Notice

Pharmacology is an ever-changing field. Standard safety precautions must be followed, but as new research and clinical experience broaden our knowledge, changes in treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current product information provided by the manufacturer of each drug to be administered to verify the recommended dose, the method and duration of administration, and contraindications. It is the responsibility of the licensed prescriber, relying on experience and knowledge of the patient, to determine dosages and the best treatment for each individual patient. Neither the publisher nor the editor assumes any liability for any injury and/or damage to persons or property arising from this publication.

Preface

Herd Health: Food Animal Production Medicine describes the role of the veterinarian in the management of animal health and production in dairy and beef cattle herds, beef feedlots, swine herds, and sheep flocks. It is about the efficient production of food-producing animals. The preface to the first edition of this book (1985) stated, "It is our conviction that the present rapid growth of animal health management services provided by veterinarians to herds and flocks will continue and that within a decade this form of veterinary activity will dominate food animal practice." The intent of the first edition of this book was to provide a starting point for undergraduate veterinary students and practitioners to gather the principles and techniques for the basis of food-animal health management programs. Numerous readers who have examined the first and second editions have commented that the information in the books provided a sound basis for the development of species-specific health management programs. The third edition has updated the text as a source of information for the new challenge in the delivery of health management programs.

Since the publication of the first edition in 1985 and the second edition in 1994, a large volume of information has been published on health and production of the food-producing animals. More articles on planned animal health and production programs appear in journals each year, and relevant continuing veterinary education programs are devoting an increasing proportion of their scientific programs to production-oriented animal health management. The volume of literature on the health and production of food-producing animals is large and complex, involving many disciplines that must be integrated. For this edition the task of identifying and integrating necessary and useful information and guidance for the undergraduate veterinary student and the practitioner was a major challenge. The most difficult task was to avoid rewriting existing textbooks on veterinary medicine, animal husbandry, nutrition and housing, and animal welfare while selecting appropriate information to be included. It is now obvious that becoming a species specialist with a comprehensive understanding of an industry, such as the dairy cattle industry, is the only hope of mastering the knowledge and skills required to provide a high-quality health management service with emphasis on the integration of animal health and production management. The targets of animal health and performance for each species were reviewed and revised according to published information. Much new information on the factors that interfere with optimum performance has been included. The methods and strategies for economical corrective action are also outlined for each species.

Rural veterinary practitioners worldwide are recognizing the need to change their attitudes about the services they provide. The traditional role of the healer of individual sick animals is gradually being complemented by the delivery of totally integrated health management programs concentrating on the performance of the herd. Veterinary colleges are revising their curricula to meet this new challenge. One of the objectives of this book is to provide a framework for a course curriculum in animal health and production management. This book is written for veterinary students and graduate veterinarians who want to study the concepts involved in development and delivery of health management programs. A common theme carried throughout this book is that sound health management programs will lead to the most efficient, economical, and profitable production of livestock while providing for the welfare needs of the animals and ensuring the product's quality.

Veterinary epidemiology has become a major influence, providing much of the new information included in this revision. Many observational studies and field trials have been performed to study the relationships between risk factors and disease and their effects on animal production. Epidemiological techniques have become important tools for developing health management programs. The collection and analysis of farm data for the implementation of health plans and actions, as well as the ongoing monitoring of the performance outcome, inherently imply the use of these tools by veterinary practitioners. In order to accomplish these activities, the computer has become a major factor in the application of epidemiological principles to herd problems. Computers are now commonplace in veterinary practice and an integral part of health management programs.

I gratefully acknowledge the contributors who have revised or rewritten the chapters from the second edition that evolved into those in the third edition.

I revised Chapter 1, "Principles of Health Management in Food-Producing Animals." The chapter outlines the principles of production-oriented medicine in food-producing animals and explains the objectives and methods used in the book. Some emphasis is given to the public health concerns about the intensification of animal agriculture and the need for veterinarians to become proactive in this area. Chapter 2, "Quantitative Tools for Production-Oriented Veterinarians," was written by Dr. Barrett Slenning. It describes in user-friendly terms the mathematical techniques used in animal health and production management. Chapter 3, "Records Systems and Herd Monitoring in Production-Oriented Health Management Programs in Food-Producing Animals," was written by Drs. Jeff Reneau and Mark Kinsel. It describes the principles of monitoring animal health and production data and generating useful information for decision making, which have become important aspects of production-oriented medicine. Chapter 4, "Control of Infectious Diseases of Food-Producing Animals," outlines the principles of control of infectious diseases of food-producing animals that should help the veterinarian plan disease control on a year-round basis and as an integral part of a totally integrated animal health management service to the producer.

Chapter 5, "Investigation of Disease Outbreaks and Suboptimum Productivity," is a new chapter written by Dr. Cheryl Waldner. It emphasizes the importance of using the tools of epidemiology in the investigation of disease outbreaks and suboptimum productivity in herds.

Chapter 6, "Health and Production Management in Dairy Herds," was revised by Dr. Pam Ruegg and deals with

Downloaded From Vet-eBooks.com

the general aspects of dairy cattle health management. Major changes have taken place in the dairy cattle industry, and these have been described and discussed in the chapter. Chapter 7, "Maintaining Reproductive Efficiency in Dairy Cattle," revised by Drs. Peter Farin and Barrett Slenning, emphasizes monitoring reproductive performance in the dairy herd. Chapter 8, "Culling and Genetic Improvement Programs in Dairy Cattle," was completely revised by Drs. Brian Radke and George Shook. The chapter represents one of few sources of such information for dairy cattle practitioners. The computer programs now available for the selection of bulls provide an opportunity for veterinarians to offer this advisory service to dairy producers as part of a complete animal health management program. New approaches to culling dairy cattle are included in the section written by Dr. Radke. Chapter 9, "Health Management of Dairy Calves and Replacement Heifers," was revised by Dr. Judson Heinrichs and myself. The section dealing with dairy heifer replacements, which represents a growing activity in dairy health management, was expanded. Chapter 10, "Mastitis Control in Dairy Herds," was completely revised by Dr. Ronald Erskine and emphasizes a 10-point control program. Chapter 11, "Dairy Cattle Nutrition," was written by Dr. Brian Gerloff and is a revision of the original. Chapter 12, "Housing and Environment for Dairy Cattle," has also been revised by Dr. William Bickert and myself and includes information on the relationship between housing and lameness in diary cattle.

Chapter 13, "Health and Production Management in Beef Cattle Breeding Herds," was written by Drs. Peter Chenoweth and Michael Sanderson. The emphasis is on the animal health strategies necessary to achieve optimum reproductive performance and calf survival in the herd. Chapter 14, "Health and Production Management in Beef Feedlots," was revised by Drs. Robert Smith, Gerald Stokka, Dee Griffin, and myself. The strategies for the clinical management and control of acute respiratory disease in recent arrivals are a major emphasis of the chapter and are described in detail, with emphasis on the need for useful health records. Chapter 15, "Health and Production Management in Swine Herds," was revised by Drs. John Deen, Scott Dee, Robert Morrison, and myself. Revising and expanding the swine chapter was a major task because of the large amount of information being published on swine health and production. Major progress has been made in swine health and production management services provided by veterinarians. Chapter 16, "Health and Production Management in Sheep Flocks," was revised by Dr. Philip Scott and represents the activities occurring in the development of sheep health and production management programs, particularly in sheep-raising countries like New Zealand, Australia, and the United Kingdom.

Animal welfare is now a major issue in animal production, and each species chapter includes some information on the welfare aspects of health and production. Production-oriented veterinarians will need to become proactive about the welfare requirements of food-producing animals.

The possible contamination of meat and milk with residues of antimicrobials, antimicrobial-resistant bacteria, growth-enchancing hormones, and other drugs used in animal health and production management represents major food safety concerns of society. The use of antimicrobials in the feed of food animals, which may lead to the development of drug-resistant bacteria with the potential to be transferred to humans, has been addressed where appropriate. Veterinarians must become proactive and educate producers on the proper use of drugs in food-producing animals.

Many thanks are given to Linda Kraft and Tracey Gilles for typing assistance of some of the tables and reference lists.

I also thank the Western College of Veterinary Medicine and the University of Saskatchewan for providing the resources, including the excellent Veterinary Medical Library, and the patient and helpful librarians. Most of all, I thank my wife, Ruth, for her patience and encouragement.

Otto M. Radostits, DVM, MSc

CHAPTER 1

Principles of Health Management of Food-Producing Animals

OTTO M. RADOSTITS

The knowledge and the technology are available to provide a cost-effective comprehensive health management veterinary service to production-oriented livestock producers. The delivery of the service by veterinarians is the greatest challenge facing food animal practitioners. The emphasis is changing from the treatment of disease to health and production management.

Radostits OM: A veterinary odyssey: prospects for large animal practice in the 21st century. Proceedings of the forty-fifth annual convention of the Canadian Veterinary Medical Association, Edmonton, Canada, 1993.

IMPORTANCE AND SUCCESS OF FOOD ANIMAL AGRICULTURE

Food-producing animals make important contributions to agriculture and human well being. One of the most important needs of humans is a dependable food supply. The Hudson Institute has estimated that the demand for farm products containing animal protein will double or triple in the next 40 to 50 years with the world population expected to be about 9 billion in the next 20 to 30 years. Thus there will be many opportunities for veterinarians in agribusiness (Gloyd, 1998). The efficient production of livestock that yield meat, milk, and fiber is a major concern of society in general and of sociologists, animal scientists, and animal specialists in particular.

One of the most important functions of domestic farm animals is the conversion of human-inedible forages, by-products, and crop residues into high-quality human food in the form of meat, milk, and eggs (Bradford, 1989). Much has been said and written about the low efficiencies of livestock in converting plant products into animal products, and it has been inferred that livestock production should be reduced in the interests of using that food supply for humans. However, at least two critical facts are frequently ignored. The first is that a high proportion of the plant materials converted by ruminant animals cannot be used directly by humans. The second is that a high concentration of nutrients, such as amino acids, minerals, and B-complex vitamins, are confined in animal food products, in comparison with those of plant origin. When the inputs and returns are considered, beef cattle production appears to be very inefficient on the basis of input and return of energy and protein; however, beef cattle actually convert human-inedible energy and protein in their diet into human food energy and protein, with estimated efficiencies of 57% and 109%, respectively. The corresponding values for milk production are 101% and 181%, respectively (Bradford, 1989).

