the effect of the signaling elicited by ROS as varying qualitatively according to the amount and duration of the associated oxidative stress, with low levels in some cases producing a cellular response of proliferation at least *in vitro*, intermediate levels often producing temporary growth arrest and an adaptive response, higher levels leading to apoptosis, and very high doses causing necrosis (Chandra et al., 2000; Davies, 1999; Gutteridge and Halliwell, 1999; Martindale and Holbrook, 2002). Thus, ROS cannot be thought of as simply and exclusively damage-causing agents; rather, it is the production of inappropriate amounts of ROS or production in the wrong place or at the wrong time that is problematic. Furthermore, the ability of ROS-generating chemicals to cause damage is not limited to their ability to generate highly reactive toxic intermediates but is also related to their ability to alter the functioning of normal signaling pathways that utilize ROS as messenger molecules. Finally, signaling by reactive nitrogen, copper, iron, and other redox-active metal species, in addition to reactive oxygen species, likely plays an important role in modulating gene expression (Gutteridge and Halliwell, 1999).

Effects of ROS on Transcription Factors

The activity of many transcription factors is dependent upon the reduced or oxidized state of redox-responsive moieties such as thiols or Fe–S clusters; as a result, oxidative stress can alter the activity of those transcription factors by altering the redox status of the cell (Arrigo, 1999; Primiano et al., 1997; Schafer and Butner, 2001; Sen, 2000). Transcription factors in eukaryotes reported to be affected in this fashion include AP-1, Maf, Nrl, NF-IL6, Sp-1 family members, protein kinase C, glucocorticoid receptors, estrogen receptors, aryl hydrocarbon receptor, NF-κB, p53, and others (Arrigo, 1999; Crawford, 1999; Dalton et al., 1999; Michiels et al., 2002; Primiano et al., 1997; Sen, 2000). ROS also increase the rate of transcription of many transcription factors, including members of the AP-1, NF-κB, and AP-2 families (Dalton et al., 1999). The upstream events leading to activation of transcription of these factors are complex and include alterations in phosphorylation of signaling molecules, release of arachidonic acid from cell membranes and subsequent metabolism of the arachidonic acid, and mobilization of Ca^{2+} (for reviews, see Dalton et al., 1999; Martindale and Holbrook, 2002; Sauer et al., 2001).

Effects of ROS on mRNA Expression

The transcription factors mentioned above are involved in numerous signaling pathways, including pathways related to cell division and differentiation, immunological response, cytokine expression and inflammatory response, xenobiotic metabolism, and many others (Finkel and Holbrook, 2000; Martindale and Holbrook, 2002; Sauer et al., 2001); thus, it is not surprising that exposure to high levels of ROS induces the expression of many genes. A small sampling of the many genes reported to be regulated (in at least some cases) in eukaryotes by ROS include c-*fos* and c-*myc* (cellular protooncogenes), *gadd*45 and *gadd*153 (growth arrest and DNA damage genes), γ-glutamyl transpeptidase, GCL (both subunits), some GST isoforms, some UGT isoforms, epoxide hydrolase, heme oxygenase, MnSOD and ECSOD but not usually CuZnSOD, metallothionein, GPX1, interleukin 8, cytochrome IV, thioredoxin, and an aldo-keto reductase (Brady et al., 1997; Burczynski et al., 1999; Crawford, 1999; Dhakshinamoorthy et al., 2000; Prestera et al., 1993; Schull et al., 1991). The expression of some of these (and other) genes is regulated by ROS via the antioxidant response element, as discussed below. As indicated by this partial listing, although many of the genes identified as upregulated by ROS could clearly play important antioxidant roles, many others are not classical antioxidants. Furthermore, the degree of induction observed in the classical antioxidants is often relatively low; heme oxygenase, not a classical antioxidant, appears to be one of the most responsive markers of oxidative stress in cells, as it shows a high degree of induction as well as specificity for oxidative stress as an inducer (Crawford, 1999). Further confusing the picture are observations that, in some cases, classical antioxidants are upregulated to a greater degree by inducers other than typical oxidants; for example, MnSOD is upregulated 20- to 100-fold by cytokines such as interleukin 1 (IL-1) and tumor necrosis factor (TNF), compared to a usually less than 5-fold induction by prooxidants such as xanthine oxidase, paraquat, iron, copper, and *t*-butyl hydroperoxide (Crawford, 1999; Stralin and Marklund, 1994; Valentine and Nick, 1999; Visner et al., 1990).

The expression of many genes is also downregulated by oxidative stress; among these are many mitochondrial genes (Crawford 1999; Fujii and Taniguchi, 1999; Morel and Barouki, 1999) and a large number of nuclear-encoded genes involved in the immune response, cell replication, carbohydrate metabolism, hormonal responses, phase I xenobiotic metabolism, and other cellular activities (Barouki and Morel, 2001; Morel and Barouki, 1999; Nebert et al., 2000). As in the case of ROS-mediated gene induction, these results seem likely to reflect not only adaptive changes directed at decreasing oxidative damage but also alterations in pathways in which ROS normally play a role as signaling molecules or simple oxidative damage to cellular macromolecules that mediate gene expression in these pathways.

Antioxidant Response Element (ARE)-Mediated Gene Regulation

The only known molecular mechanism for specifically responding to high levels of ROS in eukaryotes is the activation of a relatively large number of genes via an enhancer element termed the antioxidant response element (ARE), or electrophile response element (Dalton et al., 1999; Itoh et al., 1999; Nguyen et al., 2003b; Rushmore et al., 1991; Wasserman and Fahl, 1997). Many genes have been shown to be regulated by AREs, and many others are suspected to be ARE regulated, based on the presence of ARE sequences in the promoter regions of those genes, the inducibility of those genes by chemicals that either generate or scavenge ROS, and the regulation of those genes by putative ARE transcription factors such as Nrf1 and Nrf2 (discussed below). A list of genes known or suspected to be regulated by the ARE, grouped according to the type of evidence currently available in the literature, is presented in Table 6.1.

The identity and role of all of the transcription factors that bind to the ARE are not yet clearly defined but are an area of very active investigation. Early suggestions that AP-1 was involved turned out to be inaccurate, except in those cases where the ARE is part of a functional 12-*O*-tetradecanoylphorbol-13-acetate (TPA) response element (TRE) (Dalton et al., 1999), such as the case of the human QR1 gene (Jaiswal 1994b). Thus, although the ARE bears strong sequence similarity to the TRE, they are not the same. Furthermore, although there are similarities in terms of the transcription factors that bind the two sites, they are not identical, and the combinations that bind are usually different. At this point, the best evidence suggests that ARE transcription factors include one or more CNC-bZIP proteins (e.g., Nrf1 and especially Nrf2), perhaps as part of a heterodimer with a small

Note: The genes are sorted according to the type of evidence indicating that they are or may be ARE regulated.

Maf protein or c-Jun (Dalton et al., 1999; Dinkova-Kostova et al., 2002; Itoh et al., 1999; Jeyapaul and Jaiswal, 2000; Kwong et al., 1999; Nguyen et al., 2003b; Zipper and Mulcahy, 2002), and possibly other proteins as well (Nguyen et al., 2003b; Wasserman and Fahl, 1997). Recent evidence suggests that the "redox sensor" that activates this pathway is the cytoplasmic Nrf2-binding protein Keap1; oxidation of sulfhydryl groups in Keap1 leads to the release of Nrf2, permitting it to move to the nucleus, heterodimerize, and act as a transcription factor (Dinkova-Kostova et al., 2002). Phosphorylation of Nrf2 also appears likely to regulate the transcriptional activity of Nrf2 (Huang et al., 2000; Kong et al., 2001), perhaps in part via an increase in Nrf2 stability (Nguyen et al., 2003a). Electrophile-induced polyubiquitination of the Keap1 protein may play a role in Nrf2 release as well (Eggler et al., 2005; Hong et al., 2005), and recent evidence also supports a role for Keap1 in regulation of Nrf2 degradation (Nguyen et al., 2005). A working model based on current knowledge of cellular signaling as it relates to the ARE is presented in Figure 6.4.

To our knowledge, no piscine genes have yet been shown to have functional AREs in their regulatory regions. ARE-like sequences have been identified upstream of the GSTA gene in plaice (*Pleuronectes*

Downloaded From Vet-eBooks.com

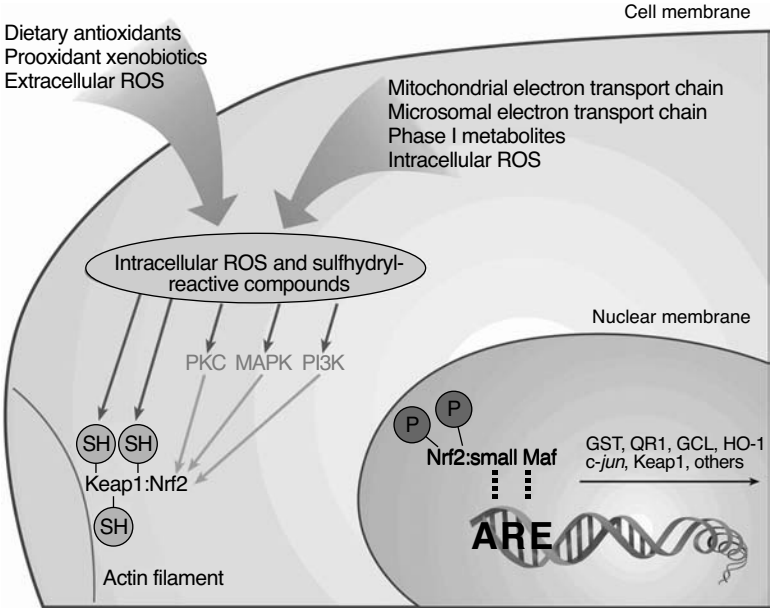

FIGURE 6.4 A working model of ARE-related signaling and gene regulation in mammals, based on references cited in the text. Extracellular and intracellular ROS from any of a number of sources either act directly on the actin-bound Keap1 protein, oxidizing sulfhydryl groups and causing release of Nrf2, or act indirectly via kinase signaling cascades to phosphorylate Nrf2, leading to dissociation of Nrf2 from Keap1 and protection of Nrf2 from proteasomic degradation. Free Nrf2 translocates to the nucleus, heterodimerizes with another protein such as c-Jun or a small Maf protein, and binds to the ARE. This binding facilitates transcription of ARE-driven genes, such as those listed (see also Table 6.1). Note that upregulation of c-*jun* and Keap1, if they occur, may result in positive or negative (respectively) feedback regulation of ARE-mediated gene induction.

platessa) (Leaver and George, 1996; Leaver et al., 1997), and the expression of that gene was inducible by treatment with *trans*-stilbene oxide, β-naphthoflavone, and perfluorooctanoic acid (a peroxisome-proliferating agent) (Leaver et al., 1993, 1997). Three additional lines of evidence support the possibility that some piscine genes are regulated by ARE sequences. First, some of the genes known or hypothesized to be induced by electrophiles in mammals via the ARE have been shown to be inducible by electrophiles in fish species at the levels of mRNA, protein, and catalytic activity. Some examples are presented in Table 6.2. One complication with interpreting these data is the fact that the isoforms of these genes present in fish have not been fully described, making it difficult to know whether the genes seen to be inducible in fish correspond to those known to be ARE regulated in mammals, particularly in the case of catalytic assays. A second line of evidence supporting the likelihood of ARE regulation of endogenous gene expression in fish comes from studies demonstrating the functionality of reporter genes driven by mammalian ARE promoter regions (murine GSTA1, murine QR1, and possibly human QR1) in zebrafish and topminnow cells exposed to a variety of prooxidant chemicals (Carvan et al., 2000, 2001; Rau et al., 2004). A final, and particularly convincing, line of evidence is the demonstration that Nrf2 and Keap1 are present in zebrafish and regulate the expression of zebrafish genes known to be ARE regulated in mammals (GSTP, QR1, and GCLH) (Kobayashi et al., 2002); therefore, the transcription factors necessary to drive ARE-mediated gene transcription in mammals are present and functional in fish, are able to recognize a mammalian ARE sequence, and regulate the expression of endogenous zebrafish genes that are electrophile inducible. These results, although not quite definitive, very strongly suggest that ARE-regulated genes exist in fish as well as mammals and that there is considerable evolutionary conservation of function of ARE-mediated gene regulation between mammals and fish.

Note: These genes are candidates for ARE regulation; no gene has yet been conclusively demonstrated to be ARE regulated in any fish species.

ROS-Mediated Modulation of Gene Expression: Summary

The alterations observed in eukaryotic gene regulation in response to ROS are highly complex. These alterations in gene expression may result from interaction with pathways that normally employ ROS as signaling molecules; antioxidant responses, including those aimed at preventing the generation of ROS, increasing the scavenging of ROS, and repair of oxidative damage; and alterations resulting from oxidation of transcription factors or other important cellular macromolecules. The expression of a wide variety of genes is altered by exposure to ROS, including many genes coding for proteins that are not typically thought of as antioxidants, but rarely involves very large changes in expression. These characteristics may relate to the fact that ROS play a normal physiological role in eukaryotes, suggesting that repressing ROS to too low of a concentration might be problematic and to the fact that the transcription factors that mediate many of the apparently adaptive antioxidant responses are involved in other pathways as well, suggesting that large alterations in their activity might be disruptive to other important biological responses.

Deleterious Cellular Effects of Reactive Oxygen Species

As discussed previously, the generation of ROS is a normal consequence of aerobic life and even in some cases a beneficial one. Aerobic organisms have evolved a complex array of antioxidant defenses that effectively deal with typical fluxes of ROS encountered by aerobic cells. As these fluxes increase, due to both natural phenomena (such as increased aerobic metabolism during physical exertion, sharp rises in dissolved oxygen in aquatic environments, or pronounced inflammatory responses) as well as unnatural variables (such as anthropogenic chemicals), cellular antioxidant capacity can be overtaxed. As described above, through mechanisms including ROS-mediated changes in gene expression, cells can adapt to some extent by enhancing their antioxidant capacity. Upregulation of antioxidant defenses comprises an early response to elevated ROS fluxes; however, such fluxes can exceed even adapted

Downloaded From Vet-eBooks.com

antioxidant capacity, at which point detrimental cellular impacts may ensue. This corresponds to the classic definition first introduced by Sies and Cadenas (1985) of oxidative stress as "a disturbance in the prooxidant–antioxidant balance in favor of the former, leading to potential damage."

A major difficulty in the study of oxidative stress is the variety of ways at which it can manifest; that is, it is far more difficult to determine if a particular chemical is acting, as a principal mechanism of toxic action, as a prooxidant causing oxidative stress vs. determining, for example, if it is an acetylcholinesterase inhibitor, an aryl hydrocarbon receptor agonist, or an estrogen mimic. A lack of effect as measured by any particular assay (or two or three) cannot be used to rule out the occurrence of oxidative stress. A similar caution applies to the measure of antioxidants as markers for exposure or adaptation to prooxidants, with the expectation that exposures below the threshold for toxicity will result in upregulations of antioxidants. Again, the complexity of mechanisms by which prooxidants may or may not augment various antioxidant system components presents major challenges to this approach. These are issues that have plagued the development of biomarkers for oxidative stress in fish, as described later.

Although oxidative stress is a complex and often difficult subject of inquiry, it remains an important underlying mechanism of cellular toxicity. Given the high reactivity of many ROS, such as ·OH, it is not surprising that they are often indiscriminant in terms of cellular targets. Principal cellular constituents, including lipids, proteins, and DNA, are subject to attack, as are cellular functions such as redox status and energetics and cellular signaling. Tools have been developed to study all of these phenomena. The following is not an exhaustive list of cellular effects but does address major ones that have received considerable research attention in a variety of organisms, including fishes. (Note that oxidative DNA damage is discussed in detail in Chapter 12 and hence is excluded here.)

Lipid Peroxidation

Perhaps the most studied targets of ROS are polyunsaturated fatty acids (PUFAs), which are fatty acids containing two or more carbon–carbon double bonds. Of particular interest are those associated with the membranes of cells, including organelles such as mitochondria, lysosomes, and endoplasmic reticula. These membranes are complex and diverse structures, typically comprised of various phospholipids (such as phosphatidylcholine, or lecithin), cholesterol, lipoproteins, and proteins that serve various functions, particularly with respect to signal transduction and transport of materials across membranes.

In PUFAs, the hydrogen atoms on saturated carbons (allylic hydrogens) adjacent to carbons participating in double bonds are most prone to hydrogen abstraction by oxygen radicals such as ·OH, RO·, and ROO·. These allylic hydrogens form less stable bonds to carbon due to the adjacent carbon–carbon double bonds; an example within a hydrocarbon chain is denoted here in bold:

$$-CH=CH-C\mathbf{H}_2-CH=CH-$$

Abstraction of an allylic hydrogen by an oxygen radical comprises the *initiation* step of lipid peroxidation (Porter et al., 1995; Wagner et al., 1994), which is included in the summary schematic of lipid peroxidation (Figure 6.5); susceptibility of different PUFAs to lipid peroxidation increases with increasing number of unsaturated carbon double bonds. Initiation results in a lipid radical (R·), which then undergoes rearrangement to a conjugated diene radical; under typical aerobic conditions, this lipid radical will readily react with O_2, yielding a lipid peroxyl radical (ROO·). The peroxyl radical can react with another PUFA, thereby abstracting hydrogen, becoming a lipid peroxide (LOOH), and generating another R·. This second R· can also react with O_2 to yield ROO·, and this process can be repeated many times, constituting a free-radical chain reaction termed *propagation* of lipid peroxidation; thus, initiation by one molecule of an oxygen radical can potentially result in the peroxidation of many PUFA molecules. Propagation is an important feature of many free-radical reactions whereby one radical can stimulate a cascade of potentially deleterious reactions in biological systems; this phenomenon is addressed again later.

A number of other important reactions are associated with the process of lipid peroxidation; for example, the peroxyl radical can react with other membrane lipids (e.g., cholesterol) or proteins, in addition to PUFA, thus altering these molecules while forming ROOH. Transition metals such as iron and copper, in addition to enhancing production of the powerful initiator ·OH through Fenton chemistry,

Downloaded From Vet-eBooks.com

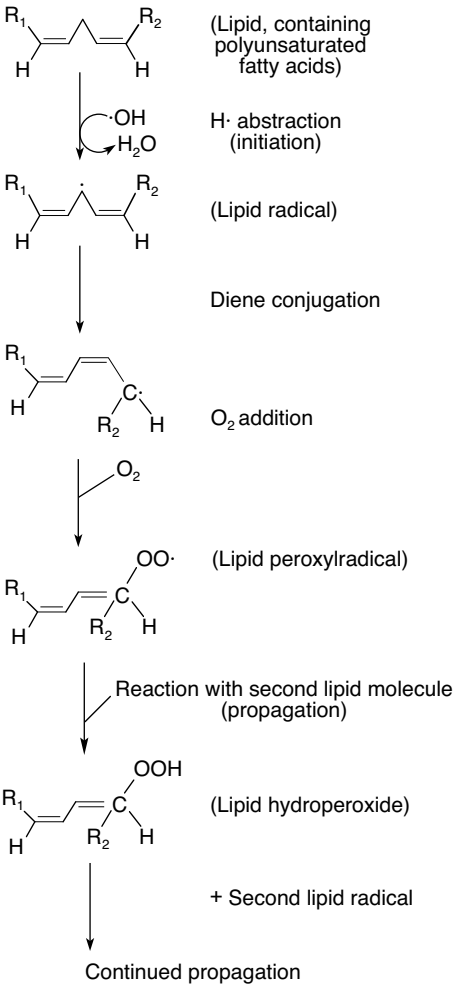

FIGURE 6.5 The biochemical process of hydroxyl radical (·OH)-initiated lipid peroxidation.

can also react directly with ROOH to produce RO· and ROO·, which can initiate new radical chain reactions. In fact, it is thought that transition metals are required for lipid peroxidation to proceed at a significant rate (Sevanian and Ursini, 2000). Lipid peroxidation can be terminated by the reaction of two lipid radicals to produce nonradical products. Additionally, lipid peroxidation can be slowed by the action of α-tocopherol, as described earlier. While stopping a particular radical chain reaction, donation of hydrogen to ROO· by α-tocopherol (yielding the relatively unreactive α-tocopherol radical) results in ROOH, which is still subject to metal-catalyzed radical generation. This is repaired by the action of glutathione peroxidases, discussed earlier, that reduces ROOH to the corresponding alcohol (ROH), effectively preventing further lipid peroxidation. Major consequences of membrane lipid peroxidation include decreased membrane fluidity, increased permeability resulting in inappropriate leakiness to some molecules, and inhibition of membrane-bound enzymes (Richter, 1987).

Protein Oxidations

The effects of ROS on proteins have received less attention than lipid peroxidation, yet it is clear that many proteins are susceptible to attack by ROS, which can have deleterious consequences. Important consequences of protein oxidations by ROS include enzyme inactivation, alteration of receptors and other proteins involved in signal transduction, and perturbed ion homeostasis (via effects on ATPases,

Downloaded From Vet-eBooks.com

for example) (Halliwell and Gutteridge, 1999). Direct effects of ROS on specific amino acids in proteins include oxidations of the reduced sulfur moiety of cysteine and methionine to produce disulfides and sulfoxides/sulfones, respectively (Dean et al., 1997); the production of carbonyl groups (aldehydes and ketones) on side chains of some amino acids, particularly of proline, arginine, lysine, and threonine (Dalle-Donne et al., 2003); and oxidations of the aromatic side chains of phenylalanine, tryptophan, tyrosine, and histidine (Stadtman and Levine, 2003). Among these effects, the production of carbonyls is considered the most common effect, and increases in their production have been associated with a number of human diseases, including Alzheimer's disease, cystic fibrosis, diabetes, and amyotrophic lateral sclerosis; consequently, many assays have been developed to detect protein carbonyls (Dalle-Donne et al., 2003).

Redox Status and Energetics

The redox status of a cell (or cellular compartment, tissue, etc.) refers to the collective ratios of interconvertible oxidized and reduced forms of redox couples. (For a lucid description and a formal approach for quantifying "redox environments" in the context of cellular oxidative stress, the reader is referred to Schafer and Buettner, 2001.) Key redox couples underlying redox status include $NADH/NAD^+$, $NADPH/NADP^+$, and GSH/GSSG. Reduced forms of these couples are critical for a number of fundamental cellular functions including energy production (e.g., mitochondrial ATP production linked with electron release by NADH, resulting in oxidation to NAD^+), biosynthesis (many pathways employ NADPH), and protection from ROS (wherein GSH plays a central role as described previously); therefore, cells and tissues maintain overall reducing environments that favor the reduced forms of most redox couples, including those just mentioned.

Reactive oxygen species can drive redox status to a more oxidized state through a variety of direct and indirect mechanisms. GSH can be oxidized directly by ROS, as well as through GPX-catalyzed reductions of H_2O_2 and lipid peroxides (Equations 6.15 and 6.16). The reduction of GSSG resulting from GSH oxidations back to GSH is catalyzed by glutathione reductase, which requires the oxidation of NADPH. NADH and NADPH are also oxidized during the activity of quinone reductase (Equation 6.19). Both reduced pyridine nucleotides can be oxidized during the generation of ROS by redox-cycling chemicals, a phenomenon described later. There is also evidence that NADH and NADPH can act directly as ROS scavengers, resulting in their oxidation (Kirsch and De Groot, 2001). This activity is suggested to be important in mitochondria, where their concentrations are similar to that of GSH (~5 m*M*). In all of these cases, however, oxidations of reduced intermediates impose an energetic cost.

Deleterious Organismal Effects of Reactive Oxygen Species

The preceding discussions have focused on molecular and cellular aspects of ROS and oxidative stress, and the complexity and varied nuances of these phenomena should be apparent; therefore, it is not surprising that a diverse array of diseases and pathologies have been associated with oxidative stress. It is beyond the scope of this chapter to discuss these in detail; however, a number of diseases (most described in humans), pathologies, and other effects are noted here to provide a sense of the breadth of health outcomes that are at least in part associated with oxidative stress.

Oxidative stress, as measured by cellular effects described above (e.g., oxidations of lipids, protein, DNA, perturbed redox status, and altered antioxidant capacity), has been observed in association with many disease states and tissue injuries, but it is important to bear in mind that such associations do not confer causality. Evidence of oxidative stress may be encountered in any tissue undergoing trauma due to infection, injury, or cell death (apoptosis or necrosis)—such tissues are inherently more prone to oxidative damage due, for example, to compromised energetics. Determining that oxidative stress is the cause of a disease or tissue damage rather than the result requires careful analysis. Moreover, many diseases have complex etiologies, and attempts to pinpoint a single cause, such as ROS, are often erroneous.

Downloaded From Vet-eBooks.com

Diseases Associated with Oxidative Stress

Compelling evidence exists that oxidative stress is an important contributing factor for numerous diseases and pathologies. Atherosclerosis, for example, is a disease of the arteries characterized by the thickening of the vessel walls; it is a major contributor to heart attacks and stroke, which are the leading causes of death in the United States and Europe. The causes and progression of the disease are complex and not fully understood, but ample evidence implicates ROS and RNS as important components (Halliwell and Gutteridge, 1999; Harrison et al., 2003). Also, chronic inflammatory diseases such as arthritis are generally believed to be in part caused by ROS produced by activated phagocytes at inflamed sites, in part an autoimmune response (Closa and Folch-Puy, 2004). The brain is considered particularly prone to oxidative stress due to its high rate of oxidative metabolism, presence of autooxidizable neurotransmitters (dopamine and norepinephrine), high levels of highly unsaturated fatty acids, relatively modest antioxidant defenses, and presence of cytochrome P450s (Halliwell and Gutteridge, 1999). Neurodegenerative diseases such as Alzheimer's disease, Parkinson's disease, and amyotrophic lateral sclerosis are believed to be in part due to ROS, although precise mechanisms remain unresolved (Anderson, 2004). Cancer encompasses a diverse set of diseases with a complex etiology and has been studied extensively in fishes as well as humans. Considerable evidence supports a role for ROS and other free radicals in tumor initiation, promotion, and progression (Klaunig et al., 1998); relevant studies in fish models are described in Chapter 12.

In addition to these and other diseases, an important pathology closely associated with oxidative stress is referred to as *ischemia-reperfusion tissue injury*. Ischemia refers to a loss of blood flow to a tissue, a key consequence of which is hypoxia. Hypoxia can result from atherosclerosis, physical tissue damage, surgical procedures, and depletion of environmental O_2. The effects of hypoxia are variable, depending on severity, time course, and tissue involved and can range from mild and reversible to irreversible tissue damage to death. A somewhat paradoxical aspect of ischemia is that sometimes tissue injury coincides with reperfusion (i.e., restoration of blood flow and normoxia) (Halliwell and Gutteridge, 1999). This injury is associated with oxidative stress due to cellular changes such as ATP depletion and enhanced ROS generation via the xanthine oxidase system (McCord, 1987) and altered mitochondrial enzyme activities (Powell and Jackson, 2003). Evidence also suggests that an environmental analogy to this phenomenon may occur in some aquatic systems such as shallow lakes and estuaries that display marked diurnal and seasonal fluctuations in dissolved oxygen levels (Hermes-Lima and Zenteno-Savin, 2002; Hochachka et al., 1996).

Aging and Oxidative Stress

The processes that govern the aging process and determine the limits of lifespan of organisms have been the subject of debate and research for many years. Considerable evidence supports an important role for oxidative stress in these phenomena, although other factors are likely involved (Beckman and Ames, 1998; Finkel and Holbrook, 2000). Supporting evidence for the free-radical theory of aging includes the increased accumulation of oxidized proteins, lipids, and DNA with age; increased lifespan in organisms engineered to overexpress antioxidant enzymes (e.g., CuZnSOD and GR) in some studies; and increased lifespan associated with caloric restriction (which reduces mitochondrial production of ROS, a key component of this theory). As described earlier, ROS modulates several cellular signaling pathways, including stress-responsive pathways considered adaptive to oxidative stress. The responsiveness of some pathways, such as heat shock proteins, appears to decline with age. Fish display a range of patterns with respect to aging, including rapid senescence in some salmonids, and may provide useful models for ageing research.

Chemicals and Oxidative Stress

Numerous chemicals including natural products, drugs and environmental contaminants have been shown to impact organismal health via, at least in part, oxidative stress. Some better understood examples, largely from mammalian studies, are noted in the following text.

Downloaded From Vet-eBooks.com

Natural Products

The Gram-negative bacterium *Pseudomonas aeruginosa* can cause pneumonia via secretion of two compounds: procyanin and pyochelin (5-methyl-1-hydroxyphenazine). Procyanin generates $O_2^{\bullet-}$ via redox cycling (described in the following section), and pyochelin is a siderophore that binds iron and promotes Fenton-chemistry-like generation of ·OH (Britigan et al., 1992). Juglone (5-hydroxy-1,4-naphthoflavone; see Figure 6.2) and plumbagin (5-hydroxy-3-methyl-1,4-naphthoflavone) are redox-cycling quinones produced by walnut trees (*Juglans* spp.). They suppress germination and growth of other plant species (hence, the term *allelotoxins*), and their use in cosmetics has raised concerns for human health (Inbaraj and Chignell, 2004; Seguraaguilar et al., 1992). In part, the hepatotoxicity of ethanol, a byproduct of glucose metabolism by yeast, is believed to be associated with ethanol-mediated induction of cytochrome P4502E1 (CYP2E1) and a resulting shift in ethanol metabolism to include a greater contribution by CYP2E1 vs. the dominant pathway (alcohol and acetaldehyde dehydrogenases). CYP2E1 is a relatively leaky P450, and substantial $O_2^{\bullet-}$ and H_2O_2 are generated as a result of its activity, which can thereby contribute to oxidative stress in the liver during chronic ethanol exposure (Caro and Cederbaum, 2004).

Drugs

The deleterious side effects of some drugs are associated with oxidative stress. The liver and kidney damage produced by high dosages of the common pain reliever acetaminophen occurs via GSH depletion by the drug and a CYP2E1 metabolite (*N*-acetyl-*p*-benzoquinone) and accompanying effects on calcium metabolism (Moore et al., 1985). Acetaminophen has been used frequently in suicide attempts, underscoring its toxic nature at high doses. The common urinary tract antibacterial nitrofurantoin is a nitroaromatic, and both its bactericidal activity and major deleterious side effect (lung damage) are thought to be due to ROS generation via redox cycling through a nitro radical intermediate (Suntres and Shek, 1992). A number of antibiotics, such as penicillins, natamycin, tetracyclines, streptonigrin, and gentamicin, have been shown capable of generating ROS that are believed to underlie the tissue damage that sometimes accompanies their use (Halliwell and Gutteridge, 1999). The addictive recreational drug cocaine is a hepatotoxicant and neurotoxicant that is thought to act in part via ROS-generating reactive metabolites (Boelsterli and Goldin, 1991), as well as through vasoconstriction that can also exert oxidative stress, as indicated by elevated oxidations of glutathione and α-tocopherol (Lipton et al., 2003).

Environmental Pollutants

Numerous environmental pollutants have been demonstrated to impact organismal health via oxidative stress; several illustrative examples are described here. Carbon tetrachloride (CCl_4) is a common solvent and intermediate in the production of other chemicals and was the first environmental toxin to be shown to exert toxicity through a free radical mechanism. Many of its uses, including as a solvent and cleaning agent, have declined since the 1970s due largely to its great potency as a hepatic and renal toxicant, as well as its carcinogenicity and contributing to stratospheric ozone depletion (ATSDR, 1994). Its toxicity is based on its conversion by cytochrome P450s, particularly CYP2E1, to a trichloromethyl radical ($CCl_3^{\bullet}$) (Recknagel et al., 1989; Zangar et al., 2000). This radical can bind to proteins and lipids directly and also react with O_2 to produce the thrichloromethylperoxyl radical ($Cl_3COO^{\bullet}$). Both processes lead to extensive membrane damage, including lipid peroxidation, and can lead to elevated intracellular Ca^{2+}, an important component of CCl_4 cytotoxicity (Stoyanovsky and Cederbaum, 1996).

Benzene is a ubiquitous contaminant used as a precursor for various products; benzene is particularly toxic to mammalian bone marrow, and epidemiological studies indicate that elevated exposures cause leukemias in humans, as well as other cancers (Snyder, 2002). The metabolism of benzene to toxic intermediates is also initiated by cytochrome P450s, particularly CYP2E1, which yield various phenols. These phenols are distributed to various tissues, where additional metabolism can yield highly redox-active quinones via the action of various peroxidases, such as myeloperoxidase, which is highly enriched in bone marrow. Quinones comprise a large set of reactive intermediates of numerous compounds, including PAHs, estrogens, and catecholamines, that have been shown collectively to produce acute

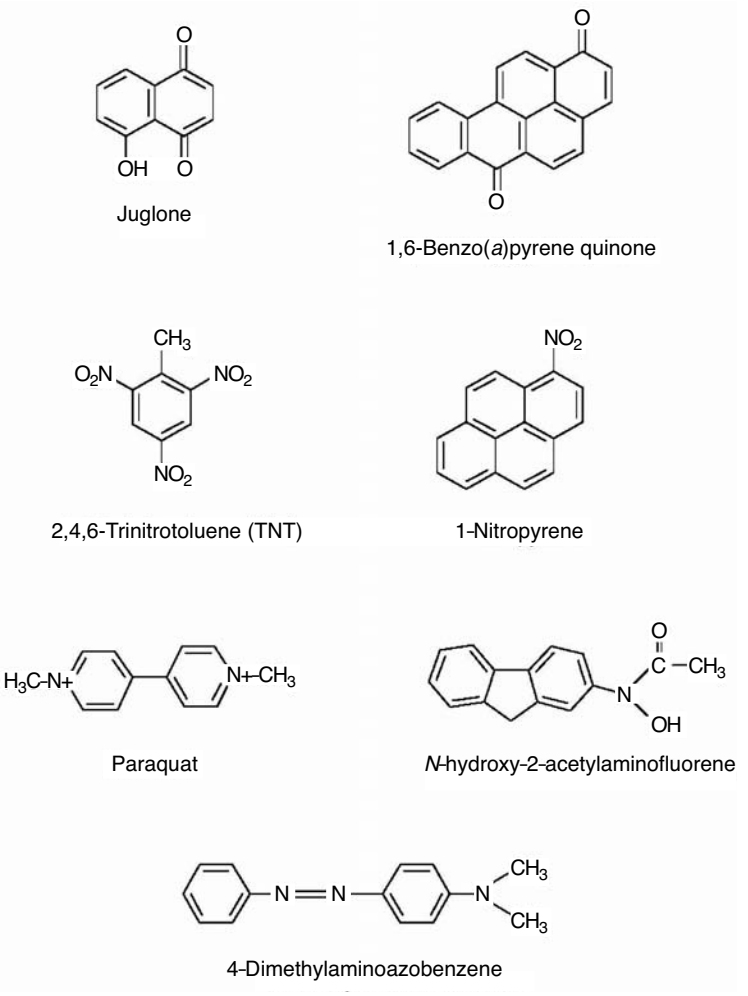

FIGURE 6.6 Representative redox-cycling chemicals including a natural product (juglone), a metabolite of the procarcinogen benzo(*a*)pyrene (1,6-benzo(*a*)pyrene quinone), the explosive 2,4,6-trinitrotoluene (TNT), a common combustion byproduct (1-nitropyrene), an herbicide (paraquat), a carcinogenic aromatic hydroxylamine (*N*-hydroxy-2-acetylaminofluorene), and an azo dye (4-dimethylaminobenzene).

cytotoxicity, immunotoxicity, and carcinogenicity (Bolton et al., 2000). Quinone toxicity can result from ROS generation via redox cycling as well as from direct alkylations of protein and DNA.

Paraquat (Figure 6.6) and diquat are broad-spectrum, bipyridyl-based herbicides that have been used extensively in no-till farming and marijuana control (paraquat) and for the control of nuisance aquatic plants (diquat). The toxicity of these compounds to plants is based on their efficiency as redox cyclers in chloroplasts that copiously transfer electrons and generate O_2 during photosynthesis (Bowler et al., 1994). Their toxicity to animals also involves their ability to redox cycle and produce oxidative stress. Paraquat is unusual in that, regardless of route of exposure in mammals, it is selectively toxic to lung tissue. This phenomenon appears to be due to its propensity to be actively transported by systems involved in the transport of polyamines such as putrescine (Smith and Wyatt, 1981). Polyamines are endogenous compounds that, like paraquat, contain positively charged quaternary nitrogen atoms. They are involved in cellular growth and differentiation and are actively taken up by lung cells; thus, the selectivity of paraquat to lung tissue appears to be due to its active transport by these cells, which have high O_2 concentrations that facilitate redox cycling.

Mechanisms of Chemical-Mediated Oxidative Stress

As mentioned earlier, oxidative stress has been defined as "a disturbance in the prooxidant–antioxidant balance in favor of the former, leading to potential damage" (Sies, 1985). Following this definition, two broad sets of mechanisms by which pollutants can produce oxidative stress can be delineated: mechanisms that enhance ROS production and mechanisms that reduce antioxidant capacity. Illustrative examples of both are described below.

Enhanced ROS Production

Mechanisms by which chemicals can enhance ROS (and in some cases NOS) production include redox cycling, interactions with electron transport chains (notably in mitochondria and microsomes, as well as chloroplasts in plants), and photosensitization. Additionally, some chemicals are metabolized to carbon-based free radicals that can donate unpaired electrons to O_2 thereby generating $O_2^{\bullet -}$; CCl_4 (described above) is a notable example. Moreover, some air pollutants occur as radicals themselves, such as nitrogen dioxide, $NO_2^{\bullet}$.

Redox Cycling

Redox cycling is perhaps the most common mechanism by which a diverse array of chemicals including many environmental pollutants can generate intracellular ROS. Redox cycling chemicals include diphenols and quinones, nitroaromatics and azo compounds, aromatic hydroxylamines, bipyridyliums, and certain metal chelates, particularly of copper and iron (Di Giulio et al., 1989, Halliwell and Gutteridge, 1999). These include large classes of compounds of broad industrial use, many pesticides, ubiquitous elements, and metabolic products of numerous pollutants. Examples of these redox active chemicals are provided in Figure 6.6.

In the redox cycle, the parent compound accepts an electron from a reduced cofactor, such as NADH or NADPH; this reaction is typically catalyzed by a reductase such as xanthine oxidase or cytochrome P450 reductase (Kappus, 1986). Cytochrome P450 reductase normally functions to transfer electrons from NADPH to cytochrome P450 via FAD and flavin-mononucleotide (FMN) contained in this reductase (Chapter 4). However it is also a key catalyst in xenobiotic redox cycling in which the electron donated by NADPH yields a radical of the xenobiotic. In the presence of O_2, the unpaired electron of the radical metabolite is donated to O_2, yielding $O_2^{\bullet -}$ and regenerating the parent compound; importantly, the parent compound can repeat this cycle until it is cleared or metabolized to an inactive product. In the course of each redox cycle, two potentially deleterious events occur—a high-energy reducing equivalent is expended (the oxidation of NADPH to NAD^+, for example), and an oxygen radical is produced. Moreover, the proliferative nature of these potentially harmful outcomes associated with redox cycling (i.e., one molecule of xenobiotic causing the oxidation of many molecules of NADPH and the production of many molecules of $O_2^{\bullet -}$) is observed in other aspects of free radical biology, such as lipid peroxidation described earlier. Redox cycling of some chemicals also occurs in the mitochondria (Doroshow and Davies, 1986; Cadenas and Davies, 2000). A generalized redox cycle that includes associations with cellular toxicities and antioxidant defenses is shown in Figure 6.7. It should be noted, however, that in some cases redox cycling chemicals are toxic by mechanisms other than ROS production (Imlay and Fridovich, 1992); thus, the *in vitro* capability of a chemical to cause oxidative stress is not a definitive demonstration of an *in vivo* mechanism of toxicity.

Uncoupling or Inhibition of Electron Transport

Another important mechanism by which chemicals can enhance ROS production is through interactions with electron transport chains, particularly those in mitochondria and endoplasmic reticula (microsomes) in animals. As discussed earlier, these systems are important sources of ROS during normal aerobic respiration due a degree of inherent uncoupling between NAD(P)H oxidation and substrate reduction.

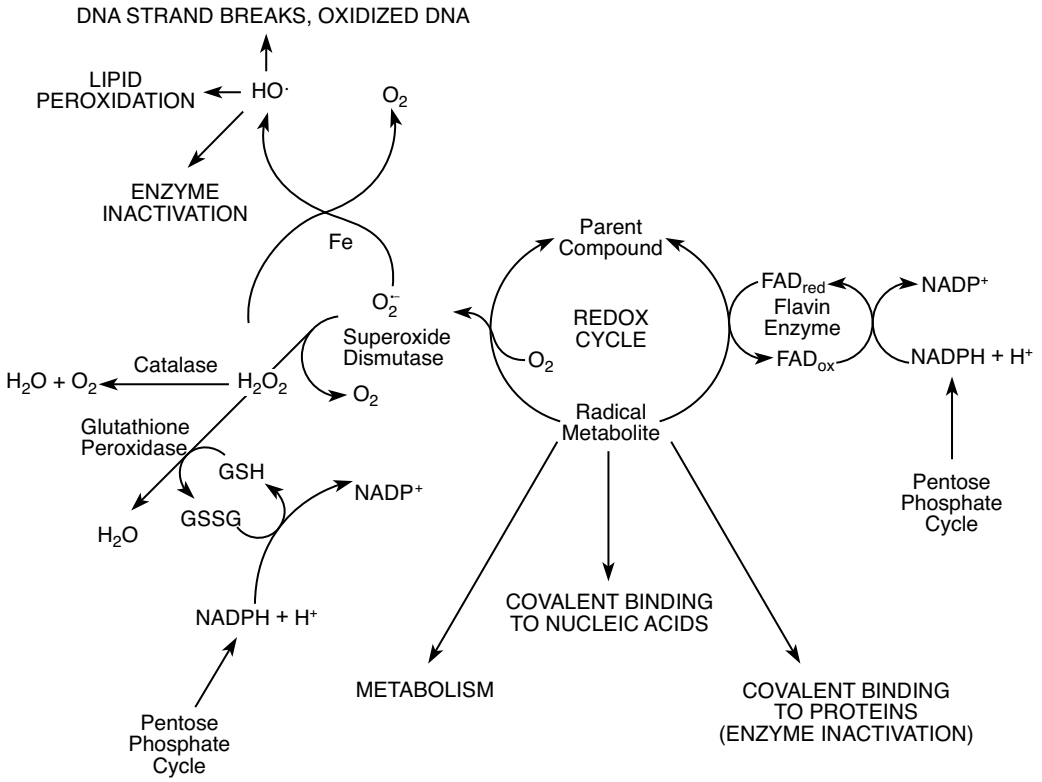

FIGURE 6.7 An overview of ROS generation by redox cycling, key enzymatic antioxidant defenses, and cellular targets of ROS. (Adapted from Kappus, H., in *Oxidative Stress*, Sies, H., Ed., Academic Press, London, 1985, pp. 273–310.)

Chemicals can enhance ROS production by these chains in several ways. Planar halogenated aromatic hydrocarbons (PHAHs) such as 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) and certain polychlorinated biphenyls (PCBs) that bind to the AhR and upregulate expression of genes for biotransformation enzymes including CYP1A (see Chapter 4) have been observed to enhance ROS generation in mitochondria, microsomes, and whole cells (Nebert et al., 2000; Park et al., 1996). In the case of TCDD-enhanced H_2O_2 production in mice mitochondria, this effect was found to be dependent on TCDD binding to the AhR but independent of CYP1A activity (Senft et al., 2002). Studies with 3,3′,4,4′-PCB and 3,3′,4,4′,5-PCB (PCB 77 and PCB 126, respectively, both established AhR ligands) in the marine fish scup (*Stenotomus chrysops*) demonstrated the ability of these AhR agonists to potently induce CYP1A and at higher doses to uncouple microsomal electron transfer, resulting in increased ROS production and inactivation of CYP1A (Schlezinger and Stegeman, 2001; Schlezinger et al., 1999). In this case, the production of ROS was thought to be associated with interactions of the active site of the enzyme with these chlorinated chemicals that are recalcitrant to metabolism and thereby uncouple normal electron flow to the substrate (i.e., PCB), resulting in ROS.

Inhibition of electron transport in mitochondria can also lead to production of ROS; blockage of the flow of electrons leaves mitochondrial proteins in a highly reduced state, which can lead to the reduction of oxygen and ROS production. Chemicals known to produce ROS by this mechanism include rotenone, an insecticide (Li et al., 2003); antimycin A, an antibiotic frequently used to study inhibition of mitochondrial electron transport (Chen et al., 2003); 1-methyl-4-phenylpyridinium (MPTP), a compound used to study Parkinson's disease (Smith and Bennett, 1997); certain oxidatively modified PAHs (Tripuranthakam et al., 1999); and cadmium (Wang et al., 2004). In some cases, however, xenobiotic-mediated uncoupling of electron transport in mitochondria can result in reduced production of ROS (Kowaltowski and Vercesi, 1999; Turrens, 1997).

Photosensitization

Ultraviolet (UV) radiation is typically divided into three general categories: UVC (200 to 280 nm), UVB (280 to 320 nm), and UVA (320 to 400 nm). UVC is not environmentally relevant, as it is effectively blocked by the Earth's atmosphere; however, UVB and UVA radiation to differing degrees do have the ability to penetrate the Earth's atmosphere and water columns to depths dependent on the wavelength of the radiation and the clarity of the water. Both are capable of generating ROS and free radicals either directly or via excitation of photosensitizing chemicals, including both endogenously produced compounds (Young, 1997) and many common pollutants of aquatic systems (Larson and Weber, 1994). Many polycyclic aromatic hydrocarbons (PAHs), for example, are orders of magnitude more acutely toxic to aquatic organisms, including fish, in the presence of ultraviolet radiation than in its absence (Ankley et al., 1997; Arfsten et al., 1996; Bowling et al., 1983; El-Alawi et al., 2002). Energy absorbed by the chemical bonds present in these compounds excites electrons to higher energy orbitals; this energy can lead to changes in the chemical structure of the PAH and in some cases reaction with other molecules, such as oxygen, in a process referred to as *photomodification* (Huang et al., 1997; McConkey et al., 1997). The extra energy can also cause the loss of an electron from the PAH, or the extra energy can be given off by the compound in a variety of ways (Larson and Weber, 1994; Schwarzenbach et al., 1993). As an example, photosensitization occurs when the energy gained by the PAH that absorbed the photon (the photosensitizer) is then passed on to another molecule that would not have been chemically able to absorb that energy directly from the photon, such as O_2 (El-Alawi et al., 2002; Schwarzenbach et al., 1993). Both photosensitization and photomodification of PAHs can lead to the production of ROS; for example, when an electron is lost, it is often absorbed by oxygen, leading to the production both of superoxide anion and a radical compound. Similarly, when energy is lost from the excited compound, it can be transferred to oxygen, producing the reactive singlet oxygen, which is highly reactive and toxic (Briviba et al., 1997). Of course, high-energy radiation such as UV radiation can cause damage in the absence of photosensitizers; however, although UV radiation has been shown to cause oxidative stress, DNA damage, and other biological effects in fish (Charron et al., 2000; Fabacher et al., 1994; Lesser et al., 2001), the environmental relevance of this source of oxidative stress to fish is unclear (Williamson, 1995).

Diminished Antioxidant Defense

Although less studied than enhanced ROS production, interference with antioxidant defense system components represents another mechanism by which chemicals can exert oxidative stress in animals. Inhibition of antioxidant enzymes comprises an important component of this phenomenon; for example, quinones have been shown to inhibit SOD activities (Smith and Evans, 1984). This effect may be mediated by H_2O_2 generated via redox cycling, as prolonged H_2O_2 exposure can inhibit CuZnSOD and FeSOD (Halliwell and Gutteridge, 1999). Relatedly, extracts of diesel exhaust particles were observed to effectively inhibit CuZnSOD *in vitro*, and this effect was surmised to be associated with quinone components of the extracts (Kumagai et al., 1995). Dowla et al. (1996) examined the effects of several chemicals used in agriculture (acephate, cadmium, methamidophos, maleic hydrazide, and nicotine) on activities of human blood SOD, cholinesterase, and δ-aminolevulinic acid dehydrase (ALAD) and found SOD to be the most sensitive to inhibition by all chemicals tested. Plant polyphenols such as chalcones and tannic acids were shown to be potent GR inhibitors *in vitro*, with IC_{50} values in the micromolar range (Zhang et al., 1997). The relevance of such *in vitro* studies to *in vivo* exposures remains speculative. Methylmercury, however, was shown to inhibit hepatic GPX activities and reduce GSH levels in rat pups; these effects were associated with increased lipid peroxidation and hepatotoxicity. These results support the purported prooxidant role of methylmercury, a metal complex that cannot directly generate ROS via redox cycling or Fenton chemistry, as is the case for metals such as Fe and Cu. Moreover, the reactive nature of the sulfhydryl group of GSH makes this critical antioxidant prone to depletion by a number of oxidants and electrophiles.

Studies with Fishes

A large number of studies of oxidative stress in fish have been carried out in the last 25 years or so, with different motivations (Di Giulio et al., 1989). These motivations might be summarized as: (1) increasing the understanding of basic biochemical and molecular mechanisms related to oxidative stress in fish, (2) developing biomarkers related to oxidative stress fish, and (3) investigating the relationships between oxidative stress and the health of wild populations of fish. Some of the results of the studies carried out are presented below with respect to these three concerns.

Basic Biochemical and Molecular Mechanisms of Oxidative Stress in Fish

The study of the toxicity of prooxidant xenobiotics in fish serves both to inform risk assessment with regard to fish populations and to inform our understanding of the toxicity of such chemicals in other organisms, including humans (Bailey et al., 1996; Di Giulio et al., 1989; Kelly et al., 1998; Winston, 1991). Mechanistic studies in fish can be further categorized as characterizing the ability of a xenobiotic to generate ROS in fish cells or living fish, as well as characterizing the antioxidant defenses present in different species of fish, either with or without prior xenobiotic exposure. It is often useful to employ comparative studies involving different species (piscine and nonpiscine) to better understand the impact of prooxidant chemicals in the environment.

In Vitro Biochemical Generation of ROS

In vitro studies have clearly demonstrated that ROS are generated in subcellular fractions (microsomal, mitochondrial, and cytosolic) of fish tissues. Generation of ROS in fish, as in mammals, is sometimes involved in normal physiological processes such as immune function (Anderson, 1994); moreover, release of ROS by phagocytic cells can be stimulated after pollutant exposure in fish (Fatima et al., 2000). In addition, laboratory and field exposures to prooxidant chemicals have resulted in increased ROS production in subcellular fractions of various tissues, particularly liver, gill, and kidney (Lemaire et al., 1994; Livingstone, 2001; Livingstone et al., 2000; Peters et al., 1996; Schmieder et al., 2003; Washburn and Di Giulio, 1988). As discussed previously in this chapter, xenobiotics have been shown *in vitro* to enhance ROS production and oxidative stress by diverse mechanisms, including redox cycling, depletion of glutathione or other antioxidants, facilitation of Fenton chemistry, uncoupling of mitochondrial electron transport, and uncoupling of cytochrome P4501A monooxygenation reactions.

Enzymatic Antioxidant Defenses in Fish

Studies aimed at understanding the biochemistry and, to a much lesser degree, the molecular biology of fish antioxidant systems have also been carried out. Many if not all of the basic antioxidant defenses (enzymatic and nonenzymatic) characterized in mammals are also present in fish. Representative studies describing antioxidant enzymatic activities, reactivity of mammalian antibodies to presumably homologous fish antioxidant enzymes, and sequences for antioxidant genes in fish are presented in Table 6.3. In addition, similar evidence supports the existence of many of the phase II enzymes that can be viewed as playing an antioxidant role or that are regulated by an ARE in mammals (discussed earlier in the section on the ARE and in Chapter 4). Certain GST isoforms in mammals, for example, may play an antioxidant role both by conjugating electrophilic compounds in general (Chapter 4) and by metabolizing 4-hydroxy-2-nonenal (HNE) (Eaton and Bammler, 1999). HNE is a lipid peroxidation product that is both highly toxic and involved in ROS-related signaling (Poli and Schaur, 2000); recent evidence indicates that fish species also express a GST isoform capable of metabolizing HNE (Leaver and George, 1998; Pham et al., 2002; 2004). Similarly, there is evidence that in fish, as in mammals, some GST isoforms possess a glutathione peroxidase activity (Martínez-Lara et al., 2002).

Unfortunately, the exact isoforms of antioxidant enzymes present in different fish species have rarely been carefully identified and characterized. In most cases, enzyme activities have been measured with slight adaptations of assays developed with mammalian species and may reflect the activities of multiple

Note: Sequences submitted to GenBank but not yet published in the literature are included only when no sequence has been published but are in some cases also available in other species for genes whose sequences have been published. Genes not traditionally considered antioxidant but that may play a certain antioxidant role (e.g., GSTs or UDPGTs, as discussed in the text) are not included in this table.

enzymes. As a result, the number of enzymes performing specific catalytic activities, their molecular regulation, and their biochemical characteristics are usually unknown. Studies that have been carried out with genes related to xenobiotic metabolism such as the UGTs (Clarke et al., 1992; George and Taylor, 2002), GSTs (Gadagbui and James, 2000; Leaver et al., 1997; Ramage and Nimmo, 1984), and AhR pathways (Hahn, 2002), as well as other gene families such as the Hox genes (McClintock et al., 2001) in fish, suggest that multiple isoenzymes will be discovered in many fish species, perhaps in some cases more than observed in mammals. Some evidence already exists supporting the possibility of multiple antioxidant isoenzymes such as glutathione peroxidases (Kryukov and Gladyshev, 2000) and metallothioneins (Bargelloni et al., 1999) in fish. Unique catalytic properties that may belong to novel enzymes have been identified in fish species (Hasspieler and Di Giulio, 1994). A theoretical reason to expect multiple antioxidant enzymes in fish is that many fish species are tetraploid because of a chromosome duplication event that occurred after the phylogenetic divergence of ray-finned fishes from other vertebrates (Carroll, 1988). Furthermore, in addition to differences between mammals and fishes, it is likely that very large differences will be identified among different fish species, given the long time over which fish species have been evolving.

Nonenzymatic Antioxidant Defenses in Fish

The major nonenzymatic antioxidant defenses observed in mammals have also been studied in fish. By far the most studied from a toxicological perspective is glutathione, which is present in fish tissues at levels comparable to those observed in mammals (e.g., millimolar concentrations in liver tissue) (Nimmo, 1987). As observed in mammals, tissue glutathione levels are often depleted after short-term oxidant exposures but elevated after long-term exposures. Furthermore, glutathione depletion sensitizes fish, like mammals, to the toxicity of prooxidant xenobiotics (Gallagher et al., 1992a). Other important antioxidants, such as vitamin C, vitamin E, ubiquinone, and carotenoids, have been less studied relative to toxicology in fish but likely play an important role (Bell et al., 2000; Olsen et al., 1999; Parihar and Dubey, 1995; Payne et al., 1998; Tocher et al., 2002). In addition, important differences clearly exist in terms of the ability of different fish species to synthesize vitamin C (Moreau-Regis and Dabrowski, 1998). Although the majority of studies of nonenzymatic antioxidants in toxicology have historically focused on glutathione, it is increasingly clear that other compounds are also important. Studies of the total oxyradical scavenging capacity (TOSC) (Regoli and Winston, 1999; Winston et al., 1998) of tissue homogenates from both aquatic and nonaquatic organisms have demonstrated that compounds other than the classical antioxidants such as glutathione, vitamin C, and vitamin E can contribute very significantly to the *in vitro* oxyradical scavenging capacity of those tissue preparations. As in mammals, it is likely that diet plays a very important role in determining the nonenzymatic antioxidant capacity of fish tissues (Mourente et al., 2000; Nakano et al., 1999; Olsen et al., 1999; Pascual et al., 2003).

In Vivo Prooxidant Studies in Fish

As previously stated, the fact that a chemical produces ROS in an *in vitro* situation does not mean that the same chemical will cause oxidative stress *in vivo*. The additional complications introduced by kinetics of uptake, metabolism, and excretion in a living organism can be understood only by testing the effect of a chemical in an *in vivo* system. Table 6.4 is a representative list of stressors shown to exert oxidative stress either in intact fish or, in a few cases, in fish cells. It is important to bear in mind that not all chemicals in the chemical classes listed in column 1 are expected to be prooxidants. Specific chemicals that induced oxidative stress in the studies cited are listed in parentheses as examples. Generally speaking, the chemicals shown to cause oxidative stress in mammals have also done so in fish.

Many chemicals are more or less toxic depending on other factors. An example that has received considerable attention recently is phototoxicity, which is the greatly enhanced toxicity of specific chemicals (especially many PAHs) in the presence of ultraviolet radiation. UV radiation can excite an electron of such chemicals, and the resultant excited-state molecule is more reactive and often ultimately more toxic. Empirical studies with fish have strongly supported the hypothesis that the phototoxicity or photo-enhanced toxicity of PAHs resulting from the process of photosensitization is mediated by oxidative stress (Choi and Oris, 2000; Weinstein et al., 1997). In addition, chemical structure alterations produced by UV irradiation can produce compounds such as quinones and phenols that are capable of redox cycling and interfering with electron flow in electron transport chains of mitochondria (Huang et al., 1997; Tripuranthakam et al., 1999), both processes that can lead to oxidative stress. Thus, phototoxicity represents a distinctive source of oxidative stress that may be of particular importance in aquatic systems with clear water columns. It is important to note, however, that most of the studies carried out thus far have been conducted under laboratory or constrained field conditions, so the ecological relevance of phototoxicity is controversial (McDonald and Chapman, 2002).

Differences between Fish and Mammals

As we have seen, many of the basic mechanisms of ROS production and damage are shared between fish and mammals. Despite the overall similarities in antioxidant defenses, however, important differences exist between fish and mammalian species, some of which are summarized here. ROS production in microsomal fractions was higher in rainbow trout, as well as in two aquatic invertebrate species, with

[a] As indicated by markers such as lipid peroxidation.

[b] As indicated *in vitro* either by dyes whose fluorescent properties are altered by exposure to ROS or by reporter transgenes.

Note: Not all chemicals pertaining to the chemical classes listed are prooxidant; specific examples studied in the references cited are listed in parentheses.

NADH than with NADPH as a source of reducing power, in contrast to the situation seen in rats (Jewell and Winston, 1989; Kennish et al., 1989). Glutathione depletion under conditions of starvation was much slower in mullet (*Mugil cephalus*) (Thomas and Wofford, 1984) and channel catfish (*Ictalurus punctatus*) (Gallagher et al., 1992b) than in rodents. Perhaps because of the observed low (relative to rodents) rate of turnover of glutathione in catfish, administration of buthionine sulfoximine (BSO), an inhibitor of GCL, did not completely deplete hepatic glutathione, although coadministration of BSO and diethyl maleate (DEM), a glutathione depletor, led to nearly complete depletion of glutathione (Gallagher et al., 1992b). There is considerable variability in the reported catalytic activities of many of the antioxidant enzymes, both between fish and mammals and between different fish species (Di Giulio et al., 1989; Forlin et al., 1995; Gadagbui et al., 1996; Hasspieler et al., 1994a,b; Ploch et al., 1999; Rana and Singh, 1996; Winston, 1991). Biochemical differences that are important in terms of sample preparation and treatment also exist; for example, mammalian CuZnSOD is a remarkably thermostable enzyme, but the CuZnSODs from two different fish species are much more labile at high temperatures (60°C and above) (Capo et al., 1997; Nakano et al., 1995). Vitamin E levels appear to be generally higher in fish cell membranes than in mammalian cell membranes, but it is unclear whether this difference is protective in the context of the typically higher levels of PUFA observed in fish cell membranes (Bell et al., 2000; Singh et al., 1992). Some studies have found that fish cells are more resistant than mammalian cells to oxidative stress *in vitro* (Singh et al., 1992; Venditti et al., 1999), while others have found the opposite (Rau et al., 2004).

Biomarkers of Oxidative Stress

How is it possible to know if oxidative stress is a problem in a given field situation? Many studies have attempted to identify and evaluate reliable biomarkers of exposure to pollution (see Chapter 16). Despite a large number of laboratory exposures to pure compounds (Almeida et al., 2004; Bergman et al., 1994; de Pandey et al., 2001; Dorval et al., 2003; Rau et al., 2004) and environmentally relevant contaminant mixtures (Bergman et al., 1994; Celander et al., 1994; Di Giulio et al., 1993; Livingstone et al., 1992; Meyer et al., 2003; Nishimoto et al., 1995; Steadman et al., 1991) and field studies (Bacanskas et al., 2004; Bainy et al., 1996; Eufemia et al., 1997; Livingstone et al., 1992, 1995; McClain et al., 2003; McFarland et al., 1999; Otto and Moon, 1996; Porte et al., 2002; Rodríguez-Aziza et al., 1992; Stein et al., 1992; Stephensen et al., 2000; van der Oost et al., 1996; Ventura et al., 2002), no single biomarker of oxidative stress has emerged that is as sensitive and specific as other established biochemical biomarkers such as acetylcholinesterase activity for organophosphate insecticides, δ-ALAD activity for exposures to lead, or CYP1A expression/activity for aryl hydrocarbon receptor agonists (see Chapter 16). Various studies have identified GSSG:GSH ratios, levels of MT or lipid peroxidation, and activities of GR, microsomal GST, or microsomal GPX as the most sensitive indicators in the system being studied, but these markers have been completely unresponsive in other contexts. An extensive review of biomarker studies that included a specific review of biomarkers of oxidative stress (van der Oost et al., 2003) failed to identify any marker that was responsive in a high percentage of the studies reviewed, with lipid peroxidation being perhaps the most consistent marker. Representative examples of field studies employing biomarkers of oxidative stress are provided in Table 6.5.

Why have better markers of oxidative stress in wild fish not been identified? A variety of factors may be involved. First of all, as in mammals, large inductions (e.g., comparable to the inductions in CYP1A observed after exposure to certain xenobiotics, as discussed in Chapters 4 and 16) in antioxidant enzymes have not been observed in fish exposed to prooxidants. As a result, any confounding factors present have a strong chance of hiding an otherwise observable effect. Unfortunately, there are many such confounding factors. An environmental pollution mixture will rarely be expected to exert toxicity only by oxidative stress, so other forms of toxicity may be occurring. Additionally, sex and reproductive condition can affect many antioxidant parameters (Livingstone et al., 1995; McFarland et al., 1999; Meyer et al., 2003; Winzer et al., 2001, 2002a,b) but are not always taken into account. In that case, the variance associated with sex becomes "noise," potentially obscuring real differences. Similarly, temperature can greatly alter the metabolic capacity of poikilotherms and has been shown to affect antioxidant defenses in fish (Heise et al., 2003; Olsen et al., 1999; Parihar and Dubey, 1995; Parihar et al., 1996). Diet alters the activity of many antioxidant enzymes (George et al., 2000; Hidalgo et al., 2002; Mourente et al., 2000, 2002; Pascual et al., 2003), as well as altering the tissue concentrations of nonenzymatic antioxidants, as mentioned above. Dissolved oxygen (Cooper et al., 2002; Hermes-Lima and Zenteno-Savín, 2002; Lushchak et al., 2001; Ritola et al., 2002; Ross et al., 2001) and salinity (Kolayli and Keha, 1999; Martínez-Álvarez et al., 2002) have also been observed to affect antioxidant parameters. Seasonal effects have been observed (Bacanskas et al., 2004; Ronisz et al., 1999) and are likely to incorporate many other biological and environmental variables, such as temperature, reproductive status, and food sources. Additionally, time courses can be complicated; for example, although total glutathione levels can increase dramatically in response to prooxidant exposure, the initial response is often depletion, and degree of induction is very likely to be additionally affected by diet, as the availability of cysteine can be limiting for the production of GSH. Antioxidant enzymes have also been observed sometimes to be depressed at the level of activity or expression after exposure to prooxidants (Fujii and Taniguchi, 1999; Kim and Lee, 1997; Pedrajas et al., 1995; Radi and Matkovics, 1988; Stephensen et al., 2002; Zikic et al., 1997). Developmental stage is another variable to be considered (Peters and Livingstone, 1996).