The estimates just mentioned are based on production practices in developed countries, using substantial amounts of feed grains. In developed countries, livestock have an important buffering effect on cereal grain prices and food supplies. For example, the beef feedlot industry in North America developed in response to the availability of inexpensive grains because of the large increase in yields per acre, from about 1950 to 1970, associated with the adoption of new technologies for grain production. In developing countries most animal production uses no human-edible inputs. The improvement in quality and nutrient balance of human diets from the inclusion of animal products is particularly important in developing countries, where protein quantity and quality tend to be limited.

In some developing countries, where feed grains are in short supply, an increase in the use of small ruminants such as sheep and goats, which can convert a wide variety of plant products into human food energy and protein, is a major development. Another important contribution of animals in developing countries is their buffering effect on food supply and income. Herds are built up during good seasons and years and slaughtered for food during periods of drought. In some countries where credit and banking services are not available, livestock are used for their monetary value and can be sold more readily in times of need than most other commodities produced on the farm. In such an economic system, the cost of maintaining a nonproductive animal or one of low productivity is viewed differently than in a system in which animals are sold at the optimum time relative to biological efficiency and the proceeds banked (Bradford, 1989).

Some animals provide 75% to 90% of the draft power for agriculture in large regions of the world. Draft animals constitute the most important component of the animal sector in more than half of the world's countries. Because many countries lack the capital required to purchase the mechanical tractor power and fuel needed for modern mechanized agriculture, animal draft power is likely to remain an essential component of agriculture in many countries for a long time. Farm livestock also provide fertilizer in the form of manure, which may become more important in efforts to sustain soil fertility in areas that have experienced excessive erosion because of continuous tilling and cropping. Animals are also used effectively for weed control and for keeping roadsides free of accumulated vegetation. For example, goats and sheep are now being used to graze the forage under

Downloaded From Vet-eBooks.com

rubber and palm oil trees. In addition to the production of meat from a currently unused forage resource, covering millions of hectares, the grazing of sheep can reduce herbicide use and the cost of weed control. Such a practice illustrates the importance of integrating livestock production with other components of the agricultural system (Bradford, 1989).

In addition to the important biological functions performed by livestock in agricultural systems in developing countries, animals often have significant social and cultural or ethnic value. The slaughter of a ram for the annual religious festival of Islam is extremely important, with the result that a substantial portion of the annual sheep slaughter in Islamic countries occurs on one day of the year.

CHANGES IN FOOD ANIMAL AGRICULTURE

Food animal agriculture is changing, and the changes have implications for the organization of veterinary service to farm animals (Getz, 1997). First, economies of scale have emerged in the management of livestock. *The average herd size is increasing as the number of farms declines.* As a result, large animal practitioners are serving fewer but larger farms. Large farms tend to spend less on veterinary services per animal, but the total health management costs including animal health products such as drugs and vaccines are much greater on a herd basis than on smaller farms. Second, a growing number of farm operators have production contracts with agribusiness called integrators. The integrators may provide livestock, feedstuffs, and advice to many farms. The integrators may also provide veterinary services to all farms they have on contract. Growing numbers of food animal practitioners are salaried employees of corporate agribusiness integrators.

Scale in Livestock Production

In the United States, from 1974 to 1992, the average size of the farm increased remarkably and continues to increase. The average herd size at least doubled for dairy, pork, chickens, and broilers and nearly doubled for turkeys. The growth in average herd size paralleled the decline in the number of farms. With the development of new production methods, the average cost of production shifts downward. Producers who fail to change production methods may still have the old average cost structure and may suffer economic losses. The process of technical change improves the welfare of consumers by making livestock products available at lower costs. Farming remains economically profitable for those who adopt the new scale and techniques. In fact, farms that innovate first—the *early adopters*—may enjoy extraordinary economic profits for a time until the industry fully adjusts to the new technologies. Farms that do not adopt the new methods will be economically disadvantaged. During the same period, all of the real livestock prices fell by more than 30%. The real price of milk fell by 47%, beef cattle (live weight) fell by 43%, and pigs fell by 60%. The magnitude of the price decline over the 18 years in question was so substantial that farms that did not adjust their production methods have suffered dramatically lower net incomes. Farmers will say, "It is very tough to make a living out there because of the low prices for commodities while the costs of inputs have continued to increase."

CONTEMPORARY ISSUES IN FOOD ANIMAL AGRICULTURE

Although food-producing animals contribute in many important ways to human welfare, they also are a source of potential problems. Livestock, particularly nonruminants, can compete with humans for available human-edible food supplies, such as cereal grains and other plant products. Ironically, whereas there is concern about livestock using human-edible food, a major concern in developed countries is the overproduction of meat, milk, and wool. World surpluses of animal products have come to dominate national and international agricultural policies. Consumer concern about the potential health hazards associated with the consumption of animal products can increasingly dictate the quality and quantity of the outputs. The perceived problems of overgrazing and the environmental degradation of pastoral systems in arid and semiarid regions of the world must be addressed. Individuals concerned about animal welfare and rights are now expressing their concerns about how food-producing animals are handled and managed. The relationships of agricultural and economic policy to the health of farm families, livestock, and the environment are now major concerns (Donham and Thu, 1993). Sustainable agriculture is now being emphasized. These issues and whether animals should be used at all for food production are discussed elsewhere in this book.

Animal Disease

Disease in farm livestock has always been a problem of considerable importance to farmers. Good livestock husbandry means caring for animals properly and maintaining them in good health to obtain optimum production of their products. As production methods become more intensive, the health status of animals becomes increasingly a primary determinant of productivity on livestock farms. The modern livestock producer attempts to maintain the performance of the herd or flock by proactive health and production management. The assistance of the veterinarian and of other agricultural specialists who can provide knowledge, skills, and other resources may be sought. The entire process is aimed at the production of wholesome human food, such as meat and milk, and of other commodities, such as wool at a reasonable price to the consumer, while yielding a net profit for the farmer.

The epidemic of foot-and-mouth disease in pigs, cattle, and sheep in the United Kingdom and continental Europe in February 2001 is an example of how one animal disease can be so devastating to the overall economy of a country and can create anxiety in other countries that fear introduction of the disease. The epidemic of foot-and-mouth disease in the United Kingdom in 2001 will be a major "watershed" event for food-animal production worldwide. Farming methods, the movement of animals, the intensification of animal agriculture, the identification of individual animals. international trade in livestock and animal products, and the methods used to control epidemics of animal disease will be examined closely. It may no longer be acceptable to slaughter hundreds of thousands of otherwise healthy animals as part of a foot-and-mouth disease eradication program compared with ring or mass vaccination even though vaccination may not be sufficiently efficacious.

Economics of Food Animal Production

The food animal industries are facing global competition and revolutionary changes (Meeker, 1999). Changes are occurring in agribusiness that are restructuring the livestock production industry. The primary factors responsible for these changes are capital and technology. The successful livestock producers in the future will use these factors to assemble *value chains* that are based on quality. (A value chain refers to the vertical cooperation among the participants in an industry.) Globalization of the competitive market place is reality. Communication technologies and free trade

Downloaded From Vet-eBooks.com

agreements between trading countries accelerates the process (BeVier and Lautner, 1994). As economies improve and discretionary incomes increase, meat production and consumption rise. The various protein sources compete for market share with cost of production as the major competitive factor. Progressive producers are becoming more aware of the needs of their consumers and are striving to improve product quality. Checkoff funds from producers (levies on each animal sold at market) are used to finance promotion, research, and consumer information programs and are increasingly used to finance producer education.

Industrialization trends in the livestock industries are changing the needs of constituencies, delivery mechanisms, and relationships with the people involved. Characteristics of nonprogressive livestock operations include high production cost, outdated technology, smaller size, older operators, and lack of management focus. Successful livestock operations tend to be growing in capacity, are system-oriented, maintain high throughput, keep accurate records, use outside consultants, and control production costs. Modern livestock production has lowered the cost of production with the integration of new production and management technologies. In order for producers to be successful in the future, access to technology, capital, and timely information will be critical.

Controversial Issues

Food animal production and the animal and veterinary sciences face a series of challenges that have become embroiled in controversy (Thompson, 1999). Controversial issues affecting animal agriculture are among the most critical challenges facing the livestock industry today. Like all of agriculture, livestock producers are commonly unfairly portrayed as polluters and as contributors to a decline in environmental quality.

Industrialization (or intensification) and vertical integration in poultry, dairy, and hog production have placed livestock producers into conflict with advocates for rural communities. A few well-researched books, such as *Pigs, profits, and rural communities* (Thu and Durrenberger, 1998), have been written about the advantages and disadvantages that industrialization of the swine industry has had on the environment and society. The modern intensified swine industry is frequently cited as evidence for the economic advantage of industrial agriculture, the wide availability of abundant food at extremely low cost to the consumers, and the superior productivity and efficiency of modern farmers. But does cheap food for the consumer outweigh problems created by industrialized forms of food production? As reasonable as it sounds, this approach ignores a fundamental component of industrial agriculture. An intrinsic feature of industrialized agriculture is the concentration of power over the production and distribution of precious resources. Industrial agriculture has survived and prospered for the last half century because certain sectors benefit.

Changes in dietary recommendations have changed the public's attitudes towards meat. Consumers want agribusiness to produce a safe, healthy, nutritious product while maintaining acceptable environmental practices in conjunction with humane treatment of animals. Experiments with animal cloning and genetic engineering have placed animal scientists on the front pages of the world's newspapers. The use of antimicrobials in animal agriculture is blamed, perhaps unfairly, for the increase in antimicrobial resistance in human medicine (Khachatourians, 1998). Animal welfare concerns attract much attention. Membership in organizations dedicated to the protection of animals has grown for two decades. Animal protection groups that once confined their interest to pet animals or animals used in biomedical research are placing more emphasis on the well being of agricultural animals. The use of biotechnology in agriculture has created considerable suspicion about the safety of food products. Animal science departments are responding to some of these issues, such as animal waste, animal welfare, and food safety in their teaching, research, and extension programs (Swanson, 1999).