Physiological or genetic adaptation to pollution has been shown to lead to an altered response even in biomarkers that are usually fairly robust, such as CYP1A (Elskus et al., 1999; Hahn 1998; Meyer et al., 2002; Roy et al., 2001; see also Chapter 15). Although the possibility of adaptation to oxidative stress in fish has been less studied, it may also be a significant factor in some cases (Bacanskas et al., 2004; McFarland et al., 1999; Meyer et al., 2003). Markers of damage, such as lipid peroxidation and DNA damage, may only reflect recent or constant damage, as both can be repaired. Another important

Note: Representative biomarker studies were performed on fish from contaminated field sites or on fish exposed in the laboratory to contaminated sediments taken from field sites. Note that in many cases exhaustive chemical analysis was not performed, so the chemicals to which the fish were exposed are not well defined in those cases. Not all biomarker responses observed are listed but only those that fall into the category of oxidative stress and which showed a clear change.

Downloaded from Wet-Books.com

concern is that most fish populations are highly outbred with a high degree of genetic variability (compared to typical laboratory mammalian models), which may contribute additional variability to the responses observed. Finally, as mentioned earlier, the various antioxidant isoenzymes potentially represented in fish are not well characterized, and it may be that potentially good biomarkers are being overlooked due to nonspecific substrates, antibodies, etc. An improved understanding of biological and environmental modulation of oxidative stress and antioxidant defenses in fish, along with careful experimental design and improved techniques, should enhance the utility of biomarkers for oxidative stress in the future; however, as discussed above, no single broadly applicable biomarker for oxidative stress is likely to emerge in the foreseeable future.

Oxidative Stress and the Health of Wild Fish Populations

As described above, oxidative stress is known to play an important role in many disease processes and chemical-mediated toxicity in humans. Furthermore, it is clear that there are many similarities among humans, mammalian models, and fish in terms of production and cellular effects of oxidative stress, as well as in terms of antioxidant defenses; nonetheless, the importance of oxidative stress to fish populations in the wild is not yet fully understood. Biomarkers of effect of exposure to ROS such as lipid peroxidation (Di Giulio et al., 1993; Eufemia et al., 1997; Livingstone et al., 1993) and DNA damage (Di Giulio et al., 1993; Eufemia et al., 1997; Malins and Gunselman, 1994; Payne et al., 1998; Rodríguez-Aziza et al., 1999; Stein et al., 1992; Stephensen et al., 2000; Sugg et al., 1996; Theodorakis et al., 1997, 1999) indicate that fish inhabiting polluted environments exhibit oxidative stress (although not all of these DNA damage studies are necessarily strictly oxidative-stress related). Some common fish diseases, such as jaundice and methemoglobinemia ("brown blood disease") have been associated with oxidative stress (Jensen, 1996; Sakai et al., 1998). Some studies suggest that the highly teratogenic effects of TCDD are related to its ability to produce ROS mediated by the catalytic activity of cytochrome P4501A (Cantrell et al., 1996; Dong et al., 2002; Schlezinger et al., 1999; Teraoka et al., 2003); however, this remains controversial (Carney et al., 2004).

Fish populations adapted to inhabit ecosystems contaminated with chemical mixtures containing prooxidants such as creosote (Meyer and Di Giulio, 2003) and metals (Weis et al., 1999; Xie and Klerks, 2003) have been shown to be less fit than their counterparts from clean sites in several contexts. There are many published examples of fish populations inhabiting sites contaminated with prooxidant chemicals that exhibit high rates of DNA damage and cancer (Black, 1983; Malins and Gunselman, 1994; Malins et al., 1984; Mix, 1986; Vogelbein et al., 1990). Although the chemicals present at such sites are not exclusively toxic via prooxidant mechanisms, a strong relationship exists between oxidative stress and cancer (Klaunig et al., 1998). Furthermore, the ability of channel catfish to avoid cancer in the same polluted environments that cause liver cancer in brown bullhead catfish has been associated with higher antioxidant defenses (Hasspieler et al., 1994a,b; Ploch et al., 1999). Dietary exposure to hydrogen peroxide enhanced the development of oxidative DNA damage (8-OHdG) and hepatic tumors in rainbow trout exposed to the carcinogen *N*-methyl-*N*′-nitro-*N*-nitrosoguanidine in a laboratory study (Kelly et al., 1992). As in the case of human epidemiological studies, however, it is difficult to unequivocally link a given pollutant or form of toxicity with population-level measurements of health. Long-term laboratory exposures will likely be needed to better define the links between exposure to oxidative stress and ecologically relevant alterations in fish populations, and improved markers of oxidative stress will be necessary to analyze the responses of populations of wild fish to oxidative stress.

Future Directions

A better understanding of which antioxidant genes are present in fish, how they are regulated, and what their biochemical characteristics are will greatly improve our ability to understand the impact of oxidative stress and the impact of prooxidant chemicals on fish. Similarly, application of the knowledge gained in studies of oxidative stress in mammalian models will inform improved generation of hypotheses and experimental design; for example, we know now that very large inductions in expression of classical

Downloaded From Vet-eBooks.com

antioxidant genes such as superoxide dismutase, catalase, or glutathione peroxidase should not be expected either in mammals or in fish. Future studies will be likely to examine the expression of genes shown in mammals to respond strongly to oxidative stress but which have received less attention in fish (e.g., heme oxygenase). Similarly, they may examine additional parameters and subcellular compartments; for example, mitochondria are an important target of oxidative stress (Cadenas and Davies, 2000; Finkel and Holbrook, 2000; Kowaltowski and Vercesi, 1999; Krumschnabel et al., 2005; Outten et al., 2005; Yakes and Van Houten, 1997), but mitochondria or mitochondrial-specific parameters such as MnSOD, mitochondrial glutathione pools, and mitochondrial GPX have received little attention. Molecular characterization of antioxidant enzymes in fish may provide guidance by demonstrating which genes are ARE regulated and which are not. Future studies should also take into account (through experimental design and/or statistical analysis) as much as possible the effects of confounding biological and environmental factors such as sex, season, oxygen tension, and diet. Improved methodology for the measurement of DNA damage, lipid peroxidation, and other biomarkers of effect will permit more sensitive assays, and increased knowledge of fish-specific forms of antioxidant enzymes will provide more specific assays. Further testing of relatively new techniques such as the TOSC assay may lead to powerful new tools. The development of transgenic fish with reporter genes activated by oxidative stress (Carvan et al., 2001) may result in highly specific measurements of the generation on ROS *in vivo*, in the laboratory, or in the field. Assays that take advantage of fish-specific biology may also prove valuable; for example, the presence of nucleated blood cells in fish permits a nonlethal measurement of DNA damage (Tiano et al., 2001; Villarini et al., 1998) as well as other endpoints (Anderson, 1994; Bainy et al., 1996; Gabryelak and Klekot, 1985; Ritola et al., 2002).

At the same time as biochemical and molecular methodologies are improved and mechanistic understanding of oxidative stress in aquatic organisms is refined, it will be important to begin to more carefully explore relationships between exposure to oxidative stress and population-level effects. The associations between contaminant exposure and cancer epizootics and other fitness costs mentioned above suggest that oxidative stress is an ecologically important phenomenon; however, few attempts have been made to quantify the costs of the oxidative damage caused by environmental pollutants for individual fish, fish populations, and aquatic ecosystems. Although a mechanistic understanding of oxidative stress in fish is important from the standpoint of comparative toxicology and basic biology, a solid understanding of the ecological importance of oxidative stress is dependent upon studies of higher level effects.

Introduction

A range of contaminants including carcinogens, metals, biotoxins, and persistent organic pollutants injure the livers of fishes, and, although some mechanisms of liver injury are unique to fish, often hepatic injury in these aquatic vertebrates arises from mechanisms similar to those observed in mammals. Development and approval of pharmaceuticals, personal-care products, and cosmetics and the identification of occupational safety risk factors have led to an abundance of information regarding hepatic injury in mammals. For fish, no such large-scale programs have served to further understanding of hepatic toxicology. For students of the toxicology of fishes, it is important to review some of the interests that have led to the current state of our knowledge regarding toxicity in this target organ. Interest in the investigation of liver toxicity and injury in fishes stems from several motivations, including developing an understanding of vertebrate comparative physiology and anatomy; addressing problems in aquaculture associated with liver pathologic conditions caused by nutrition-related factors or improper storage of dietary components; analysis of the pathogenesis of liver neoplasia in selected fish species; and, more recently, development of biomarkers of exposure and effect and use of toxic alterations/responses in risk effects assessment. The latter interest stems from the fact that the aquatic medium is a sink for many anthropogenic contaminants (Long and Buchman, 1990; Mackay, 1992a,b; Tanabe et al., 2004). Pioneering workers recognized the unique strengths emanating from toxicological and biomedical studies comparing the spectrum of vertebrates (Guarino, 1987). Also, within the taxonomic class of fishes, where the largest group of vertebrates are found, comparative approaches can provide important insights, given the numerical, physiological, and ecological diversity herein. Recently, the transfer and incorporation of exciting new molecular technologic advances from the biomedical arena to environmental monitoring and assessment have been realized (Larkin et al., 2003; Rise et al., 2004; Williams et al., 2003). Strengths of fish models are now increasingly recognized and being used by the biomedical community (Barut, 2000; Dodd et al., 2000; Larkin et al., 2003; Loosli et al., 2000). Students of fish liver toxicology will need to achieve integration of various approaches/disciplines to use these new tools effectively and to interpret findings in their model systems. There is a need to push our understanding of fish liver toxicology while maintaining contact with advances in the biomedical arena. We feel that the time is ripe for a critical assessment of the hepatic toxicology of fishes, and we hope that this chapter portrays the progress achieved and stimulates and guides future studies.

The Liver as a Target Organ

In part, the structure and function of the normal liver in fishes make it a target organ for toxic chemicals. To better understand this statement, we must first consider the position of the liver, its afferent and efferent vascular relationships, its microvascular properties that facilitate uptake, and how toxicants

Downloaded From Vet-eBooks.com

reach this organ. The liver has a dual blood supply. Arterial blood reaches the liver by way of the hepatic artery, a branch of the celiacomesenteric artery from the dorsal aorta. An afferent venous supply, the hepatic portal vein, is the major source of blood to the liver. Whether the source is arterial or venous, blood from both sources enters the capillary bed, hepatic sinusoids, or microvasculature of the liver. In turn, this bed of capillary-like vessels, the hepatic sinusoids, is the basis for the liver being referred to as a richly perfused compartment, one especially equipped with special modifications of the endothelial cells (i.e., fenestrae and an absence of basement membrane) that facilitate rapid uptake of substances. The exit path for hepatic blood is also of great importance, as the release of toxic substances such as acute-phase proteins following liver injury may affect the structure and function of downstream organs (heart, gill, brain). Venous flow from the liver is described later in this chapter.

Due to the dual blood supply of the liver, it is important for us to consider two principal routes of uptake that may lead to hepatic distribution of potentially toxic compounds. These are the intestinal uptake route and the branchial one. For important information in this regard, the reader is referred to two other chapters in this text, Chapter 8 and Chapter 3.

For those compounds with log K_{ow} values of 3 to 4, accumulation by fish is primarily by the aqueous route (McKim and Nichols, 1994), and much of this will involve the gill. These compounds may first interact with the surficial branchial and branchial endothelial cells. From here the compounds may take a more direct route to the liver but one that requires passage into the dorsal aorta and its branches, as described above, before it reaches the liver. For that portion of branchial blood that goes directly to the head or is distributed to organs, such as the swim bladder, an indirect path involving venous return of compounds back to the heart and another pass through the branchial circulation before entry in liver are used. Clearly, the liver is not an initial or primary target for compounds taken up by tissues such as the gills (Barron et al., 1989) but may be exposed to a combination of parent compound and metabolites from more proximate cells and tissues. With the swallowing of water, the gut becomes a possible route for the uptake of polar compounds. With this route, the liver is a more direct target, but metabolism within the wall of the intestine (Van Veld et al., 1997) is likely prior to entry in liver.

For those compounds with log $K_{ow} > 6$, uptake will likely be by the dietary route. This includes polychlorinated biphenyls (PCBs), dioxins, dichlorodiphenyltrichloroethane (DDT) and its metabolites, and other persistent organic pollutants (POPs). For the sake of liver toxicity, important questions include: How much and what type of metabolism occurs prior to entry in liver? On a volume basis, the liver receives the vast majority of its blood supply by way of the hepatic portal vein. This strategic location means that capillary beds within the walls of the stomach (gastric fishes), the entire intestinal tract, and the spleen are tributaries to the hepatic portal vein. The liver is therefore an early but not the first organ to encounter ingested nutrients, vitamins, metals, drugs, and environmental toxicants, as well as waste products of bacteria that enter hepatic portal blood. At the present, we lack information on first-pass metabolism in the wall of the alimentary canal and in the spleen; however, ample evidence from studies with toadfish (*Opsanus tau*), spot (*Leiostomus xanthurus*), channel catfish (*Ictalurus punctatus*), mummichog (*Fundulus heteroclitus*), and tilapia (*Oreochromis mossambicus*) suggests that the intestine, and not the liver, is the initial metabolic organ following dietary exposure to polycyclic aromatic hydrocarbons (PAHs) and halogenated hydrocarbons (James and Kleinow 1994; James et al., 1996, 1997; Kleinow et al., 1998; Van Veld et al., 1987, 1988; Vetter et al., 1985; Yeung et al., 2003). How much of the compound is sequestered in other organs prior to the liver? We are not aware of studies that have shown a differential hepatic toxicity in relation to the uptake route. At the present time, it is difficult to make a reasonable prediction on the relevance of specific uptake routes for liver toxicity.

Finally, the skin may represent an important route for uptake, particularly for the early life stages of fish. From the skin, venous return to the sinus venosus, passage through the heart, and return through the branchial circulation (to a varying degree dependent on development) would be necessary before the compounds would reach the liver. Given the strategic location of the liver, however, its complement of enzymes, its dual blood supply, and the enterohepatic circulation, this organ is a major target for xenobiotics whatever the exposure route considered.

Major Functions of the Liver

The three major functions of the liver essential for life of the organism are:

- *Uptake, metabolism, storage, and redistribution of nutrients and other endogenous molecules*—The synthetic and excretory functions of the liver maintain the homeostasis of the organism. To achieve this, specific molecules are synthesized in hepatocytes, packaged in the Golgi apparatus, transported in a specific direction for release into the intercellular spaces and to the bloodstream, where they are taken up by other organs and utilized. Some examples of storage, synthesis, and redistribution functions include glycogenolysis and hepatocyte release of glucose to govern blood glucose levels; hormone synthesis and release (e.g., somatomedins); synthesis and release of proteins, as in the case of serum albumins, the yolk precursor vitellogenin, and the zona radiata protein or choriogenin. The removal, metabolism, and eventual excretion of compounds also participate in the homeostatic role of the liver; for instance, hormones are taken up and broken down by the liver.
- *Metabolism of lipophilic compounds, including xenobiotics*—Biotransformation reactions catalyze the conversion of endogenous as well as exogenous compounds with poor water solubility to more hydrophilic metabolites that can be readily excreted. With respect to xenobiotics, the majority of hepatic biotransformation reactions may be considered as a detoxification process decreasing toxic body burden by enhancing excretion. However, during the biotransformation process, generation of electrophilic reactive species can lead to interaction with basic cellular constituents such as DNA and proteins. The end result of this process may be disruption of normal cellular function and overt toxicity, including acute forms and chronic states such as carcinogenesis and tumor formation.
- *Formation and excretion of bile*—Bile excretion is important for the elimination of degradation products of endogenous compounds such as heme or steroid hormones, as well as for the elimination of xenobiotics and their metabolites and some metals such as copper and mercury.

All of these hepatic functions—synthesis and redistribution of nutrients and intermediary metabolites, biotransformation, and bile formation—have been shown to be involved not only in physiological states but also in processes leading to alterations in hepatic morphology and physiology. It is this great metabolic capacity of the liver that makes it both a target and an organ of defence. When toxic hits on the target occur, they may lead to alterations or injury in liver structure and function. Because of the multiple physiologic functions of the liver and its considerable plasticity, the liver responds to toxic insults in many different ways; thus, there appears to be no prototype single reaction classification of hepatotoxicity. Rather, a combination of morphologic pattern, functional alteration, and mechanisms is used to classify hepatotoxicants in mammals (Vandenberghe, 1996) and could be used for fishes as well.

The deterioration of hepatic structure and function not only is relevant for the liver itself but may also lead to aberrations in other organs and to death of the organism. Loss of biliary function alone is incompatible with life. Hepatic clearance function and dysfunction involving the microvasculature and the intrahepatic biliary system for excretion of compounds as well as the pronounced metabolic capacity of this organ may all play a role in the spectrum of toxic conditions possible in this organ. The liver also possesses a pronounced capacity to acclimate to toxic stress, producing protective molecules or performing efficient repair and full or partial recovery. The latter may be considered acclimation, providing for survival of the altered host.

An understanding of chemical hepatotoxicity requires an appreciation of anatomic and physiologic features of the liver. With respect to fish liver, it is important to emphasize that, although fish and mammalian liver agree in many features, there are still differences that may influence chemical toxicity and especially its interpretation. Also, although there are basic similarities of structure and function common to the fraction of the total fish species that have been investigated, species differences must always be considered, and this should involve considerations at all levels of biological organization.

Downloaded From Vet-eBooks.com

In this chapter, we seek to: (1) briefly review key aspects of liver morphology and physiology of fish, emphasizing those features that differ among fish species and between fish and their mammalian counterparts, and emphasizing why and how these features are relevant to understanding the liver toxicity of fish; (2) review the literature on liver pathology in toxicant-exposed fish and provide insight into major pathological and pathophysiological response patterns of fish liver; and (3) identify specific information gaps and provide suggestions for future directions.

Liver Structure

Fundamental aspects of fish liver anatomy, especially those important in the interpretation of toxicity, were recently reviewed (Hinton and Couch, 1998; Hinton et al., 2001), and the interested reader is referred to these detailed descriptions. In an extensive treatise on the biology and pathobiology of the human liver by Arias et al. (1988), six specific principles were listed that are required and govern structure and function of a liver. We paraphrase these as follows: (1) exocrine and metabolic functions expressed in the same cell (the hepatocyte); (2) a double blood supply (arterial from the dorsal aorta and afferent venous from the hepatic portal vein); (3) a specific architectural arrangement of single cells and cell masses that facilitates exchange between blood and hepatocytes; (4) features of perihepatocellular or perisinusoidal spaces (of Disse), such as the absence of basement membrane, thereby maximizing the exchange between blood and hepatocyte; (5) separation of the lumen of biliary from blood spaces, thereby compartmentalizing excretory from other hepatocytic functions; and (6) specific biochemical activities of hepatocytic receptors, enzymes, organelles, and cell membranes that regulate and enable specific functions.

As is demonstrated in subsequent sections of this chapter, fish hepatocytes fulfill requirement 1 above. In addition, we review and provide new evidence for the dual blood supply (requirement 2). The specific architectural pattern of cell masses is very similar in embryos and larval equivalent livers of mammals and fishes; however, with respect to requirement 3, mammalian adult liver differs from livers of fishes, reptiles, amphibians, and birds. Electron microscopic observations reveal fenestrae in sinusoidal endothelium of mammals and fishes, and both lack a basement membrane to facilitate exchange (requirement 4). Fish liver meets requirement 5, and these functional characteristics are reviewed in the subsequent section.

Despite of the many structural similarities between the livers of fishes and those of mammals, certain features of hepatic gross and microscopic anatomy of fishes are recognized as different (Hampton et al., 1985, 1988, 1989). Some of these include the number of lobes; presence or absence of lobules and portal tracts; architectural arrangement of hepatocytes; the absence in many fish species of Kupffer cells; and the distinctive and common presence of macrophage aggregates in fishes (Table 7.1).

Coverage of liver anatomy in fish is not complete without mention of the exocrine pancreatic cells that occupy the periadventitia of portal veins within the body of the liver. Certain species contain abundant pancreatic cells (varying in amount), thus leading to the term *hepatopancreas*. The recent observations and three-dimensional reconstructions of the tilapia (*Oreochromis niloticus*) should be consulted (Figueiredo-Fernandes et al., 2007).

The above structural similarities and differences represent more than a simple academic exercise in comparative liver anatomy; rather, they are important in interpretation of toxic responses within livers of fishes. *In vitro* studies with isolated primary hepatocyte preparations (Rabergh and Lipsky, 1997) or precision slices of trout liver (Singh et al., 1996) have clearly shown that exposure is followed by the presence of cytosolic enzymes in culture medium, validating the toxic nature of these responses. Architectural (the absence of lobules) and physiological (lack of metabolic zonation; see below) differences in fish vs. rodent livers apparently lead to different histological patterns of toxicity. Assuming that the absence of a mosaic pattern of response, such as centrolobular necrosis following carbon tetrachloride exposure of rodents (see below), indicates that fish are not capable of responding to such agents is erroneous; instead, other patterns of morphologic response are likely in fish (Droy, 1988).

TABLE 7.1

Comparison of Rodent and Fish Hepatic Anatomical Features

Feature	Rodent	Fish
Liver lobes	Multiple	Usually single; cyprinids are exception
Lobules	Distinct	Indistinct or absent; implies different arrangement
Portal tracts	Classic lobule contains bile duct, portal venule, and hepatic arteriole and defines sites where arterial blood enters hepatic microcirculation	Absent; larger bile ducts may coexist with hepatic artery in so-called "biliary arterial tract"; no portal vein branches are in biliary arterial tracts
Blood supply	Dual supply by hepatic artery and hepatic portal vein (major volume); capillary-like sinusoids contain arterial and afferent venous blood	Dual supply by hepatic artery and hepatic portal vein (major volume); capillary-like sinusoids contain arterial and afferent venous blood
Venous drainage	Hepatic veins to caudal vena cava	Hepatic veins to sinus venosus
Architecture of parenchyma	Laminae of hepatocytes predominantly one-cell thick and usually separated by sinusoid from nearest neighbor; no biliary epithelial cells in parenchymal compartment	Hepatic tubules comprised of five to eight hepatocytes clustered about a lumen (biliary passageway); parenchyma often contain biliary epithelial cells (see below)
Biliary system	Canaliculi sole component in lobules, with network extending from center of lobule to periphery; cholangioles (ducts of Hering) at lobular margin; small bile ducts in portal tracts; large intrahepatic ducts near hilus	Canaliculi formed by lateral plasma membranes of adjacent hepatocytes; after short course communicate with lumen of hepatic tubule; transitional biliary epithelial cells and cholangioles present at center of tubules
Kupffer cells	Present	Generally absent; *Ameiurus* species are exceptions
Perisinusoidal macrophages	Present	Present
Macrophage aggregates	Absent	Present

In early embryonic stages, human hepatocytes form cords or tubules in which (as in a gland) multiple epithelial cells appear on the cut surface to surround the lumen. The epithelial cell masses cluster around a biliary vascular axis to which afferent blood is brought from hepatic arteries and portal veins, and bile is secreted in the opposite direction (Arias et al., 1988). As metabolic demands rise for mammals, the gland-like cords are transformed into a sponge-like wall work, or cellular mass, which is composed of hepatocellular plates (or laminae) that are predominantly one hepatocyte thick; they meet at different angles and surround the hepatic lacunae (microvasculature and spaces immediately surrounding the capillary such as sinusoids). In the human, metamorphosis from cord or tubule to laminae of hepatocytes is completed by age 5 (Arias et al., 1988). In contrast, the livers of amphibians, birds, fishes, and reptiles retain the tubular architectural pattern as the adult phenotype (Hampton et al., 1985; Hinton and Couch, 1998; Hinton et al., 2001). This glandular arrangement of cells within the piscine liver translates into an abundance of biliary epithelial cells in close proximity to hepatocytes within the parenchymal compartment (Hinton and Couch, 1998).

Gross inspection of the livers of fish reveals that most are in the form of a single lobe (Figure 7.1), whereas livers of mammals have multiple lobes. Cyprinid fishes such as *Cyprinus carpio* and *Danio rerio* have extensions from the major liver mass that extend along loops of the intestine (Amlacher, 1954). These may be regarded as multiple lobes (Figure 7.2). The relationships of the liver to neighboring organs are shown in Figure 7.3 and Figure 7.4.

The classic lobule, a consistent microanatomical feature of mammalian liver, is not present in the livers of fish, as has been illustrated in high-resolution light micrographs from medaka liver (Figure 7.5). Mammalian portal tracts, found at corners of the classic lobule, are variably delimited in different mammalian species by perilobular connective tissue containing the bile duct, portal venule, and hepatic

Downloaded From Vet-eBooks.com

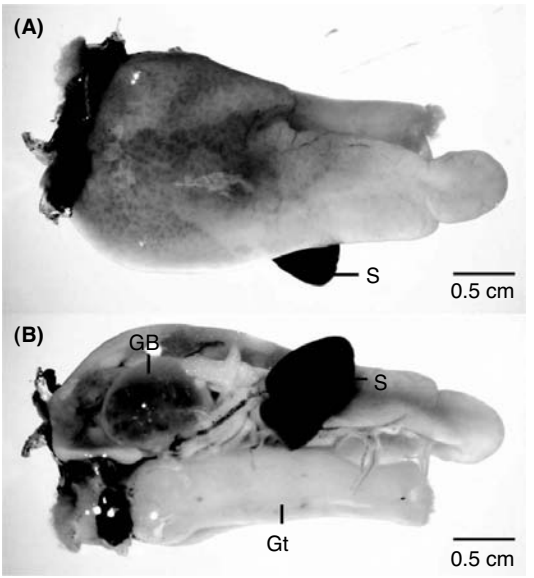

FIGURE 7.1 (See color insert following page 492.) (A) Ventral view of freshly dissected liver of *Fundulus heteroclitus*. This liver is typical of the compact, single-lobed livers of many teleosts. (B) Dorsal view of the liver shown in A. Between the gallbladder and larger spleen, the hilus of the liver is seen. It is here that the hepatic ducts leave the liver and the arterial and afferent venous blood supplies enter the organ. GB, gallbladder; Gt, gut; S, spleen.

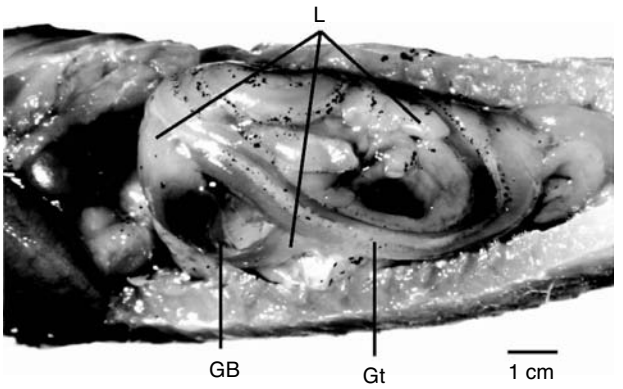

FIGURE 7.2 (See color insert following page 492.) Freshly dissected visceral mass from goldfish (*Cyprinus carpio*) illustrating the liver pattern of some teleosts in which the organ is comprised of multiple lobes or extensions between coils of the intestine. The black material is due to melanocytes in the visceral peritoneum of this abdominal cavity. Establishing a precise liver weight or dissecting the organ for biochemical or molecular analyses would prove difficult with livers of this form. Arrows point to portions of the liver in close proximity to the elongated intestinal tract. GB, gallbladder; Gt, gut; L, liver.

arteriole (with a lymphatic vessel and a nerve). Portal tracts are anatomic indications of sites where arterial and afferent venous blood enters the parenchymal compartment (lobule). Hepatocytes adjacent to portal tracts receive more oxygenated blood than do those cells at central portions of lobules. This lobular zonation of mammals (Sasse et al., 1979) is important when interpreting toxic responses and classifying various hepatotoxicants when exposure results in a mosaic pattern of altered and unaltered parenchyma, depending on the targeting of afferent or efferent zones by the toxicant. No such anatomical mosaic pattern has been observed in fish exposed to reference hepatotoxicants (see section on responses of fishes to reference hepatoxicants, below). The heterogeneity of mammalian hepatocytes has been demonstrated with regard to oxygen saturation, cell volume, glycogen, isoforms of cytochrome P450 and other enzymes, and cell shape. This has led to the concept of metabolic zonation within the

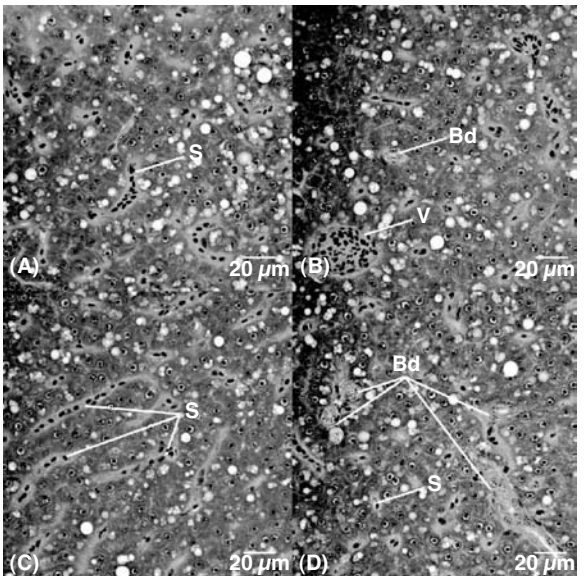

FIGURE 7.5 (See color insert following page 492.) High-resolution light micrographs of medaka liver showing elements of hepatic architecture. (A) Hepatic tubules comprised of hepatocytes and biliary epithelial cells are partially separated by sinusoids (S). No lobular architecture is apparent. Rounded white structures are lipid vacuoles. Lipid was removed during alcohol dehydration in processing. (B) Hepatic sinusoids contain nucleated red blood cells (top right of field). Larger venule (V) has no arterial or biliary structure associated. (C) This field shows sinusoids (S) between which are found hepatic tubules in longitudinal array. Note the double row of hepatocytes making a single tubule. Tubules are incompletely separated by sinusoids. (D) Region near the hilus of the liver is shown. Intrahepatic bile ducts of varying sizes (Bd) are shown. Note the difference in staining and in nuclear profiles in biliary epithelial cells vesus hepatocytes.

mammalian liver lobule (Jungermann, 1995; Osypiw et al., 1994); however, investigators studying the livers of teleosts report less (Schar et al., 1985), little (Segner and Braunbeck, 1988), or no (Hampton et al., 1985) evidence for hepatic metabolic zonation (see section on heterogeneity in fish liver metabolism, below).

Cells of the Liver

Detailed light and electron microscopic studies of fish liver have shown that the morphology of this organ includes at least ten resident cell types (Lester et al., 1993). By far the most numerous, hepatocytes occupy about 80 to 85% of the liver volume and represent about 95% of the resident cell number (Hampton et al., 1989). Together with bile preductular epithelial cells (BPDECs) they form hepatic tubules (see review in Hinton and Couch, 1998). Other epithelial cell types include biliary epithelial cells of ductules and intrahepatic ducts located near the liver hilus, together comprising the intrahepatic biliary system (explained in greater detail below); exocrine pancreatic cells; and centroacinar and ductular cells of exocrine pancreas. These cells share a common embryonic origin: endodermal derivatives from embryonic foregut epithelium (Elias and Bengelsdorf, 1952). The remaining cells are mesodermal in origin, arising from yolk sac epithelium, primitive blood islands, and septum transversum. These mesodermal derivatives include hepatic stellate cells, endothelium and smooth muscle of blood vessels, macrophages, and fibroblasts.

Hepatocytes

Hepatocytes are the most numerous cell type in the hepatic parenchyma, and they occupy greater than 80% of the liver volume in trout (Hampton et al., 1989; Rocha et al., 1994). Surface modifications of the hepatocyte plasma membrane form canaliculi (Figure 7.6), the initial portion of the hierarchy

Downloaded From Vet-eBooks.com

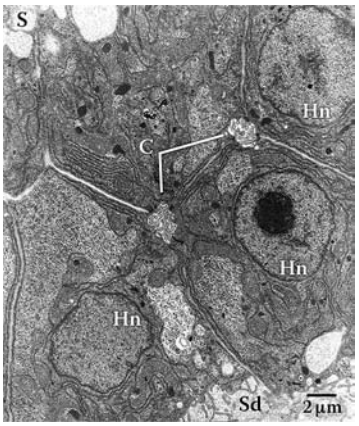

FIGURE 7.6 Transmission electron micrograph of liver from larval medaka. Portions of six hepatocytes are shown. The space of Disse (Sd) is at the bottom right and top left corners. Here, hepatocytes extend finger-like spaces toward sinusoids. This field shows no stellate cells of Ito in the space of Disse. Hepatocyte plasma membranes form junctional complexes that form walls of bile canaliculi (C). In these spaces, numerous microvilli from hepatocytes fill portions of the lumen. Hn, hepatocyte nucleus; S, sinusoid. The bodies of high electron density in the top-center hepatocyte are lysosomes.

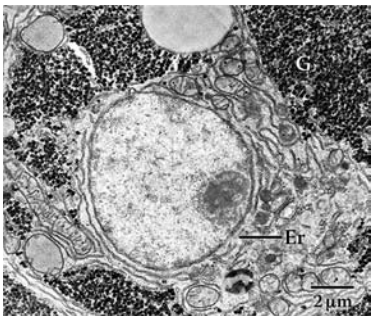

FIGURE 7.7 Area of hepatocyte from common carp with nucleus and surrounding cytoplasm showing polarity. The perinuclear area is abundant in endoplasmic reticulum (Er) and also shows numerous mitochondria. More peripheral areas of the cell are sites of large glycogen depots (G).

of biliary passageways in the liver. Other surface modifications, such as the finger-like projections into the perisinusoidal space of Disse (Figure 7.6), increase the absorptive area for nutritional storage functions of the liver. Hepatocyte nuclei are spherical and are surrounded by a perinuclear sheath of granular endoplasmic reticulum (Figure 7.7). Mitochondria, lysosomes, and peroxisomes are abundant. Cisternae of endoplasmic reticulum (ER) are the sites of various transport lipids. Usually, a prominent Golgi apparatus communicates with ER-derived vesicles. The Golgi apparatus is important in the modifications of ER-derived vesicles that make it possible for them to fuse with plasma membrane, thus enabling exocytosis of contents. The hepatocyte is an example of a single cell serving both endocrine and exocrine functions. Hepatocytes of reproductively mature female fish contain large arrays of granular ER and mitochondria that facilitate their synthesis and the transport of vitellogenin. In contrast, adult males contain large glycogen depots (Figure 7.7) in the peripheral region of hepatocytes. This difference makes it possible to differentiate sexually active females from males by their basophilic hepatocytes seen in standard hematoxylin and eosin stains of paraffin embedded liver. Fish hepatocytes are polar, with sinusoidal plasma membrane representing the basal and canalicular plasma membrane representing the apical aspect. Lysosomes are more numerous in the pericanalicular regions (Hampton et al., 1985, 1988). Table 7.2 provides additional information on the regional distribution of organelles in hepatocytes of rat and carp.

[b] Data from Senger (unpublished).

Note: The numbers indicate organelle distribution along a virtual axis from the cell nucleus to the cell periphery. The axis was subdivided into three zones: a perinuclear zone (A), a middle zone (B), and a peripheral zone (C).

Nonhepatocyte Cells of the Liver

It is important to note that liver toxicity is not always the straightforward consequence of toxic impact on hepatocytes, as nonhepatocytes or interactions between hepatocytes and other liver cells can also be key players in the toxic response of the organ.

Biliary Epithelial Cells and the Intrahepatic Biliary System

The biliary system begins with the hepatocytes that are responsible for the uptake of xenobiotics and potentially toxic byproducts of metabolism. Briefly, hepatocytes form water-soluble conjugates that are transported across the plasma membrane into specialized passageways, the canaliculi (Figure 7.6), which are formed solely by junctional complexes between plasma membranes of hepatocytes. The canalicular lumen is delimited by tight junctional complexes (between the membranes of mammalian hepatocytes) that permit the paracellular exchange of solutes (ions and salts) between blood plasma and the canalicular lumen (Arias et al., 1988). Normal lumina of fish canaliculi (like their mammalian counterparts) are nearly completely filled by hepatocyte microvillar processes (Braunbeck et al., 1992; Hampton et al., 1985; Rocha et al., 1997). Intrahepatic bile passageways (IHBPs) are comprised of bile canaliculi (see Figure 7.6 and Figure 7.8) and bile ductules (cholangioles). In addition, morphological studies of normal

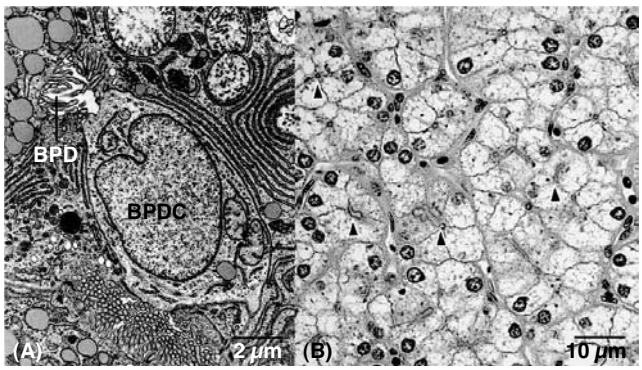

FIGURE 7.8 (See color insert following page 492.) Canaliculi and transitional zones of intrahepatic biliary system are illustrated. (A) Transmission electron micrograph of liver shows portions of two hepatocytes and one transitional biliary epithelial cell, termed bile preductular epithelial cell (BPDC). This cell shares junctional complexes with hepatocytes and forms portion of wall of bile passageway now termed bile preductule (BPD; a transitional zone). Note the absence of microvilli supplied to bile passageway by the BPDC. (B) Light micrograph of paraffin-embedded sturgeon liver. Hepatocytes of this species contain little stainable material in cytoplasm with H&E stain. Note the eosinophilic margins of the cells at bile canaliculi and their extensions toward tubule lumen (black arrowheads). We seldom see bile canaliculi staining this well in other species.

Downloaded From Vet-eBooks.com

liver from trout (*Oncorhynchus mykiss*) and channel catfish (*Ictalurus punctatus*) have revealed numerous transitional passageways between the canaliculi of hepatocytes and biliary ductules (Hampton et al., 1988). Transitional passageways (Figure 7.8A), the bile preductules (Hinton and Pool, 1976), are sites where hepatocytes and biliary epithelial cells with oval perikarya share junctional complexes (Hampton et al., 1988). This terminology in fish was adopted based on the flow of bile and the finding of transitional cells in rodent liver between epithelial cells of cholangioles and hepatocytes (Steiner and Carruthers, 1961). Biliary epithelial cells between canaliculi and ductules or cholangioles (completely lined by biliary epithelial cells) were designated in fish as bile preductular epithelial cells (BPDECs) (Figure 7.8). These small, oval cells form junctional complexes with both hepatocytes and adjacent bile ductular epithelial cells. The fine structure of these cells includes scant cytoplasm, intermediate filaments, and an absence of a basal lamina (Hampton et al., 1988). Hampton et al. (1988) extended their observations to bile ductules and ducts in control rainbow trout. As the diameters of bile preductules enlarge, additional biliary epithelial cells contribute to the channel wall (Figure 7.9).

The transition from bile preductules to ductules occurs when the biliary lumen is completely surrounded by biliary epithelial cells, usually two or three, joined by junctional complexes. Lumens of ductules are usually patent and contain few to no microvilli. Some structural variances in canalicular structure have been observed among various teleost species. Cyprinid fishes, for example, have finger-like indentations of the plasma membrane (not shown in the figures) that extend into the hepatocytes and show continuity with the typical interhepatocellular canaliculi (Vogt and Segner, 1997). Mammalian biliary epithelial cells (BECs), or cholangiocytes, are known to play a major role in bile synthesis and secretion. Although BECs account for 3 to 5% of the total population of liver cells in rodents, they are estimated to produce up to 40% of the daily bile output (species dependent) while also modifying bile content (organic or inorganic constituents) through various reabsorptive mechanisms (Boyer, 1996; Nathanson and Boyer, 1991). Few quantitative studies exist for fishes, although biliary epithelial cells in two species of trout comprised 1.3% and 1.4% of the parenchymal volume (Hampton et al., 1989; Rocha et al., 1997) and 3.1% of parenchymal volume in the cyprinid golden ide (Table 7.3). In rainbow trout, when magnesium-dependent adenosine triphosphatase (ATPase) histochemistry is performed, it is apparent that bile ductules receive preductules and canaliculi directly. In addition, scanning electron microscopy, performed on freeze-fractured liver pieces, has shown both the centrotubular location of bile ductules and the connections of canaliculi to these structures (Hampton et al., 1988). Cuboidal biliary epithelial cells rest on basal lamina and line ductules. Near the hilus of the liver, large bile ducts lined by columnar epithelial cells are seen in older trout. The association of macrophages with bile ductules in these control trout suggests that leakage of bile might occur at these sites (Rocha et al., 1994). Collectively, biliary epithelial cells are the second most abundant cell type in teleost liver (Hampton et al., 1989). Examples of the above intrahepatic bile passageways are shown in Figure 7.5D.

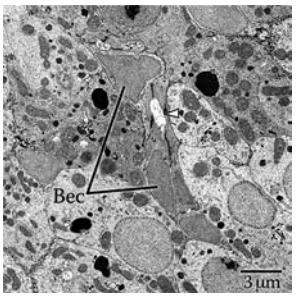

FIGURE 7.9 Transmission electron micrograph of bile ductule. White arrowhead points to the ductule lumen. The ductule is completely surrounded by squamous to cuboidal biliary epithelial cells. Note the relative absence of microvilli in the ductule lumen.

It is often important to be able to differentiate biliary epithelial cells from their neighbors in the liver. To do this, a variety of approaches have proven useful. The circumferential arrangement of ductular and ductal epithelial cells may be visible in sections. Also, a variety of chemical markers for these cells have been reviewed (Hinton, 1993a). The enzyme histochemical reaction for alkaline phosphatase is particularly strong in the connective tissue sheath of medium-sized and larger intrahepatic bile ducts. Biliary epithelial cells are the single resident liver cell type in which gamma-glutamyltranspeptidase is normally found. Magnesium-dependent ATPase is particularly strongly reactive over ductular and ductal epithelium; other enzymes (e.g., glucose-6-phosphate dehydrogenase, diphosphate glucuronosyl dehydrogenase, and DT diaphorase) also mark biliary epithelial cells (Hinton, 1993b). The plasma membrane of biliary epithelial cells is usually positive with the periodic acid Schiff (PAS) reagent, and the mucous granules of tall columnar biliary epithelial cells stain positively. Biliary epithelial cells are positive for cytochrome P450 when immunohistochemical procedures using anti-P450 LM2 IgG, anti-P 450 LM4

IgG, and anti-CYP1A are carried out. Ultrastructural localization of the latter antibody, directed against scup CYP450E (Park et al., 1986) and used in conjunction with immunogold procedures (Lester et al., 1993), confirmed the light microscopic observations. In addition, a method to isolate and characterize biliary epithelial cells from trout liver was developed (Blair et al., 1995), and western blot analysis of cytokeratins from trout hepatocytes and biliary cell preparations proved very useful. A significant observation was that hepatocyte preparations exhibited strong immunostaining of a major 52-kDa cytokeratin band with the anti-cytokeratin AE1/AE3, despite the fact that intact hepatocytes (liver sections) did not stain with this antibody. Enrichment of a 55-kDa cytokeratin band in biliary cell preparations compared to starting liver extract indicated a major enrichment of biliary cells by this isolation procedure. A major difficulty in obtaining large amounts of highly enriched populations of biliary epithelial cells from the livers of rats and humans has been their low abundance compared to other cell types of the normal liver. As a consequence, workers have had to rely on conditions that enhance the abundance of biliary epithelial cells. These include bile duct ligation or exposure to toxic chemicals. One advantage of the trout and likely other livers of other fish as a source of biliary epithelial cells is their relatively high abundance under normal circumstances. A ratio of one biliary epithelial cell to every seven hepatocytes has been estimated based on morphometric procedures (Hampton et al., 1989).

Putative Stem Cells of Teleost Liver

The intrahepatic progenitor cells, which are also known as oval cells, and ductular cells of mammalian liver are located at the periphery of the hepatic lobule where they connect with bile canaliculi and extend by canals of Hering into the portal tract. Cells of trout, medaka, and channel catfish found in the intrahepatic biliary system (see above) were shown to form junctional complexes with hepatocytes and to form transitional passageways between canaliculi and biliary ductules (Steiner and Carruthers, 1961), known as bile preductular epithelial cells (BPDECs). These cells of fish share many histological and ultrastructural features with those described for mammalian oval cells (Evarts et al., 1987, 1989; Farber, 1956), and the latter have been shown to proliferate after exposure of rodents to known hepatocarcinogens. A review by Okihiro and Hinton (1999) described the conditions under which oval cells may transition into hepatocytes (Evarts et al., 1989) or biliary epithelial cells (McLean and Rees, 1958; Steiner and Carruthers 1962, 1963). Furthermore, the presence of shared phenotypic markers among hepatocytes, oval cells, and biliary cells, as well as the appearance of transitional phenotypes, has prompted many

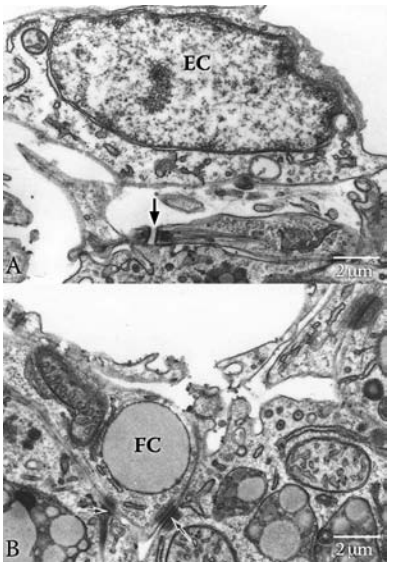

FIGURE 7.10 (A and B). These transmission electron micrographs illustrate the fine structure of sinusoidal endothelial cells and the space of Disse containing portions of stellate, fat-storing cells of Ito. (A) Nucleus of endothelial cell (EC) and perikaryon showing sparse mitochondria, pinocytotic vesicles, and few profiles of endoplasmic reticulum. Beneath the endothelial cell, the arrow points to the junctional complex between two stellate cells. The hepatocyte is at the bottom of the field. Stellate cells contain extensive cytofilaments and form a skeletal framework in some conditions (see text). (B) This figure shows a round lipid vacuole (FC) in a stellate cell. The stellate cell shares junctional complexes with hepatocytes, which show evidence of steatosis.

researchers to support the hypothesis that oval cells are bipolar progenitor cells for both hepatocytes and biliary epithelium in mammalian liver. Results of partial hepatectomy and bile duct ligation in trout (*Oncorhynchus mykiss*) supported the contention that BPDECs of fish are morphologically, enzymatically, and immunohistochemically similar to mammalian oval cells (Okihiro and Hinton, 2000). Our data are also consistent with studies of trout hepatic cells in long-term primary cultures (Ostrander et al., 1995). The longest lived cells in culture were morphologically similar to BPDECs and had cytokeratin profiles nearly identical to BPDECs in the *in vivo* trout study (Okihiro and Hinton, 2000). The maintenance of presumptive BPDECs (up to 70 days) in culture is indicative of relatively immature (i.e., undifferentiated) cells that retain the ability to divide and to survive and is consistent with a stem cell or progenitor role. BPDECs of fish liver appear to be the teleost equivalent of bipolar hepatic stem cells.

Sinusoidal Endothelial Cells

Endothelial cells comprise the wall of the hepatic microvasculature and are therefore the most abundant of the liver endothelial cells (Figure 7.10). Abundant information is available from various species (Ferri and Sesso, 1981a; Fujita et al., 1980; Gingerich 1982; Hacking et al., 1978; Hinton and Pool, 1976; Langer 1979; Nopanitaya et al., 1979a,b; Tanuma and Ito, 1980; Tanuma et al., 1982) to characterize these cells. Endothelial cells of hepatic sinusoids in channel catfish have greatly attenuated cytoplasmic processes forming a thin barrier between the sinusoidal lumen and the perisinusoidal space of Disse (Hinton and Pool, 1976). The endothelial cell cytoplasm contains numerous free ribosomes, sparse granular ER, abundant pinocytotic vesicles (Figure 7.10), and fenestrae of variable diameters (Hinton and Pool, 1976; Hacking et al., 1978; Langer 1979). Lysosomal abundance differs, as they are rarely seen in some species (Hacking et al., 1978; Tanuma and Ito, 1980) and are more common in others (Ferri and Sesso, 1981a; Tanuma et al., 1982).

Fenestrae have received considerable attention. These structures facilitate the passage of macromolecules from the sinusoidal lumen to the perisinusoidal space of Disse. Freeze-etch replicas (Ferri and Sesso, 1981a; Nopanitaya et al., 1979a; Tanuma et al., 1982) and scanning electron microscopy of liver

Downloaded From Vet-eBooks.com

following vascular perfusion fixation (McCuskey et al., 1986) were used to study fenestrae. In goldfish (*Cyprinus carpio*), 15 to 20 fenestrae were grouped as sieve plates, like their mammalian counterparts (Wisse, 1972). Trout fenestrae were not as tightly grouped as those of carp. When their diameters were estimated, they ranged from 75 to 150 nm (McCuskey et al., 1986).

Sinusoidal endothelium has proved to be particularly reactive for alkaline phosphatase in enzyme histochemical preparations. In addition, the antibodies directed against the cytochrome P450 isozymes LM2, LM4, and CYP1A label endothelial cells (Lorenzana et al., 1989). Location immediately adjacent to blood cells and the presence of attenuated cytoplasm helps to differentiate endothelial cells from neighboring cells; for example, the strong response with alkaline phosphatase assists in differentiating endothelial cells from hepatic stellate cells (Hinton, 1993b). Little attention has been given in fish to differentiation of venous from arterial endothelium of liver.

Hepatic Stellate Cells

The morphology and functional properties of Stellate cells in various vertebrates have been reviewed (Hinton, 1993b; Wake 1980). The connective tissue cells of the teleost liver include hepatic stellate cells (Ito and Nemoto, 1952), fibroblasts associated with the hilus of the liver, and cells incorporated as a sheath around major blood vessels and bile ducts and located immediately beneath the liver capsule and the blood cells. These cells (see Figure 7.10) and the fibroblasts provide a supportive framework for the liver. Hepatic stellate cells contain an elongated and frequently indented (by lipid droplets, the solvent of vitamin A) nucleus with peripheral heterochromatin. Well-developed granular endoplasmic reticulum with dilated cisternae also characterizes these cells (Rocha et al., 1997). In one significant review, livers from 48 species of fishes were investigated, and fat-storing cells were reported in all but three species (Ito et al., 1962). Since then, two studies (Hinton et al., 1984b; Lauren et al., 1990) have demonstrated the presence of fat-storing cells in medaka (*Oryzias latipes*), one of the three species originally reported to lack them. Another variant of the hepatic stellate cell is devoid of lipid droplets (Nopanitaya et al., 1979a). These cells are fibroblast-like cells with well-developed granular endoplasmic reticulum (Ito and Shibasaki, 1968). First described in human adults and embryos, the cells have been described in various fishes and reptiles. In teleosts, injection of vitamin A causes the number of fibroblast-like cells to decrease while the number of lipid-laden cells increases (Fujita et al., 1980; Takahashi et al., 1978). Perhaps the heaviest accumulation of lipids is found in the Antarctic fish *Dissostichus mawsoni* (Eastman and deVries, 1981). Numerous desmosomal junctions between hepatic stellate cells and other liver cells suggest a mechanical, supporting role for the cells. Numerous cytofilaments are also distinguishing features of these cells. If the cytofilaments are contractile, as has been suggested, the orientation of the hepatic stellate cells may have a role in the regulation of blood flow within the sinusoid. The contribution of these cells to the volume of the parenchyma was estimated for trout (Hampton et al., 1989); they occupied 1.37% of the parenchymal space of females, and the male hepatic stellate cell compartment was about half that of females. Actual volume may be underestimated, as cellular processes are elongated and the terminal portions may be difficult to differentiate from portions of other cell types.

Vitamin A shows apple-green autofluorescence, which fades upon continued excitation. Alcian blue pH 2.5 is positive for acidic glycosaminoglycans of fat-storing cells. When present, lipid vacuoles stain positively with any of a variety of lipid stains. Semi-thin sections of Epon-embedded material stained with toluidine blue reveal the lipids of fat-storing cells as aquamarine droplets. To differentiate hepatic stellate cells from others, their location, shape, and contents (or lack thereof) have been found to be useful. Differentiation of hepatic stellate cells from endothelial cells appears to be the greatest challenge. Their common origin (mesoderm) and the presence of cytoplasm, vesicles, and cytofilaments illustrate the degree of shared features of the cell types. Alkaline phosphatase, positive in endothelial but absent in fat-storing cells, may be the strongest differentiator at present for fish.

Interhepatocytic, Perisinusoidal Macrophages

Interhepatocytic, perisinusoidal macrophages appear as single cells and are often devoid of pigment. They have been reported in rainbow trout (*Oncorhynchus mykiss*) (Hampton et al., 1985; McCuskey et al., 1986) and European brown trout (*Salmo trutta fario*) (Rocha et al., 1997). Interestingly, when quantitative

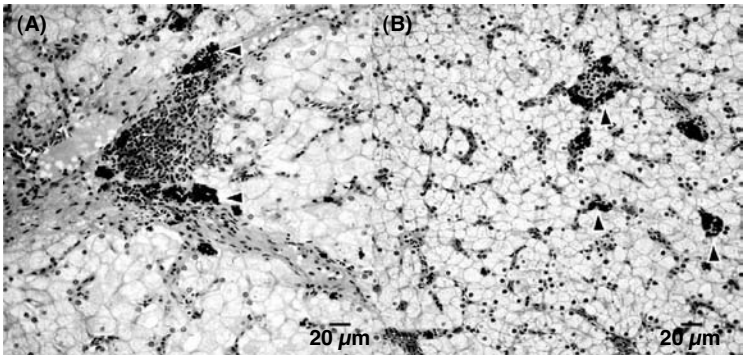

FIGURE 7.11 (See color insert following page 492.) Hematoxylin and eosin stained sections from liver of juvenile sturgeon. (A) Melano–macrophage aggregates (black arrowheads) are seen in the connective tissue tract at margins of inflammatory focus (eosinophilic granular leukocytes and mononuclear cells). (B) Liver parenchyma has smaller melano– macrophage aggregates in this juvenile. Black arrowheads point to perivascular aggregates.

assessments of livers were done in these species (Hampton et al., 1989; Rocha et al., 1997), each reported a greater number of interhepatocytic, perisinusoidal macrophages in livers of female vs. male fish.

Pigmented Macrophage Aggregates

In a recent review, the liver of mature fish was not considered to be as important to immune function as in mammals (Rice, 2001); however, macrophage aggregates are common in the liver of certain species, such as the sturgeon (*Acipenser transmontanus*) (Figure 7.11), as well as in the kidney and spleen (Agius, 1985; Kennedy-Stoskopf, 1993). The function of these cells is debated; for example, some regard these to be the phylogenetic precursors of germinal centers, but, as others have shown, they increase in number with age and also show an increase in number under oxidative stress. These aggregates are seen in the presence of disease even in younger fish (Camp, 1997; Rice, 2001). In certain species of fishes, pigments abound in these aggregates, including lipofuscin, melanin, hemosiderin, and, in some cases, ceroid (Rice, 2001). Hemosiderin is a breakdown product of hemoglobin degradation, but melanin has antioxidant properties and is a predominant feature of macrophage aggregations in channel catfish during disease states (Camp, 1997; Rice, 2001). Lipofuscin and ceroid are byproducts of saturated fat oxidation. Most authors agree that macrophage aggregates are sites of inflammation, oxygen radical formation, and lipid oxidation. In addition, the review by Rice (2001) included findings suggesting that genetic resistance to certain diseases in channel catfish were correlated with increased numbers of splenic macrophage aggregations (Camp, 1997; Camp et al., 2000).

Kupffer Cells

Some species of fish possess cells that resemble the fixed, resident macrophages of the mammalian liver (Kupffer cells). Other species, despite intense investigation, seem to lack these sinusoidal lining cells (Hampton et al., 1985; Rocha et al., 1997). Hampton et al. (1987) conducted an evaluation of resident macrophages in the livers of brown bullhead catfish (*Ictalurus nebulosus*, now *Ameiurus* sp.). These cells shared properties of the Kupffer cells of mammals, including phagocytosis and degradation of erythrocytes, as well as being strongly positive for peroxidase, intensely positive for glucose-6-phosphate dehydrogenase, and positive for phagocytosis of intravascular-induced submicron latex beads. In contrast to mammalian Kupffer cells, resident macrophages of brown bullhead showed no invaginations of the plasma membrane analogous to vermiform processes. Kupffer cells of mammals are very active in the first-order defense of the liver (Cho et al., 2000; Seki et al., 2000); in the human, they perform intricate signaling that primes other cells to react, thus providing protection against bacterial infections and hematogenous tumor metastases (Seki et al., 2000). We do not know which cells provide this or similar roles in fish. For those species examined, Kupffer cells are often absent, and much more information is needed regarding this aspect of defensive roles for teleosts livers.

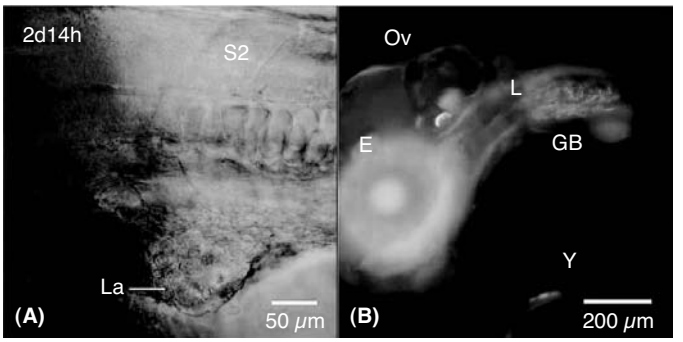

FIGURE 7.12 (See color insert following page 492.) (A) *In ovo* imaging of medaka liver anlage (La) emerging from the ventral endoderm 62 hours after fertilization. In medaka, this occurs below the first to third somite (S2). Distinct at this stage of development are hepatic tubule formations, elucidated here with the cytochrome P450-3A substrate 7-benzyloxyresorufin (7-BR). Embryonic medaka exposed to aqueous concentrations of 7-BR exhibit CYP3A activity, indicated by the red fluorescence of resorufin (the metabolic byproduct of CYP3A, via dealkylation of 7-BR) in the tubule lumens of the developing liver (red punctuate features). (B) By 5 days after fertilization, the liver (L) of medaka is found in a left lateral orientation, with the gallbladder (GB) at the liver caudal margin. Red fluorescence in the liver and gallbladder is the fluorescent CYP3A byproduct resorufin. Here, the fluorophore is seen in transit through the intrahepatic biliary passageways of the liver, with concentration in the gallbladder. E, eye; Ov, otic vesicle; Y, yolk (sac).

Selected Landmarks of Fish Liver Development

The development of fishes is considered a simple model for understanding this process in other vertebrates. Simplicity is derived from the fact that the chorion is transparent in certain fishes and provides detail for imaging key events and relationships of development *in vivo*. One species that has been used extensively as a model for studying vertebrate ontogeny is the zebrafish (*Danio rerio*), particularly for the study of liver development (Field et al., 2003; Ober et al., 2003). Another model teleost species, medaka, is an excellent experimental animal (Yamamoto, 1975). The see-through medaka is genetically deficient in pigments (Wakamatsu et al., 2001) and is being studied as a model for morphological and molecular investigations on organogenesis in the later stages of fish development and throughout the life span. Recent published and unpublished observations of the see-through medaka, made in the Hinton laboratory (Hinton et al., 2004), are used to illustrate the following: liver appearance in the embryo, anatomical position of the embryonic and larval liver, and assumptions regarding the adult vascular supply and drainage, as well as biliary function.

The liver of fishes arises from the ventral foregut. In the medaka (Figure 7.12), a bulge is seen at somites one to three on the left side of the embryo during the second day after fertilization (Iwamatsu, 2004; Iwamatsu et al., 2003) (Table 7.4). This bulge continues to grow until the left lateral longitudinal liver leaflet (L5) is formed (Figure 7.12 B). As described below, L5 is the liver of the embryo and early larval stages. The caudal-most extent of this leaflet is closely associated with a prominent, round gallbladder (Figure 7.12) the fluid of which becomes pigmented (Hinton et al., 2004), suggesting that metabolism of yolk is linked to formation of bile in the embryonic medaka. L5 is the liver during mid- and late stage embryos and extends into the first week following hatching (Hinton et al., 2004). Unpublished electron microscopic observations from this laboratory reveal that bile canaliculi are present on lateral plasma membranes of hepatocytes. In addition, *in vivo* microscopic analysis clearly shows that the L5 liver contains hepatic tubules. As is shown in Figure 7.13, transverse sections of embryonic tubules are comprised of six to eight hepatocytes whose apical plasma membranes are in contact with the tubule lumen while their basal plasma membranes face the microvasculature; therefore, even during early development, hepatocytes are polarized. Bile of the gallbladder and intestinal lumen fluoresces under ultraviolet light and may be detected through the body wall and chorion of the embryo using brightfield and widefield fluorescence microscopy (Figure 7.14). In addition, when embryos are exposed to 7-benzyloxyresorufin, a cytochrome P450 substrate, the phase I enzyme cleaves the alkyl group from

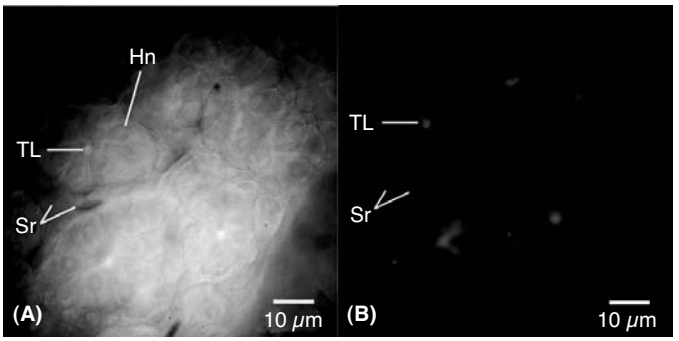

FIGURE 7.13 (See color insert following page 492.) *In vivo* microscopy of dechorionated medaka embryos 5 days after fertilization; tubular architecture in developing liver of medaka. (A) Autofluorescence of hepatic parenchyma (widefield fluorescence microscopy). Six to eight hepatocytes can be seen to, in transverse section, form the hepatic tubule. The apical membranes of hepatocytes form the tubule lumen, a central biliary passageway. Hn, hepatocyte nucleus; Sr, sinusoid with red blood cells; TL, tubule lumen. (B) Same image as A but showing TRITC fluorescence of 7-benzyloxyresofufin (7-BR) (red). 7-BR-exposed medaka embryo shows fluorescence of resorufin in lumens of hepatic tubules and in canaliculi, thus providing *in vivo* evidence for CYP3A metabolic activity and concentrative transport of fluorophore from the sinusoid to the tubule lumen.

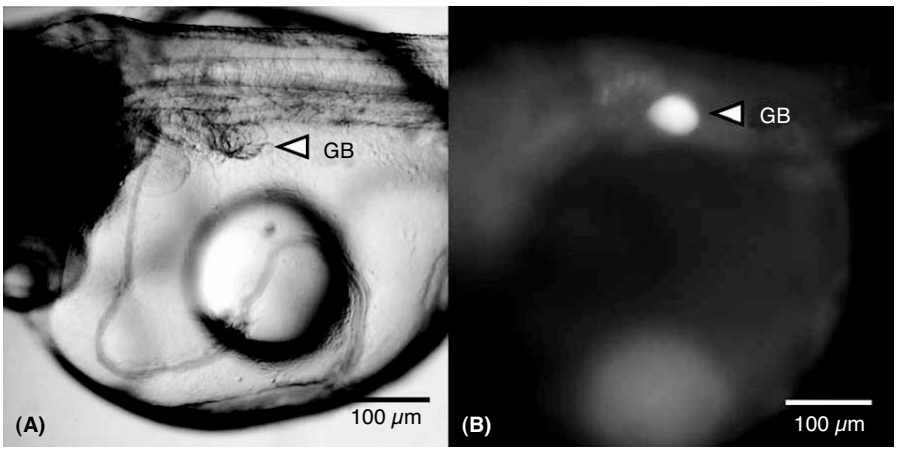

FIGURE 7.14 (See color insert following page 492.) *In vivo* microscopy (brightfield illumination) of dechorionated medaka embryo. (A) Yellow/green pigment in the gallbladder (GB) is seen. This signifies bile synthesis and export. The liver is in left upper abdominal cavity immediately dorsal to lipid droplet. The circuitous left duct of Cuvier is shown, and a portion of the media yolk vein is at the caudal margin of the yolk sac. (B) Same orientation as in A, demonstrating autofluorescence in the gallbladder and to a lesser extent in the intrahepatic passageways.

resorufin, resulting in resorufin fluorescence. Resorufin can then be detected in the canalicular network, tubule lumens, larger bile passageways of liver, gallbladder, common bile duct, and intestinal lumen (Figure 7.14). Iwamatsu et al. (2003) reported that the medaka anal aperture is not open until the fish reaches approximately 5.3 mm total length (stage 40, after hatching). This may explain the retained fluorescence of the intestinal lumen late in embryogenesis.

Another important feature of L5 is its blood supply, microvasculature, and venous drainage. *In vivo* observations (Hinton et al., 2004) have shown that a single vein (hepatic vein) drains L5, with blood flowing from the liver to the left duct of Cuvier. There is no afferent venous supply to L5; the apparent sole source of hepatic blood supply, at this time, is arterial from the dorsal aorta (Hinton et al., unpublished observations). We have observed erythrocytes tumbling through the hepatic microvasculature and passing through the hepatic vein to the left duct of Cuvier.

During the second week of larval life, an apparent metamorphosis occurs when the yolk sac is apparently completely absorbed, the gut elongates (Iwamatsu et al., 2003), and the liver (L5) assumes

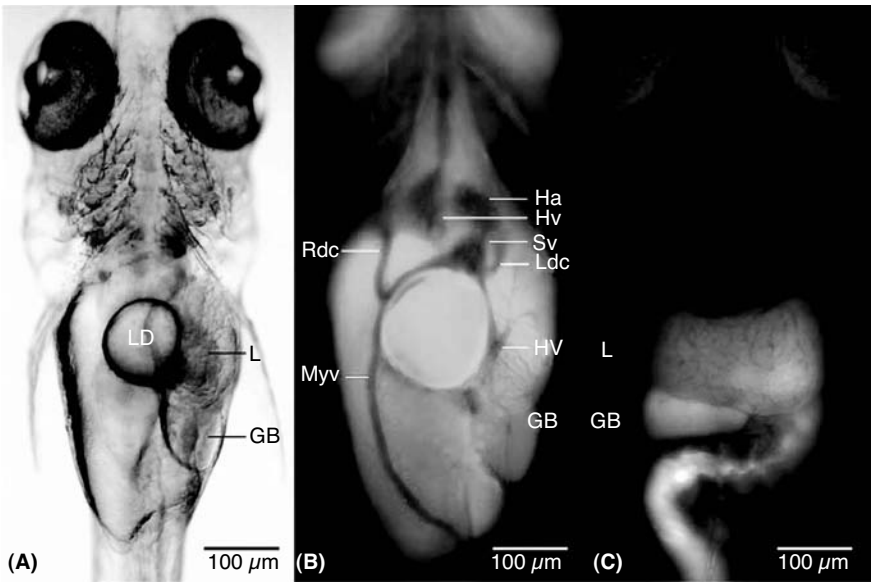

FIGURE 7.15 (See color insert following page 492.) A and B are ventral view of medaka at 10 days after fertilization. (A) Note right half of abdominal cavity is largely filled by yolk sac showing evidence of utilization of yolk. (B) DAPI/TRITC composite showing vasculature at this developmental stage. Note that the large rounded lipid droplet is maintained despite loss of most of the yolk sac. (C) Medaka at 20 days after fertilization revealing adult phenotype. Note depletion of the lipid droplet (absence). The liver is in the ventral rostral portion of abdominal cavity and partially covers the gallbladder. Autofluorescence in the gut is largely due to algae. The liver shows an extensive vascular network (dark nonfluorescent sinuous lines). GB, gallbladder; Ha, atrium of heart; HV, hepatic vein; Hv, ventricle of heart; L, liver; LD, lipid droplet; Ldc, left duct of Cuvier; Myv, median yolk vein; Rdc, right duct of Cuvier; Sv, sinus venosus.

the adult position of lying transversely in the rostral-most portion of the abdominal cavity (Hinton et al., 2004). Because the gallbladder was originally closely associated with the most caudal portion of L5 and becomes closely associated with the right side of the liver in the adult position, the liver appears to make a 90° rotation, with the original rostral portion of L5 (Figure 7.15A) becoming the left portion of the adult liver and the caudal portion of L5 becoming the right portion of the transversely positioned larval liver (i.e., stages 42 to 44) (Iwamatsu et al., 2003) and the adult liver. Afferent venous supply (the hepatic portal vein) is apparently established (Figure 7.15B) when the larval medaka liver assumes the transverse position, bringing it into close contact with the rostral portion of the vitellocaudal or median yolk vein (Hinton et al., 2004).

Specifics of Liver Function

The liver of fishes has a central function in the maintenance of organism homeostasis in that this organ regulates blood composition through: (1) synthesis, interconversion, and redistribution or removal of nutrients, vitamins, essential metals, and endogenous compounds, including hormones and blood proteins; and (2) removal of endotoxins, particulates, or metabolic wastes, such as bilirubin and ammonia. For example, after meals, in the postprandial absorptive stage, the liver takes up nutrients from the plasma. Later, stored nutrients are released during catabolic states such as starvation or stress. In this way, the liver smoothes out potentially large fluctuations in blood composition and allows nutrients to reach peripheral tissues. The liver further synthesizes and secretes a number of proteins such as fibrinogen and albumin; also, in female trout and medaka, the egg-yolk protein vitellogenin and eggshell membrane protein choriogenin are produced. In the fathead minnow (*Pimephales promelas*) and zebrafish (*Danio rerio*), however, the eggshell membrane proteins (choriogenin, zona radiata protein, zona pellucida, vitelline envelope proteins) are produced in the maturing oocytes (Arukwe and Goksøyr, 2003; Carvan et al., 2007).

Downloaded From Vet-eBooks.com

The important metabolic role of the liver is related to its unique location within the systemic circulation. This location is also responsible for the importance of the liver in the uptake, storage, metabolism, redistribution, and excretion of environmental toxicants and makes it at the same time a target of toxic substances. The livers of fishes can store large amounts of either glycogen or lipid. The type of storage product may change with species. Some species, such as salmonids, preferably store glycogen in the hepatocytes; others, such as cod, deposit large amounts of lipids, and cyprinids can shift between the deposition of glycogen or lipid (Bohm et al., 1994; Fujita 1985; Welsch and Storch, 1973). Also, physiological factors such as sex (Braunbeck, 1998; Peute et al., 1978) or environmental factors such as nutrition or temperature can strongly change the quantity and type (glycogen/lipid) of hepatic energy stores (see, for example, Braunbeck et al., 1987; Berlin and Dean, 1967; Gas and Serfaty, 1972; Segner and Braunbeck, 1988, 1990a; Segner and Moller, 1984; Segner and Witt, 1990). Such changes are indicative of an in-depth reorientation of hepatic metabolism in response to endogenous or exogenous change, and the changing metabolic state can directly or indirectly influence the toxicant sensitivity of the fish (Braunbeck and Segner, 1992; Braunbeck et al., 1989; Koehler 2004).

Liver Metabolism

Aspects of liver intermediary metabolism, liver xenobiotic metabolism, and experimental *in vitro* hepatic systems have been covered in detail by other reviews and in other chapters of this book. Here, we summarize a few issues that are important for our coverage in this chapter. We refer interested readers to the following relevant reviews: For *in vitro* metabolism, see Mommsen et al. (1994), Pesonen and Andersson (1997), Denizeau (1998), Monod et al. (1998), and Segner (1998). For information on aspects of *in vivo* liver xenobiotic metabolism, see Andersson and Forlin (1992), Stegeman et al. (2004), and Schlenk et al. (2006). For intermediary metabolism and aspects of liver metabolism, see Cowey and Walton (1982), Moon and Foster (1995), Navarro and Gutierrez (1995), Hemre et al. (2002), and Moon (2004).

Research over the past two decades has established that the livers of fish contain many of the same metabolic pathways and enzymes known for mammalian liver (Cowey and Walton, 1982; Moon et al., 1995); however, important differences exist (for more details, see Hinton et al., 2001). An important difference between fish and mammalian liver with respect to toxicant action is the apparent absence of a functional metabolic zonation. In the mammalian liver, storage products such as glycogen and lipid as well as many metabolic enzymes are heterotopically distributed in the parenchyma. The distribution patterns appear to be related to the direction of microvascularization. The capacity for oxidative metabolism (e.g., β-oxidation of fatty acids, amino acid catabolism, or oxidative energy metabolism) is higher in the periportal than in the perivenous zone or centrolobular (zone 3 of the liver acinus model in mammals) (Jungermann and Katz, 1989). Accordingly, the upstream cells show greater mitochondria and larger cristae area than do the downstream cells (Loud, 1968). It is supposed that the concentration gradients of oxygen, hormones, and substrates in the sinsusoidal bloodstream lead to the expression of different enzyme levels in the bordering hepatocytes. The concept of metabolic zonation (Jungermann and Katz, 1989; Teutsch, 1981) suggests that the biological significance of this functional heterogeneity might be to enable the liver to perform antagonistic metabolic functions at the same time.

The distribution of enzymes and storage products within the liver parenchyma of fish has been determined by enzyme histochemistry in frozen sections and by digitonin pulse infusion. For most enzymes studied, histochemical investigations were not able to demonstrate a heterotopic distribution in the liver parenchyma of fish (Burkhardt-Holm et al., 1993; Hampton et al., 1985; Schar et al., 1985; Segner and Braunbeck, 1988) (Table 7.5). Glycogen phosphorylase is the only enzyme for which all studies report a heterogeneous distribution in fish liver; however, it is not clear to what extent the observed phosphorylase pattern is determined by, or associated with, the hepatic microvasculature.

To separate hepatocytes from sites adjacent the afferent vasculature from those adjacent the efferent vasculature, a short pulse of cytotoxic digitonin from either the portal (anterograde) or hepatic vein (retrograde) is used. Subsequently, cell isolates presumably enriched in periportal or perivenous liver cells may be prepared and analyzed for their metabolic properties. For teleosts, such studies have been done with rainbow trout (*Oncorhynchus mykiss*) (Mommsen et al., 1991), toadfish (*Opsanus tau*) (Mommsen and Walsh, 1991), and catfish (*Ictalurus melas*) (Ottolenghi et al., 1991). None of the cited studies observed

[d] Data from unpublished work of Segner.
Note: Enzyme distribution was studied by means of enzyme histochemistry.

significant differences in enzyme activities between the two cell populations; however, in rainbow trout, small differences existed with respect to the rates of gluconeogenesis (Mommsen et al., 1991). Significant differences in metabolic enzyme activities were only detected when trout liver cells were not isolated with respect to their topographical localization but with respect to cell size (Mommsen et al., 1991). This result may indicate the existence of a cell-to-cell microheterogeneity in fish liver that is different from the parenchymal zonation that exists in mammalian liver or the presence of smaller, nonhepatocytic cells.

In conclusion, the available evidence for metabolic zonation in fish liver is weak. Although liver subpopulations appear to exist to some extent, the distribution pattern clearly differs from that seen in mammals. The apparent absence of metabolic zonation in teleost liver might be explained by the irregular and largely undefined hepatic microvasculature in fish (see above).

The absence of a functional metabolic zonation in fish liver has consequences with respect to toxicant action. A zonal toxicity can result from the heterogeneous distribution of metabolic enzymes, oxygen, etc. in mammalian liver (Treinen-Moslen, 2001); for example, the toxicity of CCl_4 that is related to the metabolic production of the CCl_3 radical is mainly expressed in the perivenous zone (centrolobular region, or acinus zone 3), as hepatocytes of this zone have more P450-dependent enzymes and lower O_2 levels. In fish, functional zonation of the liver parenchyma is lacking; consequently, no zonal toxicity has been observed. This does not mean that toxicity has not occurred, because when cells are evaluated *in vitro* toxicity is verified by the leakage of cytosolic enzymes to media in culture systems (Rabergh and Lipsky, 1997).

Liver cells are important for xenobiotic metabolism and have high constitutive activities of many phase I enzymes that convert xenobiotics to reactive electrophiles, including cytochrome P450 isozymes, alcohol dehydrogenases, and quinone reductases. Also, hepatocytes have a rich collection of phase II enzymes that add a polar group to a molecule, rendering it more soluble in water and enhancing its removal from the body. In fish, the best-studied biotransformation enzyme is cytochrome P4501A, which shows the highest specific activities in the liver (Hahn and Stegeman, 1994). The enzyme is localized in hepatocytes, biliary epithelial cells, and vascular endothelial cells. In contrast to mammals, where cytochrome P4501A shows a heterogeneous distribution throughout the liver parenchyma, no zonation can be observed in teleost liver (Lorenzana et al., 1989; Ortiz-Delgado et al., 2002; Smolowitz et al., 1992). Subcellularly, cytochrome P4501A is localized at the membranes of the rough endoplasmic reticulum and the outer leaflet of the nuclear envelope (Lester et al., 1993).

Phase I Metabolism: CYP1A

Hepatic CYP1A expression of fish can be induced by exposure to specific environmental contaminants, including halogenated aromatic hydrocarbons (e.g., dioxins, furans, polychlorinated biphenyls) and polyaromatic hydrocarbons (PAHs). The induction response is mediated via an intracellular receptor, the dioxin or aryl hydrocarbon receptor (AhR; see below). Due to the specific ligand–receptor interaction required for

Downloaded From Vet-eBooks.com

activation of the AhR pathway and AhR-dependent CYP1A induction, this biochemical response has been used extensively as a biomarker of exposure of fish to dioxin-like contaminants (Hahn, 2002; van der Oost et al., 2003; Whyte et al., 2000) and has been used in a range of field biomonitoring studies (Behrens and Segner, 2005; Collier et al., 1995; Goksøyr and Förlin, 1992; Payne and Penrose, 1975). Typically, CYP1A induction, measured as catalytic 7-ethoxyresorufin-*O*-deethylase (EROD) activity, as CYP1A protein, or as CYP1A mRNA, is assessed in the liver because specific CYP1A expression is highest in this organ.

Although CYP1A is induced in various resident liver cell types, responding cells appear to differ in their induction response to xenobiotics. Environmental exposure led to a particularly strong increase of cytochrome P4501A immunoreactivity in the biliary and endothelial cells of cod and flounder, while hepatocyte staining remained weak (Husoy et al., 1996). In contrast, in lemon sole (*Microstomus kitt*), the cytochrome P450 induction response was stronger in hepatocytes than in vascular cells (Husoy et al., 1996). In scup, 3,3′,4,4′-tetrachlorobiphenyl treatment strongly increased CYP1A immunoreactivity in both hepatocytes and nonhepatocytes (Singh et al., 1996). It is possible that the cell-specific induction response varies with the type of inducer (readily vs. slowly metabolized compounds), dose of inducer, or fish species (Anulacion et al., 1998; Goksøyr and Husoy 1998; Ortiz-Delgado et al., 2005). Another relevant factor influencing hepatic CYP1A response could be the exposure route. A stronger increase of CYP1A immunostaining occurred in hepatocytes of mummichog (*Fundulus heteroclitus*) when exposure took place via the water than by the dietary route (Van Veld et al., 1997).

Hepatic CYP1A induction is a measure of the exposure of fish to dioxin-like chemicals; it is not a direct measure of the ability of a species to metabolize these compounds. A direct correlation was demonstrated in mammals and birds between ability to metabolize 3,3′,4,4′-tetrachlorobiphenyl and their hepatic EROD activity; however, no such relation was seen in rainbow trout and flounder (Murk et al., 1994). This finding possibly reflects species differences in the participation of different CYP isoenzymes in the metabolism of the toxicant. In line with this speculation is the observation that the liver of turbot exposed to benzo(*a*)pyrene produced different metabolites before and after induction of hepatic EROD activity (Telli-Karakoc et al., 2002).

Phase I Enzymes Other than CYP1A

Phase I metabolic enzymes have not been as intensively studied in fish liver, but recent advances are noteworthy. With the completion of genome sequences for several teleosts, including medaka, zebrafish, pufferfish, and stickleback, full complements of CYP gene families are being discovered (Nelson, 2003; http://drnelson.utmem.edu/CytochromeP450.html). Although the functionality for many of these enzymes remains to be determined, several have been investigated using recombinant systems such as CYP3A38/40 (Kashiwada et al., 2005) , CYP2N (Oleksiak et al., 2000), CYP2K1 (Yang et al., 2000), CYP2M1 (Yang et al., 1998), and CYP3A27 and CYP3A45 (Lee and Buhler, 2002, 2003). In general, the catalytic activities and substrate specificity of teleost CYPs are highly similar to their mammalian homologs. Examples include the preference of CYP1A for aromatic hydrocarbons, CYP3A for steroidal compounds, and CYP2 for arachidonic acid, lauric acid, and sex steroid hormones. In some instances, however, activities may be specific to teleosts. Mammalian forms of CYP3A preferentially catalyze 6β-hydroxylation of testosterone with lower levels of the 2β-, 15β-, and 1β- hydroxides (Krauser et al., 2004). In comparison, teleost CYP3A forms catalyze testosterone hydroxylation at the 6β-, 2β-, and 16β- positions (Kullman and Hinton, 2001; Lee and Buhler, 2002, 2003), illustrating an inherent difference in catalytic profiles that exists between teleost and mammalian species. Any physiological significance of this difference has yet to be determined. Often, the optimal requirements for cofactors, including CYPOR, cytochrome b_5, lipids, and temperature, differ among teleosts. This is not surprising given the fact that these organisms inhabit a range of environmental conditions from extreme cold to tropical temperatures and fresh to seawater (Kashiwada et al., 2005). The availability of modern molecular techniques has made it much easier to identify specific isoforms and has thus stimulated research on the CYP isoenzymes in fish. With these new technical developments, a more in-depth characterization of the phase I metabolism of xenobiotics in fish liver will become possible. Of great interest is a further understanding of CYP temporal and spatial expression, the mechanisms of gene regulation, and catalytic function, much of which remains unknown for many of these enzymes.

Hepatic Phase II Metabolism

During phase II reactions, xenobiotic metabolites produced from the first phase are conjugated to polar endogenous substrates (e.g., sulfate, glucuronide), facilitating their subsequent elimination from the body via bile or urine (Stegeman, 1989). Biliary excretion is often chemical specific (see detailed coverage below). Low-molecular-weight compounds are poorly excreted into bile, but high-molecular-weight xenobiotic compounds conjugated with sulfate and glucuronide are readily excreted into the bile (Klaassen and Watkins, 1984). Several types of petroleum hydrocarbon metabolites have specific fluorescence properties, and exposure of fish (e.g., Atlantic cod, Atlantic salmon, English sole) to crude oil results in increases in bile fluorescent aromatic compounds (FACs) (Aas et al., 2000; Gagnon and Holdway 2002; Krahn et al., 1986). Significant correlation has been established between the prevalence of hepatic lesions and mean biliary metabolite concentration in fish, and analysis of FAC in fish bile is recommended as a sensitive method for detection of PAH contamination from both pyrolytic and petroleum origin (Krahn et al., 1986).

In general, conjugation reactions, such as glucuronidation or glutathione conjugation, have not received sufficient attention, and further studies must be conducted in the future. Just as was shown for phase I metabolism, the liver is quantitatively the most important site for phase II metabolism in fish (Clarke et al., 1991). In mammals, phase II enzymes such as glutathione *S*-transferases and UDP-glucuronyltransferases represent multigene families, and there is evidence that this applies for fish as well, although the characterization of the various isoenzymes requires more attention (Leaver et al., 1992, 1993). In field studies of fish from contaminated sites, phase II conjugates of xenobiotics were detected in bile. Examples include fuel-oil PAHs (Collier and Varanasi, 1991), phthalate ester plasticizers (Melancon and Lech, 1983), and the pulp mill constituents chlorophenols and resin acids (Hardig et al., 1988; Oikari et al., 1985; Stuthridge et al., 1997). The importance of phase II metabolism for the bioconcentration and toxicity of xenobiotics in fish may be exemplified by an organophosphorous compound. In several fish species, dimethylphosphorothioates are rapidly metabolized in the liver and eliminated via bile as glutathione conjugates. In addition, this rapid phase II metabolism is associated with lower bioconcentration and lower toxicity than observed for related organophosphorous compounds that are metabolized by the oxidative system (Debruijn et al., 1993). Another example is provided by the lampricide 3-trifluoromethyl-4-nitrophenol. The selective toxicity of this substance to sea lampreys was found to be related to a greatly reduced capacity of this species to glucuronidate the compound (Lech and Statham, 1975).

To study liver xenobiotic metabolism, *in vitro* preparations of fish liver cells have proven to be a valuable experimental model. Isolated hepatocytes can be kept as fresh isolates (Moon et al., 1985), as longer term monolayers (Pesonen and Andersson, 1997; Segner 1998), or as aggregate cultures (Cravedi et al., 1996). These preparations have the advantage of making it possible to analyze the fate of xenobiotics specifically in the liver, in the absence of systemic influences. Further, they offer the possibility for interspecies comparison of chemical metabolic conversion under fairly comparable conditions (Coulombe et al., 1984; Cravedi and Baradat, 1991; Murk et al., 1994). Fish hepatocytes *in vitro* are valuable tools for study of induction of biotransformation enzymes as well as the formation of xenobiotic metabolites (as reviewed in Segner and Cravedi, 2001). Generally, the metabolite pattern produced by fish liver cells *in vitro* agrees well with the *in vivo* metabolism of the substances, although possible differences should not be overlooked when extrapolating from *in vitro* to *in vivo* hepatic metabolism (Cravedi et al., 1999; Morrison et al., 1985; Nishimoto et al., 1992). An interesting example of such an *in vitro* and *in vivo* differences was provided by Cravedi et al. (2001), who found the toxicologically relevant hydroxylamine metabolite of 2,4-dichloroaniline in the *in vitro* hepatocyte preparations but not *in vivo* in the bile fluid. The likely explanation for this difference is that the hydroxylamine metabolite is unstable; therefore, it can be detected only in the culture media, which are processed after a 1-hour incubation period, while the bile is sampled only at 24-hour intervals.

Nuclear Receptors in Liver Biology

Major functions of livers—the uptake, metabolism, storage, and redistribution of nutrients and endogenous molecules; metabolism of xenobiotics; and formation and excretion of bile—are regulated by nuclear receptors (NRs). Mammalian liver NRs are endogenous sensors, regulating many of the above

Downloaded From Vet-eBooks.com

hepatic functions. With certain large gaps in information, a qualitatively similar story is unfolding in fish. Importantly, livers of oviparous species have an additional hepatic function as an integral component of the reproductive axis. In response to estrogen, hepatocytes in these organisms synthesize vitellogenin, a yolk precursor protein, and choriogenin, a component of the outer egg envelope. Thus, hepatic NRs of fishes will likely perform key roles, as above, but we need to know more about the molecular mechanisms of NR action, their roles in critical liver functions, and the molecular mechanisms associated with gene regulation.

Mammalian Liver Nuclear Receptors

Nuclear receptors are ligand-dependent transcription factors that bind lipophilic signaling molecules and result in the control and expression of target genes. Mammalian NRs facilitate cellular responses to endogenous and exogenous ligands by coordinating complex transcriptional responses (Mangelsdorf and Evans, 1995). The NR superfamily includes receptors for multiple endobiotics, such as steroid hormones, retinoids, thyroid hormone, vitamin D, bile acids, and prostaglandins. Also of importance are exogenous ligands, including dietary components and xenobiotics.

Nuclear receptors commonly share a conserved *N*-terminal DNA-binding domain (DBD) and a *C*-terminal ligand-binding domain (LBD). The DBD contains two zinc-finger motifs that form a single structural domain containing an α-helix reading head that controls specific DNA sequence recognition (Lin and White, 2004). The LBD confers ligand specificity and also contains a ligand-inducible transactivation function (AF2) essential for transcriptional activation. In the absence of a ligand, NRs are associated with a nuclear receptor corepressor complex, resulting in inhibition of the basal transcription activity of the associated promoter (Mangelsdorf and Evans, 1995; Ordentlich et al., 2001). Corepressor proteins (SMART, NCoR) couple non-liganded, DNA-bound NR to enzymes with histone deacetylase activity, resulting in chromatin condensation and a subsequent repression of gene expression (Polly et al., 2000). Ligand binding causes a conformational change within the carboxy-terminal LBD (Rochel et al., 2000), resulting in the release of corepressors and facilitating protein–protein interactions with dimerization partners, coactivators, and mediator proteins (MEDs) (Glass and Rosenfeld, 2000). Coactivators couple ligand-activated NRs to enzymes displaying histone acetyltransferase activity, thereby facilitating chromatin remodeling. In subsequent steps, ligand-activated NRs interact with additional MED family members to form a bridge to the RNA polymerase II (Pol II), resulting in transcription activation. NRs bind to DNA as homodimers or heterodimers (usually with RXR) to hexameric response elements (HREs) (5′-AG(G/T)TCA-3′), arranged as direct repeats (DRx), inverted repeats (IRx), or everted repeats (ERx) separated by "x" base pairs.

The NR superfamily in mammals is composed of approximately 50 functional genes, 48 in humans, 47 in rats, and 49 in mice (Zhang et al., 2004). Interestingly, teleost fishes have a larger complement of NR genes (68 in pufferfish) due to whole genome duplication events (Maglich et al., 2003). The current official nomenclature for NRs divides the superfamily into seven families (NR0–6), with further subclassification designated by alphanumeric characters representing sequence similarities (Bertrand et al., 2004).

Fish Nuclear Receptors with an Emphasis on Teleosts

Genomics efforts in pufferfish, zebrafish, and medaka have revealed orthologs for most mammalian NRs, including those for steroid hormones, orphan receptors, and members of all seven NR families. In fact, most NRs from teleosts, some cartilaginous fishes, and other lower vertebrates exhibit strong homologies to mammalian sequences; however, certain structural modifications suggest functional differences that may reflect adaptations arising with the movement of vertebrates from aquatic to terrestrial environments. In addition, genome duplication resulted in a greater number of NRs in teleosts than in most mammals (Venkatesh, 2003; Volff, 2005); for example, those NRs for which duplicate genes exist include the vitamin D receptor (VDR), farnesol X receptor (FXR), glucocorticoid receptor (GR), and estrogen receptor (ER), among others (Maglich et al., 2003). As a result, questions regarding molecular function and diversification of paralogus sequences remain. Gene duplication events have different outcomes. Formation of a nonfunctional, duplicate gene may result. Subfunctionalization of duplicated genes may occur followed by degenerate mutations that modify expression or activity patterns of the single ancestral

Downloaded From Vet-eBooks.com

gene. Also, neofunctionalization may occur in which duplication of one daughter gene with the ancestral function occurs while the other acquires new functions (He and Zhang, 2005). It seems likely that subfunctionalization or neofunctionalization of NR paralogs may have been involved in the generation of fish variability. Additionally, from a molecular perspective, multiplicity of nuclear receptors may be an important factor that contributes to both signal diversification and specification (Gronemeyer et al., 2004). In this capacity, gene paralogs may impart novel functions that suit the unique physiological demands of inhabiting an aquatic environment or specific reproductive strategies. As discussed below, additional differences are noted between teleost and mammalian NRs, including structural changes resulting in differential ligand-binding characteristics (peroxisome proliferator-activated receptor [PPAR] alpha and gamma), absence of particular NRs, constitutive androstane receptor (CAR), or quantitative differences in ligand binding (ER).

The NR1I Subfamily

The NR1I subfamily has received a great deal of attention due to an essential role in regulating phase I and II genes involved in xenobiotic metabolism. For many years, the mechanisms governing cytochrome P450 gene induction following xenobiotic exposure remained elusive. AhR–CYP1A interactions were well described, but the processes by which induction of CYP2, CYP3, and CYP4 families occurred had yet to be determined (Hahn et al., 2005). With the discovery of the nuclear receptors CAR and pregnane X receptor (PXR), our mechanistic understanding of CYP regulation was greatly enhanced. Both CAR and PXR are low-affinity (high substrate concentration) xenosensors in mammals, capable of regulating genes associated with the metabolism, transport, and elimination of exogenous substrates. Human and rodent PXR can be activated by a variety of compounds known to induce hepatic P450 enzymes, including prescription drugs, steroids, and bile acids, and by several suspected endocrine-disrupting compounds (Hurst and Waxman, 2004; Masuyama et al., 2002; Moore et al., 2002). This broad substrate promiscuity of PXR is due to a 50- to 60-amino-acid insert between helix 1 and helix 3. The position of this insert was confirmed by x-ray examination, which revealed an unusually large ligand-binding pocket capable of accommodating a wide range of lipophilic ligands (Moore et al., 2002). Significant species differences arose from structural changes in the LBD resulting in an array of ligand-binding and transactivation specificities. PXR was initially identified as a candidate xenobiotic receptor based on its association with the induction of the hepatic P450 enzymes CYP2B and CYP3A (Savas et al., 1999; Waxman, 1999; Xie and Evans, 2001). Subsequent work proved that PXR mediates metabolism and the elimination of harmful hepatotoxic compounds by the concerted action of the oxidative phase I CYP enzymes, phase II conjugating enzymes, and drug transporters (Willson and Kliewer, 2002). To date, PXR is involved in the regulation of transcription targets for phases I, II, and III, including CYP2B, CYP3A, UGT1A1, MDR1, CYP24, and 5-AAS (Reschly and Krasowski, 2006). The development of PXR transgenic and knockout mice, the use of microarrays, and being able to screen mammalian genomes for putative PXR response elements have helped identify numerous PXR genes and their targets, including cell growth and differentiation and heme biosynthesis, among others, thus raising the possibility of a broader physiological role for PXR (Hartley et al., 2004).

The molecular characteristics of CAR and PXR have been compared in mammals. CAR differs from PXR in ligand-binding affinities, cytoplasmic localization, basal activity, and transrepression by specific ligands, including androgen steroids (Kakizaki et al., 2003). CAR does not contain the helix 1–3 insert as PXR does, with the result that a smaller ligand-binding pocket in CAR restricts the diversity of suitable ligands. The action of CAR as a xenobiotic receptor was confirmed by several studies examining CAR-dependent gene transcription (Ueda et al., 2002). Unique to the NR1I nuclear receptor family, CAR can undergo ligand-independent activation following treatment with phenobarbital (PB). The manner in which this is achieved may involve PB initiating a phosphorylation-dependent signal cascade that leads to translocation of CAR from the cytoplasm to the nucleus without direct PB binding (Kodama and Negishi, 2006). Additionally, CAR and PXR share overlapping transcriptional targets through recognition of similar DNA response elements. This cross-talk is hypothesized to operate as a metabolic safety net between receptors (Maglich et al., 2002); however, given the striking differences in their pharmacologic profiles, these receptors may have evolved to serve distinct physiological roles (Moore et al., 2002).

Pregnane X Receptor (PXR) in Fish

While the NR1I family has been extensively studied in mammalian species, much fewer functional data for these members of the NR family are available for teleosts and for cartilaginous fishes. PXR has been identified in pufferfish, zebrafish, and medaka, and mining their genomes suggests the presence of a single PXR/CAR-like gene in each species. These teleost receptors retain similarity to mammalian PXR, having a 50- to 60-amino-acid insert between helices 1 and 3 (Moore et al., 2002), and may be a functional precursor of mammalian PXR. Interestingly, transactivation studies with a chimeric Gal4–zfLBD system from zebrafish PXR demonstrated limited diversity of functional ligands. While responsive to prototypic PXR ligands (nifedipine, phenobarbital, clotrimazole, and 5β-pregnane-3,20-dione), transactivation was low in comparison to mammalian PXR. These differences, however, may reflect the high degree of sequence variation in the ligand-binding domain. Comparative cross-species analysis of PXR suggests a high degree of variation at this site (Reschly and Krasowski, 2006). Analysis of endogenous biliary ligands demonstrated that zebrafish PXR activation was restricted to the C27 bile alcohol cyprinol sulfate, the major zebrafish bile salt. By comparison, C24 bile acids (found in birds and mammals) were ineffective (Krasowski et al., 2005a). Fish bile acids are highly variable, with some species containing C27 bile alcohols and acids and others C24 bile alcohols and acids. Some, such as the medaka, contain both C27 and C24 bile acid components (Lee Hagey, pers. commun.). The role of PXR as an endogenous sensor for bile acids may be highly species specific and subject to selective adaptations depending on the metabolic requirements.

From a toxicological perspective, it is important to know whether PXR is associated with induction of teleost P450 enzymes, specifically CYP3A. In one study, typical mammalian PXR receptor agonists, including dexamethasone (DEX), the macrocyclic antibiotic rifampicin (RIF), and the synthetic steroid pregnenolone-16α-carbonitrile (PCN), were seemingly ineffective at altering teleost CYP gene transcription (Celander et al., 1989, 1996). In tilapia (*Oreochromis niloticus*), however, PCN treatment resulted in a twofold induction of CYP3A proteins (Pathiratne and George, 1996). Similarly, exposure of zebrafish to PCN resulted in a slight increase in PXR, CYPA, and MDR1 gene transcription. No change was observed with other prototypic PXR agonists, including the antimycotic clotrimazole (CTZ) or the antianginal drug nifedipine (NIF) (Bresolin et al., 2005). 4-Nonylphenol, the major byproduct of alkylphenol ethoxylates, induces CYP3A in several fish (Hasselberg et al., 2005; Kullman et al., 2004). In a recent study, nonylphenol-induced expression of CYP3A correlated with an increased expression of salmon PXR, suggesting possible coregulation (Meucci and Arukwe, 2006). A similar finding was observed with DDE, illustrating the broad substrate affinity of Atlantic salmon PXR to environmental contaminants (Mortensen and Arukwe, 2006). In a recent review by Goksøyr (2006) on endocrine disruptors in the marine environment, the nature of the effect of such compounds was considered to be due to dose-dependent routing and cross-talk between different classes of nuclear receptors. Zebrafish CYP3A65 transcription is enhanced by administration of DEX and RIF (Tseng et al., 2005). Interestingly, CYP3A65 is additionally responsive to 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), indicating possible cross-talk between PXR and AhR. To date, however, there exists only indirect evidence that teleost PXR is associated with CYP expression based on similarity in response to mammalian PXR ligands. Although gene sequences for PXR have been identified, few functional data exist regarding the role of PXR in the transcriptional activation of hepatic metabolic genes and their physiological significance. *In vitro* transactivation studies and identification of cognate hormone response elements upstream of teleost CYP3A genes may provide some evidence that nuclear receptors are involved in transcriptional regulation; however, this has not been determined to date.

Constitutive Androstane Receptor (CAR) in Fish

Genomic data have revealed a wide diversity of CYP2 genes in several fish species (Nelson, 2003). Findings suggest that this CYP family has greatly diversified in fishes as compared to mammals; however, both structure and function have been conserved. To date, the functional properties of few teleost CYP2 genes have been thoroughly investigated. Heterologus expression of CYP2M1 and CYP2P demonstrated a diversified role in xenobiotic and endobiotic metabolism (Oleksiak et al., 2003; Yang et al., 1998). Unlike mammals, however, teleosts exhibit an apparent lack of CYP2B and CYP2 gene induction

Downloaded From Vet-eBooks.com

following exposure to the potent mammalian CYP2B/CYP2C inducers phenobarbital and 1,4-*bis*[2-(3,5-dichloropyridyloxy)]benzene (TCPOBOP) (Elskus and Stegeman, 1989; Kleinow, 1990). In mammals, induction of CYP2B proceeds through activation of CAR (Honkakoski and Negishi, 1997; Honkakoski et al., 1998a,b). Curiously, efforts to clone CAR from numerous teleosts have proven unsuccessful, and the mining of several teleost genomes suggests an obvious lack of CAR. In agreement with genome sequencing, experimental evidence has demonstrated that in teleost species only a single PXR/CAR-like gene is present. Iwata et al. (2002) identified a single immunoreactive protein from scup liver cytosol with CAR-like antigenic properties; however, no induction of CYP2-like protein or translocation of such protein was observed following treatment with TCPOBOB. Phylogenetic analysis suggests that NR genes appear to be subject to strong purifying selection, particularly in the DNA-binding domains (Krasowski et al., 2005b); however, estimates of the ratio of the nonsynonymous to synonymous nucleotide substitutions for the NR1I subfamily indicate that only PXR and CAR have undergone recent positive selection. Current convention suggests that CAR arose with duplication of a premammalian PXR (Krasowski et al., 2005b). It is most likely that teleosts lack a CAR-like receptor. In fishes, however, other members of the NR1I family (PXR and VDR) may demonstrate broader ligand profiles. An alternative hypothesis is that CAR has been lost in some teleosts species.

Vitamin D Receptor (VDR) in Fish

The vitamin D receptor (VDR) has been cloned from a number of teleosts, including flounder, trout, zebrafish, salmon, carp, sea bass, and medaka. Recently, VDR was also cloned from the jawless agnathan lamprey, which represents the most ancient lineage among extant vertebrates (Whitfield et al., 2003). Prior to the cloning of VDR in aquatic organisms, general convention held that the $1,25(OH)_2D_3$–VDR system originated in terrestrial animals. It is well known that vitamin D is one of the oldest hormones and is present in the earliest life forms, including phytoplankton and zooplankton (Holick, 2003a,b). Workers have questioned the significance of the capacity for vitamin D production in early eukaryotes, and one hypothesis is that vitamin D photoproducts serve as a photon sink, protecting DNA, RNA, and proteins from the damaging effects of high-energy ultraviolet radiation.

Certain fish are very rich sources of vitamin D as compared to higher vertebrates, which have insignificant amounts of this vitamin. This high level of vitamin D is found both in teleosts and in the cartilaginous elasmobranchs, signifying that high levels are not related to skeletal calcium. This finding led to speculation that function of vitamin D and the VDR in fish may be different from its known classical functions in terrestrial animals (Rao and Raghuramulu, 1999a,b). Moreover, endocrine physiology in fish has adapted to an external aquatic environment that provides a constant source of calcium ion; thus, the mechanisms regulating calcium mobilization may differ between aquatic and terrestrial organisms and between marine and freshwater fish species (Power et al., 2002). To date, however, the role of vitamin D in calcium regulation in teleosts remains equivocal. Studies in different fish species are contradictory, with a majority of evidence suggesting that VDR does not classically mediate calcium mobilization from fish enterocytes (Larsson et al., 2003; Nemere et al., 2000; Rao and Raghuramulu, 1999a). These results may reflect the enormous diversity in teleost physiology.

Recently, in mammals, VDR had been demonstrated to act as a low-affinity receptor for the secondary bile acid lithocholic acid (Makishima et al., 2002). This action may act as a hepatoprotective mechanism similar to that observed with FXR and PXR for the metabolism and export of toxic bile acids. To date, VDR exhibits receptor cross-talk with PXR for the transcriptional regulation of the broad-specificity hepatic and intestinal phase I enzymes CYP2B6, CYP2C9, and CYP3A. Thus, other than the high-affinity endocrine effects, VDRs exhibit considerable overlap in metabolic transcriptional targets. The role of teleost VDR in regulating hepatic and intestinal metabolizing enzymes has not been fully investigated. Like many teleost genes, two VDR genes (VDRα and VDRβ) are observed in some fish species. In concordance with subfunctional portioning theory (Postlethwait et al., 2004), the tissue distributions of the VDRα and VDRβ forms are quite different. In pufferfish, VDRα exhibits a ubiquitous tissue distribution, including strong expression in brain, gill, heart, and to a lesser extent liver (Maglich et al., 2003). Pufferfish VDRβ, on the other hand, is localized solely in the gut. The distribution of both VDRα and VDRβ in the Japanese flounder is widespread, with high expression levels in the gill, brain,

Downloaded From Vet-eBooks.com

heart, ovary, testis, and gut (Suzuki et al., 2000). Flounder VDRβ expression was found to be weak in liver, whereas VDRα was absent. In both species, the strong expression in the intestine and gut signifies a putative role in regulation of intestinal metabolic activities.

The presence of a high-affinity VDR in the sea lamprey suggests that regulation of calcium is not a critical function of ancestral VDR (Whitfield et al., 2003). Supporting this claim is the observation that VDR expression precedes bone formation during *Xenopus* development (Li et al., 1997). Furthermore, in mammals, VDRs mediate critical functions other than calcium and phosphate regulation, including immune function, skin development, cell proliferation, and catabolism of endogenous and exogenous substrates. The latter two are of particular importance in this consideration of liver toxicology. The fact that lamprey VDR is capable of binding and transcriptional activation of mammalian CYP3A4 promoter demonstrates conservation in the DNA binding behavior of an early form of this receptor and a possible role in endobiotic and xenobiotic metabolism in the livers of fish (Whitfield et al., 2003). More functional data are needed regarding the role of VDR in endobioitc and xenobiotic metabolism. Interesting, like PXR, VDR contains a large insert between helices 1 and 3. While significantly different in sequence than PXR, this insert may be associated with novel low-affinity ligand binding/transactivation activities of VDR, specifically given the differing physical and nutritional environments between aquatic and terrestrial species.

Peroxisome Proliferator-Activated Receptor (PPAR) in Fish

Peroxisome proliferator-activated receptors are ligand-dependent transcription factors belonging to the NR1C subfamily of nuclear receptors. PPARs typically bind natural and synthetic fatty acids and certain pharmaceutical ligands. More recently, however, it has been demonstrated that select members of the PPAR subfamily bind environmental contaminants such as phthalate monoesters and organotins, making them putative mechanistic targets for endocrine disruption (Grun and Blumberg, 2006; Hurst and Waxman, 2004). PPAR nuclear receptors exist in three forms: PPARα, PPARβ, and PPARγ. The ligand-binding affinities for each form differ, as does the tissue-specific expression (Lee et al., 1995, 2003; Schoonjans et al., 1996). In teleosts, all homologs of all three mammalian-defined PPAR isotypes (α, β, and γ) have been identified in both marine and freshwater fish, although differences in total number of PPAR genes (variants of the three isotypes) and their tissue distribution exist in comparison to mammals (Andersen et al., 2000; Batista-Pinto et al., 2005; Ibabe et al., 2002; Leaver et al., 2005; Maglich et al., 2003; Robinson-Rechavi and Laudet, 2001). From the molecular perspective, teleost PPARs heterodimerize with RXR and bind to peroxisomal proliferator response element (PPRE)-like direct repeat elements in promoter/enhancer regions, resulting in altered expression of target genes similar to that observed in mammals (Leaver et al., 2005). Structurally, the *N*-terminal A/B domains of the PPARs are the least conserved regions between fish and mammals; however, DNA-binding domains and ligand-binding domains demonstrate a high degree of sequence identities among fish, amphibians, and mammals, although the LBDs are generally longer in fish (Andersen et al., 2000; Leaver et al., 2005). PPARγ from pufferfish, salmon, flounder, and flatfish are unique in that they contain key amino acid differences within the ligand-binding domains, thus preventing the binding of acidic ligands. It has been suggested that fatty acids are not likely to activate fish PPARγ (Leaver et al., 2005; Maglich et al., 2003). This represents a significant difference between teleostean and mammalian forms of this receptor and is perhaps reflective of early adaptations of the receptor to specific demands present in aquatic environments.

In mammals (rat and mouse), PPARα activation leads to peroxisome proliferation (number and volume) and concurrent transcriptional activation of genes involved in lipid homeostasis. Genes involved in fatty acid uptake and binding (fatty acid binding protein [FABP]), fatty acid ω-oxidation (acyl-CoA oxidase [AOX]), lipoprotein assembly and transport (various apolipoproteins), and others are all modulated by PPARα (Desvergne and Wahli, 1999; Hamadeh et al., 2002; Martin et al., 1997; Schoonjans et al., 1996; Yadetie et al., 2003) and thus are excellent targets of investigation in fish model systems. Although some studies have suggested that fish are refractory to peroxisome proliferation (Baldwin et al., 1993; Pretti et al., 1999), *in vivo* and *in vitro* experiments show that many fish species are responsive to PPARα ligands such as the fibrate-based pharmaceuticals and other natural peroxisome proliferators (Donohue et al., 1993; Haasch et al., 1998; Ruyter et al., 1997; Scarano et al., 1994; Yang et al., 1990). More

Downloaded From Vet-eBooks.com

recent studies suggest that peroxisome proliferation and AOX expression (typical PPARα-induced liver responses) may be used as biomarkers in aquatic organisms (Cajaraville et al., 2003). Interestingly, however, as with gene regulation of CYP2, little evidence suggests that PPARα activation results in altered expression of CYP4, a common PPARα target in mammals. This again represents a significant departure in CYP gene regulation between teleosts and mammals. Although CYP4 has been identified in several fish species (either by direct cloning or by genome analysis), the mechanisms of CYP gene regulation in teleosts have not been well investigated. Initial similarities between AhR and CYP1A activation suggested that disparate species would share common mechanisms; however, recent observations reveal a lack of induction of CYP4 and CYP2 genes in addition to the lack of CAR. CYP gene regulation in teleosts may be quite different from that of their mammalian counterparts. Moreover, given the dynamic diversity of teleosts and their diverse habitats, significant differences may be observed in the spectrum of NR ligands, binding affinities, and mechanisms regulating gene transactivation.

Role of Nuclear Receptors in Bile Acid, Lipid, and Cholesterol Homeostasis

Multiple NRs play pivotal roles in the regulation of cholesterol, lipids, and bile acid in the livers of mammals. In keeping with the theme that NRs serve as cellular sensors for nutrients and their metabolites, it is now understood that the effects of many dietary compounds, including cholesterol, fatty acids, and fat-soluble vitamins, and other lipids, are mediated by the action of NR binding. Nutritional lipid intake constitutes an important determinant of disease susceptibility and is often exacerbated by dislipidemia. Numerous studies are now addressing questions of the influence of dietary lipids on gene regulation and subsequent changes in metabolism with a goal of establishing how diets can be modified to improve health. Identifying and understanding the activity of nuclear receptors as cellular sensors of cholesterol, lipids, and bile acids and thus their regulation are the subjects of intense study. Cholesterol is essential for all vertebrate cells and is required for maintenance of membrane fluidity and permeability, as a precursor for steroid biosynthesis, and for bile acid production. Homeostatic control of lipoprotein cholesterol uptake and synthesis is regulated at multiple checkpoints through a series of negative feedback loops that respond to elevated intracellular cholesterol levels. These checkpoints are governed by a family of membrane-bound transcription factors—sterol regulatory element binding proteins (SREBPs)—which activate expression of genes involved in the synthesis and uptake of cholesterol and lipogenesis (Horton et al., 2002). To prevent cytoxicity due to cholesterol, oxysterol, and bile acid accumulation, liver X receptor (LXR), farnesol X receptor (FXR), and additional NRs (PXR, LHR, PPAR, HNF4, and SHP) promote sterol storage, transport, and catabolism (Ory, 2004). Key to the coordinated function of these receptors is their role as cellular sensors for lipids, sterols, and bile acids (i.e., PPAR, fatty acids; LXR, oxysterols; FXR, bile acids; PXR/CAR, bile acids). Receptor ligand binding of NRs initiates specific transcriptional programs that regulate sterol homeostasis, including cholesterol uptake and catabolism, triglyceride metabolism, reverse cholesterol transport, lipoprotein biosynthesis, and bile acid synthesis, transport, and metabolism (Chiang, 2004; Ory, 2004).

Completion of genome projects in certain teleosts such as pufferfish, medaka, and zebrafish demonstrated the presence of LXR, FXR, and other NRs associated with cholesterol and lipid homeostasis. These results suggested a similar repertoire of NR function in lower vertebrates. To date, however, information regarding the functional mechanism of NRs in sterol homeostasis in teleosts and other aquatic organisms is lacking and can only be inferred via gene homologies. Identification of many of the genes regulated by these NRs including CYPs, apolipoproteins, and various transporters, however, has provided the additional information that teleosts share a common mechanism of sterol homeostasis with mammalian liver.

Summary

Nuclear receptors are ligand-dependent transcription factors that bind to lipophilic signaling molecules, resulting in the control and expression of target genes in liver and often other tissues. They facilitate the cellular response to endogenous and exogenous ligands by coordinating complex transcriptional responses; therefore, they must be considered in the study of toxicity. Analysis of the evolution, molecular

Downloaded From Vet-eBooks.com

behavior, and physiological function of NRs is of particular interest given their diverse role in coordinating numerous biological processes. The origins of nuclear receptor interactions are unknown, yet NRs have been found in almost all animal species examined thus far. NRs play a significant role in the liver physiology of all animals, including the uptake, metabolism, storage, and redistribution of nutrients and endogenous molecules, metabolism of xenobiotics, and formation and excretion of bile. Studies in teleosts to date suggest that there are substantial differences in the structure and possibly functions of teleost NRs. Because fish stand between invertebrates and higher vertebrates in evolution, they may serve as unique models for the study of the evolutionary and physiological significance of NRs. From a toxicological perspective, we have yet to determine if these NRs are true targets for exogenous compounds and xenobiotics as described for mammalian species. With PXR, numerous species-specific ligand-binding profiles exist, but the molecular and physiological functions of teleost NRs have yet to be determined. As we continue to explore the molecular dynamics of teleost nuclear hormone receptors and analyze ligand-specific interactions, DNA-binding characteristics, and comodulator recruitment, we will gain new insights into the evolution of NR-mediated transcription regulation and the importance of receptor subfunctionaliztion and will broaden our understanding of the role of NRs in governing liver-specific processes in lower vertebrates.

Introduction to Bile Synthesis and Transport

Bile acid synthesis and secretion, performed by hepatocytes and biliary epithelial cells, are vital for the assimilation of lipid-soluble dietary nutrients (e.g., vitamins A, K, and E; triacylglycerols) and the elimination of endogenous metabolic byproducts and wastes (e.g., bilirubin, hormones). Equally important is the role of bile in the elimination of xenobiotics (environmental toxicants, carcinogens, drugs, and their metabolites). The physiological importance of these processes renders bile synthesis and secretion critical life functions.

The hepatobiliary transport of substances (e.g., bile salts, inorganic and organic solutes) from blood to bile includes three major steps. First, uptake of substances from blood plasma across the sinusoidal membrane and then into the hepatocytes must occur. This in turn is followed by intracellular transport and metabolism. Finally, transport of the parent substances or metabolites occurs across the apical membrane of hepatocytes into biliary passageways (Groothuis and Meijer, 1996; Nathanson and Boyer, 1991).

As a brief review of the biliary passageways in liver, the terminal branches of the intrahepatic biliary system are canaliculi, microscopic passageways 1 to 2 mm in diameter, that are formed by, and between, adjacent hepatocyte membranes and delineated by tight junctions. Next are transitional zones in which bile preductular epithelial cells (cells with high nuclear-to-cytoplasmic ratios) form junctional complexes with hepatocytes, at which are created bile preductules. Bile preductules provide for movement of bile from canaliculi to bile ductules (cholangioles). The walls of the latter are completely comprised of biliary epithelial cells. From here, bile passes through a network of ductules that feed larger intrahepatic bile ducts as the bile moves toward the liver hilus. From the hilus, bile is conducted to the extrahepatic biliary system. The latter is comprised of one or more hepatic ducts that conduct bile into the bile duct. From this structure, a cystic duct arises that conducts bile to and from the gallbladder. From the point between the cystic duct and the intestinal wall, the passageway is known as the common bile duct. All of these components are discussed in the section on cells of the teleost liver.

Because pressures within bile spaces exceed those of the sinusoids, hydrostatic forces alone cannot account for bile flow (Trauner and Boyer, 2003). Flow of bile from sinusoids to canaliculi (blood to bile transport), through the hepatocyte, is a secretory and concentrative process driven by a suite of transmembrane transporters (discussed later in this chapter); for example, in rodents blood to bile transport is uphill against a 100- to 1000-fold concentration gradient. Bile flow in the intrahepatic biliary system is also regulated by the contraction of canaliculi, the functional aspects of which are mechanically governed by cytoskeletal elements in the pericanalicular cytoplasm. Because cytoskeletal proteins are key regulators of proper canalicular development and function, impairment of cytoskeletal function by endogenous or exogenous compounds is a key mechanism by which altered bile transport (toxicity)

Downloaded From Vet-eBooks.com

occurs. In the mammalian liver, altered bile transport (cholestasis) is a common response of the liver to xenobiotic exposure and a key mechanism of toxicity for many drugs. Changes to cytoskeletal function, for example, are associated with a loss of canalicular microvilli and diminished canalicular contractility (Phillips et al., 1986; Song et al., 1998; Watanabe et al., 1983).

In the intrahepatic biliary system of mammals, biliary epithelial cells (BECs), like hepatocytes, are key regulators of bile transport, responsible for regulating: bile fluid alkalinity (through the Na^+-dependent Na^+/HCO_3^- and CL^-/HCO_3^- exchange symporters), electrolyte content (via ion channels), water composition (a major components of bile, via active transport of aquaporins), and bile salts. Bile salt uptake into cholangiocytes and gallbladder epithelial cells may also serve an important role via cell signaling for regulation of secretory and proliferative processes (in response to injury) within the biliary tree (Alpini et al., 2001, 2002).

Biliary epithelial cells (BECs) are known target cells in a number of pathologic conditions (cholangiopathies) of mammalian liver, including primary biliary cirrhosis (PBC) and primary sclerosing cholangitis (PSC), as well as diseases associated with BEC proliferation or loss. For example, in rodents, cholangiopathies that result in impaired bile synthesis or flow can be induced by several experimental conditions, such as chronic administration of CCl_4 or the reference toxicant α-naphthylisothiocyanate (ANIT) (Kanno et al., 2001). Because of the critical role of BECs in bile homeostasis, impairment of BEC function can be a primary source of hepatotoxicity through altered bile synthesis and transport. Although BECs have been identified in several fish species and their morphology characterized, their complex transport and bile regulatory mechanisms remain poorly understood. It is likely, however, that their functional characteristics are equally important in the hepatobiliary toxicity of fishes.

Bile Synthesis

Hepatocytes and biliary epithelial cells coregulate bile synthesis, volume, composition, and transport in response to changing physiologic needs. In all vertebrates, bile synthesis is part of the mechanism of cholesterol elimination, accomplished by conversion of cholesterol to water-soluble amphipathic bile salts (Moschetta et al., 2005). In higher vertebrates, metabolic conversion of cholesterol to the primary bile acids cholic acid (CA) and chenodeoxycholic acid (CDCA) occurs in hepatocytes via two pathways. The classic (neutral) synthetic pathway involves modification of the sterol nucleus (e.g., 7α-hydroxylation and β-oxidations of the side chain of either cholesterol or one of three oxysterols containing a hydroxyl group at the C24, C25, or C27 position of the side chain) by 7α-hydroxylase (CYP7A1), leading to formation of CA and CDCA. The acidic, or alternative, pathway is catalyzed by sterol 27-hydroxylase (CYP27A1) located on inner mitochondrial membranes, leading to the generation of CDCA. In both processes, the end products CA and CDCA are subsequently amidated to anionic bile salts (bile acids exist as bile salts at physiological pH) via glycine or taurine conjugation, rendering them impermeable to cell membranes and hydrophilic. During enterohepatic transport, CA and CDCA are metabolized by intestinal flora (bacteria) to the secondary bile acids deoxycholic acid (DCA; from CA) and lithocholic acid (LCA; from CDCA).

In primitive vertebrates, including fish, bile synthesis pathways consist of different means of hydroxylating cholesterol, followed by conjugation with a strong anion (usually sulfate). The most common products in lower vertebrates are bile alcohol sulfates with four, five, or six hydroxyl groups per sterol nucleus. It is presumed that, through evolution, bile salts gradually assumed more diverse biological roles, reflected in structural variations (lipid solubilization, bactericidal). One of the more significant evolutionary advancements in bile synthesis was the shift from nonrecycling C27 bile alcohol sulfates (e.g., fish and reptiles) to enterohepatically cycling C24 bile acids. C24 bile acid structures have been achieved in virtually all vertebrate groups through convergence, with each group achieving the C24 bile acid structure independently. A survey of the transition in bile synthesis in various species found three primary evolutionary transitions: (1) C27 alcohol sulfates to C24 taurine-conjugated acids, (2) C27 alcohol sulfates to C27 taurine-conjugated acids to C24 taurine-conjugated acids, and (3) C27 alcohol sulfates to C24 glycine-conjugated acids to C24 taurine-conjugated acids. The first pathway is considered quite rare and has been observed only in fish. The second pathway is the classical, most commonly used route in lower vertebrates, and the third pathway is the one utilized in mammals. Vertebrate groups in

Downloaded From Vet-eBooks.com

which species have evolved over a long enough period of geological time have members that form C27 bile alcohol sulfates, species that are in the process of transition (selecting one of the three pathways), and species that form C24 taurine-conjugated acids. Hence, bile acids in vertebrates can be broken down into three classes based on side-chain functional group: C27 bile alcohols and C27 and C24 bile acids. Bile alcohols, which occur in many fish species, are conjugated by esterification of the terminal C27 hydroxy group with sulfate, whereas bile acids are typically conjugated by *N*-acyl amidation of the terminal C27 or C24 carboxyl group with taurine or glycine (Moschetta et al., 2005).

In terms of bile synthesis and composition, the majority of fish fall into two groups: ancient (utilizing C27 bile alcohol sulfates) and modern (utilizing C24 taurine-conjugated acids). C27 bile alcohol sulfates, characteristic of a more primitive bile synthetic pathway, are ubiquitous among vertebrates. They are the dominant bile salts of ancient mammals (e.g., elephant, manatee, rhinoceros) and the major bile constituents in cartilaginous fish, herbivorous bony fish, and some amphibians. In the few fish species examined, the ratios of bile acids to bile alcohols differ from those of mammals; for example, medaka synthesize bile using the classical pathway (a transition fish), with approximately 50% C27 taurine-conjugated acids and 25% C24 taurine-conjugated acids, while a sulfated bile alcohol, scymnol sulfate (ScyS), is the major bile salt in the little skate (*Raja erinacea*), and 5-cyprinol sulfate, a more common piscine bile alcohol, is the major bile salt in zebrafish. Similar differences in bile acid/bile alcohol composition are described in the coelacanth (*Latimeria chalumnae*) and Japanese eel (Kihira et al., 1984; Masui et al., 1967). Of interest is that bile alcohols are known to be stable at 4°C, which may be of evolutionary significance in cold-water species.

Bile Transport

The vast majority of the bile salt pool is localized to enterohepatic circulation and is regulated in mammals by a suite of distinct transmembrane transporters in hepatocytes, BECs, and enterocytes (Trauner and Boyer, 2003). Bile salt homeostasis is also governed through tight negative feedback control via transcriptional regulation; for example, after intestinal absorption bile salts return to liver where they regulate their own synthesis (see discussion on nuclear regulators). Hepatobiliary transport mechanisms determining uptake and excretion of bile salts and other biliary constituents in liver and extrahepatic tissues are well characterized in mammals and are likely well conserved across vertebrate species (with anticipated subtle species differences). Transmembrane transport proteins, localized to both sinusoidal and apical membranes of hepatocytes and biliary epithelia, have been functionally characterized, cloned, and studied in transgenic animal models, and several genes regulating transporter synthesis have been identified through mutations in inherited forms of cholestasis (Boyer, 1996; Pauli-Magnus and Meier, 2005; Trauner and Boyer, 2003).

The primary mammalian hepatocytic transporters include the sinusoidal Na^+ taurocholate cotransporting polypeptide (NTCP; SLC10A1), organic anion-transporting polypeptides (OATPs; SLC21A), the organic cation family of transporters (OCTs), multidrug resistance-associated proteins (MRP1–6; ABCC1–6), and members of the family of multidrug resistance P-glycoproteins, such as MDR1 (ABCB1), MDR3 (ABCB4), and the apical bile salt export pump (BSEP) (ABCB11) (Boyer, 1996; Groothuis and Meijer, 1996; Pauli-Magnus and Meier 2005; Sturm et al., 2001b; Trauner and Boyer 2003). Bile salt transporters have also been identified in biliary epithelia, enterocytes, the renal proximal tubule of the kidney, and placenta. An important characteristic of MDR-encoded gene products (e.g., MDR1, MDR3) is their broad specificity; they are able to transport an array of structurally and functionally diverse substrates, including anticancer drugs such as paclitaxel, vinca alkaloids, anthracyclines, and epipodophyllotoxins (Ueda et al., 1997), as well as numerous other classes of compounds such as calcium channel blockers, HIV protease inhibitors, hormones, pesticides, cyclic and linear peptides, and immunosuppressive agents (Stouch and Gudmundsson, 2002).