Whereas farm income was once the most controversial issue in animal production, producers, animal scientists, and veterinarians now face complex risk issues that have overlapping constituencies. There is a need to develop a forum in which these contentious issues can be discussed responsibly (Thompson, 1999). Such a forum will provide opportunities for written and verbal exchange of views on the various aspects of contentious issues. Journals, conferences, seminars, workshops, and formal graduate training constitute the possible venues for such a forum. Animal scientists and veterinarians should give immediate attention to the broad social changes that are affecting animal agriculture and that have changed the requirements of scientific and professional ethics for researchers, livestock producers, and the animal production industry. In particular, debate should focus on the changed nature of risk and on the ethical and political implications of that change.

In addition to the general issues just mentioned, specific incidents occur that spark public outrage, causing major political decisions that have far-reaching short- and long-term economic effects on animal agriculture in certain countries (both nationally and internationally). An excellent example was the epidemic of bovine spongiform encephalopathy (BSE) that was recognized in cattle in the United Kingdom in 1986, causing major economic costs and international controversy about the safety of beef as a human food (Bruce et al, 1997). The disease is not of major economic significance to individual herds because of the low within-herd incidence. However, the national and international costs associated with detection and control procedures, the cost of compensation and disposal of affected animals, and the loss of export markets was extremely high (billions of dollars) and probably unprecedented in modern history. The occurrence of this disease has also led to a public questioning of the safety of cattle products as human food and a shift in the dietary habits of concerned people. The threat of the human disease caused a significant fall in beef consumption and prices. In response to market forces, the United Kingdom instituted a compulsory slaughter of at-risk but healthy cattle, with significant economic and social costs. Subacute spongiform encephalopathies occur in humans (Creutzfeldt-Jakob disease) and the occurrence of a new spongiform encephalopathy in cattle used for human food has caused considerable debate on the risk to human health. In recognition of this, beef products with risk for infectivity were banned for human consumption early in the outbreak, and the list was enlarged as further information on infectivity of by-products became known. The Phillips Inquiry into the emergence and identification of BSE and variant Creutzfeldt-Jakob disease (vCJD), and the action taken in response to it up to March 20, 1996, was handed to the Government on October 2, 2000 (Phillips, 2000). As a result of over 2 years of inquiry, the report comprises 16 volumes containing findings and conclusions. It is now accepted that the new vCJD in humans in the United Kingdom is directly linked to the epidemic of BSE that was first described in 1986.

Outbreaks of foodborne illness in humans now make headline news. Hamburger disease in humans from the consumption of inadequately cooked ground beef containing *Escherichia coli* 0157:H7 was first identified as a cause of disease in humans in 1982 in people who had eaten hamburgers prepared in fast-food outlets (Powell and Leiss, 1997). A 1993 outbreak in Tacoma, Washington, was associated with

Downloaded From Vet-eBooks.com

a particular chain of restaurants and involved 700 confirmed cases; 125 people had to be admitted to the hospital. Cattle, sheep, and deer have been identified as reservoirs of *E. coli* 0157:H7. The organism can be found as a normal inhabitant of the intestinal tracts of cattle, and during the slaughter process the surface of the beef carcass can become contaminated, which can lead to subsequent contamination of ground beef. By 1994 the U.S. Department of Agriculture (USDA) introduced a new test that could detect bacteria on meat. By 1996, the USDA and U.S. President Bill Clinton announced that, for the first time in 90 years of federal regulations, every slaughter plant would have to test its raw products for bacterial contamination using a Hazard Analysis Critical Control Points (HACCP) system. These food safety issues have led to the emergence of risk communication as an important aspect of health management in livestock production. In addition, *E. coli* 0157:H7 in ground beef is considered a food adulterant, and such contaminated meat must be withdrawn from the market and destroyed.

Risk identification, analysis, and *communication* are now major areas of interest in the food industry. Risk is the probability of harm in any given situation, and the probability is determined by two factors: the nature of a hazard and the extent of anyone's exposure to that hazard. The product of the two factors (hazards and exposures) adds to the overall risk. Risk communication is the process of exchanges about how best to assess and manage risks among scientists, regulatory agencies, public interest groups, and the general public (Powell and Leiss, 1997). Risk communication does not mean denying that a potential problem exists. The risk must be acknowledged and evaluated.

The work of risk communication occurs within that large gap that often separates two evaluations of risks: those of scientific experts on the one hand and those of members of the public on the other. Good risk communication practice seeks to bridge that gap by ensuring that the meaning of scientific risk assessments is presented in understandable terms to the public and, equally, by ensuring that the nature of the public's concerns is known by and respected by risk managers. Often there is little or no effort by either group, and a risk information vacuum interposes itself between experts and the public. Trapped in the resulting solitudes, experts bemoan the public's irrationality while being repaid with the public's contempt for their indifference and arrogance (Powell and Leiss, 1997). These solitudes represent risk communication failure.

Problems in communicating about risks originate primarily in the marked differences that exist between the two languages used to describe the experience with risks: the scientific and statistical language of experts on the one hand and the intuitively grounded language of the public on the other.

There is a need to narrow the gap between society's perception of the risk and what the risk really is, and what people can do to protect themselves. All of the players in the food chain, from producer to consumer, have a responsibility to recognize the importance of food safety and to use judicious and prudent methods to minimize the risks to human health.

Many opportunities exist during production, processing, distribution, retail, marketing, and consumption for pathogens to find their way into beef and beef products. Eliminating pathogens and therefore the risk of contracting a foodborne illness from beef products is a monumental, if not impossible, task. Therefore the approach must be *the exploration of methods of risk reduction rather than complete risk elimination.*

This book describes the role of the veterinarian in planned animal health and production in food-producing animals, particularly cattle, sheep, and swine. The major importance of poultry as a food-producing animal is recognized, but this book does not deal with poultry health and production.

A planned animal health and production management program, commonly known as herd health, is a combination of regularly scheduled veterinary activities and good herd management designed to achieve and maintain optimum animal health and production (Blood, 1979). Herd health programs vary from simple systems, in which the veterinarian visits the herd on a regular basis to examine animals and their performance and to make recommendations for the control of disease and improvement of production, to intensive programs, in which the veterinarian—with the assistance of other agricultural science specialists—makes detailed recommendations about the daily management of the animal health production program. This may include recommendations on nutrition, housing, genetic improvement, purchase of breeding stock, selling of animals ready for market, and cash flow.

Some veterinarians are now employed as resident herd managers and are responsible for ensuring maximum use of all available resources by coordinating the services and advice provided by all the agricultural advisors who are involved with the herd.

The terms *production-oriented medicine* and *performance medicine* are now being used to emphasize the importance of animal diseases and production problems that impair productivity rather than cause clinical disease. Of even greater importance in this context is the close relationship between animal health and production and the need to develop an integrated approach to production-oriented health management programs. *Herd health, preventive veterinary medicine, health management, health and production management,* and *production medicine* are expressions used synonymously throughout this book, and they generally refer to the same activities. An understanding of production medicine is essential if veterinarians are to have a role in the livestock production industries of the future (Guterbock, 1994).

OBJECTIVES OF HERD HEALTH MANAGEMENT

The primary objective of a health and production management program for herds of food-producing animals is the maintenance of animal health and production at the most efficient level that provides competitive economic returns to the animal owner. The ever-present goal is to control and manage animal health and production at a high level of efficiency while seeking and introducing new techniques that can continue to improve efficiency. Of major importance is that health and production management practices must document that they have a sound economic basis for success.

Some equally important secondary objectives include the provision of comfortable animal facilities and housing commensurate with reasonable animal welfare. Good animal production and animal welfare are complementary veterinary concerns. In addition, the minimization of pollution of the environment by animal wastes, the prevention of zoonoses (diseases transmissible from animals to humans), and the avoidance of contaminants and residues in animal products are all important considerations.

TARGETS OF ANIMAL HEALTH AND PRODUCTION PERFORMANCE

The objectives of herd health are achieved by the application of the concept of target of performance. *A target of performance is the level of animal health and production considered to be*

Downloaded From Vet-eBooks.com

optimum and to yield the best economic returns on investments. Targets of performance are determined from the performance found on a sample of farms considered to be representative of the economically conscious commercial farm population.

In a herd health management program, the actual levels of animal health and production are determined on a continual basis and compared with the targets of performance. The differences between the targets of performance and actual performance are the shortfalls in performance. The reasons for failure to achieve the targets of performance are then identified. Recommendations for improvement are made and performance is monitored continuously to assess the effectiveness of the action taken. These measures are then repeated on a continuous basis (Fig. 1-1).

HISTORICAL ASPECTS OF HEALTH MANAGEMENT OF FOOD PRODUCING ANIMALS

The historical development of health management of food-producing animals can be divided into four phases of activity (Table 1-1).

Phase 1

Phase 1 began about 100 years ago. National and state governments were involved in the eradication of diseases, such as brucellosis and tuberculosis, which were the causes of large economic loss and were transmissible from cattle to humans. By the end of the twentieth century, these diseases had already been eradicated in some countries, and real progress is currently being made toward eradication in others. Some countries have been involved in the control of contagious diseases, such as foot-and-mouth disease, rinderpest, and trypanosomiasis. These efforts were introduced to reduce livestock losses, which lead to widespread nutritional deficiencies among the human population. National disease eradication programs were directed toward effective control of diseases in the animal population on a geographical basis. As each area became free of the disease, only disease-free animals were allowed to enter. In this way, the disease theoretically could be eradicated from the entire country. These programs have been successful because the diagnostic tests were reliable, the testing was compulsory, and the financial resources necessary to do the job were made available from the public treasury.

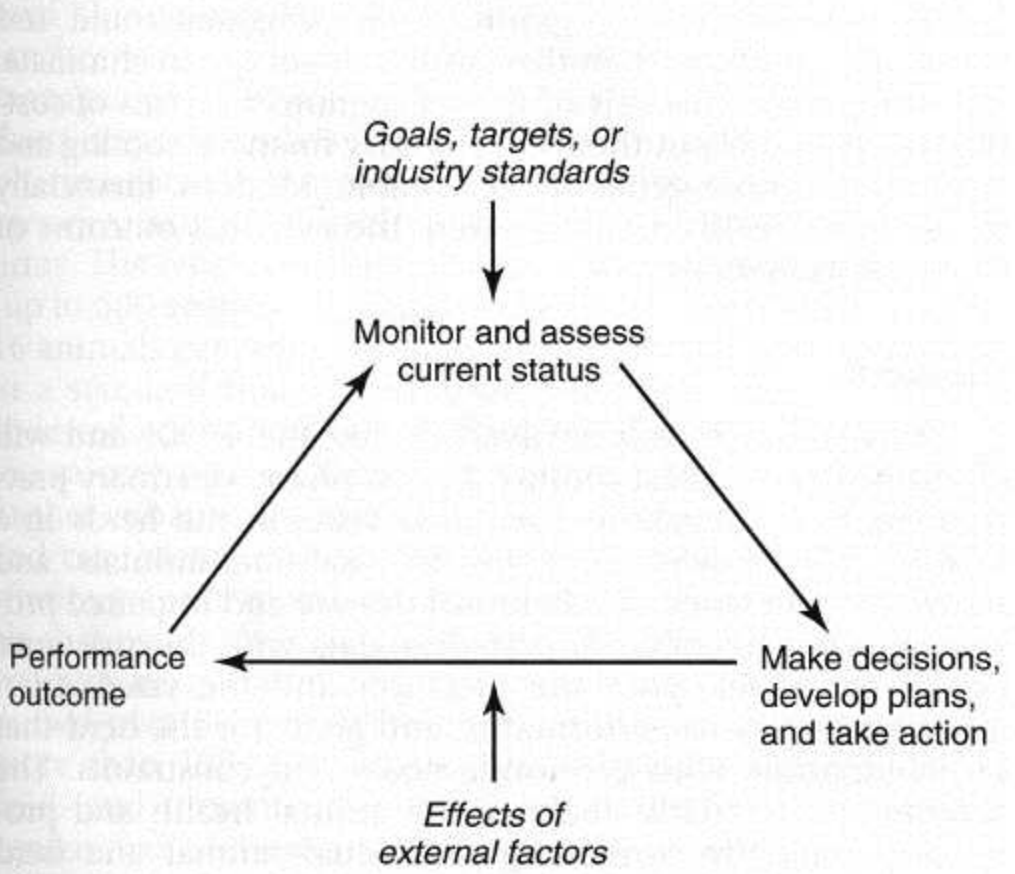

FIG. 1-1 Health management feedback cycle.

Phase 2

Phase 2 began around 1940 when meat-, milk-, and fiber-producing animals (cattle, swine, and sheep) became valuable as animal farms began to sell livestock and by-products off the farm as a source of net income. Before this time, most practicing veterinarians were involved in equine practice, which consisted largely of seasonal routine work. With the decline of the horse as a source of mechanical power on the farm, veterinarians turned their activities to cattle, swine, and sheep practice. Between 1945 and 1965, an exceptionally large growth occurred in rural large animal practice. This period coincided with a sharp increase in the standard of living in developed countries, which created an unprecedented demand for meat and milk. The law of supply and demand increased the price of meat to the consumer, and in turn farm animals became valuable. When animals became ill, it was economical to call the veterinarian to treat them on an individual basis.

Veterinary college clinical practices were developed in the "Phase 2" period. Veterinary graduates possessed the knowledge and skills to treat a wide variety of animal diseases successfully. Antimicrobials were also introduced, and veterinarians could treat many more of the common infectious diseases, such as pneumonia and enteritis, with spectacular results. Veterinary graduates were taught how to perform aseptic surgery. For example, the cesarean section became a common surgical procedure in bovine practice. This created a large demand for veterinarians and their services. However, because of a shortage of veterinarians, those who were in practice were busy and spent most of their time treating individual sick animals. This activity was referred to as *fire engine practice.* Because of a lack of time, little effort was made to control or prevent diseases or to manage health and production on a herd basis. The emphasis was on the individual animal affected with a clinical disease. Disease control efforts consisted mainly of large-scale testing and vaccination programs for diseases such as brucellosis. In North America, for example, veterinarians spent considerable time vaccinating pigs for hog cholera and cattle for brucellosis as part of national control and eradication programs.

Phase 3

Phase 3 developed around 1965 when both veterinarians and producers began to appreciate the value of being proactive in the maintenance of a high level of animal health and efficient production on a herd basis. Producers themselves gradually learned how to recognize and treat some of the common diseases of farm animals. In the earliest stages of this phase, preventive medicine consisted of recommendations for the control or prevention of specific diseases. For example, an outbreak of blackleg in young cattle was followed by a recommendation to vaccinate all susceptible animals with a clostridial vaccine. This was later followed by the veterinarian's recommendations for control of a number of specific diseases that were likely to occur in the herd. As veterinarians became more involved on a regular basis and more familiar with the herd and the producer, the presence of subclinical disease and inadequacies in management that caused poor animal performance was recognized. Subclinical disease in its broadest sense was recognized as the major cause of economic loss in food-producing animal herds. For example, diseases such as infertility and subclinical mastitis in dairy cows and intestinal helminthiasis in sheep responded dramatically and economically to strategic

TABLE 1-1

Historical Development of Health Management Veterinary Services

Phase	Principal Preoccupation	Principal Mode of Action	Principal Agent	Support Mechanism
1	Area problems; protection of all herds by control of disease on area basis	Government-sponsored health programs on area basis; brucellosis and tuberculosis eradication programs	Government veterinary officer	Troubleshooter from government agency
2	Treatment of individual animals gives rise to inquiries about health management programs	Incidental preventive programs, (e.g., mastitis control, fertility, maintenance, parasitic disease status)	Private practitioner	Private, university, or government consultant
3	Positive action through herd programs to maintain health status, (e.g., reproductive efficiency, quarter infection rate)	Packaged herd disease preventive programs; planned actions at programmed visits	Private practitioner (or government or employed veterinarian)	Consultants (as above) with specialties in individual diseases
4	Integration of health maintenance plans with production and management plans to give whole-farm best effect	Positive action through herd programs (as above) with control data handling for all participating herds; data bank makes production planning and prediction possible	Private practitioner (or employed veterinarian); may be in conjunction with production advisor	Disease consultants and production advisors, but data laboratory most important for providing statistical and financial analysis

prophylactic procedures and changes in management. During this phase, the use of the word disease was expanded to include not only clinical and subclinical disease but also management inefficiency; all three can result in suboptimal performance (Blood, 1979).

The recognition that economic benefits could be derived by taking positive action against subclinical disease was followed by the development of planned herd health programs. Veterinarians began to make regularly scheduled visits to farms to examine the animal health and production status of the herd and to make recommendations for improvement. Herd health began to evolve. Between 1970 and 1980, there was considerable activity in the development of herd health programs for dairy cattle (Goodger and Ruppanner, 1982a). Considerable progress was made in dairy and swine health management. Programs for beef breeding herds and feedlots and for sheep flocks began to develop in a meaningful way. In 1983 a Canadian survey of food animal practitioners revealed that 80% indicated that some of their work was health management, with an overall average of about 30% of total time devoted to herd health activities (Magwood, 1983). In the 1980s considerable progress was made in the health management of dairy cattle, beef breeding herds, beef feedlots, swine herds, goat herds, and sheep flocks. During this phase farmers and veterinarians recognized the value of keeping good records of animal health and production so that an objective analysis of health and production, including the costs of production, could be made.

The inclination was to fill the program with every known preventive measure (e.g., whether the disease was likely to occur, whether a particular technique was highly effective), and often the program included more than one technique to prevent one disease. This was one of the false steps made in the early stages of this new expansion into herd and flock health management programs. Such programs could and often did cost more than the waste they set out to eliminate. The subsequent analysis of these programs in terms of cost-effectiveness has put them on sounder financial footing and made them more generally acceptable. Modern, financially viable herd health programs were the eventual outcome of this evolutionary process.

Phase 4

Phase 4 has mostly evolved during the 1990s and will continue into the 21st century. In this phase, veterinary practitioners make regularly scheduled visits to the herds in a health management program to examine animals and records for evidence of subclinical disease and impaired productivity and to collect and analyze data with the assistance of the computer. Both the producer and the veterinarian agree on targets of performance and goals for the herd that are compatible with economic goals and constraints. The veterinarian regularly analyzes the animal health and production data. By comparing individual animal and herd mean actual performance with the targets of performance, the component of the production cycle in which there is a

Downloaded From Vet-eBooks.com

shortfall is identified. Subsequently, the veterinarian attempts to determine the reasons for failure to achieve the desired targets of performance. With the assistance of agricultural advisors (nutritionists, geneticists, engineers, economists), the veterinarian can make recommendations for improvement in animal health and production. The ideal objective is to maximize the use of the resources available on the farm through the "whole-farm" approach (Howe, 1988).

Progressive food-producing animal veterinary practices of today and the future will be a multiple-person practice providing comprehensive health and production management veterinary service to livestock producers who are in the business of food animal production. The practice will provide a complete animal health management service, including consultative advice on treatment and control of disease, a complete record keeping system, and regular, even daily, animal health and production reports of the herd. Such veterinary practices will be staffed by species-oriented veterinarians with special expertise in some aspect of food animal production. Animal health data collection and analysis will be a major activity. In some practices with access to large numbers of animals, clinical research on the efficacy of drugs and vaccines will become a significant activity. Biostatistics and the preparation of research reports will become a major activity. Some veterinary practices will restrict their services to certain clients, such as beef feedlots, dairy herds, swine herds, or beef-breeding herds. Animal health technicians are now employed by these practices to assist in the treatment of animals, collection of laboratory samples for herd investigations, routine elective procedures, and collection of health and production data. Clearly, the emphasis will be on the health and production of healthy animals and getting paid for healthy animals rather than a fee for service for attending to sick animals. Thus the paradigm is shifting from emphasis on health and production rather than on the traditional role of the veterinarian as "a healer of the sick."