Mammalian bile salt transport occurs via both Na^+-dependent and Na^+-independent mechanisms. The primary Na^+-dependent transporter is the sinusoidal NTCP (Ntcp in rodents), which is exclusively expressed in hepatocytes and mediates the hepatocellular uptake of bile salts (Fardel et al., 2002; Groothuis and Meijer, 1996; Lecureur et al., 2000). In addition to bile salts, rat Nctp has been shown to support the hepatic uptake of estrone-3-sulfate, dehydroepiandrosterone sulfate, and the thyroid

Downloaded From Vet-eBooks.com

hormones T_3 and T_4. Sodium-independent transport is regulated by the adenosine triphosphate (ATP)-dependent superfamily of transporters (e.g., MDR1/ABCB1, MDR3/ABCB4, MRP2/ABCC2, BSEP/ABCB11) and the multispecific organic anion and cation transporters (e.g., OATPs/SLC21A, OCTs). Of these, MRP2, which transports primarily glutathione and glucuronyl conjugates, including the physiologically important conjugates of bilirubin, estradiol, and xenobiotic metabolites (Faber et al., 2003; Keppler et al., 1997), is the major determinant of bile-salt-independent bile flow and the only known MRP-related canalicular transporter.

Expression of transporter proteins is regulated by multiple and complex biofeedback mechanisms, involving gastrointestinal hormones and peptides such as secretin, vasoactive intestinal peptide (VIP), bile salts within the bile pool, intermediate bile acid metabolites, nuclear receptors, and the cholinergic nervous system (Boyer 1996; Trauner and Boyer 2003; Trauner et al., 2000). Bile acids and salts themselves function as specific ligands for nuclear hormone receptors where they regulate transporter expression via transcriptional events (Chawla et al., 2001).

Fish Studies

Although we currently have only a nascent understanding of piscine hepatobiliary transport mechanisms, it is becoming clear that certain transport mechanisms may be conserved in vertebrate evolution; for example, basolateral uptake of bile acids by trout hepatocytes, as well as the disruption of these transport processes by toxicants, has been demonstrated (Rabergh et al., 1992). Likewise, a sodium-independent carrier system that mediates taurocholic acid and cholic acid transport has been identified in trout (Rabergh et al., 1994). Hepatocellular uptake of bile acids in trout was found to resemble corresponding systems in mammalian liver cells, although trout carriers were distinguished by high efficiency at low temperatures. Below is a comparative summary of known transporters in fish.

MDR-Encoded Transporters

Several highly conserved members of the MDR1 (P-glycoprotein [Pgp]) transporter family have been identified in rainbow trout (Sturm et al., 2001b) and winter flounder (*Pleuronectes americanus*) (Chan et al., 1992). Immunohistochemical studies have also shown conserved distribution of Pgp epitopes in the tissues of guppy (*Poecilia reticulata*), epitopes that resemble mammalian forms (e.g., react with mammalian antibodies) (Hemmer et al., 1998). Other studies have identified MDR-like proteins. Localization experiments using immunohistochemical techniques with an antibody prepared against human Pgp revealed positive reaction at the bile canalicular pole in *Fundulus heteroclitus* hepatocyte cultures (Albertus and Laine, 2001). Similarly, a Pgp-related protein of approximately 170 kDa was demonstrated in the intestine and liver of catfish (Doi et al., 2001). Several studies using isolated fish hepatocytes have demonstrated transport activities exhibiting characteristic Pgp-mediated transport (Albertus and Laine, 2001; Sturm et al., 2001b; Tutundjian et al., 2002). Pgp reversal agents, for example, have been shown to preclude the transport of Pgp substrates in teleost hepatocytes. In rainbow trout hepatocytes, both the accumulation and efflux of the fluorescent Pgp substrate (rhodamine 123) were modified by the reversal agents verapamil, cyclosporin A, and vinblastine, as well as the ATPase inhibitor vanadate (Sturm et al., 2001b). In contrast, tetraethylammonium chloride, a substrate for type I sinusoidal organic cation uptake systems and electroneutral canalicular H^+/organic cation antiporter, had no effect on rhodamine 123 transport (Sturm et al., 2001b). *In vitro* preparations of isolated killifish and turbot hepatocytes and *in vivo* studies in carp and catfish have demonstrated the uptake of fluorescent Pgp substrates that proved to be verapamil and estradiol (E2) sensitive (Albertus and Laine, 2001; Kleinow et al., 2004; Smital and Sauerborn, 2002).

Organic Anion-Transporting Polypeptides (OATPs)

Organic anion-transporting polypeptides have been cloned and functionally characterized in the skate (*Raja erinacea*) (Cai et al., 2002). Phylogenetic and sequence comparisons with a liver-specific OATP isolated from hepatocytes indicate that skate OATP is most closely related to OATP-F (SLC21A14) from human brain (50.4% identity) and rat OATP4, which is also called Lst1 (Slc21a10; 41.2% identity) (Cai

Downloaded From Vet-eBooks.com

et al., 2002). A multispecific organic solute and steroid transporter that requires the coexpression of two gene products, Ostα and Ostβ, has also been isolated and functionally characterized in skate. The cDNA and predicted amino acid sequences of Ostα and Ostβ appear to be novel and are likely to be members of an additional family of transporters. The overall substrate specificity of Ostα and Ostβ is most similar to that of the OATP family, in particular to that of human OATP-C (also known as LST1 and OATP-2) (Wang et al., 2001). Jacquemin et al. (1995) also identified an organic anion transport protein in skate liver, and these studies suggest that the primitive skate OATP is most closely related to humans.

Multidrug Resistance-Associated Proteins (MRPs)

Genes for MRPs have been identified in red mullet (*Mullus barbatus*) (Sauerborn et al., 2004), and an MRP2 ortholog has been characterized in the liver of the small skate (*Raja erinacea*) (Cai et al., 2003). Antibodies directed against mammalian MRP2-specific epitopes labeled a 180-kDa protein band in skate liver plasma membranes and stained canaliculi by immunofluorescence, indicating that skate livers expressed a homologous protein (Rebbeor et al., 2000). Investigations of ATP-dependent transport in skate liver plasma membrane vesicles suggest that the transport of anions is mediated by a functional analog of mammalian MRP.

Functional and Structural Evidence for a BSEP/SPGP

A BSEP-like protein in the canalicular membrane of the skate liver has been identified and shown to transport both bile salts and bile alcohols (Ballatori et al., 2000). A BSEP-like protein has also been identified in medaka (*Oryzias latipes*) (Hinton et al., unpublished studies).

Bile Flow

Bile flow rates, perhaps expectedly, vary between piscine and mammalian species. Although few aquatic species have been studied, bile flow information for some cartilaginous fish and teleosts exists. For comparative purposes, in humans bile acid secretion by the hepatocyte approximates 1 g/hr, 95% of which is recovered following absorption from the distal ileum into the portal venous system (Wolkoff and Cohen, 2003). The human bile salt pool size is approximately 50 to 60 μ*M*/kg body weight and averages 3 to 4 g (Trauner and Boyer 2003). In humans, bile salts are rapidly extracted from enterohepatic circulation by the liver with single-pass extraction rates as high as 80%. Na^+-dependent uptake of a variety of bile salts is considered to be the rate-limiting step in bile-acid-dependent bile flow, a mechanism that finds a Na^+/bile acid cotransport with stoichiometry of >1:1. After common bile duct ligation and cannulation, both the spiny dogfish shark (*Squalus acanthias*) and the skate (*Raja erinacea*) were observed to secrete bile for periods of 4 to 7 days with maximum rates of 1.77 ± .89 mL/kg per 24 hours in *Squalus acanthias* (approximately 100 times slower than rat) and 2.66 ± .89 mL/kg per 24 hours in *Raja erinacea* (Boyer et al., 1976a,b). Other reported bile flow rates are 33 to 74 μL/kg/hr for *Squalus acanthias* and 75 to 111 μL/kg/hr for *Raja erinacea* (Klaassen and Watkins, 1984). Bile flow in the common bile duct of cannulated rainbow trout (*Oncorhynchus mykiss*) was observed to be constant at 75 μL/kg/hr over 108 hours of experimentation (Grosell et al., 2000). The bile acid concentration in the hepatic bile of rainbow trout (15 to 50 m*M*) is within the range reported for mammals (Klaassen and Watkins, 1984; Strange 1984). A comparison of bile composition and bile flow rates can be found in Table 7.6.

Reported bile flow rates are known to vary among vertebrate species, with aquatic species showing slower rates of bile flow. Where flow rates vary markedly, the fundamental composition of bile, or bile fluid, can be similar, as can be seen in freshwater trout, rats, and humans. Saltwater fish show approximately twice the concentration of electrolytes (Na, K, Cl). Although sparse information is available for aquatic species, current data generally show that bile synthesis and transport are fairly well-conserved physiological functions; for example, skate BSEP clones were identified that share approximately 65% identity with human BSEP. Other homologous mammalian transporters identified in fish are Pgp, OATP, MRP, and NTCP. Similarly, the human nuclear receptors FXR, LXR, CAR, PXR, VDR, and PPARα, -β, and -γ have also been identified in piscine species. Given our increasing understanding of conserved

bile synthesis and transport physiology across vertebrates, it is interesting to consider the future of small fish animal models, such as STII medaka, as surrogates for human hepatobiliary transport study.

In summary, it is becoming increasingly clear that the mechanisms involved in the regulation of bile acid synthesis, lipid metabolism, and hepatobiliary transport in vertebrates are highly integrated and, not surprisingly, involve a complex biofeedback network composed of bile salts, nuclear receptors, transcription factors, and a variety of intermediate signaling proteins. The majority of currently known mechanisms have been elucidated in rodent and human studies, and, although information for piscine species remains sparse, it is increasingly apparent that many bile synthesis and regulatory mechanisms are conserved across vertebrate species.

Biliary System Toxicity: Mechanistic Considerations

During cholestasis in mammals, bile salt transport proteins undergo adaptive responses that serve to protect the body from bile salt retention and maintain homeostasis (Trauner et al., 2005). When adaptive responses of the hepatobiliary system are precluded by xenobiotic-induced alterations to hepatobiliary structure and function, impairment of bile transport may be a major source of toxicity, either through the direct action of toxic bile salts on cell function or the toxicity resulting from impaired elimination of xenobiotics and their metabolites from within the cell or systemic circulation. Cholestasis (impairment of bile synthesis and transport) results in mammals due to exposure to a wide range of drugs and other xenobiotics and is seen in genetic disorders regarding bile synthesis and transport. The condition has received abundant attention in mammals (Anwer, 2004; Arrese and Trauner, 2003; Muller and Jansen, 1998; Trauner et al., 1998), but much less so in fish. Cholestasis is important for several reasons: (1) the formation and secretion of bile are essential for life, (2) bile synthesis and transport are among the most easily disrupted liver functions, and (3) for most cholestatic agents, the exact mechanism of xenobiotic-induced cholestasis remains unknown (Faber et al., 2003). The cholestatic response is more thoroughly understood in the mammalian liver due to investigations on the adverse effects of altered bile synthesis and transport in humans and the extensive use of rodent models in cholestasis-related research.

Downloaded From Vet-eBooks.com

Cholestasis is most commonly not fatal, although various pathologic sequelae are associated with this condition. Chronic manifestations of cholestasis include systemic toxemia, impaired immune function, and central nervous system and renal system stress. Hence, failure or impairment of bile excretory mechanisms can lead to general conditions of systemic toxemia.

Bile-acid-induced toxicity, which may result in cholestasis, is often associated with perturbation of mitochondrial respiration and depolarization (MPT) and cell death (Aguilar et al., 1996; Benz et al., 2000; Palmeira and Rolo, 2004; Rolo et al., 2004). Increasing concentrations of the bile acids LCA, DCA, UDCA, CDCA, glycochenodeoxycholic (GCDC), and taurochenodeoxycholic (TCDC) were shown to decrease mitochondrial membrane potential, decrease state 3 respiration, and enhance state 4 respiration (Rolo et al., 2004). Bile salts themselves have been observed to alter energy-dependent transport dynamics via modulation of normal cellular energy production and regulation. In short, impairment of bile transport via compromise of hepatocyte or cholangiocyte function is a major source of toxicity, from both endogenous substances and xenobiotics.

Alterations to cytoskeletal and gap- and tight-junction proteins are primary mechanisms by which cholangiopathies may occur, and they are seen following exposure to xenobiotics. The naturally occurring toxins microcystin-LR (MC-LR) and okadaic acid (OA), for example, inhibit cytoskeletal function via inhibition of dephosphorylation, and microcystin, a protein phosphorylation (PP2A) inhibitor, is known to induce cholestasis in humans via altered microtubule-dependent vesicle movement in hepatocytes (Pouria et al., 1998). OA, which also blocks PP2A, inhibits cAMP stimulation of TC uptake, translocation, and dephosphorylation of NTCP and increases cytosolic Ca^{2+} (Mukhopadhyay et al., 1998). Similarly, administration of phalloidin leads to rapid and sustained cholestasis in rats through cytoskeletal changes resulting in impaired canalicular function. These changes were linked with a total loss of MRP2 function (possibly due to altered translocation of the protein from the Golgi apparatus to the outer cell membrane) (Rost et al., 1999). Phalloidin damages cytoskeletal function and arrangement and results in sustained cholestasis in rats through impairment of canalicular function and a total loss of MRP2 expression (Rost et al., 1999).

Toxicants such as α-naphthylisothiocyanate (ANIT) are also known to alter cytoskeletal function and induce cholestasis in rats (Lesage et al., 2001; Orsler et al., 1999; Palmeira et al., 2003), and preliminary studies in the Hinton laboratory have shown that ANIT targets both hepatocytes and biliary epithelia in medaka (Hinton, unpublished studies).

Related Studies of Biliary Toxicity in Livers of Fishes

A variety of diseases related to biliary dysfunction such as primary biliary cirrhosis (PBC) and primary sclerosing cholangitis (PSC) are well recognized in mammals, but hepatobiliary-related disease states, as well as impaired transport function, are only beginning to be understood in fish species (Cai et al., 2001; Kirby et al., 1995; Lorent et al., 2004). Studies in cartilaginous fishes provide evidence for cytoskeletal-related impairment to hepatobiliary transport. They have generally employed clusters of isolated polarized skate hepatocytes, and they have provided structural and functional evidence for microtubule-dependent transcytosis. As an example, the polarized arrangement of microtubules, presence of cytoplasmic dynein, and inhibition of bile salt secretion by nocodozole were consistent with the microtubule cytoskeleton playing a fundamental role in the mediation of transcytosis, endocytosis, and bile excretory function in skate hepatocytes (Henson et al., 1995).

Published findings on xenobiotic-induced alterations of P-glycoprotein in fish are conflicting. For example, Sturm et al. (2001a) found no induction of C219-immunoreactive Pgp protein levels after *in vivo* exposure of rainbow trout to prochloraz or nonylphenol diethoxylate. Similarly, dietary exposure of channel catfish to the xenobiotics β-naphthoflavone, benzo(*a*)pyrene, or 3,4,3′,4′-tetrachlorobiphenyl did not result in elevated levels of C219-immunoreactive proteins nor in altered Pgp activity in intestine and liver (Doi et al., 2001). In contrast, the expression of hepatic C219-immunoreactive Pgp protein was significantly enhanced in the liver of killifish, both *in vitro* and *in vivo*, after exposure to chlorpyrifos oxon and the carcinogen *N*-nitrosodiethylamine (Albertus and Laine, 2001).

Complex relations between xenobiotics and Pgp expression in fish are indicated from a study on intertidal blennies (*Anoplarchus purpurescens*) (Bard et al., 2002b). Hepatic Pgp immunostaining with C219 antibody was significantly elevated in blennies collected from field sites downstream of pulp mills,

Downloaded From Vet-eBooks.com

as compared with fish depurated for more than 4 weeks in clean water in the laboratory; however, in the field-sampled fish, a gradient of hepatic Pgp expression correlating with proximity to the pulp mill effluents was not evident. In laboratory experiments, blennies exposed to oiled sediments exhibited significantly elevated hepatic Pgp levels, while blennies exposed to contaminated sediments from the pulp mill sites or injected with β-naphthoflavone showed no elevation of hepatic Pgp levels.

When a creosote-resistant killifish population from a polluted site in the Elizabeth River in Virginia was studied (Cooper et al., 1999), adult fish showed a high prevalence of hepatic tumors. In immunoblots with the C219 antibody, both normal and neoplastic livers of killifish from the polluted site contained significantly higher levels of Pgp-like proteins than did livers of reference killifish. This finding may be taken as an indication that Pgp contributes to creosote resistance, since biliary excretion is a major elimination route for PAH metabolites.

In contrast, studies on killifish in New Bedford Harbor in Massachusetts (Bard et al., 2002a) revealed an acquired resistance to planar halogenated aromatic hydrocarbons (PHAHs), and the contaminant-resistant fish showed lower levels of hepatic C219-immunoreactive protein than did killifish from a relatively unpolluted site. Interestingly, fish from New Bedford Harbor displayed Pgp-like protein in the intestine, whereas fish from the relatively unpolluted site exhibited no detectable Pgp in the intestine. The authors speculated that fish at New Bedford Harbor are exposed to xenobiotics that are inducers of a gut-specific Pgp isoform and that intestinal uptake is the dominating route of xenobiotics uptake.

The question remains whether elevated levels of hepatic or intestinal Pgp observed in contaminant-resistant killifish from polluted sites reflect an exposure to Pgp inducers. Because fish from the polluted field sites showed strongly declining levels of Pgp expression after culture in clean water (Bard et al., 2002b), the argument can be made for a role of xenobiotics in the induction of Pgp expression; however, results from laboratory exposure experiments that directly demonstrate a role of environmental chemicals in elevating the Pgp expression of killifish are elusive. Exposure of killifish to the PHAH 2,3,7,8-tetrachlorodibenzofuran, known to be present in New Bedford Harbor, did not stimulate intestinal or hepatic Pgp expression (Bard et al., 2002a). Likewise, when Cooper et al. (1999) injected both reference and creosote-resistant killifish with 3-methylcholanthrene, a PAH contained in creosote, they found no increase of hepatic levels of Pgp-like proteins. In summary, based on the current information, contaminant-resistant fish may show altered Pgp expression but the cause-and-effect relationship of xenobiotic exposure lacks verification. Overall, the database on the relation between xenobiotics and Pgp in fish is small and dispersed. Published reports do not yield a consistent pattern, and this may be explained in part by interlaboratory differences in species, xenobiotics, and experimental design; however, it may also be due to technical problems, such as the lack of fish-specific probes for Pgp, and to insufficient knowledge on the basic parameters of Pgp regulation in fish. Pgp expression can be induced as part of a general response to cellular stress, and this may be regulated by ligands of the PXR, thus sharing elements of regulation with an important group of mammalian biotransformation enzymes, CYP3A.

Further, mammalian Pgp and CYP1A share some inducers, albeit they are not regulated by the same mechanisms. For fish, no published evidence exists on PXR, and the understanding of piscine CYP3A, despite some ortholog characterization in teleosts (Kullman and Hinton 2001; Kullman et al., 2000), remains fragmentary. Several studies with fish were attempted to provoke a co-induction of CYP1A and Pgp. When *Fundulus heteroclitus* were exposed to the AhR ligand 3-methylcholanthrene and observed (Cooper et al., 1999), an induction of CYP1A but not of Pgp expression occurred. Similarly, Bard et al. (2002a) exposed killifish to the AhR ligand 2,3,7,8-tetrachlorodibenzofuran with resultant induction of CYP1A and not Pgp. In rainbow trout, prochloraz induced hepatic CYP1A but not hepatic Pgp (Sturm et al., 2001a). A correlation between CYP1A and Pgp levels was found in blennies collected at polluted field sites; however, when blennies were treated in the laboratory with the AhR ligand β-naphthoflavone, only CYP1A (not Pgp) was elevated (Bard et al., 2002b). In flounders collected at three sites with differing pollution levels in Seine Bay (English Channel), CYP1A and Pgp levels showed exactly opposite trends (Minier et al., 2000). These findings suggest that Pgp and CYP1A are not coordinately regulated in fish; however, these two proteins may act in complementary ways in cellular detoxification.

Virtually nothing is known about cholestasis in fish, and there is an urgent need for understanding piscine cholestasis given that the pathogenesis of other toxic alterations in piscine liver is at least qualitatively similar to that of mammalian liver. Two studies in medaka showed that chronic exposures

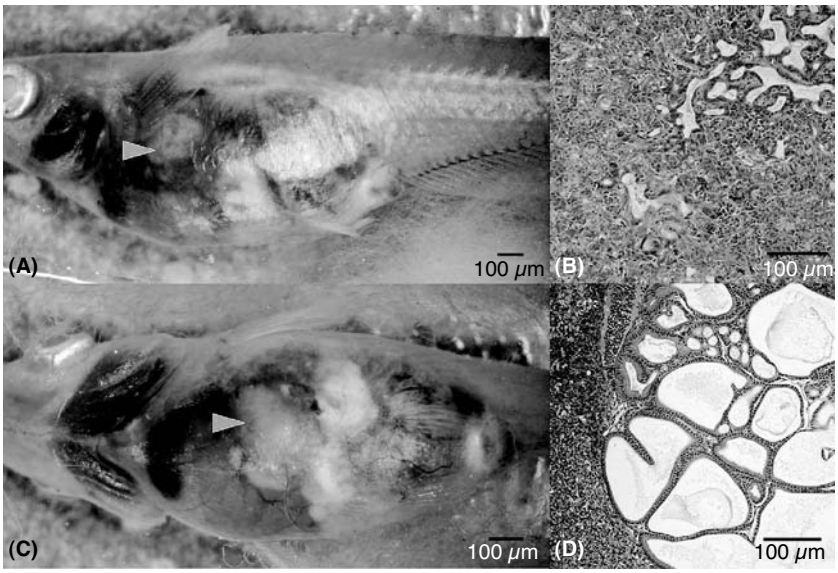

FIGURE 7.16 (See color insert following page 492.) *In vivo* imaging of tumor formation in STII medaka (brightfield microscopy). Neoplastic response following early life stage exposure of STII medaka to the reference hepatocarcinogen diethylnitrosamine (DEN). Aqueous bath exposure was of 24-hour duration at 100 ppm DEN. Fish were exposed as 14-day-old hatchlings and followed serially in a noninvasive manner for 10 months. At 10 months after exposure, a subset of cohorts developed hepatic tumors (green arrowhead). (A, C) *In vivo* imaging (brightfield) of hepatic tumor formation (green arrowheads) in DEN-exposed medaka; shown is an enlargement of the total liver mass, approximately 18% of the total body length. After anesthesia, the liver was removed and processed for histopathology. Hepatic neoplasm showed mixed hepatocellular (B) and cholangiocellular (D) carcinomas. Focus of biliary hyperplasia was seen in the same liver; here, a single layer of biliary epithelium lines large cystic spaces in the liver (D). The opaque white tissue in the brightfield images (A and B) is ovary; the gut occupies caudal most region of the abdominal cavity.

to bromodichloromethane or chloroform induced bile duct dilatation and cystic enlargement of extrahepatic bile passageways (Toussaint et al., 2001a,b). Studies of hepatic carcinogenesis in trout (Hendricks et al., 1984) and in medaka (Okihiro and Hinton, 1999) have also shown that the intrahepatic biliary epithelial cells are involved in chronic toxicity. Cholangiomas, cholangiocellular carcinomas, and mixed hepato- and cholangiocellular carcinomas have been reported (Hinton, 1993b) (Figure 7.16). From this brief review, it is apparent that the biliary system is a target of xenobiotic-induced toxicity in fishes and that better understanding of the involved mechanisms is urgently needed.

Factors Influencing Xenobiotic-Induced Liver Injury

Because of its central location in the circulatory system of vertebrates, the liver is a target for many toxicants, and it receives toxic substances both from intestinal and branchial routes. Further, due to the large exchange surface at the sinusoidal pole of the hepatic parenchymal cells, together with an array of uptake systems and transporters at the hepatocyte membrane, the liver is able to efficiently extract toxicants from the circulation. The toxic chemicals can directly impair liver structures and functions; for example, by inducing cytotoxic damage and necrosis they can induce toxic effects after being metabolized into reactive molecules, or they can act indirectly through affecting interactions and signaling between the various liver cell types. Toxicant action may also impact seemingly unrelated hepatic functions. An example is provided by the antiestrogenic activity of AhR-binding xenobiotics. Induction of the AhR pathway by these compounds is associated with a reduced synthesis of hepatic vitellogenin, which is under the control of estrogen (Anderson, 1996; Navas and Segner, 2000, 2001). This antiestrogenic effect of AhR-binding xenobiotics is mediated through a cross-talk between the AhR and the ER (Cheshenko et al., 2007; Ohtake et al., 2003), thereby resulting in a toxicant effect on an unexpected target.

Downloaded From Vet-eBooks.com

Cell Interaction

A mechanistic understanding of the mode of action of various xenobiotics is possible only with knowledge of the cell types involved in the activation and deactivation of the compound and those that become targets for toxicants. Current mammalian liver toxicity studies demonstrate signaling between individual cell types that often determines the site and extent of toxicity (Treinen-Moslen, 2001). Hepatotoxicants such as acetaminophen or carbon tetrachloride, for example, can lead to an increased number and activation of macrophages, including the resident macrophages (i.e., Kupffer cells) in the rodent liver (Laskin and Gardner, 1998). Also, the sinusoidal endothelial cells and stellate cells can increase in number and become activated following exposure of rodents to hepatotoxicants. The activation of the sinusoidal cells may occur through factors released by damaged hepatocytes (Treinen-Moslen, 2001). The activated cells release mediators such as reactive oxygen intermediates, reactive nitrogen intermediates, cytokines, bioactive lipids, and hydrolytic enzymes that then are responsible for sequelae reactions (Dong et al., 1998; Ganey et al., 2001; Junge et al., 2001; Morio et al., 2001). In the stellate cells, collagen production is stimulated (Treinen-Moslen, 2001). The mediators released by the nonhepatocyte cells can be directly cytotoxic, but they are also able to modify hepatocyte signaling pathways or xenobiotic metabolism (Cain and Freathy, 2001; Renton, 2000). Perhaps the best evidence for a role of macrophages in the pathogenesis of liver injury comes from studies where the experimental depression of macrophage function diminished hepatotoxicity (Junge et al., 2001; Laskin and Gardner 1998). Few studies have addressed the possible role of nonhepatocyte cells, inflammatory macrophages, and macrophage-derived factors in liver damage in fish.

From studies on the acute phase response of fish, evidence has been obtained that salmon hepatocytes possess cytokine receptors and that bacterial lipopolysaccharide (LPS) induces serum amyloid A transcription in the hepatocytes (Jorgensen et al., 2000); however, whether this response was a direct effect of LPS on the hepatocytes or mediated by other liver cell types was not determined. Pollutant-induced activation of catfish (*Heteropneustes fossilis*) macrophages was associated with a concomitant increase in peroxidative tissue damage (Fatima et al., 2000). The liver, however, showed the weakest response among the three target organs studied (gills, liver, kidney). In mammalian liver, cytokines suppress hepatic cytochrome P450 enzymes (Renton, 2000), and, as reported by Marionnet et al. (1998), they also suppress cytochrome P450 activities in fish liver. Furthermore, while cell types of livers of fishes are for the most part the same as those found in the livers of their mammalian counterparts, there are some differences. Exocrine pancreatic tissue is found in the connective tissue of the hepatic portal vein (variable with species) and some of its branches within the livers of certain species (e.g., carp) (Figueiredo-Fernandes et al., 2007; Vogt and Segner, 1997). This is not the general case in mammalian species. The Kupffer cell, a resident macrophage in hepatic sinusoids of mammals, is not found in most fish species (see Table 7.1). For those species in which the cells are present, their functions have been only partially determined (Hampton et al., 1987). Although the other cell types (see descriptions above) are found, their role in hepatotoxicity in fish has not been well characterized, and we have little or no information regarding signaling between various resident cells. This area requires future attention. The role of these cells in immune reactions and in initiating and mediating liver toxicity is not known. We do not know why certain hepatoxicants preferentially damage one cell type and if there exists preferential uptake or metabolism of certain toxicants by specific liver cell types. How the cells of the hepatic sinusoids and those involved in immune function influence liver pathogenesis is an area that so far has not been addressed in fishes.

Metabolism as Factor in Liver Toxicity

Xenobiotic metabolism and activation is an important factor in liver toxicity. Toxicity of a chemical may be due to the parent compound or to a metabolite generated by metabolic conversion of the former to reactive electrophiles that combine covalently with critical cellular macromolecules such as proteins, DNA, or RNA. The liver is the major site of biotransformation in fish and performs both phase I and phase II reactions of xenobiotic metabolism. Liver xenobiotic metabolism has important consequences

Downloaded From Vet-eBooks.com

for both systemic and organ-specific toxicity. First, hepatic biotransformation directly relates to bioaccumulation of lipophilic substances in fish (Schultz and Hayton, 1999; Sijm et al., 1993; Stuthridge et al., 1997). Second, hepatic metabolism influences the toxicity of xenobiotics either through effects on tissue doses of the toxicant or through generation of metabolites with either reduced or enhanced toxicity (detoxification/toxification) of the parent compound (Debruijn et al., 1993; Keizer et al., 1991; Lech and Bend, 1980). Hepatic metabolism is also important in determining species differences in the bioaccumulation (Schultz and Hayton, 1999) and toxicity (Hasspieler et al., 1994; Wirgin and Waldman, 2004) of xenobiotics in fish.

For mammals, numerous studies have shown the relation between the tissue-specific formation of a reactive intermediate and hepatotoxicity. Further differences in the distribution of xenobiotic-metabolizing enzymes among the particular liver cell types predispose them to xenobiotic toxicity. In fish a number of studies have analyzed liver conversion of xenobiotics in fish; however, information relating hepatic biotransformation to hepatotoxicity is often lacking. The distribution of metabolic enzymes such as CYP1A in the different cell types of fish liver and their roles in subsequent development of liver toxic lesions have received little attention, with the one exception being liver carcinogenesis (see chronic biliary toxicity discussion in this chapter).

One group of environmental contaminants that fish are often exposed to and for which hepatic metabolism is an important toxicokinetic and toxicodynamic determinant are polycyclic aromatic hydrocarbons (PAHs) (Altenburger et al., 2003). Several studies have investigated the spectrum of metabolites produced by fish liver preparations and found a high proportion of 7,8- and 9,10-dihydrodiols (Lemke and Kennedy, 1997; Morrison et al., 1985; Nishimoto et al., 1992). Induction of metabolic enzymes, however, can result in a shift of the metabolite spectrum (van Schanke et al., 2000). Information is available from both field and laboratory studies on the association of exposure to PAHs, enhanced expression of hepatic biotransformation enzymes, and the occurrence of DNA adducts and toxicopathic liver lesions, including neoplastic alterations (Aas et al., 2001; Dey et al., 1993; James et al., 1988; Lesage et al., 2001; Malins et al., 1988; Myers et al., 1987, 1994, 1998; Orsler et al., 1999; Palmeira et al., 2003; Spitsbergen et al., 2000a,b; Vogelbein et al., 1999). In a field study on the Puget Sound, Horness et al. (1998) were able to establish statistically significant threshold levels for the association of PAH concentrations in the sediments and the occurrence of neoplastic liver alterations in flatfish, this providing strong evidence for a causative role of hepatic PAH metabolism in carcinogenesis of the fish species.

Another example where hepatic metabolism of xenobiotics is an important determinant in toxicity is related to the hepatocarcinogenic mycotoxin aflatoxin B_1. In the liver of trout, aflatoxin B_1 is metabolized to aflatoxicol B_1 and excreted as aflatoxicol B_1 glucuronide (Loveland et al., 1984). An increase in metabolism of aflatoxin B_1 and enhanced biliary excretion as glucuronide following pretreatment by the CYP1A inducers β-naphthoflavone or Arochlor® 1254 significantly reduced liver DNA adduct formation (Bailey et al., 1987). Further, pretreatment of trout with indole-3-carbonyl (an inducer of glutathione *S*-transferase) also reduced the carcinogenicity of aflatoxin B_1 (Goeger et al., 1986). Differences in aflatoxin metabolism are also likely to be responsible for the known differences in aflatoxin sensitivity between rainbow trout and Coho salmon (Bailey et al., 1984; Coulombe et al., 1984). A contradictory example appears to be the zebrafish, as adult zebrafish rapidly metabolize and excrete aflatoxin B_1. Both *in vitro* and *in vivo* studies indicate that this species has the capacity to bioactivate aflatoxin B_1 to its reactive intermediate, and the level of hepatic DNA adducts is only moderately lower than observed in trout (Troxel et al., 1997). An apparent contradiction to these findings is the reported resistance of zebrafish when aflatoxin B_1 was administered in the diet. It is possible that mechanisms other than biotransformation protect the zebrafish against aflatoxin toxicity.

A further example where hepatic metabolism is at least partially responsible for chemical toxicity is the procarcinogen 2-acetylaminofluorene (AAF), which induces liver tumors in fish at a much lower rate than in rodents (James et al., 1994). This apparently higher resistance of fish to the hepatocarcinogenicity of AAF seems to be related to AAF metabolism. For medaka, guppy, and trout, major metabolites of AAF generated in the liver are hydroxy-AAFs, while the carcinogenic metabolite *N*-hydroxy-AAF is formed at only low rates (James et al., 1994; Steward et al., 1994). Thus, the metabolic differences between fish and mammals may partially explain the resistance of fish and susceptibility of mammals to AAF-induced hepatocarcinogenesis.

Responses of Fish Liver to Reference Hepatotoxicants

During the early stages of development of new animal models for toxicological research, there is a validation phase that demonstrates that the animal responds to compounds of proven toxicity (in this case, reference hepatotoxicants) and that the response has features similar to those seen in established models (usually rodents). Studies investigating three reference hepatotoxicants—acetaminophen (AP), allyl formate (AF), and carbon tetrachloride (CCl_4)—were reviewed by Hinton et al. (2001). The interested reader is referred to that review, as we provide only a brief summary here.

Summary of Acetaminophen Review

Although AP produces centrolobular necrosis in rodent liver, exposed rainbow trout responded with focal rather than zonal necrosis and the extent of necrosis was less. Trout exposed to AP responded with an increase in serum glutamic pyruvic transaminase (SGPT) in a dose-dependent manner (Droy, 1988) but one that was at least an order of magnitude lower than reported for hamsters and rats. Other parameters of hepatic toxicity failed to show a response relationship in AP-exposed trout. Responses of mullet (*Mugil cephalus*) were similar (Thomas and Wofford, 1984); for example, exposure to AP failed to cause significant depletion of glutathione stores, and the authors concluded that mullet liver failed to produce a sufficiently toxic metabolite. Because fish have the capacity to form certain reactive intermediates of AP, differences in metabolism were not regarded as the sole explanation for the reduced levels and the different patterns of hepatotoxicity observed. AP deserves further analysis in fish liver toxicity. It is an example of a reference hepatotoxicant that produces discrete but lowered responses, the pattern and characteristics of which will likely lead to improved understanding of fish liver toxicity in general.

Summary of Allyl Formate Review

Allyl formate is the only reference hepatotoxicant studied in fish that has selective periportal zonal toxicity in rodent liver. In rainbow trout, the magnitude of toxic response following AF exposure was appreciable, with morphologic, biochemical, and functional changes elicited (Droy et al., 1989). Ultrastructural analysis of AF-induced hepatotoxity showed that endothelial cells of sinusoids were targeted and that the hemorrhagic necrosis likely involved early lethal toxicity to this cell type. When the concentration was lowered but the route of administration maintained, enhanced morphologic response in perivenous areas suggested a zonal response. AF hepatotoxicity is likely mediated via alcohol dehydrogenase, but histochemical studies of trout liver indicated no preferential localization of this enzyme (Schar et al., 1985). Similarly, glutathione localization in trout liver is homogeneous and likely would not lead to a heterogeneous response to AF. AF response in trout was appreciable, and further analysis of its time course over a broader range of lowered concentrations will likely prove fruitful in determining the role of signaling between endothelial cells and hepatocytes in fish liver toxicity.

Summary of Carbon Tetrachloride Review

The classic example of biotransformation-mediated generation of toxicity in mammalian liver is the cytochrome P450-dependent conversion of CCl_4 and chloroform to free radicals such as $\cdot CCl_3$ and $CCl_3OO\cdot$, which then initiate lipid peroxidation, acute liver injury (e.g., necrosis), and, under chronic conditions, liver neoplastic changes (Treinen-Moslen, 2001). In rodents, CCl_4 is metabolized to CCl_3, which rapidly combines with oxygen to form the very reactive CCL_3O_2 (Packer et al., 1978); therefore, different free-radical species of CCl_4 are present under aerobic and anaerobic conditions in rat liver. Hepatic injury is maximal in centrolobular areas of mammalian liver where oxygen tension is lowest (Burk et al., 1984a,b). Also, hypoxia potentiates covalent binding of metabolites to rat liver microsomal lipids and proteins (Shen et al., 1982).

Fish appear to be more resistant to the toxic action of CCl_4. In the study by Droy et al. (1988), acute oral dosing of fish with CCl_4 was selected because this method of delivery was related to a more natural

Downloaded From Vet-eBooks.com

exposure route and obviated the solvent effect seen after intraperitoneal injections. Necrotic hepatocytes were more abundant in the high-dose group (3 mL CCl_4 per kg), and a loss of cytoplasmic basophilia with swelling characterized the affected hepatocytes. In rats used as biological controls for the experiment, the researchers found a quantity of necrosis not approximated by trout even after greater doses of the toxicant. Also, with respect to the chronic toxicity of CCL_4, trout appear to be less sensitive. In rainbow trout, chloroform enhanced the hepatocarcinogenicity of aflatoxins (Kotsanis and Metcalfe, 1991), while in medaka chronic exposure to chloroform was not hepatocarcinogenic (Toussaint et al., 2001a). The apparent higher resistance of fish to CCl_4-induced injury might be because fish liver lacks the metabolic machinery capable of bioactivating CCl_4. Evidence against this includes the report of increased lipid peroxidation and ^{14}C-labeled CCl_4 residues in trout liver 6 hours following exposure to a single intraperitoneal injection of 1 mL CCl_4 per kg (Statham et al., 1978). Also, in mullet (*Mugil cephalus*) and croaker (*Micropogonias undulates*), increased lipid peroxidation occurred as a result of CCl_4 treatment (Wofford and Thomas, 1988). Further, *in vitro* studies have provided strong evidence that fish liver cells metabolize CCl_4 to free radicals (Rabergh and Lipsky, 1997); also, Toussaint et al. (2001a) found that chloroform is metabolized in medaka liver.

A second hypothesis that could explain why CCl_4 is less hepatotoxic in trout would be the presence of higher amounts of antioxidants or free-radical scavengers such as glutathione. When trout and rat were compared after exposure to monochlorobenzene (Dalich and Larson, 1985), rat hepatic glutathione was about three times that of trout; therefore, it seems unlikely that the lack of susceptibility of trout to CCl_4 can be explained by excessive amounts of antioxidant. In addition, Toussaint et al. (2001b) showed that CCl_4 treatment of trout hepatocytes resulted in a serious depletion of cellular glutathione levels.

Droy (1988) considered the possibility that interspecies differences in oxygen tension and glutathione distribution patterns might explain the trout response to CCl_4. Glutathione is effective against CCl_4-induced lipid peroxidation in rat liver but only in the presence of oxygen, when CCL_3O_2 is readily formed (Burk et al., 1983). The relative abundance of glutathione in portal vs. centrolobular areas also contributes to the protection seen in the portal hepatocytes of rodent liver (Smith et al., 1979); therefore, glutathione appears to protect rat liver portal hepatocytes from CCl_4 because of the preferential distribution of glutathione and the likely ability of this compound to scavenge CCL_3O_2 but not CCl_3. Droy (1988) reported a refractiveness in trout to the hepatotoxic effects of CCl_4, with scattered individual hepatocyte necrosis being the typical response. Perhaps the inability of CCl_4 to produce appreciable toxicity in trout liver could be due to comparatively high oxygen tension. Under these conditions, CCl_3 would be converted to CCL_3O_2, which would then combine with glutathione and be rendered inert.

Exposure of rodents to CCL_4 produces a mosaic of altered hepatocytes in centrolobular zones and an apparent sparing of hepatocytes in the periportal zone, the more oxygenated zone. Zonal reactions are not seen following exposure of fish to CCl_4. When carrier-solvent-associated changes are removed from consideration, CCl_4 is not a particularly strong hepatotoxicant in fishes. Scattered individual hepatocyte necrosis is the usual response. Differences in CCL_4 metabolism, levels of glutathione, metabolic attack on the parent compound, oxygen tension, and absence of the Kupffer cell in trout have been suggested as possible reasons underlying this differential response.

Taken together, this body of work indicates that livers of fishes respond to reference hepatotoxicants but that the response is quantitatively different from that of rodents. The pattern of morphological alteration is different, likely reflecting innate differences in hepatic architecture and quantitative as well as qualitative differences in metabolism of parent compounds. Additional effort is needed to better characterize hepatotoxicity in fishes. Increased understanding of structure (especially architecture), of the roles of hepatocytes and nonhepatocytic cell types in toxic responses, and of metabolism will enhance our ability to interpret alterations following exposure to drugs, personal-care products, pollutants, and biotoxins.

As we shall see in the subsequent section, elegant and detailed ultrastructural studies in livers, isolated primary cells, and fish-derived cell lines have made it possible for us to demonstrate hepatocellular adaptation following exposure to reference hepatotoxicants or develop an appreciable assemblage of individual environmentally relevant compounds as is suggested by studies from wild fish collected at heavily contaminated sites.

Hepatocytes Under Toxic Exposure

Changes in hepatocytes do not necessarily signify overt toxicity and may represent sublethal cellular change as seen during adaptation to toxicants or due to an altered equilibrium state in injured tissues or cells. A detailed consideration of ultrastructural hepatic changes has been provided recently by Braunbeck (1998) and Au et al. (2004), so this review is brief. The examples are arranged by inclusion body and by specific organelle.

Lipopigments

Lipofuscin and ceroid share very similar morphology and physicochemical properties. Lipofuscin is regarded as the classical age or stress pigment, and the accumulation of ceroid is indicative of cell pathology. Lipopigments are widely regarded as the end products of lipid peroxidation, which is a free-radical chain reaction. Such a reaction is initiated when some unidentified free radical abstracts a methylene H-atom from the unsaturated fatty acid and then reacts with oxygen to yield a hydroperoxy radical. Termination of the chain reaction is often associated with polymer formation, and copolymerization of oxidized lipids with protein and other compounds would form lipopigments (Dayan and Wolman, 1993; Donato, 1981; Wolke et al., 1985). Lipopigments tend to accumulate in the lysosomal compartment as residual bodies (Holtzman, 1976; Park and Chi, 1992; Yin, 1996). This is exemplified by the fact that secondary lysosomes have often been found in the vicinity of lipopigments in hepatocytes of fishes. Early ultrastructural studies of Elbe flounder and dab collected from sites highly contaminated with organochlorines and heavy metals showed an unusual extent of transformation of lysosomes into lipofuscins and were in close association with the large lipid droplets in hepatocytes (Köhler, 1990; Köhler et al., 1992). Likewise, livers of mummichog inhabiting a PAH-contaminated (creosote) environment often exhibited sublethal cellular damage, including the accumulation of ceriod and lipofuscin in non-neoplastic hepatocytes bordering carcinomas (Vogelbein, 1993). Increased lipofuscin was also reported in the liver of juvenile grey mullets after exposure to the algicide atrazine (Biagianti-Risbourg and Bastide, 1995). A recent survey in the San Diego Bay in California (Exponent, 2003) reported that the prevalence of lipofuscin in hepatocytes of the spotted sand bass (*Paralabrax maculatofasciatus*) was most strongly associated with shipyard sites that were characterized by high levels of organic contaminants (e.g., PCBs, PAHs) in sediments. It is important to be able to quantify hepatic lipopigment accumulation with levels of pollutants. Stereological analysis was employed to quantify cytological changes in the livers of immature sole (*Solea ovata*) and juvenile orange-spotted grouper (*Epinephelus coioides*) exposed to benzo(*a*)pyrene (BaP). A dose–response relationship was generally demonstrated between volume density, absolute volume, numerical density, and absolute number of lipopigment accumulation and levels of BaP under both laboratory and field conditions, regardless of the route of PAH uptake (Au, 2004; Au and Wu, 2001; Au et al., 1999). The accumulation of lipopigment in mammals (ceroid-lipofuscinosis) is a pathological symptom known as Batten's disease. The resulting deleterious effects include blindness, seizures, dementia, and premature death (Martinus et al., 1991; Palmer et al., 1986; Yin 1996). Furthermore, large amounts of undegradable lipofuscin and ceroid in human fibroblasts were shown to increase the susceptibility of cells to oxidative stress, disturbance of lysosomal function, and cell death (Terman et al., 1999a,b). Condensation of hepatocellular content was often observed in the vicinity of lipopigments in *Solea ovata* exposed to BaP (10 mg/kg BaP), which may suggest severe lipid peroxidation in hepatocytes (Au et al., 1999). It is therefore clear that intracellular lipopigment accumulation is indicative of adverse cytological effects. Conceivably, an excessive amount of lipopigment interferes with vital cellular functions and decreases the survival of affected cells, which may eventually decrease the fitness of fish in the contaminated environment.

Lysosomes

These membrane-delimited organelles contain hydrolytic enzymes for breaking down substances within a cell (autophagy) or substances that have been taken in from outside the cell (heterophagy)

Downloaded From Vet-eBooks.com

(Bozzola and Russell, 1992; Holtzman, 1976). Alterations to lysosomal structure are usually associated with a reduction in the stability of lysosomal membranes and an increase in lysosomal enzyme activities, which may pose a potential risk to the health of the cell or the individual organism (Köhler, 1991; Moore, 1993). Reduced lysosome membrane stability and augmentation of lysosomes have been reported in the livers of feral fish collected from highly contaminated waters, and in certain cases, including exposure to heavy metals, increases in lysosome number were also observed (Baker, 1969; Braunbeck, 1998; Köhler, 1991; Köhler et al., 1992, 2002; Lanno et al., 1987; Lowe et al., 1992; Segner and Braunbeck, 1990b; Woodworth et al., 1998). A recent study by Köhler and colleagues (Köhler et al., 2002; Wahli, 2002) demonstrated a good dose–response relationship between the severity of lysosomal alterations in livers of European flounder and the levels of xenobiotic pollution. Moreover, increase in the size of lysosomes with accumulation of lipid and electron-dense content (lipopigment) coincided with decreased lysosome membrane stability in fish livers (Köhler et al., 2002). More prominent transitions of primary to tertiary lysosomes or lipopigments were observed in the livers of *Solea ovata* and *Epinephelus coioides* subjected to BaP or PAH exposure. In general, lysosome alterations are indicative of early cytopathological responses; they are sensitive but nonspecific to a wide range of contaminants, including a diverse range of toxic metals and organic chemicals (e.g., PAHs, PCBs, oil-derived hydrocarbons).

Peroxisomes

These single-membrane-limited organelles are ubiquitous in eukaryotic cells, where they play key roles in major metabolic functions such as lipid metabolism (e.g., fatty acid β-oxidation) and cellular respiration involving the metabolism of H_2O_2 (e.g., production of oxidases and catalase) (Fahimi et al., 1983). Massive proliferation of peroxisomes may occur in animals after treatment with certain xenobiotics and drugs (Fahimi and Cajaraville, 1995; Gibson and Lake, 1993; Moody, 1994). Peroxisome proliferation is defined as an increase in either peroxisomal volume or numbers which may not always be accompanied by an induction of peroxisomal enzymes (Reddy and Mannaerts, 1994). Catalase activity is one of the marker enzymes used for assessing peroxisome proliferation biochemically (Moody, 1994). Channel catfish (*Ictalurus punctatus*) and dab (*Limanda limanda*) exhibited an increase in catalase and superoxide dismutase activity after exposure to PAH-contaminated sediments (Di Giulio et al., 1993; Livingstone et al., 1993). Significant increases of volume density and absolute number of peroxisomes were demonstrated in immature sole (*Solea ovata*) after intraperitoneal injection of fish with BaP (Au et al., 1999). Induction of peroxisome proliferation has been reported in various animal tissues in response to PAHs and other xenobiotics (Bentley et al., 1993; Fahimi and Cajaraville, 1995; Krishnakumar et al., 1995, 1997; Reddy et al., 1987). Inconsistent peroxisome reactions were found in the hepatocytes of rainbow trout and zebrafish in response to various classes of toxicants; for example, the number of peroxisomes was reduced in response to 4-chloroaniline and lindane, but proliferation occurred in response to 3,4-dichloroaniline (Braunbeck, 1990; Braunbeck and Appelbaum, 1998). Species-specific variation and toxicant specificity are the factors to be considered when studying the responses of peroxisome proliferation in fish. It is also known that peroxisomal enzyme activity in fish could also be affected by other biotic factors, such as sex, and abiotic factors, such as salinity, temperature, season, and feeding habit (Braunbeck et al., 1987; Palace et al., 1993; Radi et al., 1987; Rocha et al., 1999).

Rough and Smooth Endoplasmic Reticulum

The hepatic cytochrome P450–monoxygenase system is a coupled electron transport system situated in the endoplasmic reticulum of hepatocytes (Mansuy, 1998). Early proliferation of the hepatic ER system was reported for fish exposed to PAHs, such as 3-methylcholanthrene (3-MC) and PCBs (Klaunig et al., 1979; Schoor and Couch, 1979). BaP stimulated rough and smooth ER proliferation in the livers of *Solea ovata* and *Epinephelus coioides* regardless of the route of exposure (water vs. intraperitoneal) (Au, 2004; Au and Wu, 2001; Au et al., 1999; Lemaire et al., 1992). A wide range of xenobiotics has been shown to induce hepatic ER proliferation (Braunbeck, 1998). In general, fish hepatic ER induction is nonspecific but sensitive to environmental contaminants.

Downloaded From Vet-eBooks.com

Nucleus and Mitochondria

The formation of binucleated hepatocytes was observed in livers of *Epinephelus coioides* at one week after oral exposure to BaP (12.5 μg/g BaP) and the frequency of occurrence increased with the exposure time. A dose–response relationship was demonstrated between the numerical density of mitochondria and BaP exposure (up to 5 mg/kg BaP) in *Solea ovata* (Au et al., 1999, 2004); the higher abundance of mitochondria after BaP treatments was thought to indicate active cellular metabolism to meet an increased high demand for ATP. The depletion of glycogen content was observed in a majority of hepatocytes upon exposure to BaP, regardless of the fish species and the route of exposure (Au et al., 1999, 2004). Glycogen depletion is a nonspecific adaptive response of hepatocytes to a large variety of xenobiotics and is generally regarded as a parameter for indicating acute or short-term stress (Arnold et al., 1995; Biagianti-Risbourg and Bastide, 1995; Braunbeck and Volk, 1991; Eurell and Haensly, 1981; Gluth and Hanke, 1985; Rojik et al., 1983). Lipid storage in fish liver can be both decreased and increased under toxicant exposure. Oral administration of 0.5 μg endosulfan per kg food to juvenile carp reduced the volumetric content of hepatic lipid from 14% to 5%, which may represent a general stress response as individual hepatocyte volume was also reduced by 50% (Braunbeck and Appelbaum, 1998). In both male and female zebrafish, exposure to lindane induced a pronounced steatosis microvesicular fatty transformation of the rough ER cisternae (Braunbeck et al., 1990a). Induction of steatosis by toxicants has been also reported from mammalian liver, and the underlying mechanism may be the blockage of lipoprotein secretion from the rough ER and Golgi system (Baglio and Farber, 1965).

Liver Alterations in Fish Exposed to Environmental Pollutants

The relationships between histopathologic lesions in fish livers and exposure to persistent environmental contaminants were thoroughly studied in large-scale surveys conducted by the U.S. National Marine Fisheries Services (NMFS). A total of 18 marine bottom fish species collected from 45 sites on the Pacific coast (Malins et al., 1988; Myers et al., 1993; Varanasi et al., 1989) and 22 sites on the Northeast coast (Johnson et al., 1992a,b) were included in the surveys. Results demonstrated that megalocytic hepatosis (MH), foci of cellular alteration (FCA), and biliary and hepatocellular neoplasms were prevalent in the English sole and other bottom fish species (e.g., rock sole, starry flounder, Pacific staghorn sculpin, Dover sole, and white croaker), and their prevalences were closely associated with exposure to PAHs, PCBs, and DDT in sediment, stomach content, and liver (Myers and Rhodes, 1988; Myers et al., 1993). Similar extensive surveys have also been carried out in Canada, Europe, and Australia to assess the impact of environmental contaminants on fish health (Au, 2004).

These survey data generally show a good correlation between the concentrations of various persistent chlorinated hydrocarbons and metals and liver lesions (Köhler, 1990; Malins et al., 1988; Myers et al., 1992). A recent study by Stehr et al. (2004) in Vancouver Harbour in Canada also demonstrated that the occurrence of toxicopathic liver lesions in English sole was statistically associated with concentrations of aromatic hydrocarbon (AH) metabolites in the sediment and AH metabolite levels measured in bile. Also, in numerous studies on freshwater environments, good correlations between water quality and liver histopathology have been demonstrated (Handy et al., 2002; Schmidt-Posthaus et al., 2001; Schwaiger et al., 1997; Teh 1997). Evidently, fish livers are highly sensitive to pollutant exposure. Fish liver histopathology is indicative of the general health condition of fish and levels of toxic xenobiotics, carcinogens, and urban pollution.

Other histopathologic responses, such as escalated macrophage immigration and subsequent increases in the number of macrophage aggregates (MAs), were observed in the livers of English sole and winter flounder with liver neoplasms (Myers et al., 1987) as well as in the livers of fish inhabiting degraded environments (Murchelano and Wolke, 1991). The use of hepatic MA hyperplasia was recommended as an indicator of health of grey mullet juveniles in contaminated coastal environments (Biagianti-Risbourg, 1993). Fish exposed to pulp mill effluent also showed considerably greater MA in the spleen of winter flounder (Khan and Payne, 1997) and in the livers of common jollytail and Tasmanian blennies (Woodworth et al., 1998). Moreover, field studies have been supported by controlled laboratory investigations,

Downloaded From Vet-eBooks.com

which have demonstrated early cytological changes in fish liver and damage from exposure to a wide range of pollutants, including PCBs (Klaunig et al., 1979; Köhler, 1989), 3-methylcholanthrene (Schoor and Couch, 1979) diethylnitrosamine (Couch, 1993, Hinton et al., 1988), 4-nitrophenol and 4-chloroaniline (Braunbeck et al., 1989, 1990a), BaP (Lemaire et al., 1992), and linuron (Oulmi et al., 1995). With the recent advent of digitized imaging for electron microscopy and computer software for stereological analysis, quantification of cytological changes on two-dimensional ultrathin sections is no longer a time-consuming process. Results of morphometry provide more useful quantitative data on cytological changes in response to contaminants.

Certain persistent environmental pollutants (e.g., PAHs, aromatic amines, nitroso-compounds, azo compounds) were shown to be potent hepatocarcinogens in fish (Moore and Myers, 1994). Hepatic carcinogenesis is particularly useful to indicate chronic toxicity in fish. Other hepatic lesions, such as FCA, MH, and hepatocellular nuclear pleomorphism (NP), were considered as early pathological stages in the formation of liver neoplasms (Hinton and Lauren, 1990; Hinton et al., 1992, 2001; Myers et al., 1987; Simpson and Hutchinson 1992); however, the etiology of preneoplastic liver lesions in relation to pollutant exposure remains largely unknown. The synergistic and antagonistic interactions of chemicals in water and sediment make it difficult to study cause-and-effect relationships. Moreover, it should be noted that liver tumors and histopathology are manifestations of chronic toxicity associated with prolonged latency periods. These lesions have great overall significance, especially when prevalences are used to suggest an epizootic at a localized site; however, their presence does not tell us about recent alterations in environmental quality. For many fish, migration is an annual event that makes it difficult to assess temporal and spatial aspects of exposure. As we shall see below, the use of biochemical and cytological endpoints may have more to offer especially when applied to younger fish for which habitats are known.

The correlation of biochemical and morphological (ultrastructural) changes is important. Not only do organelles and inclusion bodies show changes in hepatocytes of organisms residing at contaminated sites or exposed to usually single pollutants in controlled laboratory studies, but also a correlation exists between these alterations and certain biochemical measures (Grinwis et al., 2000).

Although most of the earlier biomarker studies concentrated on linking individual biochemical and morphological responses to exposure and effects of pollutants, only a few studies related biochemical endpoints (e.g., hepatic EROD/MFO activities) to quantitative ultrastructural changes in livers of fish upon exposure to toxicants (Chui et al., 1985; Hugla and Thome, 1999; Klaunig et al., 1979; Kontir et al., 1984; Schoor and Couch, 1979). If hepatic EROD activity can be related to quantitative hepatocytological damages, then the measurement of EROD activity would then indicate not only exposure but also adverse biological effects. Furthermore, the use of hepatic EROD as a biomarker would be more useful if linked to important biological processes. Some of the associated hepatocytological changes in fish may also serve as potential effect biomarkers for the early detection of exposure to environmental pollutants.

Recent studies sought to establish the relationship between quantitative hepatocytological changes and EROD activities in *Solea ovata* and *Epinephelus areolatus* exposed to PAHs and to provide important information regarding the use of such a relationship. Immature individuals of the demersal fish *S. ovata* were exposed intraperitoneally to benzo(*a*)pyrene, and quantitative cytological alterations were quantified (Au et al., 1999). A dose–response relationship was shown between exposure to BaP and changes in hepatic EROD activities. A Spearman rank correlation analysis revealed correlation between EROD activities and number or absolute volume of peroxisomes as well as lipofuscin granules in hepatocytes.

In a subsequent field study, chemical analysis of sediment from a dump site showed high levels of PAHs and PCBs (Au and Wu, 2001). Sexually immature fish from this site exhibited significantly higher EROD activity compared with counterparts from a reference site. In this case, a significant correlation was found only between EROD activity and volume density (Vv) of hepatic lipopigments. When this correlation was tested in juveniles of another species, the areolated grouper (*Epinephelus areolatus*), it was shown to exist (Au et al., 2004). These findings seem reasonable given the fact that lipopigment is a product of lipid peroxidation and could signify oxidative stress in cells. Excessive intracellular lipopigment accumulation could interfere with vital cellular functions and decrease survival of affected cells

Downloaded From Vet-eBooks.com

(Terman et al., 1999b). Intracellular lipopigment accumulation, indicative of adverse cytological effects, means that the biomarkers could be signifying exposure and adverse effect. Moreover, both the cytological and biochemical changes proved reversible, subsiding upon withdrawal of BaP exposure (Au et al., 2004). Hepatic EROD activity and lipopigments may therefore be useful to indicate recent exposure of the fish to BaP and PAHs.

Proliferation of the smooth and rough ER systems was repeatedly demonstrated in the hepatocytes of fish exposed to xenobiotic compounds (Au et al., 1999, 2004; Braunbeck and Appelbaum, 1998; Lemaire et al., 1992). A dose–response relationship was not obvious between ER proliferation and levels of BaP (Au et al.,1999). Earlier correlation studies demonstrated inconsistent relationship between biochemical and hepatic ER changes in response to toxicants. Catfish exposed to the PAH 3-methylcholanthrene (3-MC) (Schoor and Couch 1979) and barbell and mullet exposed to PCBs (Hugla and Thome, 1999; Klaunig et al., 1979) showed good correlation between proliferation of ER system with an increase in EROD/MFO activities. In contrast, subsequent studies on rainbow trout exposed to 3-MC (Kontir et al., 1984) and speckled trout exposed to chlorinated diphenyl ethers (Chui et al., 1985) showed no corresponding changes in ER with increased EROD/MFO activities.

Linkage of Biological Responses to Environmental Pollutants in Water and Sediment

Over the past 15 years, numerous field and laboratory studies have been conducted from all over the world to link biological responses (i.e., molecular, biochemical, histopathological, immunological, physiological) in fish to environmental pollutants (ANZECC, 1992; Au, 2004; Payne et al., 2003; Stagg et al., 1998), with an attempt to estimate exposure to and effects of environmental contaminants. A variety of biological responses, at different levels of organization, are candidate biomarkers or bioindicators for pollution monitoring. According to Peakall (1992), biomarkers are measures of suborganismal responses (i.e., molecular, biochemical, physiological, or histological response) in organisms that can demonstrate exposure to or the effects of environmental contaminants. In general, molecular responses will first occur when an organism is subject to stress. This is followed by a variety of homeostatic mechanisms in biological systems that enable the organism to restore to original conditions or to an altered state of equilibrium that is consistent with life. Biological responses at a higher biological organization (i.e., population, community, and ecosystem responses) occur if these mechanisms fail to restore to normal conditions.

Many of the molecular biomarkers used in environmental monitoring are measured from liver tissue of fish. One example is the CYP1A biomarker. The induction of the fish liver cytochrome P450 system, especially the enzyme 7-ethoxyresorufin-*O*-deethylase (EROD), has been commonly used as a biochemical biomarker for exposure to PAHs, PCBs, and petroleum hydrocarbons (Ahokas et al., 1976; Au, 2004; Au and Wu, 2001; Au et al., 1999; Behrens and Segner, 2005; Beyer et al., 1994; Bucheli and Font 1995; Collier et al., 1995; Holdway et al., 1995; Livingstone et al., 1997; Wu et al., 2003). CYP1A/EROD induction is sensitive to low levels of contamination exposure and could be more sensitive than direct measures of contaminant residuals (Collier et al., 1995); however, dose–response studies reveale CYP1A induction reaches maximal levels after exposure to moderate levels of contaminants (Banka et al., 1997; Fent et al., 1998; Wu et al., 2003). In addition, response time for EROD to PAHs appeared to be highly variable; for example, hepatic EROD activities in the *Solea ovata* subsided to background levels 7 days after an intraperitoneal injection of BaP (Au et al., 1999), while EROD activities in the dietary BaP-treated grouper fish subsided at week 4 of exposure and throughout the depuration period (Au, 2004). In contrast, sustained EROD activity was found in rainbow trout fed with 2,3,4,7,8-pentachlorodibenzofuran during the 31-day exposure period as well as the 180-day depuration period (Muir et al., 1990). The difference in response time was probably attributable to different half-lives of these compounds or the route of exposure in fish. Generally, induction of hepatic EROD activity is sensitive to a wide range of xenobiotics; the increase tends to be transient and subsides shortly after exposure is terminated. Importantly, a good relationship has been established between hepatic EROD induction and lipopigment accumulation, a harmful biological effect. The ecological relevance and

Summary of Application of Fish Liver Histopathology in Major Pollution Monitoring Programs

Pathologic Entity	Monitoring Programs	Refs.
Liver tumor	Recommended for use by the ICES	ICES (1989, 1996, 1997)
Hepatic lesions	Multidisciplinary surveys by the U.S. National Marine Service	WGBEC (2002)
	Fisheries services on the Pacific and Northeast coasts	Malins et al. (1988)
	Gulf of Mexico integrated monitoring programs	Varanasi et al. (1989); Johnson et al. (1992a,b); Wolfe (1992); Myers et al. (1993); USEPA (2000)
Macrophage aggregate	NOAA marine monitoring programs and U.S. National Estuary Program in Virginia estuaries	Wolf et al. (1992); Strobel et al. (1999)
Lycrosomal integrity	North Sea pollution monitoring in Germany	Broeg et al. (1999)

ecotoxicological value of the EROD biomarker are significant (Au, 2004). This biochemical biomarker has proved successful in identifying regions impacted by industrial pulp and paper effluents (Munkittrick et al., 1991). The use of hepatic EROD induction in fish can be found in regulations in Canada and Australia (Collier et al., 1992, 1995; Holdway et al., 1994, 1995), and such an approach is considered potentially suitable for long-term monitoring of the marine environment in Hong Kong (EPD, 2003).