There are some examples of veterinary practices that represent an advanced stage of Phase 4. Feedlot Health Management Services (Okotoks, Alberta, Canada) is a consulting company providing comprehensive herd health programs, veterinary consulting services, and computerized health recording systems to feedlots and cow-calf herds throughout western Canada and the United States. The practice currently involves six veterinarians and twelve support staff. The practice has expanded over 20 years and, as of 2001, provides production consulting services to beef feedlots with an annual throughput of greater than 1 million animals and ranches with about 10,000 beef cows. In addition to health management services to their clients, the practice also conducts research studies in feedlot and cow-calf operations for pharmaceutical companies, feed companies, government agencies, academic institutions, and independent research firms. The feedlot studies are conducted in both large pens (up to 600 animals per pen) and traditional small pens (8 to 16 animals per pen). All studies are designed and conducted to a standard that would allow for publication in a peer-reviewed scientific journal. The objective of these studies is to evaluate new and existing technologies and products to further enhance the efficiency of production and the quality and consistency of the beef produced. The results of these studies are incorporated into computerized economic models that assess the overall cost-benefit of the technology or product in question. The practice has authored or coauthored over 30 peer-reviewed scientific articles, completed more than 100 technical reports relevant to the academic field, and presented technical material at more than 175 conferences and meetings throughout the world.

In Phase 4 resident veterinarians are becoming more common. Large dairy farms, for example, employ an experienced dairy cattle practitioner as a full-time employee to manage the health and production of the herd and other aspects of the farming operation. The veterinarian needs to have an advanced understanding of all aspects of dairy cattle health and production and must be able to integrate the services of nutritionists, building and ventilation engineers, geneticists, computer programmers, and animal health technicians and animal attendants.

It is now generally agreed that subclinical diseases or production inefficiencies, many of which cause no recognizable clinical signs, are the most important contributors to reduced productivity. These production inefficiencies, which are caused by factors that impair animal health, can be eliminated in the foreseeable future by three prerequisite inputs. Production can be improved if (1) current knowledge is applied, (2) animal health delivery systems are improved, and (3) new technology is developed through basic and applied research in areas where suitable measures are not presently available. Each farm presents a unique combination of factors contributing to suboptimum performances. In addition, each producer has a different attitude to change and risk (Caple et al, 1989). Agricultural extension services have helped to make major strides in improving the efficiency of livestock production. However, it is now apparent that the solution to improving suboptimal performance in the field is to have consultants and advisors work directly with the individual producer, who is charged for the services provided.

Major changes occurred in the 1980s and 1990s that have implications for animal production in the 21st century (Anderson and Pritchard, 1980). The development of a totally integrated animal health and production management system is the most important need, and this book describes the systems proposed. In 1982, it was predicted that epidemiologic surveillance would become the "core" activity of the public and private practice of preventive veterinary medicine (Schwabe, 1982). Epidemiology now provides a wide range of methods and knowledge that will assist the animal health challenges of the 21st century (Dorn, 1992; Meek, 1993). This is especially true for the interaction of veterinary epidemiology and agricultural economics.

Management decisions affecting animal health and productivity are increasing in complexity, regardless of whether they are made at a national, regional, or farm level. Decision-makers (whether administrators, veterinarians in clinical practice, or producers) need reliable, quantitative information about the health and productivity of the livestock in their care. Epidemiology contributes to health and productivity monitoring programs by asking three questions (Dohoo, 1993): What should be monitored? How should the required data be obtained and analyzed? How should the information be distributed?

Other Changes in Phase 4

Regulatory veterinary medicine has changed dramatically (Reid, 1992). In Canada, for example, the federal regulatory veterinarian has moved out of the role of a clinician diagnosing animal disease (tuberculosis and brucellosis) into the following roles: an epidemiologist tracing the movement of disease; a biochemist or toxicologist understanding the movement of chemicals through the animal body; a zoologist understanding many species; a manager supervising staff; an innovator coping with new and unusual situations; and a promoter selling the industry, the public, peers, and superiors on the value of health programs including food safety. Food inspection has expanded to include a major emphasis on monitoring programs that are able to detect pathogens and antimicrobial and other chemical residues.

Downloaded From Vet-eBooks.com

Biotechnology offers many new approaches to the management of disease and improvement of animal health. Recent advances in cell and molecular biology have led to development of recombinant DNA technology or genetic engineering. The DNA content of cells or organisms can be manipulated so that they produce greater quantities of a protein or, alternatively, a foreign protein. Genetic engineering has the potential to generate disease-resistant strains of animals. Biotechnology provides endless opportunities for veterinary medicine, including medicinal and pharmaceutical chemistry resulting in a wide range of therapeutically important compounds, nutrition, transgenic animals and plants, and new and more accurate and rapid diagnostic tests (Headon, 1994; Jackwood, 1994). Genetically engineered vaccines for animal viral diseases retain the advantages of live viral vaccines but overcome the safety hazards and logistic disadvantages inherent in live agent vaccines (Yilma, 1994). Major advances in the diagnosis and control of parasitic diseases are being made with biotechnology (Zarlenga, 1994). Although biotechnology offers many potential new approaches to management of disease and improvement of animal health, it is, however, an area that generates a high level of interest and controversy concerning moral and ethical values within the scientific and lay communities (McDermott, 1994). These value judgments must be considered and weighed for application in the research or commercial areas.

This book outlines the remarkable progress in the development of production-oriented animal health management veterinary services for food-producing animal production units. New technological developments now make it possible to improve the quality of diagnosis, treatment, and control of animal diseases, to enhance the quality of animal life, and to effectively chart the economic implications of such changes.

Herd Health and Production Programs in Developing Countries

In industrialized countries, herd health programs developed in response to structural changes in agricultural production. Among the major changes was the reduction in the number of farms but with increasing numbers of livestock per unit, increases in gross receipts, and vertical integration within industries. Owners of these evolving farming enterprises made demands on service providers, including veterinarians, nutritionists, extension specialists, and other disciplines, to provide more cost-effective services. At first, services offered to improve livestock health were not always accepted as appropriate or cost-effective. Therefore herd health programs in industrialized countries have evolved continually to meet the perceived needs of farmers and to keep in step with biological advances and computer technology.

In contrast, in developing countries, smallholders and less capitalized livestock producers do not have ready access to, and maybe have a lesser need for, herd health programs. Some attempts have been made to offer smallholders the essential elements of herd health and production programs. Smallholders in developing countries generally are not empowered to make demands on governments for herd health programs, and private sector services are not generally available. However, smallholders require better and more readily available livestock services, and herd health and production programs can be a framework to provide these services. The Food and Agricultural Organization (FAO) of the United Nations has a mandate to promote sound scientific, technological, social, and economic actions towards the conservation of natural resources and the adoption of improved methods of agricultural production (FAO, 1993). The first Expert Consultation on the application of effective herd health and production programs to increase livestock productivity in developing countries outlined technical, financial, and socioeconomic prerequisites for applying the herd health and production program approach. Concrete actions by Member Countries and FAO to further develop and implement this approach have been described (FAO, 1993). The summary and recommendations are shown in Box 1-1.

Changes in Society that Have Special Importance to Veterinary Medicine

Changes in the environment in which veterinary medicine functions and their implications to the veterinary profession have been described (Pritchard, 1993). The most important changes are the following:

- The changing status of animals and the increased importance placed on animals by society are enhancing the social and economical value of veterinary services.
- People increasingly seek veterinarians for advice and services on the care, husbandry, health and utility, and productivity of animals, not just for medical and surgical services.
- The public expects, and increasingly is willing to pay for, high-quality veterinary services for all kinds of animals.
- Far-reaching structural and technological changes are developing in agriculture, which are profoundly changing the kinds of animal health services required by the food animal production and processing industries.

Advances in science and technology, particularly at the molecular level, are revolutionizing the understanding of life processes and disease and their control as well as increasing the power and specificity of all kinds of veterinary technology. Spectacular advances in electronics and in information management through the use of computers have the potential of markedly improving the efficiency and effectiveness of veterinary practice (Dye et al, 1994; Wise, 1992). Veterinary tasks and functions in the public and private sectors are being altered by the growing involvement of many countries in the economic and political affairs of the world (Howard, 1992).

Structural Changes in the Veterinary Profession

Many of the preceding environmental changes have been occurring for a long time (Pritchard, 1993). Since the 1940s major change has occurred in the veterinary profession in the developed countries, and the profession has undergone a process of progressive differentiation, which is continuing. The profession used to consist of a body of individuals, each of whom was as capable as any other veterinarian—within the limit of personal ability—of conducting all of the tasks and functions required of the profession at that time. It is now composed of veterinarians with different skills who focus their professional efforts on a limited component of veterinary practice (e.g., small animal practice, large animal practice, feedlot practice, dairy cattle practice, swine practice). In 1992, 57% of practicing veterinarians in the United States identified their professional activity as exclusive small animal practice. Ten percent of practitioners were in large animal practice exclusively, and 62% of those further limited their professional activity to horses, cattle, or swine. Twenty-six percent more reported their professional activity to be limited predominantly to a class of animals. Thus 67% of this group identified their professional activity to be limited exclusively to a class of animals or a species, whereas 92% declared their activity to be exclusively or predominantly devoted to a class of animals or a species.

BOX 1-1

Summary and Recommendations of the Food and Agricultural Organization (FAO)

Reducing the inefficiency in livestock production leads inevitably to reducing family welfare risks and increasing food security. These are fundamental goals of livestock raisers worldwide. These inefficiencies essentially steal from farmers and, in the aggregate, from nations. The thefts may be in the form of visible epidemic disease, invisible production losses or simply living with low productivity. Reducing or eliminating lost productivity—be it from infectious, noninfectious or production diseases—requires conscious, informed decisions by livestock owners. The herd health and production programme approach is the framework for making sound decisions, implementing actions, measuring the effects and devising future actions.

The first Expert Consultation on the Application of Effective Herd Health and Production Programmes to Increase Livestock Productivity in Developing Countries outlines technical, financial and socio-economic prerequisites for applying the herd health and production programme approach. Concrete actions by Member Countries and FAO to further develop and implement this approach are elaborated.

Bearing the above in mind, Member Governments should:

1. Improve the delivery of veterinary and animal husbandry services at the local level to increase food production efficiency, food security and sustainable agriculture production. The herd health and production programme approach is one means toward achieving these ends;
2. Continue to vigorously and consistently implement programmes to eradicate and/or control infectious and parasitic diseases in livestock. Uncontrolled infectious or parasitic diseases effectively negate investments made in genetic improvement, nutrition, control of production diseases, international trade and processing/adding value to livestock products;
3. Establish, as a matter of urgency, where it does not already exist, a consultation group for herd health and production programme management. This group should include interested persons within the government livestock services (animal health and animal production), the private sector service providers (veterinarians, nutritionists, lenders, processors, cooperatives, etc.), producers of livestock products, (and) veterinary and agricultural faculties and other interested parties (development banks, non-governmental organizations, professional associations). Each consultative group for herd health and production programmes should be capable of providing administrative, technical, publicity and organizational support for persons and groups with expertise in herd health and production programmes;
4. Recruit other interested national organizations and together focus initially on applying, developing and refining herd health and production programme methods in local areas as a pilot programme. Locally focused pilot projects can be implemented within ongoing programmes or projects. Experience and lessons gained should then direct institutional changes, for instance, in university curricula, bank lending packages, cooperative services, continuing education, etc;
5. Secure, along with interest groups, FAO and other international development agencies, Trust Funds or alternative financing to establish the required infrastructure to implement pilot projects which develop the herd health and production programme approach in local areas;

FAO SHOULD:

6. Continue to articulate and promote the herd health and production programme approach aimed at enhancing livestock productivity, food security and sustainable agriculture production. Lessons learned indicate that for effective programmes to be adopted, livestock owners need to be empowered to take the lead in demanding effective services from providers, both government and private;
7. Articulate and promote the herd health and production programme approach using the protocol developed during the Expert Consultation which consists of the following elements:
   a. Agree with the management upon proposed production and risk reduction targets;
   b. Define and develop the tools and technologies required to collect the necessary data;
   c. Interpret the data gathered from all sources into information (usable knowledge);
   d. Develop and agree upon a plan of action which includes concrete steps to reach the production and risk reduction targets set in step 1; and
   e. Monitor and evaluate progress then begin again at step 1;
8. Identify and implement pilot projects based on the herd health and production programme approach among various livestock production systems. One medium-term goal of pilot projects should be to identify, document and recommend specific activities and within herd health and production programmes which are profitable for veterinarians to offer and financially advantageous for livestock owners to purchase;
9. Promote livestock product processing techniques, and encourage livestock owners to adopt such techniques, which add value to primary products and thereby increase farmers' purchasing power and food security. Adding value to livestock products is an adjunct to sustainable financing of herd health and production programmes;
10. Focus on explaining and sensitizing veterinarians and paraprofessionals already working in the field to the benefits of herd health and production programmes. Undertake studies on viable methods to finance sustainable delivery of herd health and production programmes at the farm/village level in different livestock production systems. Such studies might evaluate alternative financing (as discussed in the text), the need for initial subsidization, how long subsidization might be required, financing alternatives in livestock systems with periodic cash flow (nomadic pastoralists, transhumants) and the public versus private goods to be derived from herd health and production programmes;
11. Review the usefulness of current data collections systems with the view to collect and dispatch appropriate data to the appropriate organizational level. The criteria for "appropriate organizational level" should be that once data are received, this organizational level is in a position to act effectively on information derived from the data;
12. Encourage (sensitize) faculties to evaluate the role that the herd health and production programme approach

Continued

BOX 1-1—cont'd

Summary and Recommendations of the Food and Agricultural Organization (FAO)—cont'd

might play in a revised curriculum for veterinary or auxiliary students;

13. Emphasize to Member Countries that the focus of the herd health and production programme approach is at the farm/village level. Therefore, training, institutional support, and data/information systems need to be designed from the bottom up assuring that the interests of local providers and livestock owners are best served;
14. Interest donors, the private sector, communities and others to finance pilot projects which develop and use the herd health and production programme approach;
15. Commission studies on and promote the use of standardized formula for production indices used by computer software developers and others when deriving livestock production information. Standardized production indices are essential requirements for consistent comparison of performance within and between livestock systems; and
16. Along with Member Countries, organize in-service training in the application of herd health and production programme approach for field staff at the local level using the most competent field personnel.

Text from Food and Agricultural Organization of the United Nations: Report of the Expert Consultation on the application of effective herd health and production programmes to increase livestock productivity in developing countries, Rome, Italy, March 30-April 1, 1993.

The proportion of veterinarians who provide services to more than one class of animals is diminishing progressively. In 1962, 66% of veterinary practitioners indicated that their professional activity involved more than one class of animals (that is, any form of mixed practice). In 1992 this figure had decreased to 33%. If all categories of professional activity are considered, this figure falls to 25%. In 2000, 70% of veterinary practitioners identified their professional activity as small animal practice (combined predominant and exclusive), 4% in equine practice, 12.8% in large animal practice (combined predominant and exclusive), and 7.6% in mixed animal practice (American Veterinary Medical Association [AVMA], 2000). However, the total number of veterinarians in large and mixed animal practice has increased slightly.

Differentiation in veterinary practice has been driven by three major forces: the growing body of knowledge about biology, health, disease, husbandry, utility, and productivity of animals and the increasing complexity of all kinds of professional activity; increasing expectations of animal owners as to quality of services delivered and the competency expected of all veterinarians in all sectors of the profession; and the desire of veterinarians to provide high-quality services for all animals. Differentiation in veterinary practice is unlike disciplinary specialization in human medicine but is growing in veterinary medicine. Veterinarians who focus their efforts on a class of animals provide primary health care of a general nature to that class of animals. This is in contrast to human medical specialists (e.g., dermatologists, internists, cardiologists, neurologists) who provide a secondary level of service, limited to a defined specialty, following referral from a general practitioner. A growing number of veterinary specialists are entering private practice.

A major change in veterinary practice evolving from differentiation is a change in the focus from individual animals to populations in most practice themes. For all classes of animals and all practice themes, except for companion animals, a population approach to problem solving and health management is the major activity, with concern for individual animals being of lesser or no importance. To prepare the profession for the tasks of the future, a greater focus on populations and population approaches to health and disease will be needed. This will necessitate the expansion of instruction in epidemiology and population health and medicine in veterinary curricula.

The need to move toward more instruction on population-based health and medicine is being recognized by veterinary colleges and courses in biomedical statistics, quantitative epidemiology, veterinary economics, and herd health and production management. Improving instruction in population health and production is a more difficult task than restructuring the curriculum to accommodate electives or tracking, which is the traditional way that veterinary medical colleges have responded to the increasing complexity of veterinary practice. A population approach requires new and different ways of thinking about health and disease, diagnostic approaches, and strategies for solving health and production problems.

The profession must radically rethink the undergraduate curriculum if it is to prepare graduates adequately for the 21st century (Halliwell, 1999). It has been suggested that if the profession does not act resolutely, with vision and boldness, it will dissipate much of its potential to serve the future needs of society (Nielsen, 1997, 1999). Designated licensure and speciation within the veterinary degree would provide veterinary students with the flexibility to pursue their areas of interest and to be much more competent at graduation than the veterinary student who has attempted to learn all aspects of veterinary medicine (Karg, 2000). (Speciation as used here means to identify a change from uniform licensing across taxonomic barriers to designation for a limited number of species.) The organized veterinary profession, not the universities, has the instruments necessary for leadership in making sure that society's needs are met, namely through veterinary licensure, regulation of internships, setting practice standards, and college accreditation. In a tracking system of education, veterinary students would have to choose one of several major career paths, such as mixed practice, small animal practice, equine practice, food animal practice, public health, food safety, comparative medicine, zoo medicine, aquaculture, or ecosystem health (wildlife) at the end of second year of a 4-year professional course. Examination for licensure would be tailored to the career path chosen (Nielsen, 1999). The effects of this approach

Downloaded From Vet-eBooks.com

would be to require students to make career choices earlier in their undergraduate veterinary program, increasing the standards of competence at graduation to more effectively meet the needs of society (Nielsen, 1997). The lack of mandatory clinical internship in veterinary medicine, as exists in human medicine, means that the undergraduate clinical education program must be as comprehensive as reasonably possible to provide the graduate veterinarian with the knowledge and skills necessary to meet the needs of the public. A veterinary graduate who becomes competent in a particular sector of veterinary medicine before graduation does not have to learn the basic clinical skills at the expense of the unsuspecting public.

It no longer makes sense for the profession to cling to an inaccurate and outdated view of the capacity of the veterinarian. The time when an individual veterinarian could reasonably be expected to possess the needed skill and knowledge to care for the health needs of all kinds of animals at a level acceptable to the public is long gone. It is an important part of the profession's history, but has no validity now and will certainly not be valid in the 21st century. It is important to recognize this reality for it accepts many things that the profession does. The concept of the universal veterinarian is an anachronism, and it should be buried with honor. The impossible dream—the DVM who can provide the health of all "creatures great and small" is inhibiting the progress of the profession. It is at the very root of serious problems facing veterinary educational issues today. (Pritchard, 1989a)

Economic Status of Veterinary Profession

An analysis of the current and future market for veterinarians and veterinary medical services in the United States identified six critical issues, all of which must be addressed successfully to improve the economic health of the profession (Brown and Silverman, 1999).