Histocytopathological alterations of fish liver are frequently used in monitoring programs as markers of fish health. Numerous field studies have reported liver histopathological changes in fish from contaminated environments, and liver histopathology has been found to be a sensitive indicator of pollution stress and impaired fish health (Handy et al., 2002; Schwaiger, 2001; Teh, 1997; Vethaak and Jol, 1996; Zimmerli et al., 2007). A drawback of liver histopathology to assess toxicant stress can be the qualitative nature of histological data; however, this can be overcome by using standardized, semiquantitative evaluation schemes (Bernet et al., 1999).

It is likely that the histocytopathological symptoms described in fish liver may decrease the fitness of the individual through disturbed metabolic homeostasis and proper functioning of vital biological processes (e.g., detoxification). Fish liver pathological symptoms are of significant ecological relevance. Moreover, hepatic lesions are highly sensitive to pollutant exposure, and certain lesions have been well correlated with contaminant exposure (Au, 2004). Some histopathological incidences are species specific; the restrictive natural distributions of many species may make monitoring results not directly comparable between various locations. Monitoring the presence of liver tumors in young fish may not be suitable due to a long latent period for disease development. Except for liver tumors that have a well-defined and validated morphology (Boorman et al., 1997), the technical difficulty is high for symptom diagnosis. Moreover, certain hepatic lesions, such as macrophage aggregates, relate to a large number of possible confounding factors (e.g., season, reproductive stage, migration pattern, nutritional conditions). This makes it necessary to strictly standardize sampling protocols, which sometimes may be difficult. This problem is further exacerbated by the low incidence of MAs in normal fish livers, and a large sample size is necessary to discern statistically significant differences between fish population in different sites or times. In general, the hepatic lesions reviewed are responsive to a variety of pollutants and are therefore indicative of the general quality of the environment rather than specific types of pollutants. Some histopathological symptoms of fish livers have already been applied in field monitoring (Table 7.7). Liver pathologies are currently classified as Category II by the OSPAR Commission, which includes criteria for quality assurance procedures that are not yet in place although they may be used for monitoring (WGBEC, 2002).

In contrast, cytological structures (e.g., lipopigments and lysosomes) that occur commonly in most living cells are easy to identify. The cause-and-effect relationships and detailed mechanisms leading to the development of most pathological symptoms are becoming clear. Fish hepatic lipopigment has shown promise as a cytological marker of effects of PAHs and BaP (Au, 2004; Au and Wu, 2001; Au et al., 1999). Lipopigment content was chosen as one of the battery of biomarkers to assess long-term effects

Downloaded From Vet-eBooks.com

of oil pollution on mussels and fish in the Ligurian Sea in Italy (Viarengo et al., 2001). Identification of lipopigment *per se* is not difficult, but quantification of abundance and size may not be cost effective for routine monitoring. Biochemical measurement of lipid peroxidation could be employed to indicate formation of lipopigments in liver.

Lysosomal alterations in fish hepatocytes have been recommended as potential cytological biomarkers for environmental pollutants. Köhler et al. (2002) demonstrated a good dose–response relationship between the severity of lysosome alterations in liver of *Platichthys flesus* and the levels of xenobiotics pollution. The results support the use of lysosomal membrane destabilization together with lysosomal enlargement as a prognostic biomarker for toxicant-induced fish liver dysfunction in biomonitoring programs (Broeg et al., 1999; Köhler et al., 2001, 2002). Methods used in the determination of lysosomal integrity in fish hepatocytes have been well established (Köhler 1991, 1992; Lowe et al., 1992), but no information is available on the reversibility of lysosomal changes upon withdrawal of contaminants. If the induction is transient and reversible, this cytological damage is short term, and induction of the cytological changes will signify recent exposure of the fish to pollutants. If the change is irreversible, permanent damage is implicated. Such information is essential for interpreting field data and evaluating the robustness of these cytological markers for pollution monitoring and risk assessment.

Both lysosomal stability and lipopigment content in fish liver have shown promise and may be useful early warning signals to indicate exposure to and effects of persistent environmental pollutants, providing that the effects of seasonal variations (temperature, salinity, and food availability) and reproductive status (sex and maturity) have been studied and standardized for the test fish species. Such information is urgently needed for evaluating the applicability of the two cytological biomarkers in pollution monitoring. The fact that major attention in biomarker production and application has focused on the liver underscores the importance of this target organ.

Need for Future Research

More data on responses of fish liver to hepatotoxicants are needed. We have a number of reports describing toxic responses in fish liver, but usually only specific aspects are addressed, and rarely do we have a database comparable to reference hepatotoxicants in mammals, where information regarding the mechanisms, pathology, and toxicology is available. With fish, we usually have only bits, but no complete picture. For rodent liver, we are aware of pathological liver changes typical for, for example, oxidative stressors, and we can even cluster hepatotoxins on the basis of gene expression profiles, but for fish we have no such systematic understanding. To broaden our database on this point requires generating a database on the mechanisms and pathological and toxicological effects of chemicals that act specifically on the liver (not just chemicals that may target another organ and have some side effects on the liver as well), which is essential for developing our still very descriptive approach to fish liver toxicology into one of sound and integrative science.

In addition to broadening our knowledge and understanding on toxic response patterns, both molecular and histological ones, we have to know much more regarding the basic functional properties of fish liver; for example, although the various sinusoidal and biliary transporters in rodent liver are well characterized, we are just beginning these studies in fish. We have some evidence for an MDR1-like transporter, and evidence is emerging for MRP-like transporters, but all this is still very fragmentary information. As long as we lack sufficient understanding of the basic functional traits of fish liver, we will not be able to understand and classify toxic effects.

We need to know much more regarding the relationships between the various liver cell types. Much liver toxicity in mammals is not triggered from hepatocyte responses but through signaling between the various liver cell types. Here, our knowledge on fish liver is almost nonexistent, despite the importance of this aspect for liver toxicology. Currently, liver histopathology is used mainly as a descriptive tool to assess the health status of fish exposed to toxicants. To more completely understand toxic responses in the liver and to further apply this knowledge, we need to integrate molecular, biochemical, physiological, and morphological findings from the cellular through organ level.

Introduction

The gills and the gut are the main entry routes for toxic agents in teleost fish, and this makes these organs important targets for such chemicals. Gills and gut are also important organs for the regulation of water and ions in fish, and this is the main reason why many toxic agents, either waterborne or present in the food, are well known for disturbing hydromineral regulation in fish. This is readily reflected in changed osmolarity and the concentration of the main ions (in particular Na^+, Cl^-, Ca^{2+}, and Mg^{2+}) in the blood plasma. Effective hydromineral control is of utmost importance in fish, as most of these animals are living either in freshwater, with an osmolarity in general less than 5 mOsmol L^{-1} and thus far below that of the blood plasma (300 to 325 mOsmol L^{-1}), or in seawater, with an osmolarity about three times higher than in the blood of seawater-dwelling fish (950 to 1050 mOsmol L^{-1}). The resulting osmotic and ionic gradients across the branchial epithelia form the driving force for passive water and ion movements between the fish and the water. These movements—the outflow of ions and osmotic uptake of water in freshwater fish and the inflow of ions and osmotic water loss in seawater fish—are counteracted by an effective control of permeability to water and ions of the integumental epithelia, particularly in freshwater conditions (Eddy, 1981; Evans, 1987). Nevertheless, compensation of the resulting water and ion flows requires a constant action of the principal water and ion regulatory organs, the gills, skin, and kidneys, in both freshwater and seawater. The functions of the three organs differ substantially between freshwater and seawater fish, and this is one of the reasons why the impact of many toxic agents is dependent on water salinity. In freshwater, the outflow of ions over the gills is offset by active ion-exchange processes in the gills and intestine, whereas the osmotic inflow of water is compensated by the excretion of large volumes of urine with a low osmolarity. In a marine environment, the osmotic loss of water is compensated by drinking seawater and the subsequent secretion of monovalent ions via the gills and monovalent and divalent ions via the kidneys. The latter processes also redress the passive inflow of ions in seawater fish.

Downloaded From Vet-eBooks.com

The exchange and secretion of ions are essential not only for compensating the passive ion flows between fish and the ambient water and the excretion of superfluous ions extracted from food, but also for the elimination of metabolically produced ions, such as H^+, NH_4^+, and HCO_3^-. The gills have a particularly important role in this respect, as they function as organs for the exchange of ions and respiratory gases as well as for acid–base regulation (Evans, 1987; McDonald et al., 1991). Thus, when considering the actions of toxic agents on hydromineral regulation in fish, the effects of these substances on gills, gut, and kidneys have to be taken into account.

In this chapter, we review the most important aspects of the interactions of toxic agents with these osmoregulatory systems on the basis of a selection of the available literature and with an emphasis on those aspects that are typical for fish as aquatic organisms. We discuss the effects of direct interaction of toxic agents with the osmoregulatory epithelia, as well as the indirect effects resulting from the actions of toxic chemicals as stressors and as disruptors of endocrine cells. Like all external factors with the capacity to disturb internal equilibria of animals or with an impact experienced as threatening, toxic agents can evoke a stress response in animals. In fish, much more than in the terrestrial vertebrates, stressors affect the hydromineral balance of the fish. This is an aspect of fish that has long been ignored or underestimated in studies on toxic mechanisms and toxic effects in these animals (Wendelaar Bonga, 1997).

The Gills

We consider here the direct and indirect effects of toxic agents on the hydromineral and acid–base balance that can be attributed to damage of the branchial structure and alterations in branchial function. Gills consist of two sets of four branches, with numerous rows of filaments; each filament has two rows of lamellae, which represent the respiratory surface. The afferent arteries to the gills open into blood sinuses in the lamellae—flat spaces lined by cytoplasmic extensions of the pillar cells. The spaces are drained by efferent arterioles, which anastomose with a central venous sinus in the filament, drained by venolymphatic vessels (Figure 8.1). Whereas the lamellae are covered by a uniform one- to two-layer flat epithelium of respiratory cells, the filament epithelium is multilayered and consists mainly of filament cells, with an apical layer of flattened pavement cells with mucus cells and chloride cells. The chloride cells are the main location of ion-dependent ATPase activity as well as ion channels and other mechanisms involved in transcellular and paracellular ion transport. There are notable indications that H^+–ATPase activity is also present in respiratory cells and/or pavement cells (see reviews by Evans, 1987; Flik et

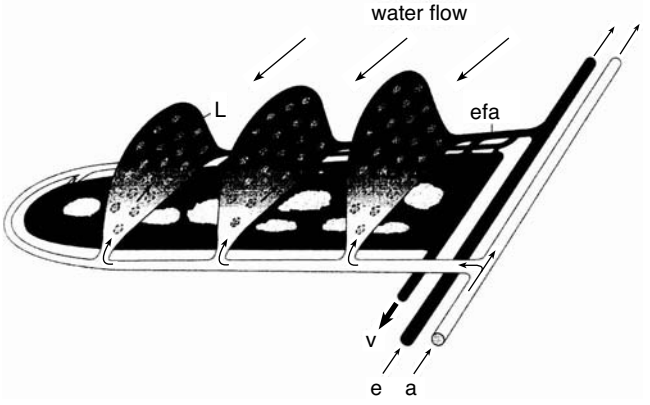

FIGURE 8.1 Simplified diagram of a branchial filament with lamellae (L; their numbers vary from 30 to several hundred per filament, depending on species). The blood enters the filament via a branch of the afferent gill arch artery (a) and enters the vascular spaces of the lamellae. These are drained by efferent lamellar arteries, which join the efferent filament artery (efa), which opens into the efferent arch artery (e). Part of the blood enters the central venous sinus of the filament, which is drained by a venolymphatic vessel (v).

Downloaded From Vet-eBooks.com

al., 1996; McDonald et al., 1991). The large respiratory surface of the lamellae as well as the extensive epithelium lining the filaments represent an important area of contact between the animals and the ambient water which facilitates an efficient exchange of respiratory gases and ions but at the same time forms an expanded and delicate target area for toxicants.

Numerous reports have been published on the effects of toxic agents on gill structure and function, mainly in freshwater fish, although interest in seawater fish is growing. Mallatt (1985) and Evans (1987) summarized the main literature on gill structure available in the mid-1980s, and they emphasized the diversity of toxic actions as well as similarities in the types of lesions induced by a large number of toxicants. Common structural alterations include necrosis of pavement cells and chloride cells; rupture of the epithelium; hypertrophy and hyperplasia of chloride cells, filament cells, and respiratory cells which may lead to lamellar fusion; epithelial swelling by widening of intercellular spaces; penetration of leucocytes from the blood into these intercellular spaces; and, in the lamellae, epithelial lifting, the separation of the respiratory epithelium from the underlying tissue. Such alterations have been confirmed for many toxicants (Grinwis, 1998; Nowak, 1992). More recently, several studies have shown that cell death by toxic agents is due not only to necrosis (accidental cell death) but also apoptosis (physiologically controlled cell death) (Wendelaar Bonga, 1997; Bury et al., 1998). In this chapter, we mainly concentrate on the literature after 1987 and focus on the underlying action mechanisms and consequences for the hydromineral balance. The effects of toxicants on the gills are twofold: (1) interaction (mainly inhibition) with the ion-transporting mechanisms of the gills, which are mainly concentrated in the chloride cells, and (2) increased permeability of the branchial epithelia to water and ions. Although the gills are mainly affected by waterborne chemicals acting from outside, bloodborne chemicals that have entered the circulation via the gut have also been reported to disturb branchial structure and function (Handy, 1992; Pratap and Wendelaar Bonga, 1993).

Disturbance of Active Ion Transport Processes

The chloride cells are the most extensively studied cell types of the gills because of their key function in ion transport activity. They are characterized by an extensive tubular system continuous with the basolateral membrane and containing membrane-bound, ion-translocating enzymes such as Na^+/K^+- and Ca^{2+}-ATPase, as well as different types of exchangers and postulated ion channels in the apical and basolateral membranes (Figure 8.2). Exposure to toxicants, particularly heavy metals, leads to a rapid inhibition of these cells. In general, at high concentrations, this is structurally reflected by focal damage or by necrosis and apoptosis of these cells. In response to cell death, differentiation of new cells is commonly observed. The acceleration of cell death and cell replacement may continue for months, although its rate in general slows down after the first week, possibly as a result of the expression in the newly formed cells of proteins such as metallothioneins (Roesijadi, 1996), which may protect the cells against the toxic action of the metals.

Chloride cells can be affected by waterborne as well as dietary metals, as has been shown for cadmium in Mozambique tilapia (Pratap and Wendelaar Bonga, 1993) or copper in trout (Berntssen et al., 1999). The toxic mechanisms involved have been elucidated for only a few metals. Copper, which is known to affect plasma Na^+ ions and Na^+ fluxes rather specifically (Laurén and McDonald, 1987; Li et al., 1998; Matsuo et al., 2004), has been shown to inactivate Na^+/K^+-ATPase activity (the driving force for Na^+, K^+, and NH_4^+ transport and indirectly for other ions such as H^+, Ca^{2+}, and, in seawater, Cl^-) *in vitro* in the nanomolar range (Li et al., 1996). The result is a net loss of sodium and other ions.

The differences among species with regard to sensitivity to copper (e.g., yellow perch is rather tolerant and rainbow trout is sensitive) have been attributed to the rate of sodium loss upon copper exposure and not to the total amount of copper bound to the gills, which are the sites of highest copper accumulation in fish. Copper accumulation was found to be 9 times higher in perch than in trout (Taylor et al., 2003). At copper concentrations causing 50% mortality (96-hr LC_{50}), cadmium is able to inhibit *in vitro* Ca^{2+}-ATPase activity, the driving force for branchial and intestinal Ca^{2+} uptake, in the nanomolar range (Schoenmakers et al., 1992). This seems to be the key toxic mechanism for this metal. Reductions in plasma Ca^{2+} concentrations after exposure to cadmium have been reported for several fish species. Conversely, an increase in waterborne Ca^{2+}, but also increased dietary calcium intake, can reduce the

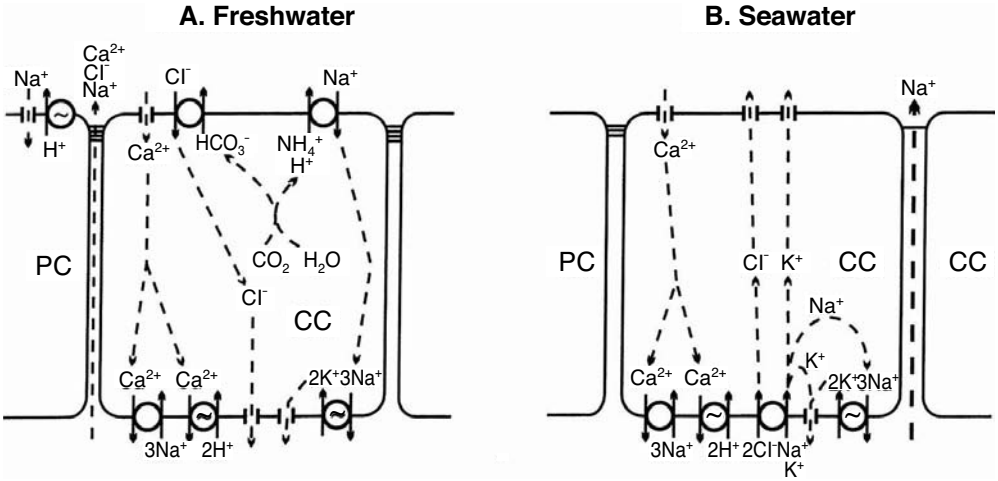

FIGURE 8.2 Diagrammatic representation of chloride cell function in freshwater fish (A) and seawater fish (B). Active transport (~) and cotransport are indicated by solid lines and diffusion by dashed lines. Tight intercellular functions are indicated as multi-stranded lines; leaky junctions as single-stranded lines. This leaky junction (in seawater) permits Na efflux driven by serosa-positive transepithelial potential. PC, pavement cell; CC, chloride cell. (Adapted from Marshall, W.S., in *Fish Physiology*, Vol. XIV, Wood, C. M. and Shuttleworth, T. J., Eds., Academic Press, San Diego, CA, 1995, 1–23; Flik, G. et al., *Physiol. Zool.*, 69, 403–417, 1996.)

toxicity of both waterborne and dietary cadmium by reducing the uptake through gills and gut (Baldisserotto et al., 2005). The uptake of inorganic mercury can be partially inhibited by the sodium-channel blocker phenamel, but not by calcium-channel blockers, indicating the possibility of competition by mercury for Na^+ uptake (Klinck et al., 2005).

For several other metal ions, the toxic mechanism has not been defined clearly. The gills are the tissue with the highest metal accumulation after exposure to waterborne lead. Inhibitory effects of lead on branchial Na^+/K^+-ATPase activity and Na, Cl, and Ca^{2+} influx have been reported for rainbow trout, as well as reduced plasma Na^+, Ca^{2+}, and Cl^- levels. The acute toxicity for lead is probably connected with ion regulatory disruption rather than, for example, respiratory failure or acid–base disturbance, but the key toxic mechanism is still unclear (Rogers et al., 2003). Waterborne nickel has no clear effect on Na^+, Cl^-, or Ca^{2+} fluxes and, in contrast to most other metals, is most likely a respiratory rather than an ion regulatory toxicant (Pane et al., 2003). At high concentrations, the plasma levels of many other ions are affected, and this can be ascribed to the destruction of the chloride cells. At sublethal exposure levels, this reduction is transient, probably as a result of replacement by more resistant newly differentiated chloride cells. Currently, no specific effects of organic toxicants on the ion-transporting mechanisms of chloride cells have been determined. Most likely, the malfunctioning of chloride cells by organic toxicants is the result of nonspecific damage to the gill epithelium or to damage of the regulatory mechanisms of these epithelia.

When examining the effects of toxicants *in vivo*, two processes interfere with each other: the toxic actions of the chemicals themselves and the compensatory responses of the fish. This interference complicates the analysis of the effects of toxic substances. Successful compensation may obscure the negative effects of toxicants and lead to an underestimation of their impact on living organisms, as compensatory processes require energy. The allocation of energy toward compensatory processes and cell-cycle acceleration limits the potential growth and reproduction of organisms and promotes aging. Compensatory processes also impair the analysis of action mechanisms, which may explain many discrepancies reported in the literature; for example, reports on the effects of metals on Na^+/K^+-ATPase activity or total number of chloride cells show many inconsistencies. Cadmium exposure induces an increased turnover of chloride cells. Depending on the balance between cell death and cell replacement, which in turn is dependent on cadmium concentration, the presence of other stressful factors, and the exposure time, the numerical density of these cells may decrease, remain constant, or increase (Wendelaar

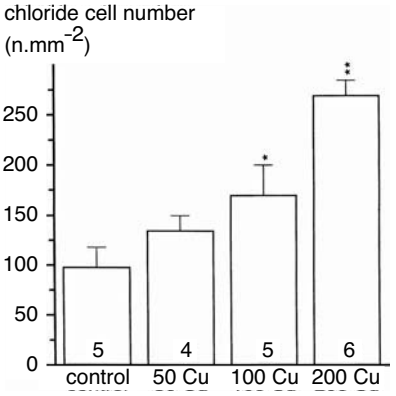

FIGURE 8.3 Chloride cell numbers in the gill opercular membrane (reflecting total gill epithelial surface area) of the Mozambique tilapia (*Oreochromis mossambicus*) exposed for 6 days to 0 (control), 50, 100, or 200 µg Cu/L. Means ± SD are indicated; numbers of fish per group are shown in the bars; $*p < 0.01$; $**p < 0.001$. (From Pelgrom, S. M. G. J. et al., *Aquat. Toxicol*., 32, 303–320, 1995. With permission.)

Bonga and Lock, 1992). Discrepancies among various studies with regard to the effects of toxicants on the Na^+/K^+-ATPase activity of gills may have a similar causes. Inhibition of Na^+/K^+-ATPase activity by, for example, copper may be masked by overcompensation by the fish through active stimulation of the formation of new chloride cells (Figure 8.3).

Disturbance of Permeability to Water and Ions

As mentioned above, maintenance of the membrane permeability to water and ions is the basis for controlling the hydromineral balance in fish. Any factor interfering with branchial permeability poses a serious threat to fish, because, at least in freshwater fish, this leads to reductions in plasma ion levels and, subsequently, ion losses from the intracellular compartments. Several types of toxic agents have direct effects on branchial permeability. Copper, for example, has been reported to increase the effluxes of Na^+, Cl^-, and K^+ (Laurén and McDonald, 1985; Reid and McDonald, 1988); silver increases Na^+ efflux (Bury, 2005); zinc and lanthanum stimulate Na^+ and Cl^- effluxes (Spry and Wood, 1985); cadmium promotes Ca^{2+} efflux (Verbost et al., 1987); and lead promotes diffusional water fluxes (Sola et al., 1994). The transcellular permeability of an intact epithelium is mainly determined by the characteristics of its membrane phospholipids and the amount of calcium bound to the negative groups of the membranes, whereas the permeability of the paracellular routes is dependent on the structure of the tight junction interconnecting the apical areas of the upper cell layers. Loss of calcium from the membranes and tight junctions of fish gills (e.g., as a result of replacement by heavy metals) has been considered an important cause of increased branchial permeability (McDonald et al., 1991; McWilliams, 1982). The protective effect of high water calcium levels against heavy metal toxicity is in agreement with this hypothesis (Pratap et al., 1989), although water Ca^{2+} may also reduce metal uptake by competing with metals for calcium channels (Comhaire et al., 1998). Extensive epithelial lesions may also affect epithelial permeability to water and ions; this could be an additional mechanism for heavy metals and perhaps the main mechanism for the (relatively few) organic pollutants with direct actions on water and ion regulation, such as perfluorooctane sulfonic acid (PFOS). This chemical is a wetting and foaming agent that reduced serum Cl^-, Na^+, and Ca^{2+} levels in carp, probably through disruption of membrane structure in the gills (Hoff et al., 2005). Branchial permeability to water and ions can also be increased indirectly, via the induction of a stress response.

A rapid rise in the blood levels of adrenaline and noradrenaline is typical of a stress response, which is evoked by such factors as toxic chemicals that threaten or disturb the physiological homeostasis of animals. High adrenaline levels increase the blood pressure in the gills, as a result of increased cardiac output and arterial vasoconstriction. Lamellar perfusion is increased by adrenaline, via opening of the

Downloaded From Vet-eBooks.com

afferent lamellar vessels and closing of the arteriovenous anastomoses (Figure 8.1). The increased blood flow and the recruitment of peripheral branchial lamellae that are barely perfused at rest increase not only the effective respiratory surface but also the available surface area for the diffusion of water, ions, and even large organic molecules (Mazeaud and Mazeaud, 1981; Randall and Perry, 1992). As a result, all factors stimulating this adrenaline release also promote the passive loss of ions in freshwater fish and the passive inflow of ions in seawater fish across the gills. In freshwater fish, diffusive losses of Na^+ and Cl^- can increase up to 40-fold during stress, resulting in a dramatic loss of total body Na^+ and Cl^- and further promoting the osmotic flow of water across the gills (see reviews by Mazeaud et al., 1977; McDonald and Milligan, 1997).

Factors affecting the release of adrenaline vary from forced increased locomotor activity or a reduction in water oxygen concentration to all kinds of social, physical, or chemical stressors. All toxic chemicals increase branchial permeability to water and ions as soon as their impact is sufficient to evoke a stress response, and severe stress can lead to edematous swelling of the lamellar and filamental epithelia and even to the phenomenon of epithelial lifting (detachment of the lamellar epithelium from the underlying tissues). As mentioned earlier, such phenomena have frequently been described in fish exposed to inorganic or organic pollutants (Mallatt, 1985; Wendelaar Bonga, 1997). More direct evidence that these chemicals can produce a stress response are the many reports on the elevation of plasma cortisol levels following exposure of fish to these substances (Hontela, 1997; Pelgrom et al., 1995; Webb and Wood, 1998). Recently, Chowdhury et al. (2004) reported increased levels of plasma cortisol, glucose, lactate, and total ammonia, all classical stress parameters, in rainbow trout exposed to waterborne cadmium. The observed rise in aspartate aminotransferase and alanine aminotransferase in gills, kidneys, and liver of common carp during cadmium exposure has also been ascribed to the stress response evoked by this metal. Both enzymes are known to be involved in protein catabolism for energy production in stressed animals (De Smet and Blust, 2001).

The recovery phase of the stress response is characterized by a compensatory increase of chloride cell density in the gills. This explains why not only toxic metals that directly affect these cells but also organic chemicals without specific effects on the gills increase chloride cell density (Mallatt, 1985; Wendelaar Bonga, 1997).

The Intestine

The intestine is one of the main targets of dietary and waterborne toxic agents, and, given the important osmoregulatory function of the intestine, it directly affects the regulation of water and ion balance. It is therefore surprising that the intestine, as an organ of hydromineral regulation, has received little attention from fish toxicologists, particularly when compared to the hundreds of papers on the gills. The main reason may be that most toxicological studies are dealing with the effect of waterborne pollutants on freshwater fish, which have low drinking rates. It should be emphasized here that, under field conditions in neutral water, toxic metals are almost exclusively complexed or bound to particles and enter the fish mainly as food contaminants.; thus, for reasons of ecological relevance, more attention should be paid to the intestinal route as far as the toxicology of metals is concerned.

In freshwater fish, the role of the intestine in the control of hydromineral balance is comparable to that of the terrestrial vertebrates, with reabsorption of calcium and magnesium being the most important activity, complementary to the mineral-accumulating function of the gills (Flik et al., 1996). The situation in seawater is essentially different. The high drinking rate of seawater fish, followed by intensive reabsorption of water to offset the osmotic water loss, is an important strain on hydromineral control as the water reabsorption is dependent on Na^+ and Cl^- uptake. The role of the intestine in hydromineral regulation is reflected by the structure of the epithelial cells. The dominating cell type, the enterocyte, exhibits apically the appearance of cells involved in nutrient reabsorption, such as a well-developed brush border and a well-developed lysosomal system, in addition to smooth and granular endoplasmic reticulum and an occasional peroxisome. Along the entire length of the intestinal tract, however, particularly in its more rectal parts, the basal parts of these cells show the typical characteristics of cells involved in the transepithelial transport of water and ions: a basal labyrinth of folded

Downloaded From Vet-eBooks.com

membranes forming slit-like lumina communicating by pores with the extracellular space at the serosal side of the epithelium, with many elongated mitochondria between these folds. The membranes are the probable location of ion-translocating mechanisms that have been demonstrated in the intestine: Na^+/K^+-ATPase, Ca^{2+}-ATPase, and a Na^+/Ca^{2+} exchanger (Schoenmakers et al., 1993). In the brush border of the enterocytes of Mozambique tilapia, a low-affinity Ca^{2+} transporting carrier has been demonstrated. Ample evidence for transcellular and paracellular ion transport has been presented (see review by Flik et al., 1996).

The structure of the enterocytes is essentially similar in freshwater and seawater fish, although the basal labyrinth is more extensive in the latter. This reflects the high intensity of the intestinal reabsorption of water, Na^+, and Cl^- in marine fish that is required to offset the osmotic loss of water across the integument in seawater; however, an important qualitative difference is the presence of the $Na^+/K^+/2Cl^-$ cotransporter in seawater fish.

The more than tenfold difference in drinking rate between freshwater and seawater fish has important consequences for the exposure of the intestine to toxic agents. Whereas in freshwater it is mainly the pharyngeal area that is in contact with the ambient water as a result of the respiratory water movements, in seawater the entire alimentary tract is exposed, particularly the rectal part, where most of the water and ions are taken up. Thus, in seawater, waterborne toxicants are potentially more threatening to fish than in freshwater; however, a direct comparison is complicated by the differences in bioavailability of toxic agents that may occur as a result of salinity effects on speciation of the toxicants. This holds in particular for toxic metals.

Heavy Metals

From the point of view of hydromineral control, the actions of heavy metals on the intestine are comparable to those on the gills, as they affect inhibition of ion-transporting mechanisms and increase the permeability of the intestinal epithelium. Reduction of intestinal Na^+/K^+-ATPase activity has been reported for several metals, including mercury (Lakshmi et al., 1991), chromium (Boge et al., 1988; Thaker et al., 1996), and cadmium (Schoenmakers et al., 1992). Mozambique tilapia has been shown to become hypocalcemic when fed cadmium-containing food (Pratap et al., 1989). Apparently, these fish could not compensate the decrease of intestinal calcium uptake by stimulation of branchial uptake from the water. This may be the result of dietary cadmium entering the blood and inhibiting branchial calcium uptake, as was shown by Baldisserotto et al. (2005) for rainbow trout. Conversely, these authors also showed that an increase of dietary calcium reduced both intestinal and branchial cadmium uptake. In tilapia, increased apoptosis and necrosis of chloride cells has been reported for Mozambique tilapia exposed to dietary cadmium, similar to what occurs after exposure to waterborne cadmium (Pratap et al., 1989). The hypocalcemia induced by cadmium already at low concentrations may be partially caused by inhibition of intestinal calcium uptake. Schoenmakers et al. (1992), studying intestinal basolateral membrane preparations of Mozambique tilapia, showed that Cd^{2+} inhibits the active transport of Ca^{2+} across these membranes, probably by inhibiting the Ca^{2+}-ATPase activity in these membranes. The same authors, studying the effects of Cd^{2+} on stripped intestinal epithelium of the same species in an Ussing chamber, further demonstrated that the addition of Cd^{2+} at the mucosal, but not serosal, side decreased the active transcellular Ca^{2+} transport across this epithelium (Schoenmakers et al., 1992). The ATP-driven calcium translocation across these membranes was extremely sensitive to cadmium, indicating inhibition via the calcium site of the enzyme (Figure 8.4). Intestinal Na^+/K^+-ATPase activity was half maximally inhibited at 2.6 μM Cd^{2+}, with cadmium probably competing for the Mg^{2+} site of the enzyme. Thus, the sensitivity for Cd^{2+} of both enzymes differs by five orders of magnitude. The Na^+/Ca^{2+} exchanger was only partially blocked by cadmium binding. Finally, the mucosal and serosal addition of Cd^{2+} resulted in increased permeability to Ca^{2+} of the paracellular route in this epithelium, and this may result in passive losses of Ca^{2+} in freshwater or the inflow of Ca^{2+} in seawater.

In an electrophysiological study on seawater eels, evidence was obtained that Cd^{2+} affects intestinal Na^+ and Cl^- reabsorption via both cellular and paracellular mechanisms. In marine fish, the intestinal Na^+ and Cl^- reabsorption is affected by the luminal $Na^+/K^+/2Cl^-$ cotransporter in conjunction with serosal Na^+/K^+-ATPase activity and Cl^- conductance (Trischitta et al., 1992). Cd^{2+} blocked Na^+/K^+-ATPase

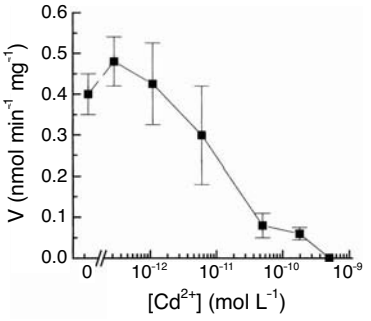

FIGURE 8.4 Cd^{2+} inhibition of the ATP-dependent calcium pump in basolateral plasma membrane vesicles from the intestinal epithelium of Mozambique tilapia *(Oreochromis mossambicus)*. Means ± SEM of nine experiments are given. The Ca^{2+} concentration was kept constant at 200 n*M*. Initial rates of ATP-dependent Ca^{2+} uptake were corrected for ATP-independent uptake. The calculated IC_{50} is 8.2 ± 3.0 p*M* Cd^{2+}. (From Schoenmakers, T. J. M. et al., *J. Membr. Biol*., 127, 161–172, 1992. With permission.)

activity and possibly also the cotransporter and affected the cation selectivity of the tight junctions. Because Na^+ and Cl^- absorption is the main driving force for intestinal water uptake, these effects of Cd^{2+} seriously threaten the water balance of marine fish (Lionetto et al., 1998).

When considering the toxicity of metal ions in a marine environment, it should be kept in mind that speciation effects, such as the formation of metal chlorides, drastically reduce metal toxicity. For cadmium, only a very small fraction is present as Cd^{2+} in seawater. In the intestine, cadmium is readily bound to the organic material present in this organ. Marked intestinal accumulation of waterborne cadmium and copper has been reported for freshwater fish (Handy, 1992). Because the low drinking rate in these animals could not account for this accumulation, the authors suggested a special role for the intestine as a store and excretion route for these metals, as suggested before for rats (Stonard and Webb, 1976). At high concentrations, cadmium may disrupt the mucosal folds in the intestine, as reported by Ghosh and Chakrabarti (1992) for *Notopterus notopterus*. These authors reported that the enterocytes were losing their regular arrangement and became necrotic, whereas the mucus secretion was stimulated. Such histopathological changes in fish intestine have also been reported for copper (Bakshi, 1991). In a study on Atlantic salmon, Lundebye et al. (1998) have shown that dietary copper and cadmium at high concentrations (up to 700 and 5 mg kg^{-1} diet, respectively) induced necrosis as well as apoptosis of enterocytes. Tissue necrosis may be accompanied by enhanced permeability of the epithelium to water and ions.

Although a direct comparison of exposure to waterborne and dietary heavy metals is complicated, dietary exposure to copper or cadmium is generally considered less toxic than exposure via the water (Lanno et al., 1985; Miller et al., 1993). This has been ascribed to the characteristics of the intestinal epithelium, which apparently represents a more effective and less sensitive barrier to toxic metals than the branchial epithelium (Handy, 1993). The complexation of metals with the organic contents of the gut, as mentioned above, may be another mitigating factor.

Organic Pollutants

No studies focusing on the effects of organic pollutants on the hydromineral functions of the fish intestine are known to the authors. Interference with these functions can only be deduced from the disruptive effects reported on the structure of the intestinal tracts and from a few studies on intestinal ion-dependent ATPase activity. Spitsbergen et al. (1988), for example, reported submucosal gastric edema and epithelial necrosis in perch and rainbow trout treated with 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD). Such effects, reported for many organic pollutants, would affect the water and ion balance as a result of nonspecific damage inflicted to the intestinal epithelium and, more indirectly, via the induction of a stress response. Chronic stress in fish, as in tetrapods, is known to be accompanied by gastric and intestinal lesions (Peters, 1982; Szakolczai, 1997).

The Kidneys

The multifunctional role of the fish kidney, which combines the functions of lungs, kidneys, and intestines of terrestrial vertebrates, is reflected by its complicated structure involving many different cell types and an intricate vascular system. From the point of view of hydromineral regulation, the main function of the kidneys in freshwater fish is the excretion of large volumes of osmotically accumulated water and the elimination of surplus ions extracted from the food, mainly K^+, sulfate, and phosphate. To limit the renal losses of valuable ions via the urine, intensive reabsorption of Na^+, Cl^-, Mg^{2+}, and Ca^{2+} takes place by means of transporting enzymes and exchangers in the epithelial cells lining the nephronic tubules, collective tubules, and bladder. In seawater fish, the excretion of divalent ions taken up by drinking is a major function of the kidneys. Water excretion has to be reduced as much as possible in a strongly hyperosmotic environment, and this is effected mainly by reduction of the glomerular filtration rate (Beyenbach, 1995). The basal parts of all the cells in the renal tubular epithelia as well as the lining of the bladder have essentially the same structure: a basal labyrinth consisting of membranes and mitochondria, with the same structure as the basal areas of the intestinal cells. In freshwater fish, the extent of the membranes and density of the mitochondria increase with the distance of the cells from the glomeruli, with maximal development of the basal labyrinth occurring at the end of the collecting tubules and in the bladder. In seawater fish, the basal labyrinth is less well developed and a gradient is usually not noticeable (Wendelaar Bonga, 1973).

Toxicological studies have revealed extensive histopathological alterations in the kidney as a result of exposure of fish to heavy metals and organic chemicals. In general, the structural damage to the kidneys seems to show little toxicant specificity. The proximal tubules appear to be the first affected, but damage progresses to the posterior segments and glomeruli, following exposure of the fish for a longer period or to a higher concentration of the toxicant. Histopathological effects vary from slight disruption of the brushborders of the proximal tubular cells, increased numbers of phagosomes and lysosomes, and structurally abnormal mitochondria to rupture of cellular membranes, swelling and vacuolization, increased cell death by necrosis and apoptosis, and large lesions in the tubular epithelia (Gill et al., 1989; Oulmi and Braunbeck, 1996; Sovenyi and Szakolczay, 1993). Cadmium is well known for its preference for renal tissue as a site of accumulation; the highest concentrations of this metal, after water as well as dietary exposure, are usually found in the kidneys (Bentley, 1991; McCoy et al., 1995; Thomann et al., 1997). As a consequence, cadmium is able to produce severe histopathological alterations (Gill et al., 1989; Ooi and Law, 1989; Oronsaye, 1989; Sovenyi and Szakolczay, 1993). Although copper has no specific affinity for the kidneys, it can also produce significant structural damage to both glomeruli and renal tubules (Bakshi, 1991). Among the many organic chemicals producing similar effects are paraquat (Molck and Fries, 1997), 4-chloroaniline (Oulmi and Braunbeck, 1996), TCDD (Henry et al., 1997), cyclosporin (Terrero and Coombs, 1989), and atrazine (Fischer-Scherl et al., 1991).

Given the severity of the histopathological changes it is clear that renal functions, including hydromineral regulation of the kidneys, will be affected with a severity depending on the concentration and length of exposure. Among the relatively few studies dealing with renal functions are reports on the inhibitory effects of silver on K^+-dependent *p*-nitrophenol phosphatase (Bury, 2005) and of cadmium, chromium (Venugopal and Reddy, 1993), copper, and mercury (Lan et al., 1993) on renal tubular Na^+/K^+-ATPase, Ca^{2+}-ATPase, and Na^+/Ca^+ exchange activity. The mechanisms of action may be similar as described for the gills and intestine: specific interactions with the ion-transporting molecules at lower concentrations and lethal cell damage at higher concentrations via induction of cellular necrosis or apoptosis. The latter, less specific way of reduction of renal ion transport activity may be typical of most organic pollutants. The reduction of Na^+/K^+-ATPase activity induced by paraquat has been related to the disruption of this chemical on mitochondrial electron chain transfer, which results in reduction of metabolic functions (Molck and Fries, 1997). The nephrotoxicity of cyclosporin is based primarily on its action as a calmodulin inhibitor, and its effects on renal hydromineral regulation have been ascribed to interference with calmodulin-dependent ion transport mechanisms (Terrero and Coombs, 1989).

An interesting finding on copper was the decreased renal Na^+ efflux of freshwater rainbow trout following exposure to waterborne copper. Given the strong inhibitory action of copper on Na^+/K^+-ATPase

Downloaded From Vet-eBooks.com

activity (Li et al., 1996), the opposite effect was expected, as reduction of Na^+ efflux points to increased tubular reabsorption of Na^+, for which Na^+/K^+-ATPase is a driving force. This phenomenon was explained as a physiological response of the kidneys to compensate the impairment of branchial Na^+ uptake (Grosell et al., 1998). This indicates that the renal Na-/K^+-ATPase activity provides better protection against copper than the branchial activity, and this is in agreement with the low renal accumulation and excretion rates for copper. Few studies are available on the physiological aspects of renal hydromineral function such as urine flow and renal ion excretion rates. Collection of such data requires cannulation techniques that are complicated and, because they are extremely stressful to the fish, often lead to results that are biased by the experimental procedures; thus, a proper evaluation of the effects of toxic chemicals on the kidneys is even more complicated than on gills and intestine.

Toxic Agents and Endocrine Control of Osmoregulation

Good evidence from fishes suggests that toxic agents can affect neuroendocrine cells and in this way interfere with neuroendocrine control processes, including osmoregulation (Hontela et al., 1993). The cell types that have received most attention in this respect are the prolactin cells and adrenocorticotropic hormone (ACTH) cells in the pituitary gland and the interrenal cells producing cortisol. Prolactin is an important hormone for the control of permeability to water and ions in the gills, intestine, and renal tubules. Activation of prolactin cells has been frequently observed in fish exposed to toxic agents and has been generally interpreted as a compensatory response to the disturbance in the permeability characteristics of these epithelia by toxicants (see review by Wendelaar Bonga and Pang, 1989). ACTH is an important secretagog of cortisol (Balm and Pottinger, 1999). The latter hormone is not only one of the primary stress hormones in fish (see under Gills) but also an important stimulator of Na^+/K^+-ATPase activity in gills, intestine, and kidneys. The multiple functions of this hormone clearly demonstrate the intimate relationship between the stress response and osmoregulation in fish. These functions of cortisol explain the stimulation of cortisol release that has been frequently reported for fish exposed to toxic agents (see reviews by Hontela, 1997; Wendelaar Bonga, 1997).

Norris et al. (1997) reported that the hypothalamo–pituitary–interrenal (HPI) axis of feral brown trout is activated in fish from sites contaminated with cadmium and zinc. They reported a higher number of immunoreactive neurons in the hypothalamus than in fish from control sites and further observed hypertrophy and hyperplasia in the interrenal cells of the fish from contaminated water; however, the relationship between some toxic agents and cortisol secretion may be more complicated and includes interference with the secretion of cortisol and ACTH. The interrenal tissue of yellow perch from a site contaminated by a mixture of heavy metals and organic contaminants secreted significantly less cortisol in response to a standardized pulse of ACTH than the interrenal tissue of fish from an unpolluted reference site (Brodeur et al., 1998).

Field studies on the effects of a mixture of contaminants (including heavy metals and PCBs) showed endocrine dysfunction in fish from natural water contaminated with a mixture of pollutants when compared with fish from an unpolluted reference site (Hontela et al., 1992, 1995). Feeding low levels of PCB 169 to rainbow trout stimulated and higher levels impaired the production of cortisol, cortisone, and other metabolites by interrenal cells as determined *in vitro* (Freeman et al., 1984). Short-term exposure (5 days) of Mozambique tilapia to PCB 126 did not influence branchial, renal, or intestinal Na^+/K^+-ATPase activity, nor did it evoke a stress response, as was concluded from the absence of a rise in plasma cortisol or glucose levels; however, when the fish were exposed to acute sampling stress, plasma cortisol levels were lower in PCB-fed fish than in controls (Figure 8.5). The interrenal cells of PCB fed fish proved to be less responsive to ACTH or cAMP stimulation *in vitro*, indicating direct toxic effects on the interrenal cells, rather than secondary effects via disturbance of hydromineral imbalance or stimulation of mixed-function oxygenase systems involved in steroid catabolism. (Quabius et al., 1997). Vijayan et al. (1997) observed an impaired ability to elicit a cortisol response in stressed trout exposed to PCB 77 and suggested that this might be caused by the enhanced hepatic cortisol clearance in these fish. Given the importance of cortisol for osmoregulation in fish, any interference with the secretion of cortisol and its secretagogs such as ACTH may be expected to have an effect on

Downloaded From Vet-eBooks.com

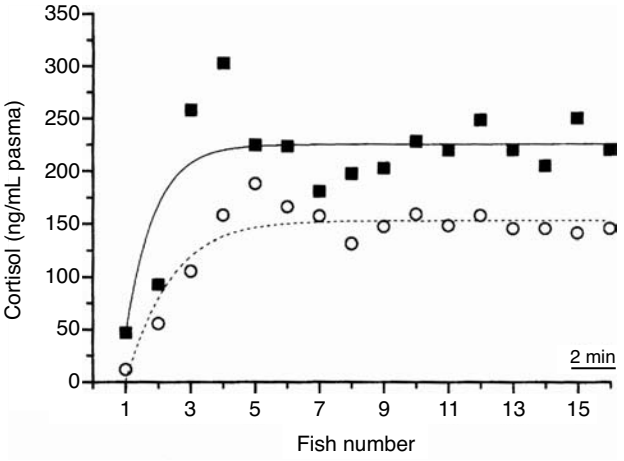

FIGURE 8.5 Effect of capture stress on plasma cortisol levels of Mozambique tilapia (*Oreochromis mossambicus*). Open circles are fish receiving food contaminated with PCB 126 (50 μg per kg fish per day for 5 days). The fish were captured subsequently at intervals of 2 minutes. Fish number 1 shows a resting cortisol level; the following fish already show a rise to a plateau level 5 minutes after. The plateau level of the PCB-treated fish is significantly lower than that of control fish (black squares), indicating an impaired cortisol response to capture by PCB 126. (From Quabius, E. S. et al., *Gen. Comp. Endocrinol.*, 108, 478–482, 1997. With permission.)

osmoregulation (McDonald and Milligan, 1997); however, the actual impact of the disruptive effects of some toxic chemicals on this process remains to be established.

The fact that toxic agents can act as stressors also implies that their effects are partially additive with those of other stressors. This is indicated by observations on Mozambique tilapia exposed to cadmium. In male fish with a low hierarchical position, the reduction of plasma osmolarity and the rise in plasma cortisol levels were more pronounced than in the dominant males (Wendelaar Bonga, 1997). Similarly, handling of the fish or crowding, known to cause a stress response in rainbow trout (Balm and Pottinger, 1995), makes these fish more sensitive to toxic agents. This is an aspect that requires more study not only in aquaculture, where, for example, the toxic effects of ammonia can be aggravated by poor holding conditions or rapid temperature changes, but also in toxicological risk analysis. For proper determination of no-effect levels or of lethal concentrations, any potentially stressful factor other than the toxic chemical should be absent. In many cases, the experimental conditions used to estimate toxicity did not meet this criterion. On the other hand, no effect and other toxicity levels determined under such rigorous conditions will easily lead to underestimation of the toxicity of a chemical in situations where the toxicant is not the only stressor.

Introduction

Few of the approximately 70,000 chemicals on the Toxic Substances Control Act inventory or the 1000 to 1600 new chemicals introduced each year in the United States have been tested for neurotoxicity to support risk assessments (NRC, 1992), even though it is estimated that 5 to 10% of them are likely to be neurotoxic. Neurotoxicity has been defined as adverse effects of physical, biological, or chemical agents on the structure or function of the nervous system in developing or adult organisms (Philbert et al., 2000). From a human health risk assessment perspective, the potential for neurotoxic effects associated with synthetic chemicals has led to the development of valid, sensitive, and reproducible methods to identify neurotoxic chemicals, to characterize neurological effects, and to determine the mechanisms by which chemicals produce neurotoxicity. Similar efforts to develop methods for assessing neurotoxicity in fish may yield further insights into neurotoxic mechanisms (Carlson et al., 1998; Drummond and Russom, 1990; Featherstone et al., 1991, 1993; Rice et al., 1997; Timme-Laragy et al., 2006; Weber et al., 1997) in addition to addressing ecological risk concerns.

This chapter aims to provide a framework from which to approach questions concerning the neurotoxic effects of chemicals in fish. First, a brief summary of structural and functional attributes of the nervous system is provided, followed by an overview of neurotoxic mechanisms of action. The final section of the chapter summarizes mechanisms of action and manifestations of neurotoxic effects for several classes of compounds. In this latter section, an attempt is made to highlight examples where structural and functional alterations to the nervous system at the subcellular to cellular level can be linked to physiological and behavioral effects. The integration of effects across levels of biological organization is essential for establishing the mechanistic basis underlying neurotoxicity, as well as for identifying and quantifying ecologically relevant neurotoxic effects in fish.

Overview of Fish Nervous System Development, Structure, and Function

Development of the Fish Nervous System

The development of the fish nervous system follows the same general design as the development of all other vertebrate nervous systems (Figure 9.1). Beginning with gastrulation, in a process known as neural induction, ectoderm is specified into either surface epidermis or neuroectoderm. Surface epidermis ultimately forms skin, while the neuroectoderm becomes neural tissue. Evidence from several model organisms, including the widely used developmental model, zebrafish (*Danio rerio*), indicates that neural induction is mediated through the bone morphogenetic protein (BMP) signaling pathway. Surface epidermis is induced when ectoderm is exposed to BMP signaling. Extracellular antagonism of BMP ligands prevents BMP signaling, allowing the ectoderm to adopt a neuroectodermal fate (Blader and Strähle, 2000; Lewis and Eisen, 2003).

Following induction, the neuroectoderm undergoes several morphogenic movements to form the rudimentary nervous system (Lowery and Sive, 2004). Initially, the neuroectoderm forms a flat epithelial sheet called the neural plate (Figure 9.1A). As morphogenesis begins, the lateral edges of the neural plate rise to form the neural folds (Figure 9.1B). Specialized neural crest cells are induced at the apex of each neural fold. These neural crest cells migrate from the neural folds and ultimately give rise to several structures, including neurons and glia of the peripheral nervous system (PNS). The neural folds are brought into apposition and ultimately join at the midline. Unlike other vertebrates, fish neural fold fusion produces a solid rod of cells called the neural keel (Figure 9.1C). Although the midline is distinct during neural keel formation, cells within the neural keel are capable of crossing the midline. Once covered by surface epidermis, the neural keel subsequently undergoes programmed cell death to become

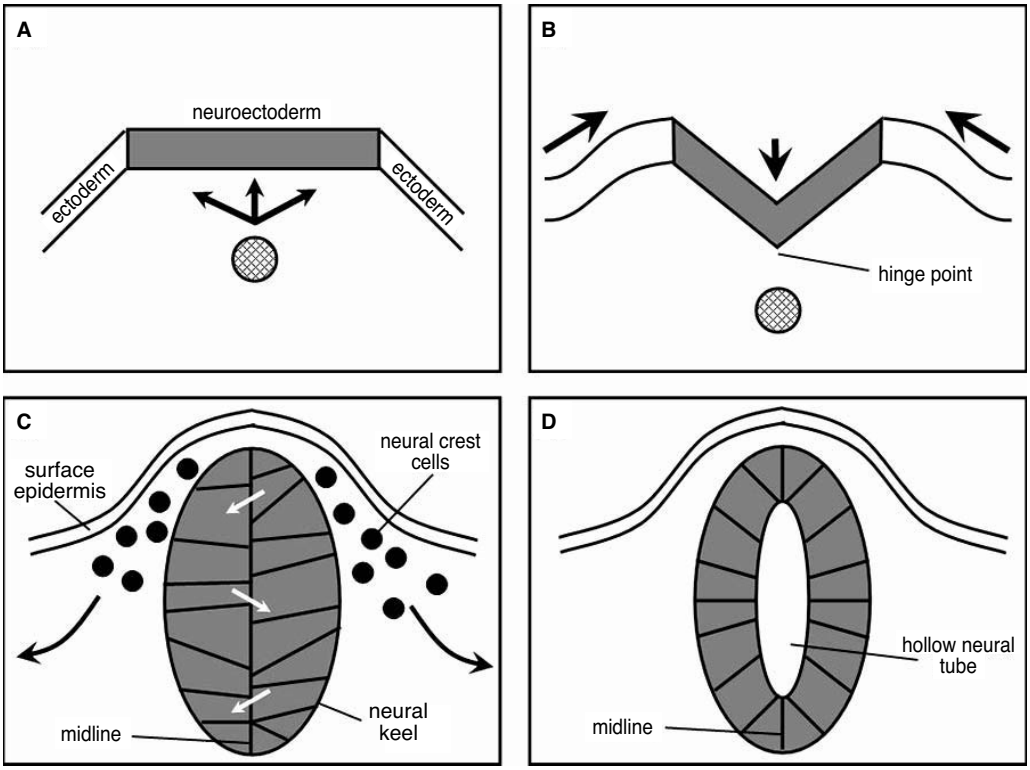

FIGURE 9.1 Overview of neural tube development. (A) BMP signaling antagonism allows the neuroectoderm to form from ectoderm, forming the neural plate. Signals from the notochord begin patterning the neural plate. (B) Morphogeneic movements begin forming the neural keel. (C) The neural keel is a solid rod of neuroectoderm tissue. Neural crest cells have begun migrating from the dorsal regions, and surface epidermis covers the neural keel. Unlike most vertebrates, cells within the neural keel are capable of crossing the midline. (D) Apoptosis of cells within the neural keel forms the hollow neural tube.

a hollow neural tube (Figure 9.1D). At the anterior end of the neural tube, bulging begins the subdivision of the brain into the prosencephalon (forebrain), mesencephalon (midbrain), and rhombencephalon (hindbrain) (Figure 9.2). The remainder of the neural tube becomes the spinal cord. Within the spinal cord, progenitor cells are patterned by secreted signaling molecules along the anterior–posterior and dorsal–ventral axes. Anterior–posterior patterning of the neuroectoderm begins during gastrulation in response to signals derived from the organizer (Blader and Strähle, 2000). Forebrain is thought to be the default state of neural tissue, with subsequent posteriorization involving retinoic acid, fibroblast growth factor, and Wnt signaling (Lewis and Eisen, 2003). Along the dorsal–ventral axis, distinct neuronal cell types are located at stereotypic positions in the spinal cord, with sensory neurons specified dorsally and motorneurons specified ventrally (Blader and Strähle, 2000; Lewis and Eisen, 2003). As with other vertebrates, sonic hedgehog protein secreted from the floor plate and notochord induces ventral motorneuron differentiation in a concentration-dependent manner (Blader and Strähle, 2000; Lewis and Eisen, 2003). In the dorsal neural tube, BMP signaling from the roof plate and adjacent non-neural ectoderm are hypothesized to induce sensory neuron fates in a concentration-dependent manner (Blader and Strähle, 2000; Lewis and Eisen, 2003).

Once neuronal fates have been specified in appropriate anterior–posterior and dorsal–ventral locations, the next step in nervous system development is axonogenesis, when neurons extend axons to their innervation targets. Embryonic nervous system development has been particularly well characterized in zebrafish (*Danio rerio*) (Bernhardt, 1999); therefore, the summary of axonogenesis given here is necessarily restricted to zebrafish, although many facets of zebrafish axonogenesis are likely to be applicable

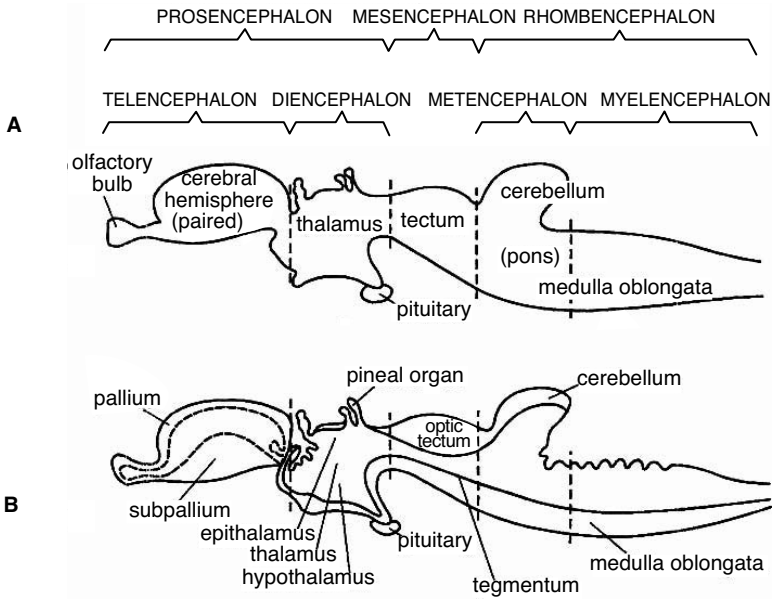

FIGURE 9.2 Major anatomical features of the fish brain (B is median section of A). (Adapted from Bond, C.E., *Biology of Fishes*, Saunders College Publishing, Orlando, FL, 1996, pp. 241–258.)

to other teleosts. A tremendous amount of descriptive information is known about zebrafish axonogenesis, with axonal pathways and targets characterized for several neuron classes (Bernhardt, 1999; Hutson and Chien, 2002; Lewis and Eisen, 2003). Unfortunately, the cellular and molecular basis for axon guidance is not as well understood. Recent genetic screens in zebrafish have identified mutants with defective axonogenesis (Hutson and Chien, 2002) and several axonal guidance gene homologs have been identified in the zebrafish genome (Bernhardt, 1999; Chilton, 2006). Although the presence of these homologs suggest that fish axon migration is regulated by integrating signals in the growth cone, the *in vivo* significance of these homologs remains to be determined.

The final step in embryonic nervous system development occurs when an axon reaches its innervation target. Active synapses are formed between neurons and their targets in a process known as synaptogenesis. Synaptogenesis has been heavily studied in higher vertebrates, with a generally accepted model of presynaptic neurons responding to both diffusible factors and distinct cell adhesion molecules in the target cell (Waites et al., 2005). Genes that play critical roles in vertebrate synaptogenesis are conserved in zebrafish (*Danio rerio*), although little functional assessment has been made (Hutson and Chien, 2002). Further insights into teleost synaptogenesis will likely come from real-time *in vivo* imaging of synaptogenesis in zebrafish (Hutson and Chien, 2002).

In the adult fish, the central nervous system (CNS) includes the neuronal structures encased within the skull and the spinal column. The PNS is comprised of nerve ganglia lying outside the spinal column as well as nerve processes found elsewhere throughout the organism. As noted above, this subdivision of the nervous system occurs during embryogenesis through ectodermal morphogenesis and patterning. The coordination and control of physiological and behavioral processes reflects the integration of structural and functional attributes of the entire nervous system.

Central Nervous System Anatomy

Although significant differences exist in anatomical features across fish species, the basic structural components of the developing CNS include the prosencephalon (forebrain), mesencephalon (midbrain), rhombencephalon (hindbrain), and the spinal cord (Figure 9.2).

Prosencephalon

The prosencephalon is comprised of the telencephalon and the diencephalon (Bond, 1996; Wullimann, 1998). The telencephalon possesses rostrally located olfactory bulbs, olfactory lobes, and, more caudally, cerebral hemispheres. The telencephalon is the site where the olfactory nerve (cranial nerve I) enters the olfactory bulbs. In actinopterygian fish, the cerebral hemispheres can be divided into dorsal and ventral components, which are homologous to the pallium and subpallium, respectively, of other vertebrates. The majority of afferent neurons entering the telencephalon are olfactory; however, there is some indication that non-olfactory ascending inputs exist, although their sites of integration have not been identified. It is now generally accepted that the telencephalon contributes to the processing of visual inputs, in addition to olfactory information, and plays a role in feeding, defense, schooling, aggressive, and reproductive behaviors (Bernstein, 1970; Bond, 1996; Davis and Kassel, 1983; Northcutt and Davis, 1983; Wullimann, 1998). Numerous studies have documented the presence of a variety of neurotransmitters in the telencephalon, as well as acetylcholine, gamma-aminobutyrate (GABA), catecholamines, excitatory amino acids (e.g., glutamate), and nitric oxide (Bissoli et al., 1989; Brantley and Bass, 1988; Byrd and Brunjes, 1995; Khan et al., 1996; Parent, 1983; Reiner and Northcutt, 1992; Sas et al., 1990; Schober et al., 1994; Sloley and Rehnberg, 1988; Sloley et al., 1992; Smith 1984). Catecholamines that have been identified in fish include noradrenaline, dopamine, and 5-hydroxytryptamine. Neuropeptides, including substance P, neuropeptide Y, and leucine-enkephalin (Byrd and Brunjes, 1995; Reiner and Northcutt, 1992), have also been found in fish nervous tissue.

The diencephalon in actinopterygian fish has been subdivided into the preoptic area, hypothalamus, thalamus, epithalamus, and synencephalon (Bradford and Northcutt, 1983). Wullimann (1998), however, considers the preoptic area an intermediate zone between the telencephalon and the diencephalon in the teleost brain. Wullimann (1998) also considers the synencephalon as part of the pretectum (see below), which is intermingled with diencephalic cell groups. Below the hypothalamus lies the pituitary gland, and the pineal organ arises from the epithalamus. The primary afferent neurons to the thalamus are the optic nerves (cranial nerve II), which enter the brain and cross anterior to the diencephalon. The hypothalamus receives a number of afferents from the telencephalon; the thalamus receives afferents from the cerebellum and serves as a relay center for the transfer of olfactory and striate-body impulses to other parts of the diencephalon and lower brain centers. In general, the diencephalon appears to serve as a coordination center for incoming and outgoing signals associated with internal homeostasis and for affecting the endocrine system through the pituitary gland (Bernstein, 1970; Bond, 1996; Bradford and Northcutt, 1983; Wullimann, 1998). Acetylcholine (Brantley and Bass, 1988), GABA, glutamate (Sloley et al., 1992), nitric oxide (Holmqvist and Ekstrom, 1997), noradrenaline, dopamine, and 5-hydroxytryptamine (Khan et al., 1996; Parent, 1983; Sas et al., 1990) have been identified as neurotransmitters in the diencephalon, primarily in the hypothalamus.