- *Veterinarians' income.* The income of individual veterinarians is much lower than that of similar professions, which may affect recruitment of highly qualified and intelligent students to the profession.
- *Economic consequences of a large percentage of women in the profession.* There is evidence that the income of female veterinarians is far below that of their male colleagues, that female veterinarians work fewer hours and are less likely to become practice owners, and that they may price their services below that of male veterinarians, thus reducing the income levels of all veterinarians. Between 1990 and 1995 the net increase in the number of female veterinarians was 9.5 times greater than that in male veterinarians (Gehrke, 1996); and the number of female veterinarians will equal the number of male veterinarians by 2004.
- *Global demand for all categories of veterinary services.* There is substantial opportunity to increase demand for veterinary services.
- *Inefficiency of the delivery system.* The majority of animal care is still delivered through a highly fragmented and inefficient system.
- *Supply of veterinarians.* On economic terms, Gehrke (1996) suggested that there is an excess of veterinarians in the United States, which is a cause of low veterinary income. More important, the characteristics of the supply of veterinarians do not closely match the demand, and there is evidence that modifications in the education of veterinarians will enable the profession to capitalize on emerging markets and to create new services.
- *Skills, knowledge, aptitude, and attitude of veterinarians and veterinary students.* Although the scientific and clinical skills of the profession are high, there is evidence that veterinarians lack some of the skills and aptitudes that result in economic success. Also, the perception veterinarians have of their abilities and what they can contribute to society potentially limits the professional and economic growth of the veterinary profession.

Economic Transition in Veterinary Medicine

The economic status of the veterinary profession in the United States has been examined from the perspective of an agricultural economist (Getz, 1997). The study suggests that veterinarians are in excess supply and that the excess will probably increase throughout the current decade. Evidence indicates that the population of veterinarians continues to expand rapidly. Eighty percent of the veterinarians who reported their employment are in private practice; 20% are salaried employees of industry, government, and academia. Among the veterinarians in private practice, 75% work exclusively or predominantly with small animals. Another 4% are in equine practice, and 8% are in mixed practice providing service to both large and small animals in approximately equal quantity. Only 16% of the private practitioners worked predominantly or exclusively with large animals. Thus only 16% of private practitioners served primarily agriculture. The number of animals is changing. Among companion animals, owners of dogs, cats, and horses make significant demands on veterinary services. With rising incomes more households are willing to spend more per pet on veterinary services, reflecting the closer personal relationships owners have with their pets. The number of families with pets continues to grow, thus explaining the overall continued growth of small animal practice.

The demand for numbers of veterinarians in agriculture appears to be stable or declining. Farms are becoming larger, and more livestock is grown on production contracts. With increased scale, fewer farms are needed to support a large animal veterinary practice, and large farms spend much less per animal on veterinary services. Many livestock operators work on long-term contract with processing corporations. Corporate farming enterprises are becoming large enough to keep a veterinarian on salary rather than relying on the fee-for-service veterinarian. When veterinarians are used more intensively, the aggregate demand for veterinarians declines. Ironically, agriculture may then be reducing its demand for veterinarians more than is indicated by the simple relationship with the stocks of animals being raised for production.

Within the last decade (1990 to 2000) there has been a growing shortage of food animal veterinarians in the United States who are knowledgeable and skilled to provide profitable health management services to livestock farms. This situation partly reflects current demographics, which indicates that farm population as a percentage of total population is only about 2%. Thus the primary pool of potential veterinary students with a significant and meaningful food-producing animal background, and who would be most likely to pursue a career in food animal practice, is relatively small.

The demand in food animal practice will be for veterinarians who are species specialists and can provide a comprehensive economically-based health and production management veterinary service. That is the challenge.

Veterinary Informatics

Practitioners are overwhelmed with new facts, new data, and new opinions. As well as the difficulties involved in keeping pace with the volume of new information, veterinarians are finding it more and more difficult to extract the kernels of

Downloaded From Vet-e-Books.com

"medical knowledge" from the growing mass of "medical information." Clinical research is described ever more in terms of often unfamiliar mathematical or computer models, and research results are in varied formats (Bellamy, 1999). This combination of problems is leading to delays in the application of the newest medical knowledge to veterinary problems. How should practitioners organize and communicate medical information so that the best new knowledge is readily available and can be applied rationally to veterinary problems? How can they revise or replace the organizational processes that force many medical decisions to be arbitrary rather than the best available? How do they maximize the benefits of veterinary research for veterinary practice and minimize the time and resources to achieve these benefits? Veterinary informatics is the study of how veterinary medical information is created, managed, communicated, and applied as knowledge to allow effective and efficient decisions to be made. Veterinary informatics encompasses veterinary information in all its forms, including words (text), numbers, mathematical models, and images (radiographic, microscopic). It examines how veterinary information is organized, classified, represented, stored, and retrieved for use. A central idea in veterinary informatics is the relationship between "information" and "knowledge"; how can information be transformed into useable knowledge that can be applied with confidence directly to making veterinary medical decisions? The computer is the main instrument of informatics. The computer is becoming as essential as the stethoscope, x-ray machine, or electron microscope to good veterinary practice and veterinary research. New computer technologies, combined with new information management and analytical tools, now provide veterinary medicine with the means to address its information challenge.

Veterinary information is the fundamental commodity of veterinary medicine; veterinary informatics is the study of how best to use this commodity. It is time to consider incorporating courses on veterinary informatics into the veterinary curriculum, providing sessions on veterinary informatics in professional development programs, and developing graduate programs in veterinary informatics to educate veterinarians and train specialists in this important emerging field. A major innovation in the delivery of the veterinary curriculum is being implemented at one veterinary college (Whithear et al, 1994). Students receive course information as interactive, multimedia databases consisting of text and an associated library of catalogued digital images, movies, and sounds. The new delivery method encourages greater autonomy and more interactive learning roles for students than occurs in traditionally taught courses. Students use their databases as the principal resource of information for undergraduate studies. A unique feature of this system is that students can modify and expand their databases during the course. The ultimate aim is for students at graduation to receive, on disc, a copy of their own databases, adapted by themselves to their particular future professional needs.

Modern telecommunications and information technology now provide unlimited opportunities for veterinary practitioners to access information through the use of desktop computers in their veterinary practice locations. The technology is now available to obtain full-length scientific journal publications over the Internet. The Internet provides an incredible amount of information on health and production of all animals. Where this will take us in the future is unknown. Certainly the amount of information now available is too much for any one person to assimilate on any one topic. It remains to be seen how we will learn to access and use this information effectively and efficiently.

CURRENT STATUS OF HERD HEALTH PROGRAMS AND THE MARKET FOR FOOD ANIMAL VETERINARY MEDICAL SERVICES

Veterinarians provide varying levels of planned animal health and production management services to dairy herds, beef cattle herds, beef feedlots, swine herds, goat herds, and sheep flocks. For daily herds with 50 to 150 cows, monthly visits are common. A smaller percentage of herds are much larger and may have up to 3000 or more cows. In these cases weekly or daily visits may be necessary. Swine herds are now very large and may have several hundred or thousand sows requiring that the veterinarian make weekly visits. Most beef breeding herds in North America are under 100 cows, and four herd health visits annually are usual. Feedlot veterinary medicine is now well advanced, and some veterinarians visit the producer's feedlots on a daily basis or at least once a week. Some feedlot veterinarians devote their entire practice to a few feedlots. Sheep-flock health and management services are now much more common. Goat producers are also requesting health and production services. There are many opportunities for veterinarians to deliver production-oriented health management services to the food-producing animal industries, which are looking to the veterinary profession for assistance. Multiple-person veterinary practices are becoming more common; these allow individual veterinarians the opportunity to develop a specialty in one of the food animal species.

Market for Food Animal Veterinary Services in the United States

The market for food animal veterinary services in the United States was surveyed by the AVMA in 1985 and 1994. In 1985 a national survey of livestock producers was conducted to obtain information on expenditures on veterinary medical service and animal health supplies, the characteristics of producers relative to their use of veterinary services and products, and the producer's perception about the knowledge, skills, and cost-effectiveness of food animal veterinarians and other suppliers of animal health information (Wise, 1987a,b, 1988a). Also, a national survey of food animal veterinarians provided data on veterinary medical service and product revenues. The perceptions that veterinarians have of food animal practitioners, livestock products, and alternative suppliers of animal health products were evaluated. The preparedness of recent veterinary graduates was explored. Finally, the survey was designed to investigate which areas of food animal practice are believed to represent the greatest and the least potential for future food animal practice growth (Wise, 1987a,b).

The findings were as follows:

1. In 1985, the total U.S. market for food animal veterinary professional services and products was estimated to be about 47% of the total agricultural retail market for animal health products and services. Of food animal veterinary revenues, the dairy market was the largest and accounted for 47%, beef cattle for 34%, swine for 15%, and sheep for 4% of the total. Professional services accounted for 62%; veterinary products accounted for 38%. At the retail level, 24% of the total livestock market for veterinary pharmaceuticals and biological agents, with the exception of feed additives, was through veterinarians, and 76% was through the over-the-counter market. Based on manufacturers' prices, 9% of the total livestock market for pharmaceuticals, biological agents, and feed additives was through veterinarians and 91% through over-the-counter channels (Wise, 1987a,b).

2. Approximately 73% of all livestock producers used a veterinarian either for professional services or for the purchase of animal health products. Food animal veterinarians

Downloaded From Vet-eBooks.com

were used annually by dairy producers about 20 times, by beef producers about 4 times, and by sheep and swine producers about 5 times. Larger livestock farms and ranches spent proportionately more money on animal health products and less money on animal health services than did smaller operations. In addition, larger livestock operations spent proportionately less of their animal health dollar with the veterinarian than did smaller livestock operations. For the analysis, operations were categorized according to three herd sizes: 1 to 49, 50 to 99, and 100 or more head. The amounts of money referred to above are total amounts for large and small farms annually; the amounts on a per-animal basis could not be determined from the data available (Wise, 1988b,c).

3. Livestock producers perceived food animal practitioners as knowledgeable and skillful in the diagnosis and treatment of sick and injured animals and in the clinical aspects of reproductive performance and breeding relative to their own knowledge and that of other suppliers of animal health information. However, producers perceived that food animal veterinarians possess about the same level of knowledge about animal and herd management, feeds, and nutritional management as they do themselves and slightly less than the feed company representative. Producers also perceived that the practitioner's knowledge of agribusiness and economics is weak relative to that of producers and agricultural extension agents.

4. The perception that the producer has of the veterinarian's knowledge and cost-effectiveness relative to other sources of information are significant determinants of who the producer first contacts for assistance. At least 7 out of 10 producers would contact a veterinarian first for the diagnosis and treatment of a sick or injured animal, 5 out of 10 would contact a veterinarian first for a reproduction problem, and about 3 out of 10 would contact a veterinarian first for a herd management problem. Only 1 out of 10 would contact a veterinarian first for a question on feeding and nutrition.