Mesencephalon

The mesencephalon, comprised of the optic tectum and the ventral tegmentum, is the primary site for processing impulses received from the optic nerve. Extensive electrophysiological and evoked response studies have been undertaken to create maps of visual fields on the optic tectum in cyclostomes, plagiostomes, and actinopterygians. The optic nerve is decussated, with projections from the right eye projecting to the left tectal hemisphere and from the left eye projecting to the right tectal hemisphere. Ascending efferent fibers from the optic tectum have been traced to the thalamus and pretectum, while descending efferent fibers proceed to the dorsolateral region of the ventral tegmentum. Some tectal outputs provide terminals to the reticular formation and cell groups in the medulla. Electrical stimulation and lesion studies support the conclusion that the optic tectum contains neuronal units that coordinate visual inputs with locomotor activity (Bernstein, 1970; Bond, 1996; Vanegas, 1983; Wullimann, 1998). Reports suggest that acetylcholine (Brantley and Bass, 1988), GABA (Rio et al., 1996), glutamate (van Deusen and Meyer, 1990), nitric oxide (Holmqvist and Ekstrom, 1997), and glycine (Becker et al., 1991) are predominate neurotransmitters within the optic tectum. Moderate catecholaminergic innervation has also been documented (Sas et al., 1990).

Downloaded From Vet-eBooks.com

Rhombenchephalon

The rhombencephalon is comprised of the metencephalon and the myelencephalon. The metencephalon includes the cerebellum and the pons, with the cerebellum being the major component. The structure of the cerebellum is highly variable in fish. In teleosts, it can be divided into three major sections that are arranged similarly to that of the cerebellar cortex in other vertebrates. These areas are termed the valvula cerebelli, corpus cerebelli, and vestibulolateral lobe. Each area contains a molecular layer, a Purkinje (ganglion) cell layer, and a granule cell layer. Primary sensory fibers in hair cell sensory systems (see sensory organ systems discussion below) and neurons from the spinal cord are important ascending inputs to the cerebellum. Efferents from the cerebellum project to the ventral tegmentum, the thalamus, and the reticular formation. The cerebellum is associated with muscle tone, motor control, and lateral line sensory input (Bernstein, 1970; Bond, 1996; Finger, 1983; Wullimann, 1998). The cerebellum has been reported to contain glutamate, aspartate, GABA, and glycine, as well as catecholaminergic neurotransmitters (Ma, 1994; Sas et al., 1990). The myelencephalon, although containing portions of the cerebellum, is predominately comprised of the medulla oblongata (Wullimann, 1998). The boundary between the medulla oblongata and spinal cord in fish is generally indistinct and can be most readily defined by the types of information transmitted with associated nerve columns. Information derived from general sensory, cutaneous, vestibular, lateral line, and trigeminal (cranial nerve V) nerve fibers is carried in the somatic sensory column. Nerve fibers derived from chemoreceptors and nerves arising in the viscera are associated with the visceral sensory column. Sensory inputs associated with sight and olfaction do not input directly to the medulla. A visceral motor column in the medulla carries efferent fibers derived from the facial (cranial nerve VII), glossopharyngeal (cranial nerve IX), and vagus (cranial nerve X) nerves to the glands and musculature of the viscera. A somatic nerve column carries efferent nerve fibers to the ocular muscles and muscles of the pharyngeal complex. The medulla of the actinopterygians contains a pair of Mauthner cells, which are giant interneurons at the level of the vestibulocochlear nerve (cranial nerve VIII) that coordinate the startle response associated with sensory inputs. The dendrites of the Mauthner cells connect with fibers of the trigeminal nerve, facial nerve, glossopharyngeal nerve, and vagus nerve to the cerebellum and the optic tectum. Their axons pass the length of the spinal cord and coordinate musculature in the tail and associated rapid swimming movements (Bernstein, 1970; Bond, 1996). Serotonin and catecholamines have been reported to be neurotransmitters in the medulla (Parent, 1983; Sas et al., 1990), in addition to glycine, GABA (Becker et al., 1991; Faber and Korn, 1988; Legendre and Korn, 1994; Triller et al., 1993), and nitric oxide (Schober et al., 1994).

Spinal Cord

In fish, the spinal cord occupies the entire vertebral canal. The cord consists of a series of segments that form dorsal and ventral roots. The dorsal and ventral horns correspond to regions of sensory input (dorsal root) and motor output (ventral root). As is generally noted within vertebrates, these roots join to form the spinal nerves. Differentiation of the spinal cord increases with evolutionary progression from Cyclostomata (lampreys and hagfish) to Chondrichthyes (cartilaginous fish) to Osteichthyes (bony fish). In the latter fishes, the gray matter is clearly divided into dorsal and ventral horns. The dorsomedial gray matter innervates the trunk musculature and specialized areas, such as the pectoral fin. Many fibers ascend to the medulla oblongata and cerebellum. The descending fibers consist of many vestibulospinal and reticulospinal fibers and the giant Mauthner cells, which contain large-diameter, well-myelinated axons. The dendrites and cell bodies of Mauthner cells are found in the medulla oblongata. These cells have many collaterals that have extensive connections with interneurons and motorneurons in the spinal cord. The role of the Mauthner cells is to mediate sensory inputs through the startle response, as mentioned previously. As a final note, spinal cords of adult and larval fish are unique from mammals in their capacity for anatomical and physiological regeneration (Bernstein, 1970; Bond, 1996).

Peripheral Nervous System Anatomy and Function: The Autonomic Nervous System

The discussion of the central nervous system and associated components in the peripheral nervous system has made reference to aspects of both the somatic and autonomic nervous system, which are responsible for "voluntary" and "involuntary" actions. In mammals, the autonomic system contributes to the regulation

Downloaded From Vet-eBooks.com

of organs and tissues such as the gut, heart, and blood vessels. In fish, the autonomic nervous system is similarly involved in the control of the gut and circulatory systems, as well as control of the swim bladder and melanophores. Studies in teleosts suggest that functional attributes of the autonomic nervous system are similar to that noted in mammals; however, the presence of gills and a swim bladder in fish and a smaller number of nerves and neurotransmitters highlight some important differences (Donald, 1998; Nilsson and Holmgren, 1998).

An anatomical differentiation of the fish autonomic nervous system into sympathetic and parasympathetic subsystems is difficult (reviewed in Donald, 1998; Nilsson and Holmgren, 1998). Instead, a terminology that differentiates cranial nervous pathways from spinal nervous pathways has been proposed. In both the cranial and spinal pathways, a preganglionic neuron runs from the central nervous system to an autonomic ganglion. A postganglionic neuron then serves as the afferent to the appropriate tissue or organ. The spinal autonomic ganglia are typically located close to the spinal column in higher vertebrates and teleosts, while autonomic ganglia associated with cranial pathways are usually located near or within the effector organ. Within the fishes, there is great variability in the anatomy of the autonomic nervous system. In the cyclostomes, the autonomic nervous system is poorly developed, with no spinal ganglia readily apparent, and it is difficult to differentiate sensory and autonomic nerve fibers. In the elasmobranchs and teleosts, autonomic ganglia are observed along the spinal column. Cranial autonomic fibers have been associated with the oculomotor (cranial nerve III), facial (cranial nerve VII), glossopharyngeal (cranial nerve IX), and vagus (cranial nerve X) nerves in the elasmobranchs. The teleost autonomic system most closely resembles that of higher vertebrates. Of note are the spinal ganglia that enter the cranium and have connections with the trigeminal (cranial nerve V)/facial (cranial nerve VII), glossopharyngeal (cranial nerve IX), and vagus (cranial nerve X) nerves. It is thought that innervation of the head and gills is associated with spinal ganglia. In the posterior region of the abdomen, the sympathetic chains fuse, and the vesicular nerves leave the chain to innervate the gut and urinogenital organs. Cranial autonomic fibers have been reported in the oculomotor (cranial nerve III) and vagus nerves (cranial nerve X), both of which reach the gut and swim bladder.

Although the number and nature of neurotransmitters are not as well resolved in fish as in mammals, compounds representative of those seen in higher vertebrates have been characterized. Assessments of catecholamine levels indicate that both adrenaline and noradrenaline are likely stored and released in adrenergic synapses. It is generally assumed within the vertebrates that acetylcholine is found in all postganglionic, parasympathetic neurons. In some teleosts, evidence for the presence of acetylcholine has been reported for the spleen, heart, and swim bladder (Abrahamsson et al., 1979; Balashov et al., 1981; Holmgren, 1977; Hsieh and Liao, 2002; Ishimatsu et al., 1986; Ovais et al., 1976; Thompson and O'Shea, 1997). Neurons containing 5-hydroxytryptamine which innervate the gut of several cyclostome and teleost species have been reported (Anderson, 1983; Anderson and Campbell, 1988; Anderson et al., 1991; Watson, 1979). Vagal neurons that innervate the gills in rainbow trout (*Oncorhynchus mykiss*) have also been reported to contain 5-hydroxytryptamine (Saltys et al., 2006; Sundin, 1995; Sundin et al., 1998). Using immunohistochemistry and radioimmunoassay techniques, a number of suspected neuropeptides have also been identified; for example, bombesin has been identified in autonomic nerves of the gut and circulatory system in several fish species (Bjenning and Holmgren, 1988; Bjenning et al., 1990; Cimini et al., 1985; Holmgren and Nilsson, 1983; Langer et al., 1979). In addition, neuropeptide Y, vasoactive intestinal polypeptide, and several somatostatins and tachykinins have been identified in fish (Donald, 1998; Nilsson and Holmgren, 1998). Nitric oxide has also been reported as a putative neurotransmitter in the autonomic nervous system (Donald, 1998).

Sensory Organ Systems

The sensory systems of fish can be divided into vision, auditory, mechanosensory, electrosensory, and chemoreception. In the assessment of neurotoxicity, these sensory organ systems are viewed as readouts of a functional nervous system. The eyes of fish generally have the same structures as those noted in the vertebrates, including the anterior chamber, an iris, a lens, and a vitreous chamber that is lined by the retina. The retina is comprised of pigmented epithelium, which consists of photoreceptors (rod and cone cells), horizontal cells, bipolar cells, amacrine cells, and ganglion cells and nerve fibers that lead

Downloaded From Vet-eBooks.com

to the optic nerve. The optic nerve is comprised of four different types of fibers, most of which are afferent and project to the contralateral side of the brain (the optic tectum). Horizontal cells facilitate information flow between photoreceptors, and amacrine cells facilitate lateral flow of information among ganglion cells. Bipolar cells direct excitatory or inhibitory responses vertically to the ganglion cells, which subsequently send information to the CNS through the optic nerve. A variety of rod and cone subtypes are observed in fish and suggest specialization in terms of discriminating wavelengths and intensity of light (Hawryshyn, 1998). Freshwater fish are generally found to have porphyropsin as their main photosensitive pigment, while marine fish typically have rhodopsin in their retina (Bond, 1996). As reviewed by Hawryshyn (1998) and Lasater (1990), glutamate is the putative neurotransmitter in the photoreceptors that mediates synaptic communication with bipolar cells, while GABA has been well-documented in horizontal and amacrine cells (reviewed in Hawryshyn, 1998; Lasater, 1990; Marc and Cameron, 2001). Glycine, dopamine, and acetylcholine have also been reported as neurotransmitters in the retina. A potential role of neuropeptides has yet to be elucidated.

The auditory, mechanosensory, and electrosensory systems include the inner ear, the lateral line (comprised of the neuromasts and canals), and the ampullary and tuberous organs of the electrosensory lateral line (Bond, 1996; Schellart and Wubbels, 1998). The ear functions contribute to balance and sound reception, while lateral line functions are related to sensing water displacement and pressure. The electrosensory lateral line is responsible for sensing electrical fields and signals. The inner ear of fish includes three otolith organs: the saccule, lagena, and utricle organs. The sacculus and lagena are primarily responsible for sound reception. The sensory epithelium, termed the macula, is comprised of sensory hair cells that are the receptor cells. Auditory stimulus causes deflections of hair bundles, leading to a depolarization of hair cells and subsequent increase in the firing rate of afferent nerve fibers to the brain. The auditory nerve (vestibulocochlear nerve; cranial nerve VIII) innervates the macula. Those portions of the brain thought to integrate auditory inputs have been discussed previously. The mechano-sensitive lateral line consists of neuromasts that are found over the entire body, either free on the skin or within pits, grooves, or canals. A neuromast consists of sensory hair cells with supporting cells, all of which are covered by a cupula. Some neuromasts are open to the water, via pores in the bone or scales. Water movement causes an impulse of fluid within the lateral line that in turn causes a deformation of the cupulae. This deformation of the hair cells results in a response in the nerve fiber innervating the neuromast. The number of innervating nerve fibers can range from a few to several hundred. The dorsal anterior lateral line nerve innervates the dorsal part of the head, the ventral lateral line nerve innervates the cheek and lower jaw, and the posterior lateral line nerve innervates the trunk and tail. The involvement of different portions of the brain in integrating responses to these inputs has been discussed previously. Of note are the projections of auditory and lateral line afferents to the Mauthner cells, which invoke the startle response.

Chemosensory systems in fishes are primarily divided into gustation and olfaction and are well developed in fish. Taste buds are comprised of 100 to 150 specialized epithelium cells, which include receptor cells, basal cells, and supporting cells. Taste buds are found primarily in the mouth, pharyngeal region, and gill arches; however, in some species they may be found on barbels, fins, and other parts of the body surface. Taste buds in the oropharyngeal cavity are innervated by the glossopharyngeal (cranial nerve IX) and vagus (cranial nerve X) nerves, while the facial nerve (cranial nerve VII) innervates taste buds on external surfaces. Receptor cells within the taste buds respond to specific compounds, such as amino acids. Many taste receptors are thought to be ion channels or proteins associated with ion channels. Binding of chemicals to the appropriate receptor elicits depolarization of the receptor cell. Through chemical synapses, the potential of the innervating nerve fiber may be modulated prior to propagation to the CNS (Bond, 1996; Sorenson and Caprio, 1998). The olfactory organs are found in pits on the anterior portion of the head. The epithelium within the olfactory chambers is arranged in a series of lamellae that form the olfactory rosette. Both sensory and nonsensory cells are found in the epithelium. The nonsensory cells serve to protect the sensory cells and transport chemical stimuli. Ciliated and microvillous receptor cells have been noted in fish. These cells are innervated by the olfactory nerve, which provides input to the olfactory bulb. The receptor cells are responsive to amino acids, bile acids, gonadal steroids, and prostaglandins (Byrd and Caprio, 1982; Caprio and Byrd, 1984; Chang and Caprio, 1996; Ohno et al., 1984; Sato and Suzuki, 2001). A variety of alcohols, amines, carboxylic acids, nucleotides, and hydrocarbons

Downloaded From Vet-eBooks.com

can also elicit olfactory responses (Kolesnikov and Kosolapov, 1993; Rolen et al., 2003). Specific receptor proteins in sensitive cells are thought to be responsible for initial olfactory responses. These receptors initiate second-messenger-mediated signal transduction pathways that open ion channels and lead to the production of action potentials (Bond, 1996; Sorenson and Caprio, 1998).

Basic Mechanisms of Neurotoxicity

Before considering some mechanisms of neurotoxicity in adult fish, it is important to remember that neurotoxic compounds are also likely to have developmental effects. In particular, the potency and mode of action of neurotoxic compounds may be dramatically altered during maturation of the nervous system. To underscore the importance of this concept, compounds with adverse effects on the immature nervous system are categorized as developmental neurotoxicants.

It is widely accepted that the developing nervous system is particularly susceptible to some neurotoxic compounds (Costa et al., 2004; Mendola et al., 2002; Stein et al., 2002). This assertion is based largely on the fact that neurotoxicant exposures having little to no effect on the mature nervous system may produce significant and lasting effects on the developing nervous system. Several processes critical for proper nervous system structure and function, including neuronal specification, migration, and synaptogenesis, all occur *in ovo*. Furthermore, several neurotransmitters have developmental roles that are distinct from their synaptic roles (e.g., acetylcholine) (Lauder and Schambra, 1999). Disruptions in any of these processes or neurotransmitters may have unique effects during development that are not seen in the mature nervous system and are potential mechanisms of developmental neurotoxicity.

In the mature nervous system, neurotoxic mechanisms of action can be associated with a variety of unique anatomical and physiological characteristics of the nervous system (Anthony et al., 1996; Philbert et al., 2000). Many aspects of the mammalian nervous system contribute to its vulnerability: maintenance of the blood–brain or blood–nerve barrier, high energy requirements, high lipid environment, complex spatial geometry, and the need for rapid transmittal of information between cells. Because the structural and functional aspects of neurons are highly conserved, the framework proposed by Anthony and coworkers (1996) for understanding mechanisms of neurotoxicity, as well as the manifestations of toxic effects, is relevant and briefly reviewed.

In terms of xenobiotic exposure, the central and peripheral nervous system are unique in that tissue and cellular attributes minimize the transport of potentially toxic compounds to sites of action. The restricted interfaces between the blood and many components of the nervous system have been termed as barriers: the blood–brain barrier encloses the central nervous system, and the blood–nerve barrier encloses the peripheral nervous system. The basis for the blood–brain barrier is that the endothelial cells lining the vasculature of the brain have extremely tight intercellular junctions. As a consequence, to gain access, xenobiotics are required to diffuse through these cellular barriers. The lipid-rich myelin surrounding axons, which is critical for insulating the nerve and ensuring rapid propagation of action potentials, may provide a barrier to hydrophilic xenobiotics. In general, the more hydrophilic the compound, the less likely it will cross one of these barriers; however, some hydrophilic compounds may gain access by piggybacking on specific transporters that are present in these barriers. Oligodendrocytes and Schwann cells found in the central and peripheral nervous systems, respectively, are responsible for maintaining the myelin sheaths that exclude water and ions from the axons and for minimizing extracellular spaces. A wide variety of specialized proteins must be synthesized and complex lipid metabolism must be maintained to support the myelin environment. Neurons also need to maintain ion gradients to support neuronal transmission. These maintenance activities require a high aerobic metabolic rate. As a consequence, the nervous system requires high levels of oxygen and glucose to maintain homeostatic ion gradients and to restore ion gradients after depolarizations.

Finally, the unique spatial arrangement of the nervous system makes it vulnerable to toxic insults. The nervous system is comprised of relatively large cells as the result of evolutionary pressures to establish high-speed intracellular communication; consequently, axon volumes are typically much greater than those of the cell bodies and have a unique demand for macromolecule synthesis. The cell body of each neuron synthesizes everything that is needed by the rest of the cell (axons and dendrites); these

Downloaded From Vet-eBooks.com

products are then transported throughout the cell to replenish cellular constituents. In addition, spent cellular constituents are transported retrogradely from the processes to the cell body. The retrograde transport also contains biochemical information related to the status of the environment in the distal portion of the neuron. Spatial arrangement of the nervous system also requires maintenance of the transmission of electrical pulses along the length of axons and across the synapses between neurons. Maintenance of both intracellular and extracellular communication is, of course, essential to the proper function of the nervous system.

In conclusion, the nervous system has a variety of unique structural characteristics that meet the need for rapid cellular communication. These unique structural characteristics are primarily associated with maintaining the integrity of the cell body and axon and the ability of the nerves to support propagation of action potentials and synaptic transmission. Xenobiotics capable of disrupting ion channels that are essential to maintaining and supporting proper ion balances or capable of disrupting chemical transmission of potentials across synapses are capable of causing neurotoxic effects. As discussed previously, the maintenance of aerobic respiration, high rates of protein and lipid synthesis, and extensive transport of synthetic products from the cell body to the axon are critical for maintaining structural and functional characteristics of the nervous system. Consequently, xenobiotics capable of disrupting neuron-specific synthetic and metabolic pathways, modifying the products of these reactions, or inhibiting or uncoupling aerobic metabolism can elicit adverse effects specific to the nervous system. It is interesting to note that some fish species have evolved specific metabolic strategies for anoxic conditions. Research suggests that anoxic-tolerant species may have decreased levels of excitatory neurotransmitters and increased levels of inhibitory transmitters in the brain that enable metabolic depression (Van Ginneken et al., 1996).

Manifestations of Neurotoxicity in Fish

Neurotoxic effects of chemicals are assessed by quantifying structural and functional responses at the subcellular to organismal levels of biological organization. Functional observations at the organismal and cellular levels can provide insights concerning potential sites and modes of action, while cellular and biochemical responses can provide insights on molecular mechanisms of action. Cellular and biochemical investigations can be used to identify neurotoxic potential, characterize the nature of neurological effects, and determine the mechanisms by which chemicals produce neurotoxic effects (Tilson, 1996). A significant challenge in developing investigative methods and associated bioassay techniques lies in linking neuromorphological, neurochemical, and neurophysiological alterations with functional (i.e., behavioral) observations (NRC, 1992). Many chemically induced biochemical, physiological, or morphological perturbations have been reported in cellular and organismal systems, but consequent behavioral effects on organism have not been established. Because behavioral responses are an integration of biochemical, physiological, and morphological processes, linking behavioral observations to these types of observations can provide the needed bridge between subcellular and cellular responses and ecological consequences (Little, 1990). Examples where chemically induced biochemical, physiological, or morphological perturbations have been mechanistically linked to ecologically relevant behavioral responses in fish are limited.

Structural Manifestations of Neurotoxicity in Fish

As discussed previously, dynamic interactions between the neuronal cell body and the axon are critical to maintaining proper neuronal structure and function. Disruption of these interactions can result in a variety of pathologies. Neuronopathies result from toxicants capable of causing injury to the cell body followed by degeneration of the remaining cell processes. Neuronal loss is typically permanent and is manifested by global symptoms or dysfunctions consistent with the specific nervous tissue target; for example, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) causes neuronopathies in mammals through its cytotoxic dihydropyridium ion metabolite. Similar observations have been reported in fish

Downloaded From Vet-eBooks.com

(Poli et al., 1990; Pollard et al., 1992). Axonopathies are associated with toxicants whose primary site of action is the axon, causing degeneration of the axon along with surrounding myelin. Because the nerve cell body is not affected, recovery and regeneration of the axon are possible. The effects of neurotoxicants capable of eliciting axonopathies are sometimes described as causing chemical transections of the nerve (e.g., acrylamide, carbon disulfide, some diketones, and certain classes of organophosphorus esters). Likewise, compounds disrupting microtubles (such as colchicine) will perturb axonal transport and thereby cause pathology. Myelinopathies are associated with compounds capable of causing intramyelinic edema, such as hexachlorophene (Kinoshita et al., 2000; Yoshikawa, 2001). Hexachlorophene-induced myelinopathies have also been reported in non-mammals (Reier et al., 1978). Other compounds are capable of causing the selective destruction of the myelin, resulting in neuronal demyelination. These responses may be due to effects on the myelin itself or due to effects on the myelinating cells.

Physiological Manifestations of Neurotoxicity in Fish

Electrophysiology

Electrophysiological techniques measure electrical potentials and the transmission of impulses in the nervous system. These techniques can be applied to *in vitro* or *in vivo* preparations and used to assess responses of the brain, spinal cord, components of the peripheral nervous system, or sensory systems to determine whether or not a neurotoxic response can be elicited by a xenobiotic. Electrophysiological techniques can be used to determine if a toxicant acts pre- or postsynaptically on specific portions of a fiber or on specific ion channels.

Measurements can be made from the surface of the organism, extracelluarly or intracellularly (Baker and Lowndes, 1986; Eisenbrandt et al., 1994; Fox et al., 1982). Bahr (1972, 1973), for example, reported an *in vivo* method to record evoked electrical activity of the trunk lateral line in surgically prepared rainbow trout (*Oncorhynchus mykiss*) for periods of up to 48 hours. Evans and Hara (1985) described an *in vivo* rainbow trout model to quantify evoked electro-olfactograms, and Kreft and coworkers (1985) described a technique to assess electroretinograms from photostimulated *in vitro* eye preparations. Schafer and coworkers (1995) described an *in vivo* anesthetized catfish (*Ameiurus nebulosus*) preparation to measure spontaneous afferent activity from electroreceptor organs. Several whole-cell and membrane preparations have also been used to study ion channels and the role of specific neurotransmitters in channel function; for example, voltage clamp analysis has been used to study the role of glycine, GABA, and *N*-methyl-D-aspartate (NMDA) in isolated lamprey spinal cord neuron function and to identify calcium channel subtypes in lamprey sensory and motorneurons (Baev et al., 1992; El Manira and Bussieres, 1997; Moore et al., 1987).

To date, most electrophysiological techniques applied to fish involved *in vitro* models or surgically invasive approaches use restrained or anesthetized animals. Although these methods yield data regarding cellular and molecular mechanisms of neurotoxic action, disruption of the nervous system or sensory organs can make it difficult to study behavioral outcomes of perturbed neurological function. Two laboratories (Carlson et al., 1998; Featherstone et al., 1991, 1993) have described an approach relating electrophysiological responses to a defined behavioral endpoint. In these studies, the electrophysiological responses of Mauthner cells, motorneurons and interneurons, and white musculature to an invoked startle response were measured *in vivo* in unanesthetized, freely moving larval fish. These waveforms are easily triggered and recorded, yielding stereotypical and reproducible results.

Respiratory–Cardiovascular

The effects of toxicants on the central or peripheral nervous system can elicit a wide variety of integrated respiratory–cardiovascular responses. In turn, these responses can be evaluated to determine the extent to which they can be associated with specific mechanisms of neurotoxic action. For example, several studies have demonstrated that specific suites of respiratory–cardiovascular responses of spinally transected rainbow trout (*Oncorhynchus mykiss*) were sufficient to differentiate effects associated with industrial organic chemicals whose sites and mechanisms of action are distinct, including narcotics,

acetylcholinesterase inhibitors, pyrethroid insecticides, cyclodiene insecticides, and strychnine (Bradbury et al., 1991a; Bradbury and Coats, 1989; Bradbury et al., 1991b; McKim et al., 1987). More specifically, distinct suites of effects on cough frequency, ventilation frequency, ventilation volume, oxygen consumption, and arterial blood oxygen, carbon dioxide, pH, hemoglobin, and hematocrit were associated with the different compound classes studied. Furthermore, these respiratory–cardiovascular responses were consistent with the neurodepressant, stimulant, or convulsant mechanisms of action of the xenobiotics studied.

Behavioral

The behavior of a fish reflects the integrated output of the nervous system at the organismal level in response to stimuli perceived in the environment. The extent to which these chemically induced behavioral changes are ecologically relevant must be considered in terms of adverse effects on an organism's ability to survive and reproduce. Behavioral endpoints can be categorized as individual or interindividual responses (Rand, 1985). Individual responses include undirected and directed locomotion and feeding. Undirected locomotion refers to the movement of an animal that is not related to the intentional placement of a stimulus. The direction of undirected locomotion is considered random. This spontaneous activity can be affected by neurotoxicants and described with a variety of qualitative descriptors (Heath, 1995). Although such observations may be difficult to interpret, Drummond and Russom (1990) demonstrated that a behavioral response checklist could be used to categorize toxicants with known modes of action within specific syndromes. Heath (1995) and Rand (1985) also summarized a variety of experimental approaches whereby fish locomotion responses can be quantitatively measured following exposure to a wide variety of organic and inorganic neurotoxicants; for example, undirected locomotion can be quantified by measuring water currents created by the movement of fish or by measuring voltage changes in the water caused by swimming fish. The use of photoelectric gates and video cameras to quantify swimming speed and exploratory activity has also been described.

Directed locomotion refers to movement in response to specific external stimuli. The ability of a fish to swim with or against a water current (negative and positive rheotaxis) is a commonly studied forced locomotive response. The directed movement of fish due to avoidance or attractiveness to xenobiotics or natural chemical stimuli has also been examined in some detail (reviewed in Hara et al., 1983; Heath, 1995). Chemosensory disruption can result in overt preference or avoidance to a xenobiotic. Avoidance of or preference to natural and xenobiotic chemical cues during or following xenobiotic exposure can also occur. Disruption in normal locomotion can be quantified by observing movements of an organism across chemical gradients. The locomotion of a fish in response to a xenobiotic is likely the result of interactions with the olfactory or gustatory receptors; however, avoidance can also be the result of irritation of mucous membranes. The ability of a xenobiotic to mask or counteract natural chemical signals used in migration, for example, may be the consequence of competition for receptor sites on sensory cell membranes. Alternatively, the xenobiotics may be directly toxic to receptor cells (Hara et al., 1983). As reviewed by Heath (1995), a wide variety of xenobiotics, including metals, petroleum constituents, detergents, and insecticides, have been observed to depress fish feeding rates. This depression may be associated with effects on olfactory, gustatory, visual, or lateral line receptors or effects on the ability of the central nervous system to integrate environmental stimuli.

Of the interindividual responses, territoriality, dominance, schooling, and predator–prey interactions have been studied most extensively (Heath, 1995; Rand, 1985). Predator–prey interactions have been examined in studies in which either the predator or the prey is exposed to the xenobiotic, as well as in studies where both sets of organisms are exposed. Endpoints in these studies can include prey survival rates, predation rates, or prey handling times. Although effects on predator–prey interactions have been observed for a variety of insecticides, herbicides, and metals, the mechanistic basis for these effects is largely unknown. The need to understand fully the basis of xenobiotic effects on predator–prey interactions has been well articulated by Sandheinrich and Atchison (1990). In this regard, Carlson and coworkers (1998) reported an attempt to relate the effects of a wide variety of organic xenobiotics on prey survival in terms of electrophysiological responses of the Mauthner-cell-mediated startle response, which initiates an escape behavior in response to predation.

Examples of Major Classes of Neurotoxicants

Narcotics

Research reported during the early 1980s in both the United States and The Netherlands established that the majority of industrial organic chemicals (excluding pesticides and pharmaceutical agents) elicit acute toxic effects in fish through a narcosis mechanism (Konemann, 1981; Veith et al., 1983). Narcosis can be defined as a *reversible* state of arrested activity of protoplasmic structures resulting from exposure to a xenobiotic. In the context of the intact organism, the terms *narcosis* and *general anesthesia* are commonly used interchangeably (Bradbury et al., 1989). Although typically described in the literature as a nonspecific mode of action, the actual mechanism of narcosis and anesthesia remains unknown and is an active area of research, as discussed in several reviews (Århem et al., 2003; Bradbury et al., 1989; Franks and Lieb, 1990, 1994; Franks and Lieb, 2004; Narahashi et al., 1998; Pryor, 1995).

Mechanisms of Narcotic Neurotoxicity

Both lipophilicity (Meyer–Overton rule) and thermodynamic activity (Ferguson's rule) (Ferguson, 1939) have been demonstrated to be related to the narcotic potency of chemicals. Thus, varying aqueous concentrations of different compounds may be required to cause comparable effects, even though their thermodynamic activity at the site of action is proposed to be the same. There is, however, ample evidence of narcotics and anesthetics whose potency is not consistent with thermodynamic theory. These departures from thermodynamic consistency suggest that sometimes potency must be viewed as a more complex toxicological and physicochemical interaction between the xenobiotic and a site of action. As a result, investigators developing hypotheses to explain the molecular events of anesthesia/narcosis are increasingly acknowledging that their models must accommodate the likelihood of multiple sites and mechanisms of action (Bradbury et al., 1989; Franks and Lieb, 1990, 1994; Franks and Lieb 2004; Miller 2002; Narahashi et al., 1998; Pryor 1995). Within the last 10 years, it has become increasing apparent that anesthesia-like compounds interact directly and specifically with proteins, most notably proteins that form ion channels (Århem et al., 2003; Franks and Lieb, 1990, 1994, 2004; Narahashi et al., 1998).

Franks and Lieb (1990, 1994, 2004) proposed that anesthesia is the result of direct interactions between xenobiotics and neuronal ion channels. This hypothesis evolved partly from x-ray diffraction experiments undertaken by these investigators showing insignificant changes in lipid membrane bilayers at physiologically relevant concentrations of narcotic xenobiotics (although see the study by Cantor, 1997). Subsequent studies with firefly luciferase established that inhibition of luciferase activity correlated with anesthetic potency and that the sites of action can have polar and nonpolar characteristics. These investigators also demonstrated that narcotics caused reversible inhibition of specific, spontaneously firing neurons in the giant snail. This inhibition was saturable and consistent with binding to a receptor site. While the specific proteins associated with narcosis have yet to be identified, an implication of this hypothesis is that classes of receptors, or receptor sites, with varying hydrophobic and hydrogen-bonding characteristics may be involved. Differential effects on target proteins, or proteins in different neuron classes, could provide an explanation for different narcosis/anesthetic effects observed at the cellular through organismal level (Bradbury et al., 1989).

In conclusion, hypotheses developed to date provide implicit or explicit basis for attributing narcosis to more than one site of action or mechanistic process. In general, all of the hypotheses attribute narcosis to neuronal dysfunction ultimately caused by changes in the properties of neuronal ion channels, which are beginning to be identified (reviewed in Århem et al., 2003).

Manifestations of Narcotic Neurotoxicity in Fish

With the development of initial acute toxicity datasets for industrial organic chemicals, it was established that the potency of narcotics in fish was dependent on the hydrophobicity of a xenobiotic (Konemann, 1981; Veith et al., 1983). Subsequent experimental studies and modeling efforts have led to general acceptance that the relationships between hydrophobicity and lethality represent the minimum, or

baseline, toxicity that a compound can elicit in the absence of a more specific mode of toxic action. With additional study it became clear that there are subclasses of narcotics, more potent than would be predicted from baseline narcosis, that could be classified on the basis of either acute potency or physiological and behavioral characteristics of the narcosis response. More specifically, narcosis induced by certain esters, phenols, and anilines (typically termed polar narcotics) seemed to be unique (Bradbury et al., 1989).

Behavioral and gross morphological signs of stress in fathead minnows (*Pimephales promelas*) associated with acutely lethal aqueous exposures to baseline narcotics include depressed locomotor activity with little or no response to outside stimuli. Body color also becomes darker as fish are increasingly intoxicated. Most fish die within 24 hours, but effects are reversible if fish are transferred to "clean" water prior to death. In contrast, acutely lethal concentrations of polar narcotics with log octanol–water partition coefficients below 2.7 elicit hyperactivity and usually overreaction to outside stimuli for 24 to 48 hours, with subsequent depression and death (Drummond and Russom, 1990). Medaka (*Oryzias latipes*) larvae exposed to phenol and 1-octanol at levels 2 to 3 times lower than acutely lethal concentrations were more susceptible to predation by bluegill (*Lepomis macrochirus*) than were unexposed fish (Carlson et al., 1998).

To evaluate further the symptomology of narcosis in fish, researchers (Bradbury et al., 1989; McKim et al., 1987) examined the respiratory–cardiovascular responses of spinally transected rainbow trout (*Oncorhynchus mykiss*) to baseline narcotics (1-octanol and MS-222) and polar narcotics (phenol, 2,4-dimethylphenol, aniline, 2-chloroaniline, and 4-chloroaniline). The responses of the trout exposed to these groups of compounds were distinct. The overall response to the baseline narcotics was a dramatic slowing of all respiratory–cardiovascular functions. While ventilation volume and oxygen consumption decreased, oxygen uptake efficiency increased as water flow over the gills slowed and the blood-to-water perfusion ratio increased. A rapid drop in heart rate (reflex bradycardia) was thought to be related to an increase in vagal tone caused by hypoxia. As respiration rate declined, total arterial blood oxygen and pH also decreased. The associated increase in hematocrit, caused by red blood cell swelling, is well documented during anesthesia and is associated with hypoxia. These effects are reversible, as demonstrated by experiments in which fish at the point of respiratory failure could be revived if clean water was perfused across the gills.

In general, the respiratory–cardiovascular symptoms associated with baseline, or nonpolar narcosis, are consistent with depressant anesthesia as described by Winters (1976). The most striking feature associated with exposure of rainbow trout (*Oncorhynchus mykiss*) to lethal aqueous concentrations of polar narcotics was the development of tremors and clonic seizures that were initiated by coughs (Bradbury et al., 1989). These tremors and seizures originated in the head and moved posteriorly to include the tail, even though the fish were spinally transected. These observations suggest that polar narcotics affect the spinal cord posterior to the transection, or perhaps the peripheral nervous system. In mammals, the primary site of phenol stimulation is thought to be the spinal cord (Deichmann and Keplinger, 1981). With increasing length of exposure, seizure intensity subsided, and the fish became unresponsive to outside stimuli. Consistent with the increased activity associated with seizures and muscular activity, oxygen uptake initially increased, yet ventilation volume and frequency eventually declined which is more consistent with a general depressant effect. Depressions of arterial blood oxygen, carbon dioxide, and pH and an associated increased hematocrit were consistent with a shift to anaerobic metabolism during seizures and subsequent respiratory failure. Fish could be revived by artificially irrigating the gills. The responses of fish to polar narcotic exposure are generally consistent with the description of cataleptic anesthesia (Winters, 1976).

Carlson and coworkers (1998) investigated the sublethal effects of 1-octanol and phenol on *in vivo* electrical impulses generated within the Mauthner cells and associated interneurons, motorneurons, and axial musculature during the startle response reflex in larval medaka (*Oryzias latipes*). With 1-octanol, electrical waveforms were depressed at exposure concentrations 5 times lower than the 48-hour LC_{50}, and the ratios of startle responses to stimuli were significantly depressed. These observations are suggestive of a sensory deficit due to an anesthetic-like effect. Phenol caused a significant decrease in the motorneuron-to-muscle delay, consistent with the initial hyperactivity and sensitivity noted in exposures to polar narcotics and reports that phenol stimulates the mammalian spinal cord (Deichmann

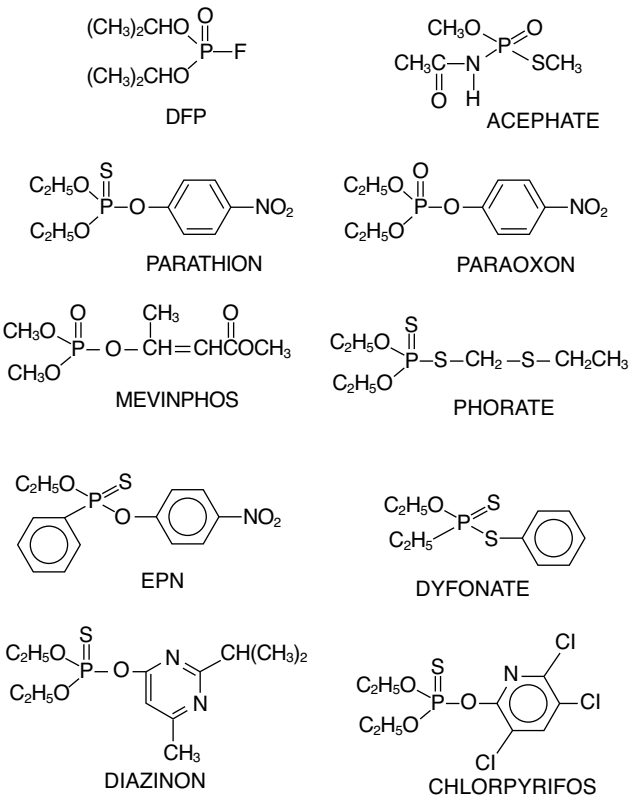

FIGURE 9.3 Examples of organophosphorus insecticides.

and Keplinger, 1981). These electrophysiological studies generally support other toxicodynamic and behavioral studies that suggest baseline and polar narcotics act through different mechanisms or sites of action.

Cholinesterase Inhibitors

Several neurotoxic compounds are known to target the cholinergic nervous system. By far the largest classes are the organophosphorus and carbamate compounds. Organophosphorus and carbamate compounds have been used extensively as insecticides, herbicides, and fungicides. Initial studies on the synthesis and activity of organophosphorus insecticides were undertaken in Germany during the 1930s. Agricultural use of insecticidal organophosphorus and carbamates increased in the 1960s as the use of organochlorine compounds declined. In the United States, use of organophosphorus insecticides peaked in the mid-1970s and has declined with increased use of pyrethroid and carbamate insecticides. Insecticidal carbamates were first introduced in 1954 and are still employed for agricultural and household applications (Abou-Donia, 1995; Metcalf, 1995).

Organophosphorus insecticides are organic phosphoric ester compounds with the general structure of $R_1P(=Y)(R_2)X$, where Y is an oxygen or thio group, X is a leaving group (e.g., halide, phenoxy, or other group), and R_1 and R_2 are typically alkyl, alkoxy, aryl, or aryloxy substituents. Representative structures of organophosphorus insecticide classes are depicted in Figure 9.3. Carbamate insecticides are organic compounds that contain a RNC(=O)O moiety; examples of common *N*-methylcarbamate and *N*-methylcarbamoyl oximes are provided in Figure 9.4. While organophosphorus and carbamate insecticides are structurally diverse, their common neurotoxic mechanism is related to their ability to phosphorylate or carbamylate esterases.

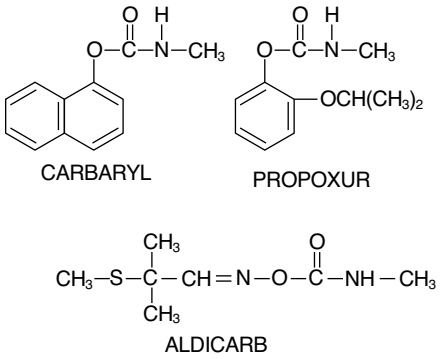

FIGURE 9.4 Examples of *N*-methylcarbamate (carbaryl and propoxur) and *N*-methylcarbamoyl oxime (aldicarb) carbamate insecticides.

Mechanisms of Cholinesterase Inhibitor Neurotoxicity

The neurotoxic mechanism for organophosphorus and carbamate insecticides is inhibition of acetylcholinesterase (AChE) in the CNS and PNS (Figure 9.5) (reviewed in Ecobichon, 1996; Taylor, 2001). AChE is responsible for hydrolyzing the neurotransmitter acetylcholine; inhibition of the esterase causes accumulation of acetylcholine in synapses and excessive stimulation of muscarinic and nicotinic receptors (Figure 9.5B). Increased levels of acetylcholine overstimulate nicotinic and muscarinic receptors in the CNS, PNS, and neuromuscular junctions, causing a wide range of signs of poisoning. These signs may include changes in body temperature, heart rate, blood pressure, muscle twitching, or tremors. Death, although rare, is usually due to cessation of respiration due to anticholinesterase effects in both the CNS and PNS. Although organophosphates and carbamates both target acetylcholinesterase, nicotine acts as a direct cholinergic agonist rather than by cholinesterase inhibition; nicotine directly binds nicotinic receptors to hyperstimulate cholinergic neurons.

Both organophosphosphorus and carbamate compounds inhibit AChE activity by acting as pseudosubstrates. Unlike the natural substrate, these compounds remain in the active site of the enzyme for much longer periods of time, thereby preventing the enzyme from hydrolyzing its natural substrate, acetylcholine (Aldridge and Reiner 1969). Inhibition of AChE activity by organophosphorus insecticides is primarily a function of the electrophilicity of the phosphorus atom, with increased electrophilicity (increased partial positive charge) associated with greater rates of bonding to the negatively charged oxygen in the serine hydroxyl group. Thus, for organophosphorus insecticides, the binding of the organophosphorus compound to AChE is reasonably fast. The hydrolysis of the organophosphorus esters, however, is very slow, leading to an accumulation of phosphorylated AChE. Phosphorylated AChE is, for all practical purposes, irreversibly inhibited due to the very low reversibility of the enzyme activity.

Recovery of active AChE activity is dependent on the synthesis of new enzyme. In some cases, phosphorylated enzymes undergo an aging reaction when an alkoxy or aryloxy R group is dealkylated or dearylated and results in a negatively charged monoalkyl or aryl enzyme. In such instances, the hydrolysis step is no longer possible; thus, the enzyme is irreversibly altered. Kinetic studies on the inhibition of AChE activity, including aging and recovery, have been reported in a variety of fish species (Carr et al., 1995; Johnson and Wallace, 1987; Straus and Chambers, 1995; Wallace and Herzberg, 1988). Typically, recovery of AChE activity in fish is slower than that observed in mammals.

Inhibition of AChE activity by carbamate insecticides is a function of the carbamylation of the enzyme. The kinetics of this inhibition are slightly different from that observed with organophosphorus insecticides. Hydrolysis of carbamates (i.e., decarbamylation), while significantly slower than that observed for acetylcholine, is much more rapid than that observed with most organophosphorus compounds; thus, although AChE inhibition elicited by an organophosphorus pesticide is, in effect, irreversible, carbamate inhibition of esterase activity may be reversed. Furthermore, aging of the carbamylated enzyme does not occur.

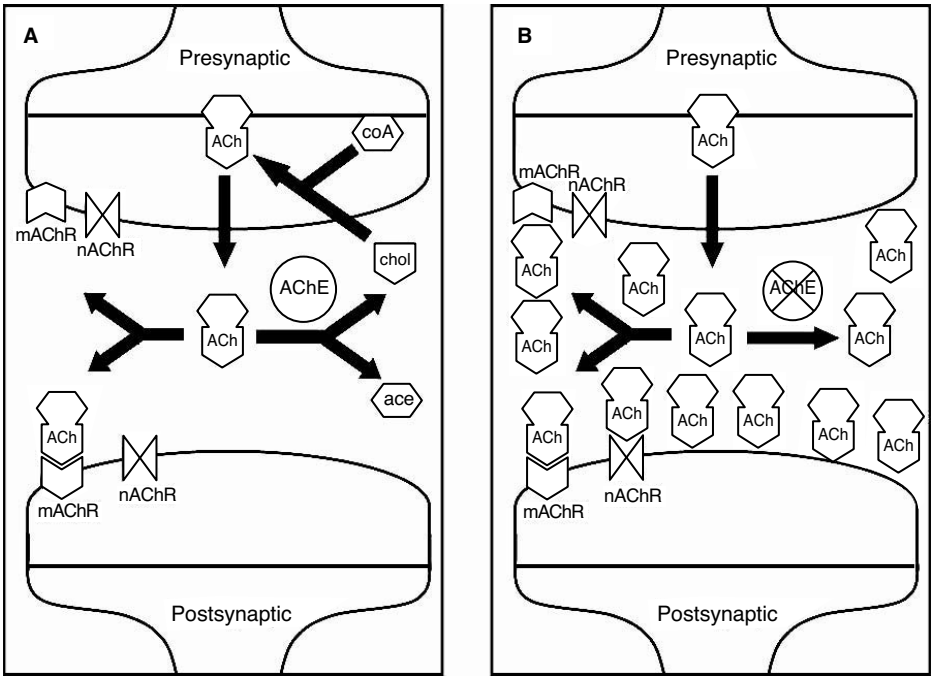

FIGURE 9.5 Role of acetylcholinesterase at synaptic junctions. (A) Typical cholinergic synapse. Acetylcholine is secreted by the presynaptic neuron into the synapse, where it binds to presynaptic and postsynaptic muscarinic and nicotinic receptors. Acetylcholinesterase breaks down acetylcholine into cholinesterase and acetylcholine. Cholinesterase is transported to the presynaptic neuron, where acetyl coenzyme A converts it into acetylcholine. (B) Effect of acetylcholinesterase inhibitors on cholinergic synapses. Acetylcholine is secreted into the synapse but is not broken down by acetylcholinesterase, leading to an excess amount of acetylcholine in the synapse. ACh, acetylcholine; AChE, acetylcholinesterase; mAChR, muscarinic receptor; nAChR, nicotinic receptor; chol, cholinesterase; coA, acetyl coenzyme A; ace, acetate.

Interestingly, although anticholinesterase compounds all disrupt acetylcholine signaling, all anticholinesterase compounds do not produce identical responses to poisoning (reviewed in Pope, 1999). Acetylcholine signaling disruption is the first step in the acute neurotoxic response but is not sufficient to explain all manifestations of toxicity. Several secondary, non-acetylcholinesterase targets have been recognized (Casida and Quisad, 2004; Pope, 1999) and are thought to play instrumental roles in the ultimate effects of cholinergic neurotoxicants. Furthermore, disruption of acetylcholine signaling alone may not fully explain the developmental neurotoxicity of these compounds. Careful consideration should be given to the non-cholinergic targets of these compounds when assessing toxicity, particularly in the developing embryo. As shown in Figure 9.5A, the biochemical mechanisms of acetylcholine production, secretion, and transmission are known in great detail. For the purposes of this discussion, only acetylcholine pathway components targeted by cholinergic agonists are addressed.

Manifestations of Cholinesterase Inhibitor Neurotoxicity in Fish

Brief exposures to organophosphorus pesticides can produce long-lasting neurological effects because of the irreversibility of AChE inhibition; in fact, depression of AChE activity is considered a primary indicator of organophosphate pesticide exposure in fish. As a result, the extensive research in fish neurotoxicity has sought to correlate acute toxicity in adult fish with level of acetylcholinesterase inhibition (Heath, 1995; Murty and Ramani, 1992; Zinkl et al., 1991). Based on work in several different fish species and with several cholinergic poisons, it is generally accepted that 70 to 80% AChE inhibition is lethal.

Acute exposures to organophosphorus and carbamate insecticides, in a variety of species including goldfish (*Carassius auratus*), fathead minnows (*Pimephales promelas*), medaka (*Oryzias latipes*), and rainbow trout (*Oncorhynchus mykiss*), increased spontaneous locomotor activity with high incidences of

convulsions, spasms, tetany, scoliosis, lordosis, and hemorrhage in the vertebral column, presumably due to damage resulting from spasms (Bradbury et al., 1991a,b; Drummond and Russom, 1990; McKim et al., 1987; Rice et al., 1997; Saglio et al., 1996). Organophosphorus and carbamate insecticides have variable effects on cough rate. Chlorpyrifos (Bradbury et al., 1991a) and fenitrothion (Klaverkamp and Hobden, 1980) have been reported to increase cough response in rainbow trout, while malathion, carbaryl (McKim et al., 1987), and acephate (Klaverkamp and Hobden, 1980) did not. Increased cough rate, however, is not thought to be associated with AChE inhibition (Klaverkamp and Hobden, 1980). Spinally transected rainbow trout exposed to chlorpyrifos exhibited increased defecation and bile loss from the anal opening, consistent with muscarinic effects of AChE inhibition (Bradbury et al., 1991a).

In spinally transected rainbow trout (*Oncorhynchus mykiss*) exposed to carbaryl, malathion (McKim et al., 1987), or chlorpyrifos (Bradbury et al., 1991a), decreased heart rate, decreased gill oxygen uptake efficiency, and increased ventilation volume were observed. Decreased heart rate has been attributed to inhibition of the heart by the vagus nerve (cranial nerve X) through cholinergic synapses. Decreased oxygen uptake by the gills and a compensatory increase in ventilation volume have been proposed to be caused by continuous stimulation of neuromuscular junctions associated with sphincters at the base of the efferent filamental arteries to secondary lamellae of the gill. The resulting vasoconstriction is thought to reduce blood flow to the lamellae, effectively reducing respiratory surface area and oxygen uptake efficiency (McKim et al., 1987; Pavlov, 1994).

Despite the wealth of acute toxicity data, relatively little is known about the developmental neurotoxicity of cholinergic agonists in fish. Existing data demonstrate that exposure either *in ovo* or as juvenile fish has detrimental consequences on learning and motorneuron development. Chlorpyrifos exposure produced hypoactivity in zebrafish (*Danio rerio*) hatchling swimming behavior (Levin et al., 2004). In addition, developmental chlorpyrifos exposure of zebrafish embryos has long-term effects on learning. Adult zebrafish exposed to chlorpyrifos during development show reduced choice accuracy and spatial discrimination (Levin et al., 2003). Behavioral effects have been seen in juveniles of other fish species as well. At concentrations of carbaryl or chlorpyrifos up to 10 times lower than 48-hour LC_{50} values, larval medaka (*Oryzias latipes*) were more susceptible to predation, although a consistent dose–response relationship between carbaryl exposure and susceptibility to predation was not observed (Carlson et al., 1998). *In vivo* electrophysiological studies of sublethal chlorpyrifos and carbaryl effects on the Mauthner cell startle response in larval medaka (Carlson et al., 1998) demonstrated an effect on neuromuscular junctions, as evidenced by a dose-related increase in the ratio of startle response to stimuli. An increase in motorneuron to muscle delay with increased exposure concentration was also noted. Both responses are consistent with AChE inhibition in the neuromuscular junction.

Interestingly, evidence from zebrafish (*Danio rerio*) suggests that AChE inhibition may not be the sole mechanism of developmental neurotoxicity. Developmental exposure to nicotine causes morphological changes in zebrafish hatchlings and impairs the swimming behavior and escape response (Svoboda et al., 2002). Using an *Islet1*-GFP transgenic zebrafish strain, nicotine was shown to delay development of spinal neurons and cause disruptions in axonal pathfinding of secondary motorneurons by nicotinic receptor activation (Svoboda et al., 2002). The molecular mechanism of developmental neurotoxicity remains unidentified for the majority of cholinergic agonists.

Pyrethroid Insecticides

Directed synthesis has produced insecticides derived from the natural pyrethrin esters of pyrethrum flowers (e.g., *Chrysanthemum cinerariifolium*) (Shafer et al., 2005). These synthetic, pyrethroid insecticides have greater stability in light and air than the natural pyrethrin esters yet maintain critical stereochemical characteristics required for alignment with target receptors (Soderlund et al., 2002). The synthetic pyrethroids are divided into two classes based on the presence or absence of a cyano group on the alpha carbon of the 3-phenoxybenzyl alcohol moiety (Figure 9.6). Type II pyrethroids all contain an α-cyano side group, while type I pyrethroids do not. Because of their potent insecticidal activity, low mammalian and avian toxicity, and varying levels of environmental stability (Bradbury and Coats, 1989; Clark, 1995), synthetic pyrethroids represent nearly 23% of the U.S. dollar value of the world insecticide market (Soderlund et al., 2002).

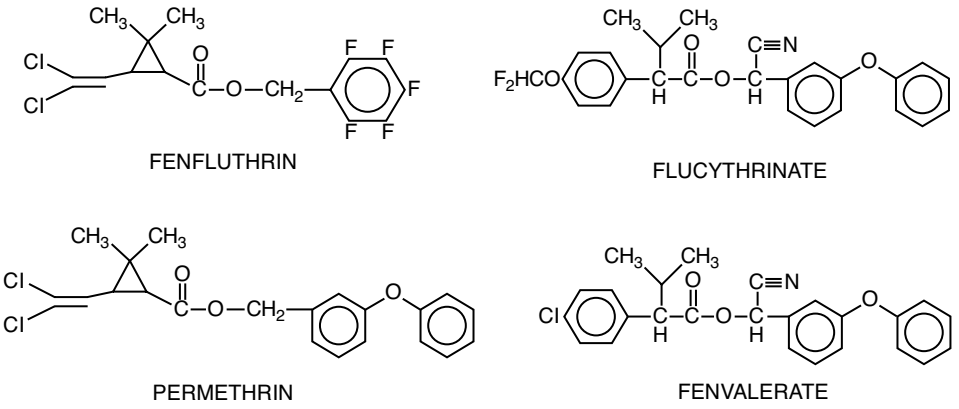

FIGURE 9.6 Examples of type I (fenfluthrin and permethrin) and type II (fenvalerate and flucythrinate) pyrethroid insecticides.

Mechanisms of Pyrethroid Neurotoxicity

In both mammals and insects, the primary mechanism of acute synthetic pyrethroid neurotoxicity is disruption of voltage-sensitive sodium channels (VSSCs) (Clark, 1995; Narahashi, 1992; Shafer et al., 2005; Soderlund et al., 2002). Mammalian VSSCs consist of a single α subunit and two β subunits (Shafer et al., 2005). The α subunit forms the channel pore, and the β subunits modify channel properties and membrane location (Figure 9.7A). Pyrethroid insecticides bind the α subunit and disrupt sodium regulation (Figure 9.7B,C). Type I pyrethroid insecticides prolong VSSC opening, allowing more sodium to cross the membrane and leading to repetitive firing of action potentials. Conversely, type II pyrethroids delay VSSC inactivation, resulting in a depolarization-dependent block that prevents action potential generation (Shafer et al., 2005; Soderlund et al., 2002). Although the primary mechanism of acute pyrethroid neurotoxicity is disruption of VSSCs, evidence suggests that numerous secondary sites and mechanisms of action are possible (Soderlund et al., 2002); for example, deltamethrin and resmethrin are toxic to *Paramecium tetraurelia*, although this organism does not have VSSCs (Soderlund et al., 2002). In this case, the synthetic pyrethoids were acting through calcium channels in the cilia membrane of the *P. tetraurelia* (Soderlund et al., 2002). Synthetic pyrethroids have also been shown to affect voltage-gated potassium and chloride channels, as well as ligand-operated channels such as the GABA receptor–ionophore complex, the nicotinic acetylcholine receptor, and the peripheral-type benzodiazepine receptor (Shafer et al., 2005; Soderlund et al., 2002). These effects, however, are usually associated with physiologically unrealistic pyrethroid exposures or nonspecific interactions. Both type I and type II pyrethroids cause repetitive firing in synapses, neuromuscular junctions, and the central nervous system. As a consequence, pyrethroid intoxication has been associated with releases of acetylcholine, GABA, dopamine, and norepinephrine. The type II compounds tend to elicit greater neurotransmitter releases than type I compounds because of enhanced ability to depolarize sensory and presynaptic nerve endings (Clark, 1995). In addition, perturbation of intraterminal calcium homeostasis, ATP-activated calcium sequestration, and responses of protein phosphorylation associated with calcium-dependent neurotransmitter release have also been suggested as playing a role in pyrethroid mode of action. Some of these effects may further accentuate neurotransmitter release caused by repetitive firing (Clark, 1995).

Unfortunately, there is little consensus on which, if any, of the acute neurotoxicity mechanisms are applicable to pyrethroid developmental neurotoxicity (Shafer and Meyer, 2004). Some pyrethroids insecticides show significant age differences in acute toxicity, with younger animals usually being more sensitive. Several studies also demonstrate persistent changes in motor activity, learning, and sexual activity following developmental pyrethroid exposure. None of these effects has been associated with a putative neurotoxic mechanism.

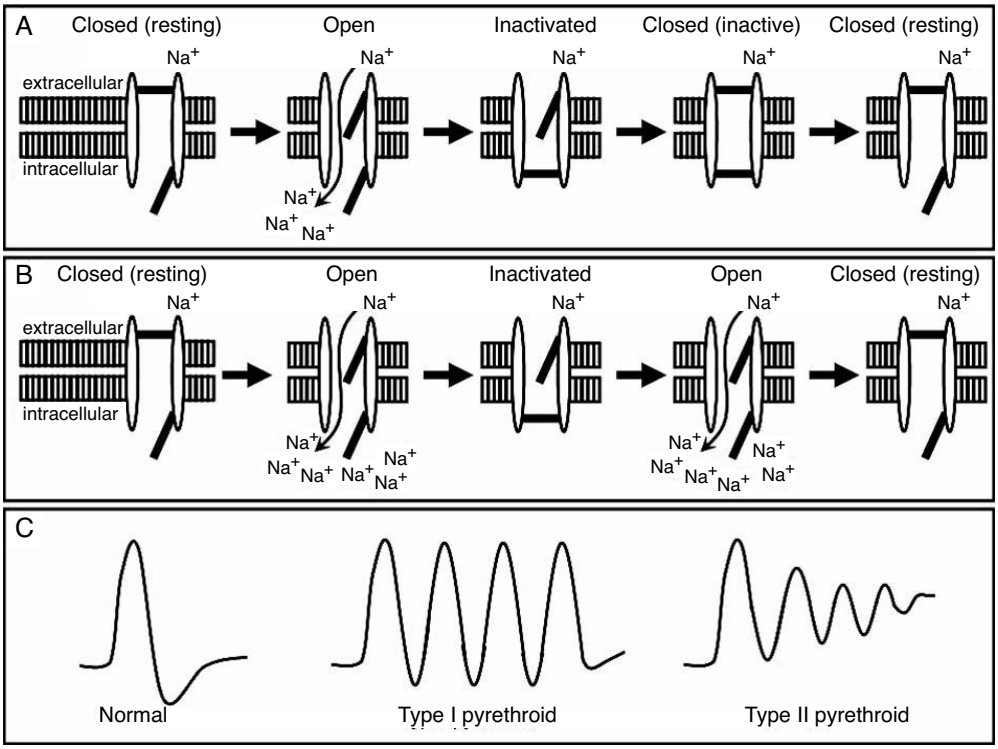

FIGURE 9.7 Effects of pyrethroids on voltage-sensitive sodium channels. (A) Firing cycle of a voltage-sensitive sodium channel (VSSC). At resting potential, the channel is closed to the extracellular environment. In response to a stimulus, the channel opens to allow sodium ions (Na^+) to flow into the cell. When the stimulus has passed, the channel closes the intracellular and extracellular gates to prevent Na^+ influx, ultimately returning to the resting state. (B) Pyrethroids can affect the voltage sensitive sodium channels in two ways. Type I pyrethroids prolong the opening of the sodium channel, leading to repetitive firing of action potentials. Type II pyrethroids prevent closing of the channel to an inactive state. (C) Comparing VSSC action potentials of normal, type I pyrethroid exposures, and type II pyrethroid exposures. Whereas type I pyrethroids lead to repetitive action potentials firings, type II pyrethroids show a gradual reduction in action potential amplitude, although never returning to the resting state.

Manifestations of Pyrethroid Neurotoxicity in Fish

Although synthetic pyrethroids have minimal mammalian and avian toxicity, they are very toxic to fish (Bradbury and Coats, 1989). Because of their high lipophilicity, the synthetic pyrethroids are readily absorbed through the gills (Baser et al., 2003; Polat et al., 2002). Fish lack at least one enzyme that metabolizes pyrethroids, meaning that metabolic turnover is particularly slow (Baser et al., 2003; Tilak et al., 2003). As a result, fish are particularly susceptible to pyrethroids entering the aquatic ecosystem. An extensive amount of research has focused on determining acute toxic dosage in adult fish (Baser et al., 2003; Das and Mukherjee, 2003; David et al., 2004; Polat et al., 2002; Rebach, 1999; Saha and Kaviraj, 2003; Tandon et al., 2005; Tilak et al., 2003; Tripathi and Verma, 2004).

As reviewed by Bradbury and Coats (1989), acute pyrethroid intoxication in small aquarium fish typically causes loss of schooling behavior, followed by hyperactivity, erratic swimming, violent whole-body seizures, and loss of buoyancy. Consistent with the steep dose–response relationships typically observed for pyrethroids, Carlson and coworkers (1998) failed to note significant effects on medaka (*Oryzias latipes*) susceptibility to predation or electrophysiological responses associated with the Mauthner-cell-mediated startle response at sublethal levels. Spinally transected rainbow trout (*Oncorhynchus mykiss*) exhibited an elevated cough rate shortly after exposure (Bradbury et al., 1991a). Increased cough rates were typically associated with an elevated secretion of mucus. Further intoxication resulted in increased hyperexcitability followed by tremors that progressed to seizures anterior to the site of the

transection. During seizures, the opercula were flared and in a state of tetany. Prior to death, seizures subsided and fish became inactive. Similar responses have been noted in bluegill (*Lepomis macrochirus*) (Bradbury et al., 1987; Little et al., 1993). The stages of behavioral changes in fish are generally consistent with those observed in mammals (Bradbury and Coats, 1989); however, an insufficient number of compounds have been studied in fish to differentiate pyrethroid intoxication syndromes as has been done with mammals (Shafer et al., 2005; Soderlund et al., 2002). Because seizures are typically stimulus dependent in hypersensitized fish, it seems reasonable to assume that pyrethroid-induced coughs could trigger convulsions. The cough response itself could be a CNS-mediated component in the seizure syndrome, a side effect due to interactions with sensory receptors in the pharynx and gill arches, or direct irritation of gill tissue. Both fenvalerate and permethrin have been shown to cause gill damage consistent with irritation (Bradbury et al., 1987; Kumaraguru et al., 1982). As reviewed by Clark (1995), pyrethroids have also been reported to cause transient dermal tingling, itching, and burning in humans and irritation to the mucous lining of respiratory passages.

Several measures of metabolic activity have been measured in fish exposed to pyrethroids. In general, protein levels and various dehydrogenases were reduced in response to pyrethroid exposure, while erythrocyte production was increased (Das and Mukherjee, 2003; Kumar et al., 1999; Tripathi and Verma, 2004). These data were interpreted as consequences of failed pyrethroid metabolism. Additionally, marked respiratory–cardiovascular effects observed in pyrethroid-intoxicated rainbow trout (*Oncorhynchus mykiss*) are consistent with increased muscular activity associated with seizures (Bradbury et al., 1991a). Increased ventilation volume was associated with moderate declines in oxygen uptake efficiency and therefore nearly constant oxygen consumption. Arterial blood oxygen levels were initially elevated but then declined dramatically, as did carbon dioxide levels and pH. Overall, these responses suggest a shift to anaerobic metabolism. These shifts in respiratory–cardiovascular and blood-chemistry parameters have also been reported in mammals and are also generally attributed to increased muscular activity (Bradbury and Coats, 1989).

Unlike studies of acute toxicity, few studies have addressed the developmental neurotoxicity of synthetic pyrethroids in fish. Exposure to sublethal levels of permethrin *in ovo* caused a hatching delay in medaka (*Oryzias latipes*). Medaka hatchlings demonstrated hyperactivity, uncoordinated movement, and an inability to respond to stimuli. These hatchlings also failed to inflate their swimming bladder and had spinal curvatures (González-Doncel et al., 2003). Unfortunately, these effects have yet to be correlated with a putative neurotoxicity mechanism, so it is unclear how pyrethroids may be inducing developmental neurotoxicity.

Organochlorine Insecticides

The organochlorine insecticides are among the largest category of insecticides and are used worldwide for public health (e.g., mosquito control) and agricultural production (Figure 9.8). The organochlorine insecticides are comprised of four distinct structural classes, which tend to be associated with unique mechanisms of action: (1) chlorinated ethane derivatives, (2) cyclodienes, (3) polychlorobornanes, and (4) lindane. Use of organochlorines has declined dramatically because of insecticide resistance and environmental concerns. Due to their persistence in the environment and their continued use in some parts of the world, organochlorine residues in sediments, soils, and biota are still observed (Woolley, 1995).

Mechanisms of Organochlorine Insecticide Neurotoxicity

As with synthetic pyrethroid insecticides, the neurotoxicity mechanism of chlorinated ethanes is the disruption of VSSCs. Studies with invertebrate and vertebrate preparations established that dichlorodiphenyltrichloroethane (DDT) prolongs the falling phase of the action potential, which typically produces repetitive firing. This repetitive neuron firing leads to the hyperexcitability and tremor noted in intoxicated insects, mammals, birds, and fish. Studies by Narahashi (1994) demonstrated that DDT caused voltage-sensitive channels to remain in the open state longer than normal and close slowly resulting in an increased overall open time. As reviewed by Woolley (1995), it appears that the type I

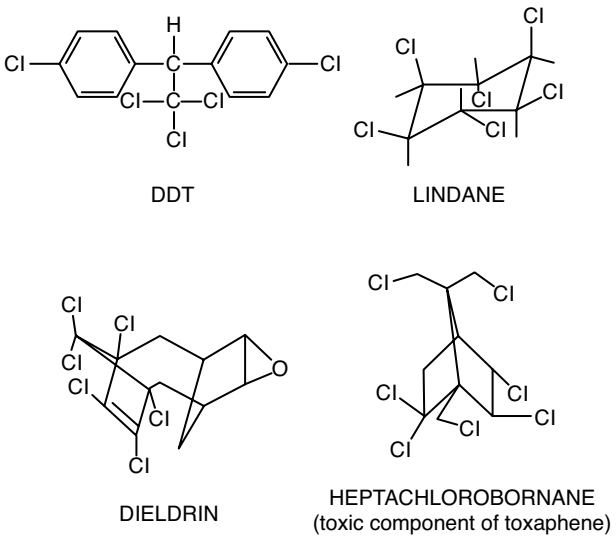

FIGURE 9.8 Examples of organochlorine insecticides.

pyrethroids and DDT likely affect the same target site on the sodium channel. Hyperexcitability is also associated with increased releases of neurotransmitters throughout the mammalian nervous system which likely reflect secondary responses but could represent an additional neurotoxic mechanism.

In mammals, the cyclodienes and polychlorobornanes cause anorexia, salivation, vomiting, and convulsions. During convulsions, insect and amphibian preparations exhibit excessive uptake of calcium into synaptosomes. This synaptosomal calcium uptake is associated with increased release of neurotransmitters. Subsequently, it was shown that cockroach strains resistant to cyclodiene insecticides, lindane, and toxaphene were also resistant to picrotoxin. Picrotoxin acts at one of the receptor sites in the GABA receptor–ionophore complex and is thought to block the channel. Normally, the GABA-gated chloride channel opens upon GABA binding, causing an increased flow of chloride, neuronal hypopolarization, and depression of excitability. Picrotoxin blockage of the GABA receptor eliminates normal chloride modulation of neuronal activity, causing hyperexcitability and, potentially, even convulsions. As these toxic effects are also induced by cyclodienes and polycholorbornanes, it was hypothesized that organochlorines may act by blocking GABA receptors. Confirmatory studies with insect and mammalian preparations established that several cyclodiene insecticides, toxaphene, and lindane act specifically at the picrotoxin site of the GABA receptor. In addition, binding at the picrotoxin site of the GABA receptor tends to correlate with toxic potency. Furthermore, these compounds inhibit GABA-stimulated flows of chloride across membrane vesicles (see reviews by Coats, 1990; Woolley, 1995).

Lindane is the gamma isomer of hexachlorohexane; it is approximately 10 times more acutely toxic to the rat than the alpha isomer and roughly 100 times more potent than the beta and delta isomers. The gamma isomer is strongly excitatory in both insect and mammalian nervous systems, while the alpha, beta, and delta isomers are weakly active or have depressant effects. At acute doses, lindane increases neuronal activity and neurotransmitter release. In addition to convulsant effects, lindane also causes anorexia, diarrhea, and hyperthermia in the rat. As discussed above, lindane is thought to antagonize GABA receptors in the CNS and the gastrointestinal tract. Consistent with this hypothesis, toxic effects of lindane can be attenuated or eliminated by pretreatment with GABA receptor agonists (Woolley, 1995).

Although disruption of VSSCs and GABA receptors are well characterized mechanisms of acute organochlorine neurotoxicity, there is little evidence for the role of these mechanisms in developmental neurotoxicity. Lindane is known to inhibit mammalian embryonic development from the eight-cell stage up to the blastocyst stage (Scascitelli and Pacchierotti, 2003). Several potential mechanisms of developmental neurotoxicity have been proposed, including disruption of endocrine homeostasis and alterations in intercellular communication (Scascitelli and Pacchierotti, 2003).

Manifestations of Organochlorine Insecticide Neurotoxicity in Fish

Organochlorine exposure affects behavior in many fish species. In unrestrained fish, cyclodiene exposure caused hyperactivity in response to stimuli, followed by recurrent tremors, rapid pectoral fin movement, and convulsions (Carlson et al., 1998). In spinally transected rainbow trout (*Oncorhynchus mykiss*), endosulfan and endrin intoxication induced branchial tremors, increased cough rate, and increased pectoral fin movement, with eventual tetany and convulsions anterior to the site of the transection (Bradbury et al., 1991a). Hyperactivity and increased cough frequency have also been reported with DDT intoxication in a number of fish species (Heath, 1995; Murty, 1986). DDT-induced hyperactivity is thought to contribute to decreased schooling behavior (Murty, 1986). At sublethal concentrations of endosulfan, medaka (*Oryzias latipes*) are less susceptible to predation, presumably due to hyperactivity; however, at endosulfan concentrations approximating the LC_{20} level, medaka are more susceptible to predation than control fish (Carlson et al., 1998). Respiratory–cardiovascular responses of cyclodiene-intoxicated rainbow trout included increased cough rate and ventilation volume, with no change in oxygen uptake efficiency, resulting in an increase in oxygen consumption. In a consistent manner, arterial blood oxygen remained near control levels until near death, while arterial blood carbon dioxide and pH levels decreased only slightly. Overall, the seizure activity in the cyclodiene-exposed trout was not associated with a shift to anaerobic metabolism. These responses were similar to those elicited by uncouplers of oxidative phosphorylation and may suggest a secondary effect associated with inhibition of ATPase activity (Bradbury et al., 1991a). Increased oxygen consumption has also been reported in a number of species following exposure to DDT and methoxychlor (Murty, 1986). *In vivo* electrophysiological studies of sublethal endosulfan exposures in medaka demonstrated increased motorneuron amplitude peaks and significantly increased stimulus-response ratio on the Mauthner cell startle response. The hyper-responsiveness of the Mauthner cell to stimuli is consistent with cyclodiene acting at the picrotoxin site in the GABA receptor–chloride complex. Furthermore, GABA is an important afferent inhibitory neurotransmitter to the Mauthner cell (Carlson et al., 1998).

Ethanol

Ethanol is a well-known neurotoxicant in mammals. Women who consume large amounts of ethanol during pregnancy often give birth to children exhibiting phenotypic abnormalities, collectively referred to as the fetal alcohol syndrome (FAS). These anomalies include growth deficiency, cognitive impairment, and distinctive craniofacial features (Coles and Platzman, 1993). The developmental potency of alcohol consumption has led to intensive investigation into the mechanisms of ethanol neurotoxicity, with particular emphasis on developmental neurotoxicity.

Mechanisms of Ethanol Neurotoxicity

Although many mechanisms have been postulated for the toxic effects of ethanol to the adult nervous system, ethanol is thought to produce neurotoxic effects mainly through interaction with the glutaminergic system, binding to the NMDA receptor and possibly interfering with the normal interaction of glycine with that receptor (Tsai and Coyle, 1998). Ethanol is a well-known developmental neurotoxicant in humans and laboratory animals. The mechanism for the toxic actions of ethanol on the developing nervous system is, however, unknown (Goodlett et al., 2005). Many hypotheses exist, including interaction with neurotrophins (Kentroti, 1997), cell-adhesion molecules (Bearer, 2001), or specific receptors (Costa and Guizzetti, 2002); increased apoptosis (Olney et al., 2002a,b); or increased oxidative stress (Cohen-Kerem and Koren, 2003). Very few studies have delved into the mechanisms of the effects of ethanol on the developing fish; however, it has been suggested that prechordal plate migration may be preturbed in ethanol-treated zebrafish (*Danio rerio*) embryos (Blader and Strähle, 2000).

Manifestations of Ethanol Neurotoxicity in Fish

Ethanol affects the function of the adult fish nervous system (Dlugos and Rabin, 2003; Gerlai et al., 2000), producing hyperactivity or hypoactivity (depending on dose), aggression, and changes in the

startle response. Studies of ethanol-induced neurotoxicity in zebrafish (*Danio rerio*) have shown that ethanol is a teratogen that produces developmental delay (Reimers et al., 2004), craniofacial abnormalities (Bilotta et al., 2004; Blader and Strähle, 2000; Carvan et al., 2004), changes in eye development (Bilotta et al., 2002, 2004), cell death (Carvan et al., 2004; Loucks and Carvan, 2004), and behavioral changes (Carvan et al., 2004). Interestingly, the occurrence or severity of these effects varies with the particular strain of zebrafish exposed (Loucks and Carvan, 2004).

Metals

The neurotoxicological effects of metal exposures must be considered in context of the chemical form of the metal, route and duration of exposure, and toxicokinetics. Effects observed in the field also require consideration of sediment and water quality characteristics associated with bioavailability (Dopp et al., 2004; Rüdel, 2003). Sources of neurotoxic metals in aquatic ecosystems include atmospheric deposition, point-source discharges, and non-point-source releases. Cadmium is primarily released through petroleum refining, fossil fuel combustion, and the use of cadmium in copper and nickel smelting (Wren et al., 1995). Mercury inputs are typically associated with atmospheric inputs from the combustion of fossil fuels and acid rain, point-source discharges from industry and gold-mining operations, and non-point-source discharges from agricultural use of organomercury seed treatments. Organotin and copper compounds have been input directly into aquatic systems as biocides in the shipping, fishing, and aquaculture industry (Blunden and Chapman, 1986; Rüdel, 2003). Globally, lead inputs include wet and dry atmospheric deposition, sewage treatment effluents, industrial and mining discharges, and non-point releases from mine tailings and highways (Gidlow, 2004; Pain, 1995). Aluminum loading to aquatic ecosystems is primarily associated with acidification and resulting releases from rocks, soils, and sediments (Lukiw and McLachlan, 1995).

Mechanisms of Metal Neurotoxicity

Generally, organismal-level effects elicited by metals are derived from multiple mechanisms. In addition to direct neurotoxic mechanisms, metals can damage respiratory surfaces and interfere with energy metabolism, osmoregulation, and endocrine function (Heath, 1995; Weber and Spieler, 1994). The extent to which metals are acting through neurotoxic mechanisms of action is a function of the metal species, dose, and route of exposure. Comprehensive reviews of primary scientific literature on metal toxicology (Chang, 1996) and neurotoxicology (Chang and Dyer, 1995) have been published, based primarily on mammalian model organisms. Below are brief overviews of neurotoxicity mechanisms for some selected metals whose neurotoxic mechanisms have been well studied.

A long environmental half-life and wide range of organ toxicity make cadmium one of the most toxic metals in the environment (Patrick, 2003). Several mechanisms have been suggested for the acute neurotoxicity of cadmium. Cadmium is thought to act as a calcium channel blocker or to bind calmodulin. As a result, cadmium disrupts neuromuscular junctions by blocking calcium-mediated neurotransmitter release (Beauvais et al., 2001). In the brain, cadmium inhibits magnesium and sodium/potassium ATPases, disrupting neurotransmitter uptake (Beauvais et al., 2001). In addition, cadmium effects on phospholipid metabolism in synaptic membranes, axonal transport, and basal adenylate cyclase activity have been reported. Cadmium-mediated disruption of cellular antioxidant defense mechanisms has also been proposed to increase neuronal damage through oxidative stress (Hastings, 1995).

Although all forms of mercury are neurotoxic to humans and animals, the most toxic forms are organic mercury compounds (Gochfeld, 2003). Organic mercury compounds are more lipophilic than elemental mercury or inorganic mercury compounds and therefore bioaccumulate in animal tissues (Shafer, 2000). Of the organic mercury compounds, methylmercury has been particularly well studied. Accumulation of methylmercury in the CNS and primary sensory tracts of mammals causes degeneration of visual cortices, dorsal root ganglia fibers, and the cerebellum. Numerous mechanisms have been proposed to explain the neurotoxicity of methylmercury in vertebrates, including disruption of the cell cycle and induction of apoptosis. Subcellularly, methylmercury is hypothesized to disrupt microtubule assembly and alter ion channel function. At the molecular level, cation homeostasis disruption and interference

with synaptic transmission have been hypothesized to mediate methylmercury neurotoxicity. Additionally, methylmercury is highly reactive with sulfhydryl groups (Shafer, 2000). Binding of methylmercury to sulfhydryl groups in critical proteins or macromolecules has been hypothesized to disrupt protein, DNA, and RNA metabolism; to perturb Ca^{2+} homeostasis; to induce oxidative damage; and to alter protein phosphorylation. Many of these mechanisms are interrelated and likely interact to produce methylmercury neurotoxicity (Chang and Verity, 1995).

Organic tin compounds are largely used as plastic stabilizers, although the major route of environmental exposure is from antifouling paints and pesticides (Rüdel, 2003). Organic tin compounds are hydrophobic and significantly more toxic than either elemental tin or inorganic tin compounds (Rüdel, 2003). Neurotoxic effects of organic tin compounds are thought to occur by a variety of interacting mechanisms; for example, triethyltin is hypothesized to uncouple oxidative phosphorylation, inhibit ATPase and phosphodiesterase activity, and initiate oxidative stress via ethane or ethylene metabolites, resulting in myleinic edema. Methyltin has been proposed to suppress mitochondrial respiration by inhibition of oxidative phosphorylation. The resulting hypoxic condition is thought to produce intracellular edema, glutamate release, and subsequent neuronal excitation. This excitation triggers neuron hyperstimulation and subsequent neuronal injury and death in the rat hippocampus (Chang and Dyer, 1995; Dopp et al., 2004).

Lead is a potent neurotoxicant in humans and animals, associated with impaired perception of spatial organization and increased distractibility (Bressler et al., 1999). A variety of mechanisms have been proposed for lead neurotoxicity, including vascular and neuroglia injury, oxidative stress, alterations in transcription, blockage of neurotransmitter release, and failure of neuronal migration (De Gennaro, 2002). A common component of these neurotoxic mechanisms is the ability of lead to mimic biologically relevant metals and cations, particularly calcium (Bressler et al., 1999; Costa et al., 2004; Marchetti, 2003). Lead mimicry of calcium has two primary consequences leading to neurotoxicity (Marchetti, 2003). Initially, lead competes with calcium for binding sites on calcium-regulated proteins such as calmodulin, synaptotagmin, and cadherin, disrupting gene expression, proteomic synaptic machinery, and neuronal migration (Bressler et al., 1999; De Gennaro, 2002; Marchetti, 2003; Prozialeck et al., 2002). Binding-site competition displaces calcium ions, subsequently exposing cells to higher levels of free calcium and potentially leading to oxidative stress (De Gennaro, 2002) and impaired myelination (Chang, 1996). The second method by which lead mimicry of calcium induces neurotoxicity is the disruption of calcium transport. Disruption of chloride ion exchange causes hyperexcitation of neurons (Chang, 1996). Lead also blocks calcium ion flux across dopamine receptors, glutamate receptors, and voltage-sensitive calcium channels (VSCCs). This blockage affects neurotransmitter synthesis and release, ultimately leading to neuron hyperexcitability and damage (Chang, 1996; Chang and Verity, 1995; Cory-Slechta and Pounds, 1995; De Gennaro, 2002; Marchetti, 2003).

Aluminum is a potent neurotoxicant in both animal brain and cultured neurons (Savory et al., 2003). Acute aluminum neurotoxicity disrupts blood–glia–neuron membranes and alters neuronal structure and function (Lukiw and McLachlan, 1995). Aluminum is of particular interest because some of its neurotoxic effects resemble Alzheimer's disease (Yokel, 2000). Similar to this late-onset neurodegeneration disease, acute aluminum neurotoxicity causes the formation and accumulation of insoluable β-amyloid, aggregation of hyperphosphorylated tau protein, and disruption of cortical cholingeric neurotransmission (Yokel, 2000). These effects arise from disruption of calcium binding (Yokel, 2000). Aluminum perturbance of calcium binding induces excessive calcium-ion influx in cholinergic neurons and mitochondria. This increase in mitochondria calcium influx causes apoptosis and may explain the significant loss of cholingergic neurons in Alzheimer's disease (Savory et al., 2003; Szutowicz, 2001). Significant pathological differences exist between Alzheimer's disease and aluminum neurotoxicity, making direct comparisons controversial (Yokel, 2000). Furthermore, several other molecular mechanisms have been proposed for aluminum neurotoxicity, including increased iron-induced oxidative stress, inhibition of Mg^{2+}-requiring enzymes, and modification of second-messenger systems (Lukiw and McLachlan, 1995; Yokel 2000).

Metals represent some of the most potent developmental neurotoxicants, particularly mercury and lead. Fetal methylmercury exposure in humans causes Minamata disease, characterized by cerebral palsy, mental retardation, and seizures (Davidson et al., 2004). Autopsies of Minamata patients reveal cerebral

and cortical brain lesions with peripheral neuropathy (Gochfeld, 2003). Furthermore, studies with model organisms suggest that low-level exposure to methylmercury may not manifest effects until much later in life (Davidson et al., 2004). Ethylmercury is thought to produce the same developmental effects as methylmercury and may be associated with the spectrum of autism, learning, and speech disorders (Davidson et al., 2004). The developing nervous system is also vulnerable to lead exposure. Children exposed to lead have poor coordination, behavioral problems, and reading disabilities (De Gennaro, 2002). Several aspects of the developing nervous system are sensitive to metal neurotoxicity. Increased absorption through an immature blood–brain barrier means that neurotoxicity may be induced at a much lower exposure level. Furthermore, sublethal metal exposure levels may alter key processes such as synapse formation, synapse refinement, and neurotransmitter release, causing effects that are manifested later in life (Marchetti, 2003). Although currently under investigation, the extent to which the acute metal neurotoxic mechanisms described above are involved in developmental neurotoxicity is not well understood.

Manifestations of Metal Neurotoxicity in Fish

Numerous reviews have summarized the behavioral responses of fish to metal intoxication (Atchison et al., 1987; Heath, 1995; Weber and Spieler, 1994). In addition to direct neurotoxic mechanisms, alterations in avoidance or attraction responses, activity patterns, critical swimming speed, respiratory behavior, intraspecific social interactions, reproduction, feeding, and predator avoidance (Atchison et al., 1987) can be attributed to direct damage to respiratory surfaces and interference with energy metabolism, osmoregulation, and endocrine function (Heath, 1995; Weber and Spieler, 1994). Examples provided below attempt to link neurophysiological or behavioral responses to neuropathological or biochemical alterations. The extent to which the neurotoxic mechanisms discussed above are relevant in fish remains to be assessed (Weber and Spieler, 1994). Studies of chemoreception have quantified the extent to which metals attract or repel fish and the extent to which metals affect responses to endogenous chemical signals such as pheromones. Alterations in avoidance or attraction responses have been observed in response to a number of metals, including cadmium, copper, and mercury. In rainbow trout (*Oncorhynchus mykiss*), lake whitefish (*Coregonus clupeaformis*), Atlantic salmon (*Salmo salar*), and goldfish (*Carassius auratus*), copper induces avoidance behavior (Atchison et al., 1987). This avoidance behavior is attributed to the effects of copper on the olfactory bulb. Copper attenuates electrical responses of the olfactory bulb and receptor cells to excitatory compounds (Hara et al., 1976; Sutterlin and Sutterlin, 1970; Winberg et al., 1992). Furthermore, copper exposure causes degeneration of specific olfactory receptor cells (Brown et al., 1982; Julliard et al., 1993), likely through oxidative-stress-mediated apoptosis (Julliard et al., 1993, 1996). Interestingly, oxidative stress may be partly responsible for the observed neurological effects in Wilson's disease, a genetic defect in copper metabolism leading to copper neurotoxicity in humans (Bondy, 1996). In fish, cadmium exposure has been correlated to changes in brain acetylcholinesterase activity, although these neurochemical changes have not been correlated with changes in swimming behavior in larval rainbow trout (Beauvais et al., 2001).

Although many metals elicit an avoidance response, mercuric chloride and methylmercury attract fish (Atchison et al., 1987; Heath, 1995). Exposure of mercuric chloride and methylmercury to the olfactory bulb and receptors of rainbow trout (*Oncorhynchus mykiss*) and Atlantic salmon (*Salmo salar*) depressed electrical responses (Baatrup et al., 1990; Hara et al., 1976; Sutterlin and Sutterlin, 1970). Methylmercury has also been found to preferentially accumulate in olfactory receptors and the olfactory nerve of Atlantic salmon following dietary exposure (Baatrup et al., 1990; Berntssen et al., 2003). Chronic dietary exposure reduced overall activity in the Atlantic salmon (*Salmo salar*) and caused preferential histopathological damage to the brain stem (Berntssen et al., 2003).

Exposure to tributyltin oxide causes a variety of locomotor effects in fish. Rainbow trout (*Oncorhynchus mykiss*) exposed to tributyltin oxide swam longer distances at higher velocities but with erratic swimming tracks, indicating a loss of orientation (Triebskorn et al., 1994). In addition, intoxicated trout had a depressed startle response and were unresponsive to external stimuli. Similar behavioral and locomotor responses have been noted in minnows (*Phoxinus phoxinus*) (Fent and Meier, 1992). Tributyltin

oxide induces cytopathological damage in the brain and eyes of several fish (Fent and Meier, 1992; Triebskorn et al., 1994; Wester and Canton, 1987). Pathological lesions observed in the optic tectum and eyes suggest that the optic system is a putative target of tributyltin (Fent and Meier, 1992; Triebskorn et al., 1994; Wester and Canton, 1987). In support of this hypothesis, ultrastructural alterations have been found in the optic tectum of tributyltin-oxide-exposed rainbow trout (Triebskorn et al., 1994).

Lead exposure caused a general increase in locomotor activity in mirror carp (*Cyprinus carpio*) (Rehman, 2003). In zebrafish (*Danio rerio*) and fathead minnows (*Pimephales promelas*), lead exposure reduced feeding ability, as evidenced by feeding miscues and increased prey-handling times (Nyman, 1981; Weber et al., 1991). This reduction in feeding ability was attributed to psychomotor coordination, based on correlations between increased brain lead levels, increased serotonin and norepinephrine concentrations, and decreased feeding ability (Weber et al., 1991). Lead exposure induced similar increases in brain serotonin and decreases in GABA in walking catfish (*Clarias batrachus*) (Katti and Sathyanesan, 1986). Yet, although lead increased brain serotonin and norepinephrine levels, lead exposure did not increase dopamine levels in fathead minnows (Weber et al., 1991).

The effects of aluminum on fish behavior have not been reported. Long-term exposure of rainbow trout (*Oncorhynchus mykiss*) to aluminum caused aluminum accumulation in the cerebrovascular endothelium and throughout the telencephalon (Exley, 1996). This finding suggests that aluminum is capable of crossing the blood–brain barrier in fish as well as in mammals (Lukiw and McLachlan, 1995; Szutowicz, 2001). Also, in the telencephalon of aluminum-exposed rainbow trout were dense extracellular deposits of aluminum apparently surrounded by a protein matrix, suggesting similar neuropathological responses in fish and mammals.

The effects of a number of metals on prey susceptibility, schooling behavior, and aggression have been studied across a wide array of species (Heath, 1995; Weber and Spieler, 1994). Although many of these adverse effects are hypothesized to reflect alterations in sensory receptors or the structure and function of the PNS and CNS, direct cause-and-effect relationships have not been established. Even less evidence is available for developmental neurotoxicity of metals in fish.

Neurotoxins

Through evolutionary pressure, plants and algae have developed a number of strategies to avoid consumption and maximize competitive advantages in accumulating resources. It has been estimated that approximately 7000 terrestrial plant species are toxic to animals, with perhaps one half of these species producing compounds targeting the nervous system. In some instances, plant neurotoxins have been exploited to facilitate fish harvesting (Bhatt, 1991). Several aquatic organisms produce fish neurotoxins and are of increasing concern in many areas (Burkholder et al., 1992). The following discussion provides an overview of the neurotoxicity of several specific neurotoxins and illustrates how these compounds are used to assess fish brain function.

Mechanisms of Neurotoxin Toxicity

Neurotoxins derived from aquatic organisms produce toxicity by a variety of mechanisms. Toxins derived from cyanobacteria, dinoflagellates, and coral act on membrane sodium channels directly or on membranes to create ion permeabilities. Such toxins are classified in terms of their ability to activate, stabilize, or occlude the sodium channel (see review by Strichartz and Castle, 1990). Toxins that activate sodium channels cause long-lasting sodium ion influx and correspondingly prolonged depolarization of excitable membranes, preventing complete inactivation. Failure of membrane repolarization also causes periods of rapid, spontaneous impulse firing (Strichartz and Castle, 1990). Brevetoxins and ciguatoxin, derived from the marine dinoflagellates *Ptychodiscus brevis* and *Gambierdiscus toxicus*, respectively, are among the most studied sodium-channel activator toxins. Toxins isolated from *P. brevis* bind VSSCs and cause activation at resting membrane potentials. Competitive binding studies have established that the most toxic brevetoxins bind preferentially at the active site within the sodium channel (Trainer et al., 1990). Frelin and coworkers (1990) have also substantiated that ciguatoxin acts as a sodium-channel activator and binds to the same active site as the brevetoxins.

Toxins stabilize sodium channels by inhibiting inactivation of the sodium current during depolarization, thus keeping the sodium channel in the open state. This sodium channel stabilization causes a prolonged period of calcium influx through VSCCs, causing increased calcium-mediated secretions and contractions (Strichartz and Castle, 1990). Toxins that stabilize sodium channels bind different sites than toxins that activate sodium channels; consequently, sodium-channel-stabilizer toxins can synergize with sodium-channel-activator toxins, causing larger membrane depolarizations at lower doses. Small peptides produced by anemones and larger proteins produced by mollusks in the family Conidae are examples of sodium-channel-stabilizer toxins. Sodium-channel-occluder toxins are small organic cations that are high-affinity, but reversible, blockers of the channel (Strichartz and Castle, 1990). The subsequent inhibition of sodium conductance renders excitable membranes inactive and halts impulse propagation. Tetrodotoxins and saxitoxins are classic examples of sodium-channel-occluding toxins. Tetrodotoxin is produced by some fish in the order Tetraodontiformes and the Costa Rican frog *Atelopus* (Ritchie and Greene, 1985). Saxitoxins are produced by marine dinoflagellates in the genera *Gonyaulax* and freshwater cyanobacteria in the genera *Anabaena* and *Aphanizomenon* (Carmichael, 1997). Some sodium-channel-occluding toxins discriminate between sodium-channel types; for example, the μ-conotoxins, from the mollusk *Conus geographus* potently block muscle sodium channels but only weakly inhibit sodium currents in neuronal and cardiac sodium channels.

Some toxins create ion permeabilities without affecting ion channels. Palytoxin, derived from coral, irreversibly increases cation permeability, perhaps by converting the sodium/potassium pump to a passive channel (Strichartz and Castle, 1990). Other aquatic neurotoxins have mechanisms that do not center on ion regulation; for example, cyanobacteria of the genera *Anabaena* and *Oscillatoria* produce anatoxins that disrupt acetylcholine function at neuromuscular junctions. Anatoxin-a acts as an acetylcholine mimic, binding nicotinic acetylcholine receptors at vertebrate muscle endplates, and is reported to be eight times more potent than acetylcholine. Furthermore, anatoxin-a is resistant to acetylcholinesterase hydrolysis, causing an overstimulation of muscle cells to the point of fatigue. The similarly named anatoxin-a(s) causes the same symptoms of neurotoxicity as anatoxin-a but by a different mechanism. Anatoxin-a(s) is a naturally occurring organophosphate that inhibits acetylcholinesterase activity in a manner similar to the organophosphate insecticides discussed previously.

In addition to aquatic toxins, terrestrial plant toxins can affect the CNS of vertebrates, including fish. Notable examples are the pyrethrins, derived from *Chrysanthemum cinerariifolium*, whose structures were subsequently modified synthetically to develop the pyrethroid insecticides, as summarized previously. Certain plant toxins have also been exploited by several cultures as an aid in harvesting; for example, piscicidal plants derived from plants of the Garhwall hills of India are of great ethnobiological importance. Bhatt (1991) has described how a flavonoid derived from *Engelhardtia colebrookiana* (Lindle) causes degeneration of neurons and neural tracts in the medulla oblongata of freshwater fish. Strychnine, an alkaloid derived from *Strychnos nux-vomica*, has long been known as a central nervous system stimulant in animals. Strychnine selectively antagonizes GABA in the brain and glycine in the spinal cord (Dorling et al., 1995) and has been exploited in fish neurotoxicology studies to elucidate the role of these inhibitory neurotransmitters.

Manifestations of Neurotoxin Toxicity in Fish

Brevetoxins and ciguatera toxins elicit similar effects in fish, consistent with their identical mechanisms of neurotoxicity summarized previously. Red tides caused by *Ptychodiscus brevis* brevotoxins are associated with massive fish kills. Exposure of ciguatera toxins to coney (*Epinephelus fulvus*), schoolmaster (*Lutjanus apodus*), mahogany snapper (*Lutjanus mahogoni*), largemouth bass (*Micropterus salmoides*), blueheads (*Thalassoma bifasciatum*) (Davin et al., 1986, 1988), and western mosquitofish (*Gambusia affinis*) (Lewis 1992) caused skin color variations, rapid opercular movement, inactivity, loss of equilibrium, erratic swimming, jerky feeding movements, loss of orientation, and death. Exposure to another toxic dinoflagellate, *Pfiesteria piscicida*, has been reported to induce sudden sporadic movement, disorientation, lethargy, and apparent suffocation followed by death in 11 species of fish, including striped bass (*Morone saxatilis*), southern flounder (*Paralichthys lethostigma*), Atlantic menhaden (*Brevoortia tyrannus*), and American eel (*Anguilla rostrata*) (Burkholder et al., 1992; Glasgow et al., 1995).

There are few reports of other aquatic neurotoxin effects in fish. Accumulations of saxitoxins, the toxins responsible for paralytic shellfish poisoning, and anatoxins in fish tissues have been documented primarily because they are monitored within the context of human health protection. Toxic endpoints of saxitoxins and anatoxins in fish, however, are rarely assessed. In mammals, including humans, tetrodotoxins and saxitoxins block vasomotor nerve function, ultimately causing death by paralysis of respiratory muscles (Ritchie and Greene, 1985). In laboratory studies, anatoxin-a and anatoxin-a(s) elicit acetylcholine and acetylcholinesterase inhibition responses in electric rays (*Torpedo californica*) and in electric eels (*Electrophorus electricus*) (Hyde and Carmichael, 1991; Mahmood and Carmichael, 1987; Swanson et al., 1991). Although anatoxin poisonings have been reported in livestock, domestic animals, and wild birds (Carmichael, 1997), effects on fish in the field remain largely undocumented.

Spinally transected rainbow trout (*Oncorhynchus mykiss*) exposed to strychnine (Bradbury et al., 1991b) rapidly exhibit increased cough rate as well as whole-body spasms that included tail arching. These spasms were similar to those elicited by polar narcotics. The strychnine-exposed rainbow trout, however, exhibited an elevated response to outside stimuli that was not observed with trout exposed to narcotics, acetylcholinesterase inhibitors, or cyclodiene and pyrethroid insecticides. Similar responses to strychnine exposure were also observed in sharks (Baldridge, 1969), medaka (*Oryzias latipes*) (Carlson et al., 1998; Rice et al., 1997), and fathead minnows (*Pimephales promelas*) (Drummond and Russom, 1990). Under acute exposure conditions to nonlethal concentrations of strychnine, medaka are less susceptible to bluegill (*Lepomis macrochirus*) predation, presumably due to heightened responses to outside stimuli (Carlson et al., 1998). Rainbow trout exposed to lethal strychnine concentrations had decreased ventilation frequency and ventilation volume, causing increased oxygen uptake efficiency and oxygen consumption (Bradbury et al., 1991b); consequently, arterial blood oxygen level decreased throughout these strychnine exposures and was associated with a drop in arterial blood pH and an increase in hematocrit. These respiratory–cardiovascular responses are consistent with anaerobic metabolism during strychnine-induced seizures. Decreased respiration and hypoxia have similarly been noted in mammals exposed to strychnine. In mammals, periods of impaired respiration during convulsions are thought to cause hypoxia, leading to medullary paralysis and death (Klaassen, 1996; Slater, 1965). Studies of the Mauthner cell startle response in strychnine-exposed medaka showed an increase in reflex response to stimuli. An associated delay between the Mauthner cell and motorneuron action potentials and minimal decline in the time between the motorneuron action potential and excitation of the tail musculature were noted (Carlson et al., 1998). These results in medaka are consistent with glycine antagonism and blockage of spinal cord motor cell inhibitory pathways, both of which are documented responses to strychnine exposure in the Mauthner cell soma and dendrites of several other fish species (Furukawa et al., 1964; Legendre and Korn, 1994).

Summary

The mechanisms and effects of neurotoxicants in fish have been studied with a wide variety of *in vitro* and *in vivo* methods. In addition to advancing understanding of fundamental neurobiology, this research helps develop techniques to assess adverse effects of neurotoxicants for ecological risk assessments. Of special note are those investigations that link structural and functional alterations of the nervous system at the subcellular or cellular level to physiological and behavioral effects. Research integrating information across levels of biological organization will further mechanistic understanding of neurotoxicants, allowing for extrapolation across species and chemicals and development of approaches to identifying ecologically relevant neurotoxic responses. The National Research Council (NRC, 1992) has observed that one of the greatest challenges in developing methods for neurotoxicology is associating neuromorphological, neurochemical, and neurophysiological alterations with behavioral changes. The *in vitro* and *in vivo* fish models described here are uniquely suited for characterizing chemical-induced neurotoxicity and understanding the biochemical, physiological, and morphological mechanisms underlying behavioral alterations.

Introduction

The endocrine, nervous, and immune systems are the primary means of communication between cells and organs in multicellular animals. The regulation of many physiological functions involves integration of nervous and endocrine systems, although typically endocrine responses are slower and longer lasting than neural ones. Specific chemical messengers, hormones, are secreted by endocrine glands directly into the blood. Although the hormones are distributed in the bloodstream throughout the body, they only act at specific target tissues. This specificity of hormone action is due to the presence of specific receptor molecules that preferentially bind the hormone in the target cells. Hormone binding activates the receptor, causing stimulation of intracellular second messenger pathways or direct binding of the hormone–receptor

complex to regulatory elements on genes, ultimately resulting in alterations in cell function. Some hormones, including the gonadal sex steroids, also function in a paracrine fashion by acting locally on surrounding target cells without entering the circulation.

Most of the information reported to date on endocrine toxicity indicates that xenobiotic chemicals primarily interfere with gonadal, thyroid, and adrenocortical (interrenal) functions in fish and other vertebrate species. Specific hormones secreted by the hypothalamus and pituitary regulate the activity of each of these endocrine glands; therefore, chemical interference with the endocrine axes controlling these three endocrine functions identified in laboratory studies are briefly reviewed in this chapter. Evidence for endocrine imbalances in fish populations exposed to endocrine-disrupting chemicals in the environment is covered in Chapters 22, 24, and 25. The current discussion is limited to evidence obtained in adult animals, although early developmental stages, such as the period of phenotypic sex determination, gonadal sex differentiation, and onset of puberty, appear to be especially sensitive to endocrine-disrupting chemicals (Gray and Metcalfe, 1997; Iguchi, 1999; Norrgren et al., 1999; Strussman and Nakamura, 2002). Most of this chapter focuses on the endocrine control of reproduction by the hypothalamic–pituitary–gonad axis and the sites and mechanisms of chemical disturbance of reproductive endocrine function, because the majority of the evidence for endocrine disruption in vertebrates has been obtained in this system. The literature on these topics is very extensive, so a comprehensive review of all the major contributions to these fields is not attempted here; thus, the emphasis of this review to a certain extent reflects the author's own research interests and findings.

Hypothalamic–Pituitary–Gonadal Axis

Hormones and other factors secreted by the hypothalamic–pituitary–gonadal (HPG) axis control the development of reproductive tissues and the initiation and precise coordination of the complex processes that occur during the annual reproductive cycle in teleost fish, culminating in the release and fertilization of mature gametes. The basic features of the HPG axis in fish are similar to those of other vertebrates and are shown in Figure 10.1. Environmental cues, such as changes in photoperiod, water temperature and chemistry, and social stimuli, as well as physiological changes such as alterations of nutritional state, are detected by peripheral and internal sensory systems, and the information is relayed via neural pathways to the hypothalamus and associated brain regions. The hypothalamus integrates this information, resulting in the secretion of various neurotransmitters and neuropeptides that influence the activities of gonadotropin-releasing hormone (GnRH)-producing neurons in the preoptic area and medial basal hypothalamus. GnRH is a decapeptide and the primary neurohormone that controls reproduction. The GnRH neurons directly innervate the gonadotropin-producing cells in the anterior pituitary (gonadotropes) of teleosts to regulate the synthesis and secretion of gonadotropins. The GnRH is released from nerve terminals in the vicinity of the gonadotropes and binds to specific receptors on the plasma membrane, resulting in activation of intracellular signaling pathways that regulate the release of gonadotropins. Monoamine neurotransmitters such as dopamine and serotonin also act on the pituitary to modulate the secretion of GnRH and gonadotropins (Figure 10.1). The neuroendocrine and intracellular second-messenger systems controlling gonadotropin secretion are briefly summarized in subsequent sections.

It is generally accepted that the seasonal reproductive cycle in teleosts, like that of tetrapods, is under dual gonadotropin control by follicle-stimulating hormone (FSH) and luteinizing hormone (LH), previously named GTH I and GTH II, respectively, in teleosts. FSH and LH are glycoprotein hormones with molecular weights of approximately 28 to 30 KDa, and they are comprised of two subunits, an alpha subunit that is common to both gonadotropins and thyrotropin (thyroid-stimulating hormone) and a beta subunit that is hormone specific. The two gonadotropins are produced in different populations of gonadotropes within the anterior pituitary (adenohypophysis) and show different secretory patterns during the reproductive cycle in salmonids, the only teleost fishes in which FSH secretion has been investigated (Gomez et al., 1999; Swanson et al., 2003). LH and FSH bind to specific G-protein-coupled receptors on the surface of somatic cells in the gonads. In salmon, one of the gonadotropin receptors specifically interacts with homologous LH (GTH II) and is localized in granulosa cells in preovulatory ovarian

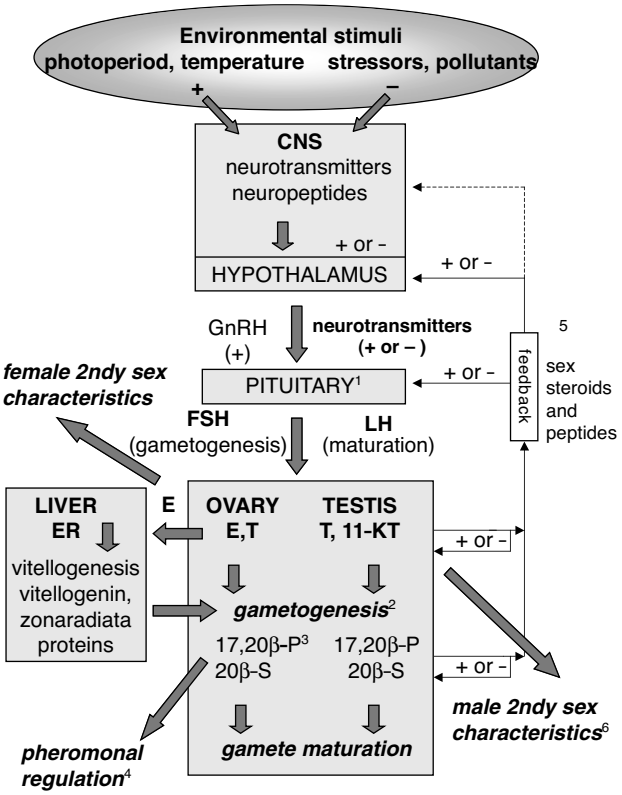

FIGURE 10.1 Schematic representation of the hypothalamic–pituitary–gonadal axis controlling reproduction in fish. [1]Growth hormone, prolactin, and thyroid hormones also influence teleost reproduction. [2]Only secondary (vitellogenic) oocyte growth is under hormonal control. [3]Either 17,20β-P or 20β-S is the primary progestin hormone in most species. [4]Conjugated metabolites of 17,20β-P and 20β-S in urine of periovulatory females influence reproductive behavior of conspecific males. [5]Feedback effects of steroids vary with the stage of the reproductive cycle; regulatory peptides include inhibin and activin. [6]Male secondary sex characteristics include male territorial behavior, gonopodia, breeding tubercles, and male coloration.

follicles and in Leydig cells in spermiating males (Miwa et al., 1994). The other receptor binds both LH and FSH (GTH I) and is present in both thecal and granulosa cells during vitellogenesis but is only present in the thecal cells in the preovulatory follicle. This receptor is present in the Sertoli cells in males at all stages of spermatogenesis (Miwa et al., 1994). The specificities of the gonadotropin receptors in other teleost species are currently unknown due to lack of purified homologous FSH. It was found that mammalian LH and FSH can activate all the receptors identified in African catfish and channel catfish to some extent (Kumar et al., 2001a,b; Vischer and Bogerd, 2003). Gonadotropin binding to the receptors results in activation of G-proteins, adenylyl cyclase, and calcium-dependent second-messenger signaling pathways (Kumar et al., 2001a,b; Miwa et al., 1994; Vischer and Bogerd, 2003). These intracellular signals subsequently cause alterations in the production and secretion of steroid hormones, growth factors, and regulatory peptides such as inhibin.

Steroid hormones are relatively stable structures, consisting of four fused hydrocarbon rings with oxygen and carbon substitutions at different positions that are characteristic for each class of steroid hormone. All steroid hormones are synthesized from a common precursor, cholesterol, via a series of biosynthetic steps catalyzed by different steroidogenic enzymes. The protein that regulates the transfer of cholesterol into the inner mitochondrial membrane, steroidogenic acute regulatory protein (StAR), is a key regulatory (rate-limiting) step in steroid synthesis whose production is upregulated by gonadotropins in the gonads and adrenocorticotropin in the adrenal cortex in mammals (Stocco and Clark, 1996) and in fishes (Kasukabe et al., 2002). Cholesterol is converted to pregnenolone, a steroid with 21 carbon

atoms (C-21 steroid) by the P450 enzyme cholesterol side-chain cleavage (P450scc). This enzyme is present on the inner mitochondrial membrane and has been characterized in teleosts (Takahashi et al., 1993). Pregnenolone, in turn, undergoes a series of isomerizations and hydroxylations by steroidogenic enzymes—3β-hydroxysteroid dehydrogenase (3β-HSD), 17α-hydroxylase (P450c17), 21-hydroxylase (P450c21), 11β-hydroxylase (P450c11), and 20β-dehydroxysteroid dehydrogenase (20β-HSD)—to form the C-21 steroid hormones progestins and glucocorticoids (Nagahama, 2000). 17α-Hydroxyprogesterone is converted to androgens (C-19 steroids) by P450c17, which has 17,20 lyase activity (removes the side chain) and by 11β-hydroxysteroid dehydrogenase (11β-HSD) to produce 11-ketotestosterone. Androgens are subsequently converted to estrogens (C-18 steroids) by the aromatase enzyme (P450arom). The sex steroids (estrogens, androgens, and progestins) are produced in the theca and granulosa cells in the ovary and primarily in the Leydig or interstitial cells in the testis. Sex steroids have both endocrine and paracrine effects mediated by binding to specific receptors on distant target tissues, such as the liver and hypothalamus, and within the gonads themselves. Sex steroids are transported in the blood bound to sex-steroid-binding proteins (Laidley and Thomas, 1994, 1997). The pattern of steroidogenesis changes during the reproductive cycle in both males and females, from the production of estrogens and androgens during the period of gamete production (gametogenesis) to the production of progestins during gamete maturation and spawning.

Endocrine Control of the Reproductive Cycle

Reproductive activity in most fishes is seasonal, and the seasonality becomes more pronounced in fish that reproduce at higher latitudes. Both external environmental stimuli and endogenous circannual rhythms are thought to influence reproductive cycles in teleosts, although evidence of the latter has only been obtained for a few species. Photoperiod and temperature are the major environmental variables that influence reproductive cycles. Photoperiod changes initiate the reproductive cycle in most temperate species, whereas temperature changes often control the completion of the cycle to ensure that larval production coincides with favorable environmental conditions for their survival (Khan and Thomas, 1999). These environmental variables and other factors such as social cues influence the activity of the reproductive neuroendocrine system by neurochemical signals and neural pathways that have not been clearly delineated. In addition, the physiological functions of the two gonadotropins FSH and LH have not been as distinguishable in some fish species as they have been in mammals, based on the limited data available at present on teleost FSH physiology. FSH (GTH I) clearly has important roles in salmonids and several other fishes during early gonadal development and vitellogenesis or spermatogenesis, whereas LH (GTH II) regulates the final stages of the reproductive cycle including oocyte maturation, ovulation, and spermiation; however, a distinct physiological role for FSH during early gonadal development has not been demonstrated to date in many teleost species, and low circulating levels of LH have been reported in several species during this period.

The initial phases of gametogenesis in females—oogonial proliferation and primary oocyte growth—do not appear to be controlled by pituitary hormones, whereas FSH has been shown to stimulate spermatogonial proliferation in male salmonid fishes. Gonadotropins, however, clearly have critical functions during subsequent stages of gamete growth and maturation in both males and females. During the secondary oocyte growth phase, the gonadotropins stimulate the synthesis of 17β-estradiol in the granulosa cells and its precursor, testosterone, in the thecal cells and their subsequent secretion into the circulation. A major function of 17β-estradiol in females is to regulate the hepatic production of vitellogenins, the egg yolk precursor proteins. Estrogen also regulates the synthesis of vitelline envelope (zona radiata) proteins in the livers of many teleost species. Vitellogenins are rapidly incorporated into the growing oocytes, whose diameters increase dramatically during this prolonged period of oocyte and ovarian growth. The vitellogenins are cleaved into the major yolk proteins lipovitellin and phosvitin, as well as a nonlipoidal derived protein, the β^1-component, whose function is currently unknown (Hiramatsu et al., 2002). The physiological significance of the high circulating levels of testosterone in females during this period is less clear. Testosterone is a precursor for estradiol synthesis, and there is evidence that it participates in the feedback control of gonadotropin secretion by aromatization to estradiol. Other ovarian hormones, such as inhibin and activin, and growth factors, such as insulin-like growth factors

(IGFs), are likely involved in intraovarian regulation of steroidogenesis and follicular growth, as well as pituitary feedback of gonadotropin secretion, although their precise functions in teleosts have not been elucidated.

Spermatogenesis can be divided into three major phases: mitotic proliferation of the spermatogonia from stem cells, meiosis of spermatocytes, and the transformation of spermatids into flagellated spermatozoa (spermiogenesis) (Schulz and Miura, 2002). Sertoli cells are in close contact with the germ cells and provide nutrients and stimuli such as growth factors that regulate their development. The function of Sertoli cells is in turn regulated by FSH and steroid hormones secreted by Leydig cells. Leydig cells produce testosterone and 11-ketotestosterone, as well as trace amounts of 17β-estradiol during spermatogenesis. Androgens regulate all stages of spermatogenesis, probably by controlling the production of IGFs and activin B by Sertoli cells (Schulz and Miura, 2002). Regulation of androgen production is largely under the control of LH when the germ cells are undergoing meiosis. The identification of a nuclear estrogen receptor in croaker testes suggests that estrogens have important functions in the gonads of male fish (Loomis and Thomas, 1999). One function of estrogens in the testis may be to stimulate stem cell renewal divisions (Schulz and Miura, 2002).

The final stages of gamete maturation and release in teleosts are controlled by LH and involve the synthesis of maturation-inducing steroids (MISs), C-21 progestins (Miura et al., 1992; Nagahama, 2000; Nagahama et al., 1993; Thomas, 1994). The MISs have been positively identified as 17,20β-dihydroxy-4-pregnen-3-one (17,20β-P) in amago salmon (Nagahama and Adachi, 1985) and as 17,20β, 21-trihydroxy-4-pregnen-3-one (20β-S) in Atlantic croaker (Trant and Thomas, 1989). The major MIS for salmonids and cyprinids is 17,20β-P (Scott et al., 1987), whereas 20β-S has been shown to be the predominant MIS in sciaenids and some other perciform fishes (Thomas, 1994). In addition, other C-21 progestins and 11-deoxycorticosteroids identified in several flatfishes may function as MISs in these species (Scott et al., 1987). In females, a surge in LH secretion initiates the process of oocyte maturation (OM), comprised of two gonadotropin-dependent stages (Patiño and Thomas, 1990a). The development of oocyte maturational competence (i.e., the ability to respond to the MIS and complete maturation) occurs during the initial MIS-independent phase (Patiño et al., 2001). This includes upregulation of the MIS receptor (Thomas et al., 2001) and the gap junctions and their associated protein, connexin. This phase is followed by the resumption of meiosis, migration of the nucleus (germinal vesicle) to the animal pole (GVM), dissolution of the nucleus (germinal vesicle breakdown [GVBD]), and changes in the ooplasm, including lipid coalescence, hydration, and formation of an oil droplet (in fish that release pelagic eggs) during the MIS-dependent phase (GVBD phase) (Patiño et al., 2001). The MIS induces GVBD via a cell-surface-initiated, nongenomic mechanism by binding to specific membrane progestin receptors (mPRs). Ligand binding to these receptors results in a decrease in cAMP levels that can be blocked by pertussis toxin, an inhibitor of inhibitory G-protein (G_i) activation, indicating that the receptor activates a G_i (Pace and Thomas, 2005; Thomas et al., 2002; Yoshikuni and Nagahama, 1994). The decrease in cAMP levels releases the oocyte from meiotic arrest via a signal transduction pathway that causes the production of maturation-promoting factor (MPF), which consists of two components: a catalytic cdc2 kinase and cyclin B (Nagahama et al., 1993). Ovulation occurs soon after the completion of OM via a genomic steroid mechanism. The MIS activates a nuclear progestin receptor (nPR) in the ovarian follicle wall (Goetz et al., 1991; Pinter and Thomas, 1997, 1999), causing activation of protein kinase C and the synthesis of arachidonic acid and prostaglandins, which in turn cause contractions of smooth muscle in the follicle wall to expel the oocyte (Goetz et al., 1991; Patiño et al., 2003).

Recent studies have shown that MISs cause maturation of spermatozoa by nongenomic and genomic steroid mechanisms, in Atlantic croaker and salmonids, respectively (Schulz and Miura, 2002; Thomas et al., 2004). Additional research will be required to reconcile these two models of sperm activation in teleosts; however, it is probable that both steroid mechanisms may operate in the same species, as both the nuclear and the membrane progestin receptors have been characterized in the testes of spotted seatrout and Atlantic croaker (Pinter and Thomas, 1997; Thomas, 2000c; Thomas et al., 1998, 2005). Increased sperm motility after gonadotropin or progestin treatment has been reported in salmonids, and this is associated with MIS-induced increases in the pH of the seminal fluid by a genomic mechanism, presumably by binding to the nPR (Miura et al., 1992). It has been demonstrated that

MISs can induce sperm hyperactivity in Atlantic croaker and spotted seatrout by binding to specific mPRs on their sperm membranes (Thomas et al., 1998), resulting in rapid increases in intracellular free calcium and cAMP concentrations (Thomas, 2003). This mechanism of sperm activation is homologous to that in mammals where progesterone binds to the sperm mPRs during their passage through the female reproductive tract to induce hyperactivity and the acrosome reaction via alterations in intrasperm calcium and cyclic nucleotide levels (Blackmore et al., 1991; Revelli et al., 1998). Interestingly, gonadotropin and progestin treatment increases testicular and sperm mPR levels in seatrout and croaker, as well as sperm motility and fertilization success (Thomas et al., 1998). The novel membrane progestin receptor (mPRα) recently discovered in seatrout ovaries (Zhu et al., 2003a) has been localized to the midpieces of fish sperm and is the likely mediator of MIS upregulation of sperm motility (Thomas et al., 2006).

Neuroendocrine Control of Gonadotropin Secretion

The neuroendocrine system controlling LH and FSH secretion in teleosts is complicated, with multiple neural pathways and complex interactions among a broad range of regulatory factors, including neurotransmitters, neuropeptides, amino acids, and steroids (Blasquez et al., 1998; Kah et al., 2000). These factors influence gonadotropin secretion by their actions on neurons that synthesize and release GnRH in the preoptic area and anterior and medial–basal hypothalamic regions or by acting directly on GnRH nerve terminals on gonadotropin-producing cells in the anterior pituitary. The neuroendocrine system of teleost fish differs from that of tetrapods in that it lacks a neurosecretory organ (median eminence) at the base of the hypothalamus for the secretion of releasing hormones and a portal system to deliver them to the pituitary cells. Instead, the anterior pituitary is directly innervated by both stimulatory and inhibitory pathways that originate in the preoptic area and hypophysiotropic regions of the hypothalamus and terminate in the vicinity of the hormone-producing cells.

Multiple forms of GnRH have been discovered in different brain regions of teleost fish (Gothilf et al., 1996; Mohamed et al., 2005). The form of GnRH released from the nerve terminals in the pituitary is the major stimulatory influence on gonadotropin secretion. Sea bream GnRH is the primary gonadotropin-releasing hormone in several perciform fishes, whereas salmon GnRH performs this function in salmonid and some cyprinid fishes (Lethimonier et al., 2004). GnRH binds to specific G-protein-coupled receptors (GPCRs) on the gonadotropes that can couple to multiple G-proteins ($G_{q/11}$, G_s, and G_o), resulting in activation of calcium-/protein kinase C (PKC)-dependent and other pathways to stimulate gonadotropin secretion (Ando et al., 2001). Hypothalamic and pituitary GnRH content increases during the reproductive cycle (Holland et al., 1998; Khan et al., 2001). GnRH regulates the number of GnRH receptors on the gonadotropes which in turn modulate the responsiveness of the cells to subsequent GnRH stimulation. GnRH receptor content increases during the later phases of the reproductive cycle to potentiate the stimulatory action of GnRH, coincident with other changes in the neuroendocrine system, to achieve a preovulatory surge in LH secretion (Habibi et al., 1989). The secretion of LH is highly regulated, whereas FSH secretion in the few salmonid species investigated to date appears to be largely constitutive, paralleling changes in FSH mRNA and protein levels (Swanson et al., 2003). The monoamine neurotransmitter serotonin (5-HT) can act on the GnRH system in the preoptic–anterior hypothalamic area (POAH) and also potentiate the action of GnRH on LH secretion in Atlantic croaker and goldfish (Khan and Thomas, 1992; Somoza and Peter, 1991; Somoza et al., 1988) at certain times of the day and phases of the reproductive cycle (Khan and Thomas, 1994). Dopamine exerts a strong inhibitory control of LH secretion in carps and some catfishes (Blasquez et al., 1998), whereas it has a minor influence in salmonids and has no inhibitory effect on LH secretion in Atlantic croaker and some other perciform fishes (Copeland and Thomas, 1989). Several other neuromeodulatory factors influence LH secretion in teleosts. GABA stimulates LH secretion in goldfish and regressed Atlantic croaker and inhibits gonadotropin secretion in croaker with fully developed gonads (Khan and Thomas, 1999; Trudeau and Peter, 1995). The negative feedback effect of gonadal steroids (estradiol, testosterone) also varies during the reproductive cycle, as it is stimulatory on GnRH-induced LH secretion in immature and early recrudescing individuals and inhibitory in fish at the end of the reproductive cycle (Khan et al., 1999; Mathews et al., 2002; Trudeau and Peter, 1995).

Actions of Hormones at Target Tissues

Activation of Intracellular Second Messengers

Binding of peptide, protein, and steroid hormones to cell-surface receptors on target cells activates intracellular signal transduction systems, leading to the hormonal response. Binding of GnRH to a specific GPCR on gonadotropes activates several signal transduction pathways in the three teleost models investigated in detail: goldfish, salmonids, and tilapia (Ando et al., 2001; Chang and Jobin, 1994; Yaron et al., 2001). GnRH causes rapid activation of a G-protein ($G_{q/11}$) and a second-messenger cascade involving phospholipase C (PLC) and the formation of inositol triphosphate (IP_3) and diacylglycerol (DAG). DAG causes activation of protein kinase C (PKC), whereas IP_3 has been shown to cause intracellular calcium concentrations to increase in mammalian gonadotropes due to mobilization from internal stores. GnRH also induces calcium influx through voltage-sensitive calcium channels (VSCCs) into fish gonadotropes. The increase in intracellular calcium concentrations seems to be of primary importance in the stimulation of gonadotropin secretion, whereas both calcium levels and activation PKC are involved in GnRH regulation of gonadotropin subunit gene expression (Ando et al., 2001; Gur et al., 2001). Moreover, recent evidence suggests that PKC acts via stimulation of mitogen-activated protein kinase (MAPkinase). In addition, phospholipase A_2 and arachidonic acid appear to be involved in gonadotropin release from tilapia pituitaries. Also, a cAMP-dependent protein, protein kinase A (PKA), is activated by GnRH in tilapia (Yaron et al., 2001). The signal transduction systems activated by gonadotropins are highly conserved among the vertebrates. The adenylate cyclase system is of central importance in mediating the steroidogenic actions of gonadotropins in fish as well as in other vertebrates (Van Der Kraak and Wade, 1994). Cyclic AMP levels increase markedly in spotted seatrout ovaries within 15 minutes of gonadotropin stimulation *in vitro*, prior to the increase in steroid synthesis (Singh and Thomas, 1993). Calcium from both intracellular and extracellular pools is also an important component of the signaling pathway (Benninghoff and Thomas, 2005). The calcium-binding protein calmodulin participates in the regulation of intracellular calcium levels, whereas VSCCs regulate calcium influx. Other second messengers such as PKC, inositol-1,4,5-triphosphate, diacylglycerol, and arachidonic acid appear to be components of the gonadotropin signaling pathway in certain steroidogenic tissues (Van der Kraak and Wade, 1994). Therefore, chemicals could potentially interfere with a variety of signal transduction systems to modulate the actions of gonadotropin.

Genomic Steroid Actions via Nuclear Steroid Receptors

The classic genomic mechanism of steroid action involves diffusion of steroids into the cell where they bind to intracellular receptors (nuclear steroid receptors), resulting in receptor activation and binding to hormone response elements on genes (in conjunction with other transactivating proteins) to alter their rates of transcription (Figure 10.2) (Beato and Sanchez-Pacheco, 1996; Tsai and O'Malley, 1994). The nuclear steroid receptors—estrogen (ER), androgen (AR), progestogen (PR), glucocorticoid (GR), and mineralocorticoid (MR)—are members of the nuclear receptor superfamily of ligand-activated transcription factors that includes receptors for thyroid hormone, vitamin D, ecdysone, and retinoids as well as many orphan receptors for which the ligands are currently unknown (Laudet, 1997). Nuclear steroid receptor proteins have a similar modular structure with six functional domains (A to F). At the *N*-terminal end, the hypervariable A/B domains possess sequences required for transcriptional activation. The DNA-binding region (C domain) is the most highly conserved region of the receptor protein (60 to 95% homology) and has two protruding zinc fingers that enable the ligand-activated receptor to bind to hormone response elements (specific DNA sequences in the regulatory regions of genes) of the target genes. The variable hinge region (D domain) is involved in nuclear localization. The large ligand-binding domain (LBD), or E domain, is conserved and displays a high degree of sequence homology, particularly with members of the same receptor subfamily (38 to 60% sequence identity between teleostean and mammalian ERs) (Hawkins et al., 2000). In addition, the LBD is involved in receptor dimerization, heat shock protein binding, and transcriptional activation. At the *C*-terminal end, the F domain is highly variable and of unknown function.

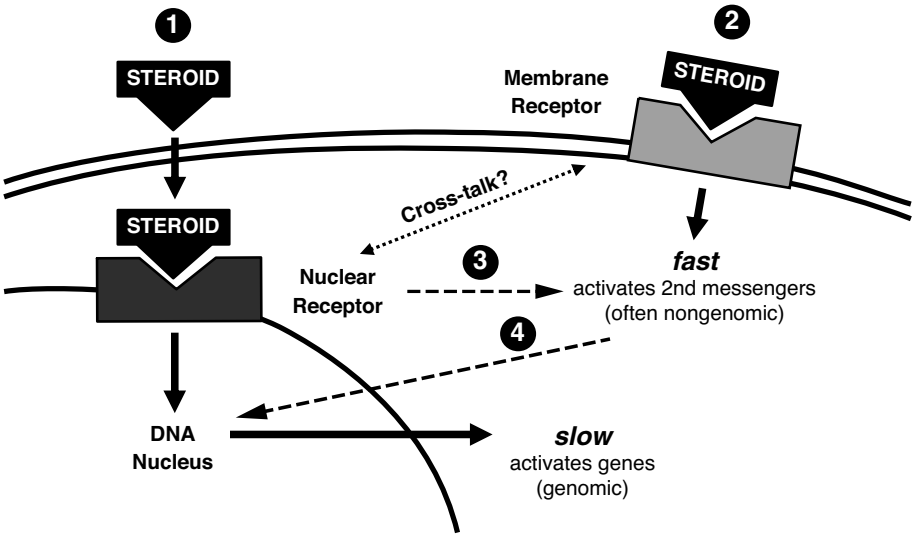

FIGURE 10.2 Major receptor-mediated mechanisms of steroid action at target cells. (1) Classic mechanism of steroid action via binding to intracellular nuclear steroid receptors, translocation to the nucleus, and binding to hormone response elements of genes resulting in alterations in their rates of transcription (genomic mechanism). This mechanism, involving new mRNA and protein synthesis, is relatively slow and occurs over a timeframe of hours to days. (2) Alternative mechanism of steroid action via binding to receptors on the cell surface, called membrane receptors, resulting in activation of ion channels or intracellular second messengers. This mechanism initiates a rapid hormonal response within a few minutes that is often nongenomic. The identities of most membrane steroid receptors are unresolved. Some membrane receptors are nuclear-receptor-like; others, such as the ovarian progestin membrane receptor, are novel proteins unrelated to the nuclear steroid receptors. Cross-talk is also possible between these two signaling pathways. Additional mechanisms of steroid action that have been identified involve (3) activation of intracellular second messengers through the intracellular nuclear receptor and (4) alterations in gene transcription via membrane steroid receptors. (From Thomas, P.C. et al., in *The Fish Oocyte: From Basic Studies to Biotechnological Applications*, Babin, P.J. et al., Eds., Springer, Dordrecht, 2007, pp. 203–234. With permission.)

Nuclear steroid receptors are localized primarily in the nucleus (ER) or cytoplasm (GR) prior to ligand binding and are associated with heat shock proteins. Steroid binding causes a conformational change of the receptor, resulting in its activation which is associated with dissociation of heat shock proteins, phosphorylation of specific amino acids, and dimerization. The activated receptor is translocated to the nucleus and binds to DNA via the DNA-binding domain (C domain). The two zinc fingers in the C domain orientate the receptor dimers to enable binding of the intervening sequences to the hormone response elements on DNA. The hormone response elements consist of two half sites, each one binding one receptor molecule of the dimer. The number, spacing, and structure of hormone response elements modulate the affinity and specificity of steroid receptor binding to genes and are thought to be critical regulators of steroid hormone action. Once the receptor is aligned on the gene, its two transcription activation domains activate transcription factors (TFBIIB and TFBIID) to signal assembly of other transcription factors and DNA polymerase II at the transcription start site (TATA box) to initiate transcription. In addition to gene activation, transcriptional repression by steroid hormones frequently occurs as a result of inhibition of enhancer elements such as AP-1 or by interactions with corepressors.

Nuclear Steroid Receptors in Fish

The responsiveness of target tissues to steroid hormones is largely dependent on their expression of steroid hormone receptors, highly responsive target tissues having elevated receptor concentrations in comparison to other tissues. Nuclear steroid receptor expression is regulated by steroid hormones and therefore fluctuates in response to alterations in steroidogenesis; for example, the nuclear estrogen receptor (nER), which is regulated by estrogens in teleosts, demonstrates a marked seasonal cycle in the livers of spotted seatrout that parallels the changes in circulating 17β-estradiol levels during the period of vitellogenesis in this species (Smith and Thomas, 1991). Similarly, nuclear androgen receptor (nAR) levels are regulated

by androgens in teleosts, and gonadal concentrations of the receptor increase during the reproductive season (Larsson et al., 2002; Sperry and Thomas, 1999a). Target tissue responsiveness in mammals and probably in teleosts to estrogens and several other steroid hormones is also dependent on which nuclear receptor subtypes are expressed. Two distinct nuclear ER subtypes (ERα and ERβ) are present in mammals and three ERs (ERα, ERβa and ERβb) in advanced teleosts with distinct but overlapping tissue distributions and different steroid-binding affinities (Hawkins and Thomas, 2004; Hawkins et al., 2000; Kuiper et al., 1997). Multiple ARs with different tissue distributions and ligand-binding properties have also been identified in teleosts (Ikeuchi et al., 2001; Sperry and Thomas, 1999a,b, 2000). This multiplicity in nuclear receptor subtypes modulates not only tissue responsiveness to natural steroid hormones but also interactions with xenobiotic chemicals, a topic that is discussed later in this chapter.

Nongenomic Steroid Actions via Membrane Steroid Receptors

In addition to the classic mechanism of steroid action, extensive evidence now suggests that steroids also exert rapid, nongenomic actions by binding to receptors on the surface of target cells and activating signal transduction pathways, leading to a biological response (Figure 10.2) (Falkenstein et al., 2000; Norman et al., 2004; Revelli et al., 1998; Watson and Gametchu, 1999). Progesterone treatment, for example, causes a marked increase in intracellular calcium levels in mammalian sperm in less than a minute, resulting in the acrosome reaction and hypermotility (Blackmore et al., 1991). Specific membrane receptors and rapid nongenomic actions for estrogens, androgens, and progestins have recently been identified throughout the reproductive system in vertebrates, including the hypothalamus, pituitary, gonads, gametes, steroidogenic cells, and primary and secondary reproductive structures such as the breast (Revelli et al., 1998). Nongenomic steroid actions have been shown to have important functions in several reproductive processes such as the activation of sperm (Blackmore et al., 1991; Revelli et al., 1998) in mammals, but their precise physiological roles in many other reproductive tissues remain unclear.

Membrane Steroid Receptors in Fish

Membrane receptors for all the sex steroids have been identified in teleosts (Thomas, 2000c, 2003). A high-affinity membrane estrogen receptor (mER) has been characterized in Atlantic croaker testicular membranes and is the likely intermediary in a rapid, cell-surface-initiated, nongenomic action of estrogens to downregulate testicular androgen production in this species (Loomis and Thomas, 2000). The mER is also present in croaker ovaries and activates a stimulatory G-protein (G_s), resulting in increased cAMP production (Thomas et al., 2003). Androgens also can regulate gonadal steroidogenesis in Atlantic croaker, causing downregulation of ovarian estrogen biosynthesis via a nongenomic mechanism (Braun and Thomas, 2003). A membrane androgen receptor has been identified in croaker ovaries and fully characterized in this species (Braun and Thomas, 2004). Probably the most intensively studied and best characterized model of a cell-surface-initiated, nongenomic steroid action is the induction of oocyte maturation (OM) in teleosts and amphibians by progestin MISs (Nagahama et al., 1994; Thomas, 1994; Thomas et al., 2002). The mPRs on oocytes thought to mediate these actions of the fish MISs, 17,20β-P and 20β-S, have been identified and fully characterized in several teleost species (Patiño and Thomas, 1990b; Thomas et al., 2002). MIS receptor concentrations are upregulated by gonadotropin during an early stage of oocyte maturation, and this is associated with the oocytes becoming responsive to the MISs and the completion of OM after hormone treatment (Thomas et al., 2001). In addition, an mPR has been characterized on spotted seatrout sperm and is the likely intermediary in 20β-S stimulation of sperm motility via increases in intracellular calcium and cAMP levels, resulting in increased fertilization success in this species (Thomas, 2003; Thomas et al., 1998).

Recently, a novel gene was cloned and sequenced from a spotted seatrout cDNA ovarian library that has all the characteristics of the mPR mediating MIS regulation of oocyte maturation in this species (Thomas et al., 2002; Zhu et al., 2003a). Subsequently, 13 additional closely related cDNAs were identified in other vertebrate species, including 3 in humans that represent 3 distinct clades and also have characteristics of mPRs (Zhu et al., 2003b). These mPRs are not structurally related to nuclear steroid receptors, but instead have 7 transmembrane domains, which is a characteristic of G-protein-coupled receptors. Recent studies show the mPR in spotted seatrout is coupled to an inhibitory G-protein

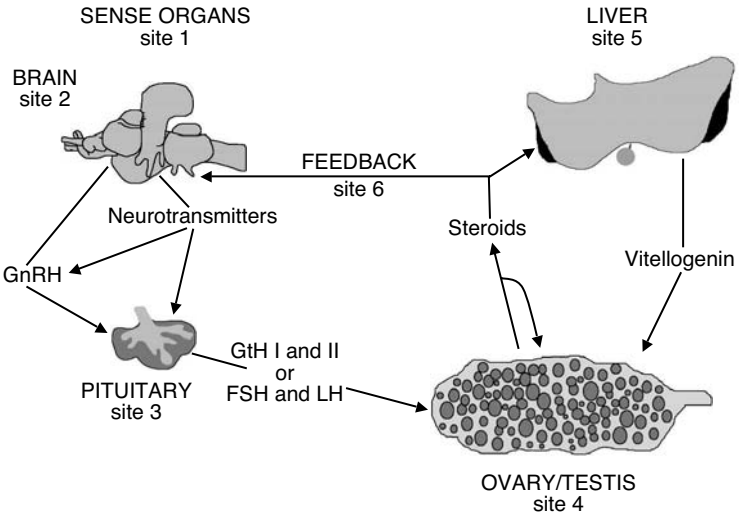

FIGURE 10.3 Potential sites of chemical interference with reproductive endocrine function in teleosts along the hypothalamic–pituitary–gonadal axis. (Site 1) Sense organs—eyes, pineal, olfactory organs, etc. (Site 2) Brain—hypothalamic regions, particularly the hypophysiotropic region of the hypothalamus; causing alterations in neurotransmitters and neuropeptides, especially GnRH. (Site 3) Pituitary—gonadotropes, GnRH, and neurotransmitter nerve terminals and their receptors; altering GnRH and neurotransmitter release and GnRH receptor concentrations and resulting in changes in LH and FSH secretion. (Site 4) Gonads—germ cells, gametes, steroidogenic cells, etc. and associated steroid receptors; resulting in altered gametogenesis, gamete maturation, steroid and peptide hormone secretion, and steroid action. (Site 5) Liver—cytochrome P-450 and conjugating enzymes; causing changes in steroid metabolism, clearance, and circulating steroid hormone titers; estrogen nuclear receptors causing changes in the production of vitellogenin and zona radiata proteins in both sexes. (Site 6) Hypothalamus and pituitary—sex steroid and gonadal peptide hormone receptors and steroidogenic enzymes; causing alterations in feedback control of neurotransmitter, as well as GnRH, LH, and FSH synthesis and secretion in the pituitary. Sex steroids also act within the gonads to exert feedback control of steroidogenesis. The steroids 17β-estradiol and testosterone are present in both sexes, although 17β-estradiol is usually low in males; 11-ketotestosterone is a male-specific androgen in the majority of species; 17,20β-dihydroxy-4-pregnen-3-one (17,20β-P) and 17,20β,21-trihydroxy-4-pregnen-3-one (20β-S) are maturation-inducing steroids (MISs) in both males and females. Other C-21 progestins may be MISs in a few species. *Abbreviations:* GnRH, gonadotropin-releasing hormone; FSH or GTH I, follicle-stimulating hormone; LH or GTH II, luteinizing hormone. (From Thomas, P. and Khan, I.A., in *Chemically Induced Alterations in Functional Development and Reproduction of Fishes*, Rolland, R. M. et al., Eds., Society of Environmental Toxicology and Chemistry, Pensacola, FL, 1997, pp. 29–51. With permission.)

and that progestin treatment causes a downregulation of adenylyl cyclase activity, resulting in a decrease in cAMP levels and release of the oocyte from meiotic arrest (Pace and Thomas, 2005; Thomas, 2003; Thomas et al., 2002). Activation of the phosphatidylinositol 3-kinase/Akt signal transduction pathway by the MIS is also required for OM in Atlantic croaker and striped bass (Pace and Thomas, 2006; Weber and Sullivan, 2001). Direct evidence for an involvement of the mPR in MIS induction of OM in zebrafish and goldfish has been obtained by blocking OM by downregulating the receptor through microinjection of oocytes with mPR antisense oligonucleotides (Tokumoto et al., 2006; Zhu et al., 2003a). The discovery of this new family of steroid receptors provides the first plausible explanation of how steroids can act on the cell surface to cause rapid, nongenomic hormonal responses in target cells.

Sites of Chemical Interference on the Hypothalamic–Pituitary–Gonadal Axis

Chemicals can act on multiple targets in the endocrine system and by a variety of mechanisms to disrupt endocrine function. Figure 10.3 shows some potential sites of chemical action on the hypothalamic–pituitary–gonadal (HPG) axis that result in interference with reproductive endocrine function. Chemicals could be detected as noxious by sense organs such as the eyes and olfactory epithelium or could interfere

with sex pheromone action by binding to their olfactory receptors, resulting in activation of inhibitory pathways controlling neuroendocrine function and reproductive behaviors (site 1) (Moore and Lower, 2001). Alternatively, the chemicals could act in the hypothalamus to influence neurotransmitter function controlling GnRH secretion or directly influence GnRH neurons (site 2) (Khan and Thomas, 2001). Changes in the secretion of GnRH and regulatory neurotransmitters would secondarily affect pituitary GnRH receptor levels and gonadotropin secretion from the pituitary in response to GnRH. In addition, certain chemicals can act directly at the pituitary to influence GnRH signaling pathways in the gonadotrope and gonadotropin secretion (site 3) (Thomas, 1993). These chemically induced changes in gonadotropin secretion often result in alterations in gonadal function and development, especially steroid hormone production and gamete maturation. Some chemicals exert their actions directly on the gonads to disrupt endocrine function by influencing the activities of gonadotropin second-messenger pathways and enzymes involved in the synthesis of steroid hormones (site 4) (Ankley et al., 2005; Benninghoff and Thomas, 2005; Freeman and Idler, 1974; Thomas and Khan, 1997; Van Der Kraak et al., 1992). Alterations in steroid production can dramatically influence steroid levels in the blood and subsequently steroid actions at their target tissues such as the gonads, accessory reproductive tissues, liver, and neuroendocrine system. Increases in the metabolic clearance rate of steroids due to induction of hepatic cytochrome P450 enzymes by certain chemicals such as polychlorinated biphenyls (PCBs) can also influence circulating steroid levels (site 5) (Sivarajah et al., 1978; Yano and Matsuyama, 1986). Steroid hormone action can also be affected at these target tissues by direct interactions of chemicals with both nuclear and membrane steroid receptors, resulting in agonism or antagonism of steroid hormone action; for example, the steroid feedback system that influences reproductive neuroendocrine function (site 6) could be affected by alterations in the production (Kishida et al., 2001), clearance, or action of steroids (Harris et al., 2001; Khan and Thomas, 1998). Similarly, the stimulation of vitellogenesis by chemicals could be due to their direct interactions with the estrogen receptor in the liver, which regulates vitellogenin production (site 5) (Jobling and Sumpter, 1993; Thomas and Khan, 1997); could occur indirectly due to actions at other levels of the HPG axis that result in alterations in blood estradiol levels; or could be due to several mechanisms acting simultaneously. For some chemicals, actions at multiple sites via several mechanisms have been demonstrated (Van Der Kraak et al., 1992).

Mechanisms of Endocrine Toxicity

The main features of the endocrine system, discussed in the previous sections, involves the secretion of hormones into the circulation, their binding to specific receptors on target tissues, and the subsequent intracellular hormonal responses. In general, the magnitude of the cellular response to hormones is dependent on the number of receptors occupied by the hormone which, in turn, is related to the concentration of free (or loosely bound) hormone in the circulation. Xenobiotic chemicals, therefore, can potentially influence endocrine function by affecting hormone levels in the blood via alterations in hormone secretion or metabolic clearance or by interfering with hormone action at the receptor or at other sites along the hormone signal transduction pathway. Evidence has been obtained for all these types of endocrine disruption in fishes.

Alterations of Hormone Secretion

Neuroendocrine Secretion

A large body of evidence, mostly circumstantial, indicates that many compounds, including lead, mercury, organochlorine and organophosphorus pesticides, PCB mixtures, and mimics or antagonists of steroid hormone action impair reproductive endocrine function (i.e., endocrine-disrupting chemicals [EDCs] that act on the reproductive system) at the hypothalamic level in mammals, fish, and other vertebrates (Cooper et al., 1999; Desaulniers et al., 1999; Katti and Sathyaneson, 1986; Khan and Thomas, 1997; Thomas and Khan, 1997). Investigations of the neuroendocrine targets of EDCs, however, are complicated by the multiplicity and complexity of neuroendocrine pathways that control reproduction and the

wide variety of potential chemical interactions; consequently, the sites and mechanisms of neuroendocrine toxicity for the majority of EDCs remain poorly understood.

Alterations of Gonadotropin Secretion via Changes in Hypothalamic Monoamine Metabolism. Chemicals that alter neurotransmitter concentrations, such as organochlorine pesticides, probably influence neuroendocrine function and ultimately reproduction, although there are only a few reports on this potentially important mechanism of endocrine disruption (Cooper et al., 1999; Goldman et al., 1990; Khan and Thomas, 1997). The strongest evidence to date for this mechanism of neuroendocrine toxicity has been obtained in the Atlantic croaker exposed to a PCB mixture, Arochlor® 1254. The marked impairment of LH secretion observed in croaker after exposure to Arochlor® 1254 provided initial evidence that the neuroendocrine system is a major target of PCBs in teleosts (Thomas, 1989). Subsequently, it was shown that disruption of LH secretion occurs in croaker with tissue PCB levels (13 ppm in brain) comparable to those in fish from heavily impacted environments and that this impairment was accompanied by alterations in brain neurotransmitter levels (Khan and Thomas, 1997). Serotonin concentrations in the hypothalamus were significantly decreased (30 to 35%) after 30-day exposures to the PCB (0.1 mg per 100 g b.w. per day) in the diet, whereas tissue levels of its metabolite, 5-hydroxyindolacetic acid, showed only minor changes. Serotonin has been shown to exert a stimulatory influence on LH secretion in croaker and other vertebrates (Khan and Thomas, 1992). A subsequent study showed that the PCB-induced decline in hypothalamic 5-HT concentrations was due to inhibition of tryptophan hydroxylase, the rate-limiting enzyme in serotonin synthesis (Khan and Thomas, 2001). The decreased 5-HT activity after PCB exposure resulted in decreased hypothalamic concentrations of GnRH and its secretion, leading to downregulation of GnRH receptors on gonadotropes and a decreased LH response to GnRH stimulation. This loss of responsiveness to GnRH and downregulation of GnRH receptors after Arochlor® 1254 treatment could be restored with an implant of luteinizing-hormone-releasing hormone (LHRH) (Khan and Thomas, 2001). Moreover, a specific inhibitor of tryptophan hydroxylase, *para*-chlorophenylanaline, mimicked these neuroendocrine effects of the PCB mixture as well as the subsequent reproductive impairment, whereas cotreatment of the PCB-dosed fish with 5-hydroxytryptophan, which bypasses this biosynthetic step, reversed the PCB effects (Khan and Thomas, 2001; Thomas and Khan, 2004). Recent studies indicate that the decrease in tryptophan hydroxylase activity is due to a decline in hypothalamic content of the protein, which appears to be related to oxidant damage, because the PCB effects can be reversed by supplementation with an antioxidant (vitamin E) in the diet (Khan and Thomas, 2004). Mammalian studies also suggest that the enzyme is susceptible to damage by reactive oxygen species, and vitamin E has a protective effect (Adachi et al, 1989; Cash, 1998). Neuroendocrine disruption associated with alterations of neurotransmitter function has also been reported in croaker after exposure to lead (Thomas and Khan, 1997). Interestingly, both Arochlor® 1254 and lead have been shown to cause increased lipid peroxidation in croaker brain and ovarian tissues in addition to altering their antioxidant status (Thomas and Juedes, 1992; Thomas and Wofford, 1984, 1993).

Gonadal Steroidogenesis

A range of chemicals have been shown to exert direct effects on gonadal steroidogenesis in teleosts via several mechanisms. Several polycyclic aromatic hydrocarbons (naphthalene, β-naphthoflavone, and retene) were shown to potentiate the stimulatory effects of gonadotropin on testicular androgen production but did not alter basal secretion (Evanson and Van Der Kraak, 2001). The site of β-naphthoflavone action appeared to be independent of calcium and to be mediated by increases in cAMP, which suggests interference with gonadotropin action (see subsequent section). In contrast, the stimulatory effects of Arochlor® 1254 on gonadotropin-stimulated ovarian estrogen production were attenuated by treatment with inhibitors of calmodulin and voltage-sensitive calcium channels, indicating a role for intracellular calcium in the stimulatory effects of the PCB mixture (Benninghoff and Thomas, 2005). The reduction in the steroidogenic capacity of gonads of freshwater fishes observed after exposure to the phytosterol β-sitosterol, a component of bleached pulp mill effluent (MacLatchy and Van der Kraak, 1995), was associated with a decrease in the mitochondrial pool of cholesterol (Leusch and MacLatchy, 2003). Peroxidation of lipids and proteins by chemicals such as PCBs, including the steroidogenic enzymes

themselves, is another potential mechanism by which steroid synthesis could be altered, although clear evidence for this mechanism has only been obtained in fish interrenal tissues (see subsequent section on HPI axis).

Interference with Hormone Actions

Intracellular Second Messengers

A well-known toxic action of heavy metals such as cadmium and lead, as well as organic compounds such as dichlorodiphenyltrichloroethane (DDT) and PCBs, is interference with calcium homeostasis (Inglefield and Shafer, 2000; Pounds, 1990). Some of these chemicals appear to alter calcium signaling in endocrine tissues, resulting in altered hormone secretion (Thomas, 1999). Chronic treatment with cadmium was found to advance gonadal recrudescence and increase the secretion of gonadotropin (LH) and sex steroids in Atlantic croaker (Thomas, 1989). It was later found that the metal can directly stimulate the secretion of these hormones from pituitary and ovarian tissues in *in vitro* incubations (Thomas, 1993). Perifusion of 50-μ*M* cadmium was shown to markedly increase basal gonadotropin secretion and restore the gonadotropin response to GnRH in calcium-free media. Moreover, the spontaneous secretion of LH in response to cadmium in the pituitary perifusion system was blocked by prior treatment with verapamil, an inhibitor of voltage-sensitive calcium channels (VSCCs), and calcium influx into the gonadotrop, which suggests that the metal activates the calcium-dependent signaling pathway normally induced by GnRH via its actions on VSCCs (Thomas, 1999). Heavy metals have also been shown to influence cAMP concentrations and adenylyl cyclase activities in endocrine tissues, possibly by alterations in calcium or zinc homeostasis or calmodulin activation, resulting in altered enzyme activities (Singhal, 1981). At the gonadal level cadmium caused a concentration-dependent increase in 17β-estradiol secretion and cAMP levels and caused significant increases in androgen and estrogen secretion at the lowest concentration tested (0.01 ppm) (Thomas and Khan, 1997). Interestingly, direct stimulatory effects of cadmium on gonadotropin secretion and gonadal steroidogenesis also have been demonstrated in mammalian tissues (Cooper et al., 1987; Laskey and Phelps, 1991).

Interference with Genomic Steroid Actions via Nuclear Steroid Receptors

Most of the evidence for chemical interference with endocrine functions in vertebrates has been obtained for genomic steroid actions via interactions with nuclear steroid receptors, especially the nuclear ER. The occurrence of significant environmental concentrations of estrogens capable of eliciting estrogenic responses was initially detected by the measurement of high levels of vitellogenin in the blood of male and juvenile fish exposed to sewage treatment works (STW) discharge water in several rivers in England (Jobling and Sumpter, 1993; Purdom et al., 1994) and has since been reported in male fish collected from many freshwater and estuarine sites in Europe, Japan, and North America (Allen et al., 1999; Folmar et al., 1996; Hashimoto et al., 2000; Larsson et al., 1999). Normally, plasma levels of this yolk precursor protein are very low or are undetectable in male and juvenile fish; however, circulating vitellogenin levels in the milligram/milliliter range have been detected in male and juvenile rainbow trout exposed to STW discharge water (Purdom et al., 1994; Larsson et al., 1999).

Numerous laboratory and field studies over the past 15 years have demonstrated that a broad range of environmental chemicals with a variety of structures can elicit estrogenic responses in fish and other vertebrates via binding to nuclear ERs (Figure 10.4). Activation of nuclear ERs by these chemicals increases the transcription of estrogen-responsive genes such as vitellogenin and zona radiata proteins and nuclear ERs, as well as a large number of genes detected on microarrays whose functions are currently unknown (Denslow et al., 1999), resulting in disruption of gonadal sex differentiation and reproductive processes such as secondary oocyte growth and testicular function (Bulger and Kupfer, 1985; Jobling and Sumpter, 1993). The structures of several estrogenic chemicals are shown in Figure 10.5. Many estrogenic xenobiotic chemicals (xenoestrogens) that bind to mammalian ERs show similar binding affinities for teleost ERs. Xenoestrogens such as *ortho,para* derivatives of DDT, nonylphenol, bisphenol A, hydroxylated metabolites of several PCB congeners, and kepone have relative binding

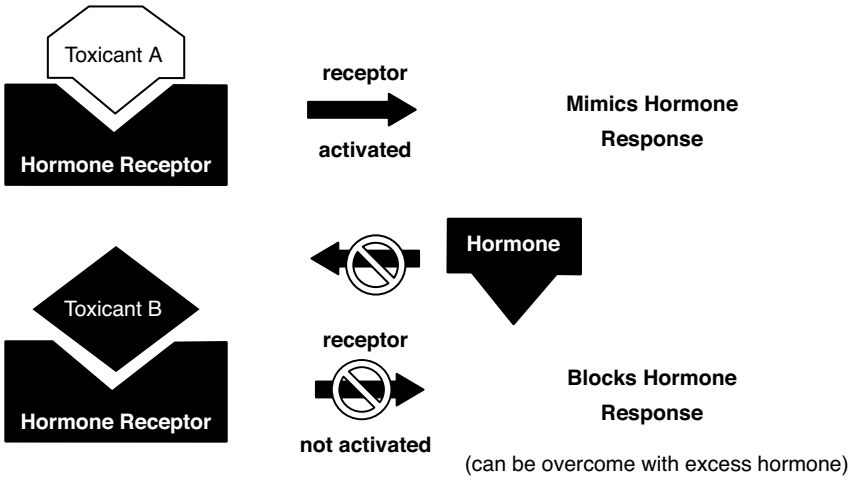

FIGURE 10.4 Possible consequences of competitive binding of a toxicant to a hormone receptor. Binding of toxicant A causes activation of the receptor, mimicking the hormone action (agonist). Binding of toxicant B does not activate the receptor or causes weak activation, resulting in either no hormonal response or blocking hormone action when the hormone is present (antagonist). Increasing the hormone concentrations will displace some or all of the toxicant from the binding site, thereby reducing its antagonistic action. (Adapted from McLachlan, J.A., *Environ. Health Perspect.*, 101, 386–388, 1993.)

affinities for teleost ERs 10^{-3} to 10^{-4} times lower than that of the natural ligand 17β-estradiol, similar to the relative binding affinities for mammalian ERs (Loomis and Thomas, 1999; Nelson, 1974). Thus, the majority of xenoestrogens are weak agonists, and their potency is due to their accumulation and persistence in biota.

In contrast, the majority of environmental contaminants that interact with nuclear androgen and progesterone receptors antagonize the actions of androgens and progestins (Gray et al., 1996, 2004; Kelce et al., 1995; Laws et al., 1995; Lundolm, 1991). Chemicals with antiandrogenic activities mediated via the nuclear AR in mammals include *para,para* derivatives of DDE and DDT, the dicarboximide fungicides vinclozolin and procymidine and their metabolites, the conazole fungicide prochloraz, and the polybrominated biphenyl mixtures DE-71 and DE-100 (Gray et al., 2004). Phthalate esters, which possess some antiandrogenic properties, do not bind to the nuclear AR. Recently, chemicals with androgenic activities that bind to the nuclear AR and cause masculinization of fish have been detected in pulp and paper mill effluents and in feedlot effluents (Gray et al., 2004; Jenkins et al., 2000; Larsson and Forlin, 2002; Larsson et al., 2006; Orlando et al., 2003; Parks et al., 2001). Masculinization effects observed include the development of a gonopodium in female mosquitofish and the development of nuptial tubercles and reduced vitellogenin levels in female fathead minnow (Ankley et al., 2003; Howell et al., 1980).

The androgenic chemicals in these effluents have not been identified to date, although trenbolone, the anabolic steroid administered to domestic animals, or an active metabolite is a likely candidate for a potent androgen in feedlot effluents. Trenbolone has recently been shown to have androgenic effects in the fathead minnow, causing the development of nuptial tubercles in females, an effect blocked by co-administration of the nuclear androgen receptor antagonist flutamide (Ankley et al., 2004). In contrast, metabolites of the fungicide vinclozolin, which are competitors for androgen binding to fish androgen receptors (Sperry and Thomas, 1999) and have antiandrogenic activities, have been shown to downregulate the activity of the aromatase enzyme in fathead minnow (Ankley et al., 2005) and therefore have the potential to impair both androgenic and estrogenic actions in fish. In conclusion, extensive evidence suggests that a broad range of contaminants that influence the endocrine system are present in sufficient concentrations in many polluted environments to alter genomic steroid action mediated by nuclear estrogen, androgen, and progesterone receptors. Factors that affect the degree of endocrine disruption by this mechanism are discussed in the following section, and evidence for its occurrence in natural populations of fish inhabiting polluted waters is reviewed in later chapters.

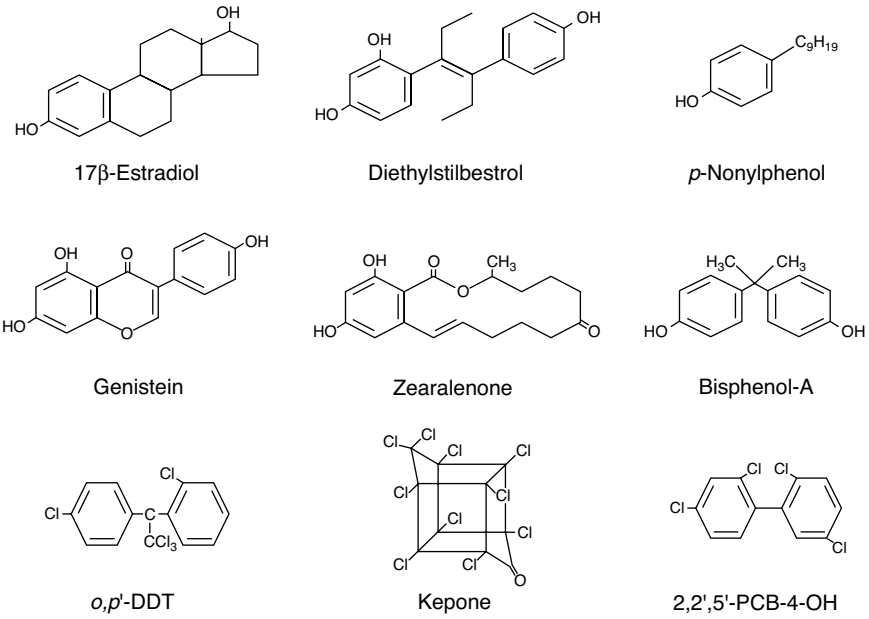

FIGURE 10.5 Structures of some estrogenic chemicals, including the natural hormone 17β-estradiol, the major estrogen in most vertebrates; diethylstilbestrol, a potent synthetic estrogen; genestein, a phytoestrogen; zearanolone, an estrogenic mycotoxin; and a variety of environmental estrogens (xenoestrogens): the organochlorine pesticide *o,p′*-DDT (1,1,1-trichloro-2-(*p*-chlorophenyl)-2(*o*-chlorophenyl)ethane) (the *ortho* and *para* derivatives of DDE and DDD are also xenoestrogens); kepone, an organochlorine pesticide (chlordecone); *p*-nonylphenol, the degradation product of the alkylphenol ethoxylate nonionic surfactants (octylphenol is also a xenoestrogen); bisphenol-A, a plasticizer; and 2,2′,5′-trichloro-4-biphenylol, the hydroxylated metabolite of the PCB 52 congener (other hydroxyl metabolites of PCB congeners such as 2′,4′,6′-trichloro-4-biphenylol and 2′,3′,4′,5′-tetrachloro-4-biphenylol are also xenoestrogens).

Factors That Influence Steroid-Receptor-Mediated Endocrine Disruption

The degree of receptor-mediated endocrine disruption is at least partially dependent on the proportion of the receptors binding the chemical which, in turn, is related to the binding affinity of the chemical for the receptor as well as the chemical and steroid concentrations in the target tissues. The endocrine-disrupting activities of these chemicals, however, can be significantly altered by a variety of other factors. Xenobiotic chemicals can act as agonist or antagonists, depending on the conformational changes to the receptor that they induce upon binding and their subsequent interactions with regulatory proteins in a cell-specific and probably a species-specific manner (Figure 10.3) (McDonnell, 2003).

Species differences in the binding of xenobiotic chemicals to nuclear steroid receptors and their affinities can potentially influence the degree of endocrine disruption and prevent broad extrapolation of results across species. The majority of xenobiotic chemicals (xenoestrogens) that bind to the nuclear estrogen receptor (nER) in mammals also bind to most teleost nERs investigated to date, although their affinities may differ. As an example, *ortho,para* derivatives of DDT bind to the nERs in both the rat and croaker, whereas the *para,para* derivatives do not (Loomis and Thomas, 1999; Nelson, 1994), although marked species differences in the binding affinities of PCBs, hydroxylated PCBs, and PCB mixtures to human, reptilian, and rainbow trout nERs were observed (Mathews et al., 2000). A wide variety of xenobiotic compounds, including DDT derivatives, that bind to the nuclear progesterone receptor (nPR) and antagonize the actions of progesterone in mammals and birds (Gray et al., 1996) do not bind to the nPR in spotted seatrout ovaries at concentrations up to 10^{-4} *M* and therefore are unlikely to interfere with progestin actions mediated by this receptor (Pinter and Thomas, 1997). Thus, it is not possible to predict from xenobiotic binding studies with the nPR in tetrapods whether these chemicals are likely to interfere with progestin action to block ovulation in fishes.

The presence of different receptor subtypes with differing ligand-binding affinities and specificities and different tissues distributions can have a marked effect on the potencies and actions of steroids and xenobiotic chemicals at different target tissues. Multiplicity of receptor subtypes is commonly observed in the nuclear receptor super family; for example, two nER subtypes, ERα and ERβ, with different ligand-binding affinities and tissue distributions, have been identified in mammals. However, two nERβ subtypes with distinct tissue distributions, ERβa and ERβb, have been described in Atlantic croaker and are also present in other teleost fishes (Hawkins et al., 2000; Hawkins and Thomas, 2004). An interesting finding is that the binding affinity of the nER in croaker testes for estrogens and xenoestrogens is 5 to 10 times greater than that of the nER in croaker livers, which suggests that estrogen actions in the testis may be more susceptible to chemical interference than those in the liver (Figure 10.5) (Loomis and Thomas, 1999). It is not known, however, whether these tissue differences in ER binding affinities are due to differential expression of nER subtypes or are a consequence of other tissue-specific factors. Two androgen receptor subtypes have been identified in croaker, kelp bass, eel, and tilapia (Ikeuchi et al.,2001; Sperry and Thomas, 1999a,b). One nAR is localized in the croaker brain and demonstrates specific binding for testosterone but has low affinity for a variety of chemicals that bind to the nAR in mammals and have antiandrogenic activity in mammalian species (Gray et al., 1996; Sperry and Thomas, 1999a,b). In contrast, the other nAR present in gonadal tissues has binding characteristics similar to those of the mammalian nARs and has a broader specificity for androgens and xenobiotic antiandrogens; therefore, androgen actions mediated by binding to the gonadal AR are likely to be susceptible to interference by xenobiotic antiandrogens, whereas those involving the brain nAR are not.

The concentrations of steroids and their receptors, as well as the potencies and actions of steroid hormones, change during the reproductive life cycles of fishes; consequently, both the pattern and degree of endocrine disruption caused by exposure to a xenobiotic endocrine-disrupting chemical will vary, depending on the fish's developmental or reproductive stage. One of the steroid hormone actions that varies markedly during the reproductive cycle of teleosts is the feedback effect of estrogens on gonadotropin secretion. Estrogens and the xenoestrogen *o,p′*-DDT exert positive effects on basal and GnRH-induced LH secretion in croaker at the beginning of gonadal recrudescence, but at the end of the reproductive cycle the influence of estradiol on LH secretion switches to a negative one (Khan and Thomas, 1998; Khan et al., 1999). Presumably, xenoestrogens also have negative feedback effects on LH secretion at this time, although convincing evidence for this is currently lacking.

Recently, it was realized that chemical interactions with nonclassical steroid actions can potentially influence the pattern and degree of endocrine disruption with the discovery that certain xenobiotic chemicals can also interfere with nongenomic steroid actions by binding to membrane steroid receptors (Thomas, 1999, 2000a,b). Most of the evidence for this mechanism of endocrine disruption has been obtained in fish and is reviewed in a subsequent section. In addition, the potential for crosstalk among various ligands, such as estrogens and epidermal growth factor (EGF), transforming growth factor α (TGF-α), and insulin-like growth factor 1 (IGF-1), and between estrogen and thyroid signaling pathways has been demonstrated in mammalian models (Ignar-Trowbridge et al., 1996; Rooney and Guillette, 2000). Dioxin (2,3,7,8-tetrachlorodibenzo-*p*-dioxin [TCDD]) and related dibenzo-*p*-dioxins, dibenzofurans, and PCBs can induce antiestrogenic effects in mammals indirectly by binding to the aryl hydrocarbon receptor (AhR) (Safe et al., 1991) and subsequently interfering with estrogen receptor binding to DNA response elements (Khara and Saatcioglu, 1996). Recent evidence, however, indicates that AhR ligands can also exert estrogenic effects and that the agonist-activated AhR/Arnt heterodimer associates with estrogen receptors, resulting in recruitment of unliganded estrogen receptor and co-activator p300 to estrogen-responsive gene promoters and subsequent activation of transcription (Ohtake et al., 2003).

Interference with Nongenomic Steroid Actions via Membrane Steroid Receptors

Recent studies have shown that a variety of xenobiotic chemicals, in addition to disrupting genomic steroid actions, can also interfere with the nongenomic actions of steroids (Nadal et al., 2000; Thomas, 1999, 2000a,b; Thomas and Khan, 2004; Watson et al., 1999). The finding that low concentrations (1 to 10 n*M*, equivalent to 30 ppb) of the xenoestrogens kepone and *o,p′*-DDD interfered with progestogen

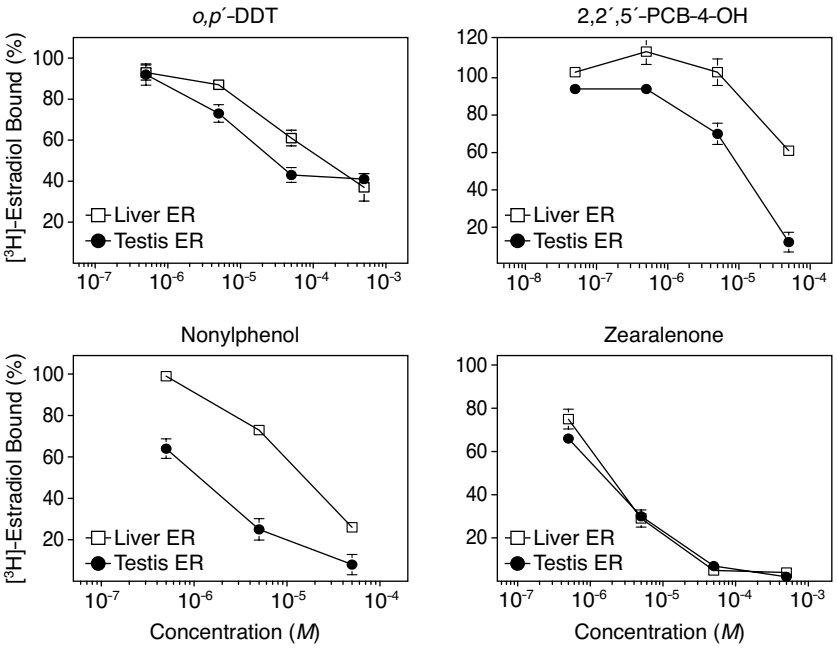

FIGURE 10.6 Comparison of the competition curves of several xenoestrogens for binding to the nuclear estrogen receptor in cytosolic fractions of Atlantic croaker ovarian and hepatic tissues. (From Loomis, A.K. and Thomas, P., *Biol. Reprod.*, 61, 51–60, 1999. With permission.)

induction of meiotic maturation of Atlantic croaker oocytes *in vitro* provided initial evidence for this novel type of endocrine disruption (Ghosh and Thomas, 1995). Subsequently, disruption of oocyte maturation by estrogenic compounds was confirmed in an amphibian species (*Xenopus*) exposed to methoxychlor (Pickford and Morris, 1999). In addition, kepone was shown to partially block the stimulatory actions of progestogens on sperm motility in Atlantic croaker (Thomas et al., 1998). Xenoestrogens such as *o,p′*-DDT and nonylphenol have also been shown to exert rapid estrogenic (agonistic) actions on rat smooth muscle cells and on croaker testicular androgen production (Loomis and Thomas, 2000; Ruehlmann et al.,1998).

Recently, direct evidence has been obtained that estrogenic compounds can disrupt nongenomic 20β-S actions on fish oocytes by a membrane-receptor-mediated mechanism (Das and Thomas, 1999). Competition binding studies have shown that these compounds bind to the mPRs on fish oocytes and sperm and to the membrane estrogen receptor in fish testes and disrupt nongenomic steroid actions in these tissues (Figure 10.6) (Das and Thomas, 1999; Loomis and Thomas, 2000; Thomas et al, 1998). The finding that a wide range of xenoestrogens display similar binding affinities for the mER as they do for the nER in croaker tissues suggests that the hormone actions they mediate may be equally susceptible to interference by these environmental contaminants (see Figure 10.6 and Figure 10.7 for comparison). Xenoestrogen binding to the oocyte mPR can be competitive and reversible; 20β-S receptor binding activity is completely restored by washing the ovarian plasma membranes (Das and Thomas, 1999). Recent evidence suggests that the inhibitory actions of xenoestrogens on 20β-S stimulation of sperm motility is also via completive binding to the receptor. If xenobiotic binding to a hormone receptor is competitive, it should be displaceable with the excess hormone, and the antagonistic actions of the chemical partially reversed (Figure 10.4). This was demonstrated with Atlantic croaker sperm acutely exposed to low concentrations of *o,p′*-DDE (0.1 μ*M*) in the presence of high concentrations (200 n*M*) of 20β-S (Thomas, 2003). Treatment with *o,p′*-DDE alone did not decrease sperm motility below control levels but completely blocked the increase in sperm motility in response to 20-n*M* 20β-S. Exposure of untreated sperm to tenfold higher concentrations of 20β-S (200 n*M*) did not increase motility above that observed with the 20-n*M* 20β-S, but treatment with *o,p′*-DDE fully restored the hormonal response. Partial restoration of sperm motility

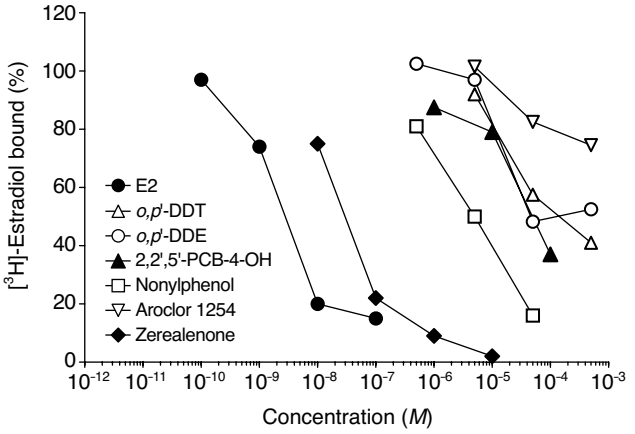

FIGURE 10.7 Competition curves for binding of several xenoestrogens to the membrane estrogen receptor in Atlantic croaker testes. (From Loomis, A.K. and Thomas, P., *Biol. Reprod*., 62, 995–1004, 2000. With permission.)

with excess steroid is also observed with higher concentrations of xenobiotics, as shown in Figure 10.8. Treatment with higher concentrations of 20β-S and another sperm receptor agonist, 11-deoxycorticosterone (conjugated to bovine serum albumen to prevent it from passing through the membrane), partially reverses the inhibitory effects of 2,4,6-PCB-4-OH on progestin-stimulated sperm motility (Figure 10.8). Both *ortho*,*para* DDT derivatives and 2,4,6-PCB-4-OH have previously been shown to compete with 20β-S binding to the croaker sperm mPR (Thomas et al., 1998). Recent evidence suggests that this nongenomic steroid action is especially sensitive to inference by low concentrations (0.01 to 0.01 μ*M*) of a wide range of environmental contaminants (Thomas and Doughty, 2004).

Hypothalamic–Pituitary–Interrenal Axis

The interrenal gland in fishes, which is homologous to the adrenal cortex of mammals, secretes corticosteroid (C-21 steroids) hormones. Cortisol is the principal teleost corticosteroid hormone in fishes, and it functions as both a glucocorticoid and mineralocorticoid hormone, regulating intermediary metabolism and electrolyte balance, respectively. Cortisol is critically important in the regulation of glucose biosynthesis by the liver (gluconeogenesis) and in adaptation to hypersaline environments by regulating chloride cell Na^+/K^+-ATPase activity and ionic efflux by the gills. Cortisol also rapidly decreases the release of prolactin, a critical hormone for adaptation to freshwater, in tilapia, and studies suggest that this cortisol action is nongenomic and is initiated at the cell surface (Borski et al., 2001). Rapid increases in corticosteroid hormones, in concert with increases in catecholamine secretion, occur in response to a wide range of stressors. These hormones regulate a wide variety of adaptive responses that may be critical for survival over the short term, including an increase in the production of metabolic reserves; however, prolonged stressor-induced elevations of cortisol can also impair reproductive and immune functions and negatively influence growth by stimulating protein catabolism.

The synthesis and secretion of corticosteroid hormones by the interrenal glands are controlled by hormones secreted by the hypothalamic–pituitary axis. Corticotropin (adrenocorticotropic hormone [ACTH]), a 39-amino-acid peptide secreted by corticotroph cells in the anterior pituitary, is the primary pituitary hormone regulating corticosteroid secretion. Corticotropin and a variety of other pituitary hormones, such as melanotropin (melanocyte-stimulating hormone [MSH]), are produced from different parts of a precursor protein, proopiomelanocortin. The secretion of ACTH, in turn, is controlled by corticotropin-releasing hormone (CRH), a peptide synthesized in specialized neurosecretory neurons in the nucleus preopticus and nucleus lateralis regions of the hypothalamus and released at the axon terminals in the vicinity of the ACTH-producing cells (corticotrophs) in the anterior pituitary. The

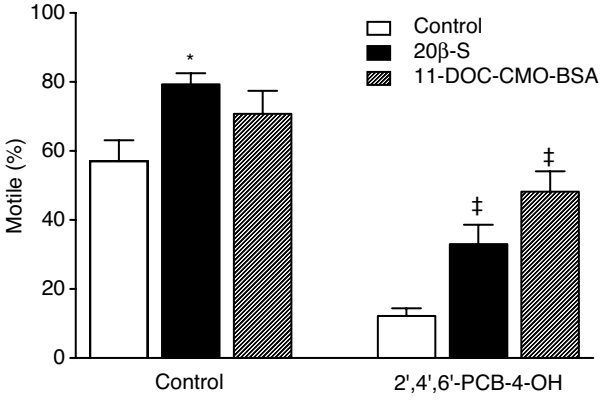

FIGURE 10.8 Stimulatory effects of 5-minute treatment with 20-n*M* 17,20β,21-trihydroxy-4-pregnen-3-one (20β-S) or 50-n*M* 11-deoxycorticosterone conjugated to bovine serum albumen (11-DOC-CMO-BSA) on sperm motility in Atlantic croaker *in vitro*. Cotreatment with 50-μ*M* 2′,4′,6′-PCB-OH alone (clear bar on right-hand side of graph) and in the presence these low concentrations of the steroids (results not shown) caused a similar inhibition of sperm motility. A tenfold increase in progestin concentrations (20β-S, 200 n*M*; 11-DOC-CMO-BSA, 500 n*M*; shaded bars on right-hand side of graph) partially reversed the inhibitory effect of the PCB. *Significantly different from no treatment control; ‡significantly different from PCB treatment alone ($n = 6$).

structure of CRH is remarkably conserved among vertebrates, the teleost form differing from the mammalian CRH only at two of the 42-amino-acid residues (Lederis, 1987). In addition, other structurally related peptides, such as urotensin I, which is produced by a caudal neurosecretory organ unique to teleosts (the urophysis), and neurohypophyseal peptides such as argine vasotocin have also been shown to stimulate ACTH secretion (Lederis et al., 1994). Details of the neuroendocrine pathways, neuropeptides, and neurotransmitters involved in activation of the HPI axis in teleosts in response to stressors are currently lacking; however, recent results suggest that serotinergic pathways and CRH mediate the stimulation of ACTH secretion in response to certain stressors (Ando et al., 1999; Winberg et al., 1997), as has been shown in mammals. Activation of the HPI axis is rapid after exposure to many stressors; plasma cortisol levels are often elevated within 5 minutes and reach maximum levels, up to 100 times initial levels within 30 to 60 minutes (Thomas, 1999). Cortisol exerts negative feedback actions on CRH and urotensin I synthesis in the hypothalamus and ACTH secretion from the pituitary (Bernier et al., 1999; Fryer et al., 1984).

Interference of the HPI Axis

Many chemicals, including heavy metals (Brodeur et al., 1998; Donaldson and Dye, 1975; Leblond and Hontela, 1999), polycyclic aromatic hydrocarbons (McFarlane and Benville, 1986; Thomas and Neff, 1985; Thomas et al., 1980; Wilson et al., 1998), organochlorine pesticides (Benguira et al., 2002; Ilan and Yaron, 1980), and nonchlorinated pesticides, have been shown to influence the activity of the HPI axis in teleosts. A wide variety of chemicals and other adverse environmental stimuli elicit a nonspecific stress response in teleosts that is characterized by activation of the sympathetic adrenergic system and HPI axis, resulting in a suite of secondary stress responses, including hyperglycemia, alterations of protein and lipid metabolism, osmotic disturbances, and altered immune function (Mazeaud et al., 1977). Exposure to relatively low concentrations of many chemicals causes an acute elevation in plasma cortisol levels within minutes to a few hours, but the response is usually transient if the treatment is sublethal, and circulating titers often have returned to control levels by 6 hours after the initial exposure (Donaldson and Dye, 1975; MacFarlane and Benville, 1986; Thomas et al., 1980, 1981a). In contrast, cadmium failed to elicit corticosteroid stress responses in Coho salmon and striped mullet (Schreck and Lorz, 1978; Thomas and Neff, 1985). Schreck and Lorz (1978) concluded from their results that only stimuli that cause "fright, discomfort or pain" are capable of inducing a corticosteroid stress response. These acute corticosteroid responses in teleosts to chemicals are similar to those induced by many moderate

physical stressors and have been considered analogous to the initial alarm phase of the general adaptation syndrome in mammals (Mazeaud et al., 1977; Schreck, 1981; Selye, 1950). After this initial response, plasma cortisol often declines to controls levels even though the chemical is still present (Donaldson and Dye, 1975; Thomas and Neff, 1981; Thomas et al., 1981a). This compensation or resistance phase will persist if the chemical stress is moderate (Schreck, 1981; Thomas, 1990); however, if prolonged exposure results in significant bioaccumulation of the chemical and toxicity, cortisol levels increase again and typically remain elevated until homeostasis can no longer be maintained and mortality occurs (Thomas et al., 1981a,b), equivalent to the exhaustion phase described by Selye (1950).

Chemicals also affect the activity of the HPI axis by specific endocrine toxic mechanisms. An early survey of the mammalian literature showed that the adrenal in mammals is the most sensitive endocrine gland to chemical-induced injury (Ribelin, 1984). Chemicals have been shown to impair adrenocortical structure and function via a variety of mechanisms, including covalent binding to proteins, metabolic activation, peroxidative damage, and reversible interactions with steroidogenic enzymes (Colby and Longhurst, 1992). Interrenal function in teleosts also appears to be especially sensitive to chemicals (Bisson and Hontela, 2002), and preliminary evidence suggests that they impair steroidogenesis by similar mechanisms; for example, a decline in cortisol secretion after exposure to the organochlorine pesticide endosulfan is associated with oxidative stress in rainbow trout interrenal steroidogenic cells (Dorval et al., 2003). In this study, the steroidogenic responses to ACTH and the cAMP analog dbcAMP were impaired, suggesting that the site of endosulfan action is downstream from cAMP generation (Dorval et al., 2003). Similar conclusions were drawn from studies involving exposure of the interrenal cells of rainbow trout to the heavy metals cadmium, mercury, and zinc (Leblond and Hontela, 1999). In contrast, tilapia exposed to *o,p′*-DDD showed an impaired response to ACTH but not to cAMP, which suggests that the site of action of *o,p′*-DDD is further upstream, possibly via downregulation or desensitization of the ACTH receptor (Ilan and Yaron, 1980). A recent study in rainbow trout, however, suggests that *o,p′*-DDD impairs corticosteroid production by interfering with interrenal cAMP generation (Lacroix and Hontela, 2003).

No evidence has been obtained to date that xenobiotic chemicals alter the activity of the HPI axis in teleosts by binding to nuclear glucocorticoid receptors. Several alkylphenols and phthalates, the pesticides dieldrin and toxaphene, and the phytoestrogen genestein showed no binding affinity for the rainbow trout nuclear glucocorticoid receptor (Knudsen and Pottinger, 1999).

Hypothalamic–Pituitary–Thyroid Axis

Thyroid hormones have essential functions in the regulation of embryological development, metabolism, and reproduction in vertebrates and also have important roles in metamorphosis and osmoregulation in fishes. The secretory activity of the thyroid in fishes, like that in mammals, is regulated by a pituitary glycoprotein hormone: thyrotropin (TSH). Unlike mammals, however, only minor amounts of the active form of thyroid hormone, triiodothyronine (T_3), are secreted in fishes, the majority being in the form of the prohormone thyroxine (T_4); consequently, the production of the active form of thyroid hormone (T_3) from the prohormone (T_4) in several fish species is largely under peripheral control by the enzyme monodeiodinase (Eales et al., 1999). TSH has a structure similar to that of the gonadotropins, consisting of a shared alpha subunit and a hormone-specific beta subunit. TSH secretion is under neuroendocrine control by a hypothalamic tripeptide, thyrotropin-releasing hormone (TRH), that exerts an inhibitory action on the release of TSH from the pituitary in some teleost species, although in mammals its action is stimulatory (Leatherland, 2000). In addition, evidence suggests that CRH influences the activity of the pituitary–thyroid axis in some fishes and therefore has the potential to be a common mediator of chemical-induced changes in the activities of both the HPI and HPT axes. TSH stimulates the synthesis and release of T_4 from the thyroid gland. An important feature of the hypothalamic–pituitary–thyroid axis is the presence of a negative feedback action of T_4 on TSH secretion, thereby regulating the synthesis of T_4 within a physiological range (Eales et al., 1999). The thyroid gland in most teleosts consists of scattered follicles comprising a single layer of epithelial cells surrounding a fluid-filled cavity containing thyroglobulin, a large colloidal iodinated protein. The epithelial cells (thyrocytes) concentrate iodine

from the blood and transport it to the lumen surface, where it is oxidized by an enzyme (iodoperoxidase or thyroid peroxidase). This enzyme also catalyzes the oxidation of certain tyrosines in the thyroglobulin molecule, resulting in the formation of monoiodotyrosine (MIT) and diiodotyrosine (DIT) and subsequently the oxidative coupling of these iodinated tyrosines to form the thyroid hormones.

Tetraiodothyronine (T_4) is produced by coupling DIT with DIT and is the major thyroid hormone product in fish, whereas triiodothyronine (T_3), which is made from coupling MIT with DIT, is produced in much smaller amounts. By a process called *pinocytosis*, the thyrocytes, upon stimulation by TSH, incorporate vesicles of thyroglobulin into their cytoplasm, where they fuse with lysosomes, and the thyroglobulin is enzymatically degraded to yield the thyroid hormones. The thyroid hormones are subsequently released into the circulation and are transported in the blood in most teleost species bound to carrier proteins (thyroid-binding globulins). The carrier proteins typically have a higher affinity for T_4 than T_3 and serve as a buffer and reservoir for these hormones. Thyroxine is converted in several tissues including the kidney, brain, and liver to the physiologically active hormone T_3 by removal of an iodide from the outer tyrosine ring by the enzyme 5′-monodeiodinase. A related enzyme, 5-monodeiodinase, which is present in certain tissues, catalyzes the removal of iodide from the inner tyrosine ring to produce reverse T_3, which is physiologically inactive. The two monodeiodinases further deiodinate T_3 and reverse T_3 to form thyronine, a major route of degradation of thyroid hormones prior to excretion; thus 5′- and 5- monodeiodinases have critical roles in T_3 homeostasis, as they regulate both the synthesis and degradation of this physiologically active form of the hormone. T_3 is lipid soluble (lipophilic) and readily diffuses into target cells, where it binds to the thyroid receptor (TR), which belongs to the same superfamily of ligand-activated transcription factors as nuclear steroid receptors. Similarly, T_3 binding to the TR results in dimerization, but, unlike the steroid receptors, thyroid receptors form heterodimers with retinoid X receptors (RXRs) to form the activated hormone–receptor complex. The TR component of this complex binds to thyroid hormone response elements on genes, resulting in alterations in their rates of transcription. There is also evidence for nongenomic actions of thyroid hormones initiated at the cell surface in several mammalian models (Norman, 2004).

Interference of the HPT Axis

A variety of environmental chemicals, including PCBs, insecticides, water-soluble fractions of oil, aluminum, lead, and cadmium, have been shown to alter the thyroid system in fishes by causing decreases in the circulating levels of thyroid hormones and hepatic 5′-monodeiodinase activity (Chaurasia et al., 1996; Fok et al., 1990; Folmar et al., 1982; Hontela et al., 1996; Leatherland and Sonstegard, 1978; Sinha et al., 1992), although the sites and mechanisms of chemical interference with thyroid function remain poorly understood. Declines in monodeiodinase activity have been reported in fishes after *in vivo* exposure to metals and insecticides (Chaurasia et al., 1996; Fok et al., 1990), but it is unclear whether these chemicals are acting directly on the enzyme or indirectly by altering other endocrine systems that influence monodeiodinase activity (Eales et al., 1999). Deiodinases contain selenium bound to cysteines and therefore are potentially susceptible to interference by heavy metals that displace selenium from these sites in proteins such as cadmium, mercury, and copper. Deiodination has been proposed as a valuable biomarker of interference of the thyroidal system in fish (Eales et al., 1999). Other potential sites of xenobiotic interference with thyroid function include interference with neurotransmitter control of neuroendocrine function (Thomas and Khan, 2004) and binding to the thyroid hormone receptor or plasma transport protein, although direct evidence is lacking (see reviews by Leatherland, 2000; Eales et al., 1999; Brown et al., 2004).

Summary

The physiological functions of the gonads and interrenal and thyroid glands in fishes, like those of tetrapods, are under complex neuroendocrine control by hormones synthesized by the hypothalamus and pituitary. The hormones secreted by the gonads and interrenal and thyroid glands in turn exert negative feedback effects on neuroendocrine function; however, the thyroid hormone function in fishes is largely

controlled peripherally by monodeiodinases, the enzymes that convert T_4 to the active form of the hormone (T_3) or to inactive metabolites. Sex steroid hormones synthesized by the gonads control critical functions in this tissue during gametogenesis (paracrine control) in addition to exerting their actions at other target tissues. Chemicals could potentially disrupt these complex endocrine systems at multiple sites along their axes and via a variety of mechanisms. Chemicals can disrupt endocrine function by altering the circulating levels of hormones, by decreasing hormone secretion, by increasing hormone metabolism, or by interfering with hormone action. Some examples in teleosts of each of these mechanisms of endocrine toxicity have been briefly reviewed. Novel mechanisms of toxicity such as interference with nongenomic steroid actions and neuroendocrine dysfunction resulting from impaired hypothalamic neurotransmitter function were first identified in fishes. Information on the mechanisms of endocrine toxicity can often be used to develop biomarkers of endocrine impairment specific for particular types of chemicals. These biomarkers have been used in environmental assessments of the health of fish populations in impacted environments; for example, the presence of the estrogen inducible proteins such as vitellogenin in male and juvenile fish has proven useful for detecting the presence of xenoestrogens in environmental samples.

Acknowledgments

This work was supported by U.S. Environmental Protection Agency STAR grant no R82945801 to the author. Izhar Khan, Duncan McKenzie, Margaret Pace, Abby Benninghoff, Chris Tubbs, and Gwen Dressing reviewed a draft of this manuscript, and their comments are greatly appreciated.

Fish Immunology

Over the past few decades, our understanding of fish immunology has greatly progressed due to studies utilizing molecular techniques, cell culture, and monoclonal antibodies. Most immunological research involving fish species has been concerned with either their phylogenetic or economic importance; thus, such groups as agnathans, elasmobranchs, and chondrosteans have been studied in attempts to elucidate the evolution of the vertebrate immune system. Also, species such as salmonids (*Oncorhynchus* spp. and *Salmo* spp.), carp (*Cyprinus* spp.), and catfish (*Ictalurus* spp.) have received interest mainly due to their use in aquacultural settings. This section primarily focuses upon teleost fish and briefly reviews current research in the area of fish immunology. The reader is directed toward reviews by Iwama and Nakanishi (1996), Bernstein et al. (1998), and Pastoret et al. (1998) for additional information in this rapidly expanding field. Following an introduction to the major lymphoid cells/tissues of teleosts, nonspecific and specific components of the teleost immune system are presented in this chapter. Both cellular (i.e.,

macrophages, granulocytes, and natural-killer-like cells) and noncellular (i.e., lysozyme, complement, and acute-phase proteins) aspects of nonspecific immunity, as well as specific (adaptive) immune responses that rely upon acquired immunity (i.e., cell- and humoral-mediated immunity), are discussed.

Immune Cells