5. Most producers consider that veterinarians are important to their operation for diagnosis and treatment. About half thought that veterinarians are important for drug purchases, regulatory testing, and advice on herd health and reproductive problems. However, only about 15% considered veterinarians as important for feeding and nutrition problems. Nine out of ten producers thought that veterinarians are good at explaining what they know and are good listeners.

The suggested implications of the findings are as follows:

1. There is a need for food animal practitioners to document the cost-effectiveness of veterinary medical services for the business of livestock management and production. Although food animal practitioners are considered knowledgeable and effective communicators, they must demonstrate to producers that production-oriented health management services can enhance the revenue and profitability of the livestock enterprise.

2. The challenge for the future is to determine what veterinary services are needed by livestock producers and how veterinarians can deliver those services economically. Whereas veterinarians are highly regarded for their diagnostic and therapeutic skills, they are perceived to be inadequate in herd management, nutrition, and farm economics.

3. In the face of growing economic pressures on livestock farms, many veterinarians believe that the diagnosis and treatment of sick animals represents the least potential for long-term growth in food animal practice.

4. Long-term growth in food animal practice can occur most likely by a large shift in the practitioner's ability to help the producer make decisions about the animal health and production of the entire herd operation by using the whole-farm approach. This means the incorporation of the production and profitability goals of the producer, a ranking of animal health and production problems, and the implementation (along with the simultaneous measurement and assessment) of health management techniques to improve the efficiency and profitability of livestock production.

5. A fundamental task for the veterinarian is to shift from a fee-for-service or task-oriented business relationship to a fee-for-advice or information-oriented business relationship that focuses on the financial performance of the farm.

6. The food animal veterinarian is the logical professional person to deliver and coordinate advice obtained from other sources.

7. The failure of veterinarians to move quickly and more widely into an information-based animal health and production management service is partly due to the absence of appropriate information in their veterinary education. The fundamentals of whole-herd, information-based health management must include expertise in herd management, production analysis, nutrition, environmental analysis, epidemiology, agribusiness, communication, and the use of computers. Most of these subjects or skills are precisely the elements of a veterinary education that have traditionally been given the least attention, and veterinarians surveyed also thought that these are their weakest areas.

8. If veterinarians can improve their knowledge and skills in nutrition, herd management and reproduction, and farm economics, they increase the likelihood that producers will contact them first for animal health and production problems.

9. The feasibility of improving the veterinarian's knowledge and cost-effectiveness relative to other suppliers of information depends on or is related to the veterinary curriculum, postgraduate continuing education programs, and marketing. From a marketing perspective, there is a need for research into how producers' perceptions are formed and how they can be changed, by how much, and at what cost. From a veterinary education perspective, veterinary medical associations and colleges must collaborate to develop educational strategies for improving opportunities for established food animal practitioners to study in those areas that can meet the needs of producers. Veterinary colleges must incorporate educational experiences in the curriculum to enhance the knowledge, skills, and confidence of the new graduate. The food animal curriculum must be intellectually stimulating and interesting to the undergraduate veterinary student if the profession expects the necessary number of graduates to enter food animal practice. Role models are needed for these students.

10. Further investigation is needed to quantify and assess veterinary medical information as an input into livestock enterprises and to measure its cost-effectiveness. Animal health and production databases need to be developed through the use of practical systems of surveillance that can be incorporated into monitoring and problem-solving models for livestock producers and veterinarians. This can best be done by cooperative efforts among universities, participating livestock farms, food animal practitioners, pharmaceutical and biologic agent suppliers, diagnostic laboratories, and production recording services.

11. There should be additional investigations into the health management needs of producers. Also, the association between the characteristics and attitudes of producers and their use of veterinarians should be studied.

12. A need exists for more effective methods of reporting on the use and purchase of drugs and veterinary services by producers. There is little reliable and useful information about producers' expenditures on veterinary services and

Downloaded From Vet-eBooks.com

animal health supplies and about how much is spent on the diagnosis and treatment of sick animals compared with the cost of health management services.

13. The status of food animal practices should be reviewed and assessed periodically to determine how changes in the livestock industry can influence what changes need to occur in the delivery of food animal veterinary services. Veterinarians need to learn how to assess local livestock conditions and trends and to implement economical animal health marketing programs to meet the needs of producers.

14. Veterinarians must learn how to develop and implement practical strategies and specific client communication techniques so that their animal health and production services and information are used profitably by the livestock community.

The U.S. Livestock Market for Veterinary Medical Services and Products (1995)

In 1994, the American Veterinary Medical Association (AVMA) commissioned the Center for Information Management to conduct a study of the livestock market for veterinary medical services (Wise, 1995). The summary is as follows:

- The structure of agriculture is changing. The number of farms and ranches has been declining since the 1920s.
- Four forces strongly influence changes in the structure of animal agriculture: industrialization, globalization, food safety linkages, and consumerism. These are all areas in which veterinarians' training and knowledge can be applied specifically. The need for veterinarians' knowledge and skills in these areas is demonstrated by the AVMA's adoption of research priorities. Food safety for all Americans; food animal well being; new and reemerging diseases of livestock; quality food from animals for a global market; and environmental quality and agriculture, among others, were adopted as 1995 to 1996 research priorities.
- In 1987, Wise (1987a) concluded that "the fundamental task for food animal veterinarians is to shift from a fee-for-service or task oriented business relationship to a fee-for-advice or information oriented business relationship that is focused on the financial performance of the livestock enterprise." This conclusion is even more relevant today than it was 14 years ago. Task-oriented, fee-for-service, or fee-for-product relationships infer multiple market transactions. That is, each time a production facility requires veterinary services or purchases animal health products, a new transaction takes place. Globalization, food safety linkages, and consumerism have, through increased competition and regulation, increased the costs inherent in these multiple market transactions.
- Industrialization of animal agriculture infers a shift from multiple market transactions with their high costs to more coordinated relationships between producers and veterinarians. These more-coordinated vertical relationships—contracting and integration, to name two—are based on a constant flow of information, services, and products between veterinarians and livestock producers. Market transactions based on individual tasks, products, or services are reduced or eliminated. The transaction is based on the delivery of a complete animal health system. However, industrialization is most evident in only one segment of animal agriculture.
- Animal agriculture is diverging into two separate segments. The first segment is characterized by small, diversified production units. Livestock production is a result of crop production or off-farm work as the household's primary income source. These operations acquire animal health services through multiple market transactions. They have high per-animal health care costs and represent a limited percentage of all animal units in the United States. The demand characteristics of these clients more closely resemble those of companion animal clients rather than their large livestock counterparts.
- The second segment is characterized by large, specialized production units. The use of vertical coordinating systems is a common practice in these operations. The managers of these operations are continually searching for more efficient animal-health delivery systems, including service contracts with local veterinarians. The largest operations may even integrate animal health services by employing staff veterinarians. Data presented in the report indicate that these operations produce most of the animal units in the United States and have the lowest health care costs per animal.
- Expenditures per animal decreased significantly as herd size increased. This infers that large herds generate less animal health revenue for animal health providers than do small herds for a given number of animals. Data also revealed long-term trends that the numbers of beef cows, dairy cows, and breeding swine would continue to decline into the next century. When combined, these factors suggest downward pressure on the total U.S. market for veterinary medical products and services.
- Offsetting this trend was a significant increase in the per-animal expenditures for animal health services and products between 1985 and 1993. All prices paid by farmers increased by approximately 15% during this time. However, per-animal expenditures with veterinarians increased by more than 50%. If it is assumed that the prices of veterinary products and services increased at the same rate as all prices paid by farmers, the implication is a real increase of more than 35% in per-animal expenditures with veterinarians. That is, livestock producers used more services and purchased more or improved products from veterinarians.
- Expenditure and revenue data also suggest that products dominate the total animal health budget of livestock production operations. A significant portion of product expenditures was made with suppliers other than veterinarians. With the exception of swine practitioners, veterinarians' revenue data indicate that 40% or less of each veterinarian's individual revenue was from product sales. Interestingly, swine veterinarians produce the highest individual revenue and have the highest percentage of revenue from product sales.
- The results just mentioned, combined with a fee-for-information, vertically coordinated orientation, infers that veterinarians must include products as an integral part of the total animal health package that they provide. However, veterinarians should concentrate on providing the knowledge, not the products. This infers that products provided as part of the package must be competitive with products provided by outside suppliers. Veterinarians should concentrate on providing a knowledge-based package of animal health services and products because this is the area in which they have a competitive advantage.
- Producers consider veterinarians very knowledgeable and highly cost-effective problem solvers in areas concerning livestock production. Veterinarians are the most highly regarded individuals concerning reproduction, diagnostics, and treatment of disease and injury. They are producers' primary outside contact in these areas when problems arise. Producers generally consider veterinarians as knowledgeable as themselves and other individuals concerning animal and herd management, feed and nutrition, and agribusiness and economics. However, producers often rely on other sources of information in these areas, especially concerning agribusiness and economic problems.

Downloaded From Vet-eBooks.com

■ Despite producers' high regard for the knowledge and cost effectiveness of veterinarians concerning reproduction, diagnostics, and treatment, they rated local veterinarians' knowledge and cost effectiveness slightly lower in 1994 than in 1985. These results do not infer that veterinarians are less knowledgeable and cost effective, but it does suggest that producers perceive them to be so. This is important because perception drives demand.

■ Veterinarians have the knowledge and skills to influence the perceptions of producers. First, producers generally rate veterinarians as good communicators. Second, veterinarians are generally producers' first choice for an information source concerning problems in reproduction, diagnosis, and treatment.

■ If the business relationship between veterinarians and producers is a task- or product-oriented market relationship, the major objective of the transaction becomes the provision of the task or product. The task or product becomes the focus of the relationship, between the veterinarian and client. The knowledge of the veterinarian and the cost effectiveness of animal health services provided become secondary attributes. When the task or product is the objective, price is the motivator and the lowest price will prevail.

■ When the business relationship between veterinarians and producers is an information-oriented coordinated relationship, the major objective becomes the cost-effective application of animal health services based on the veterinarians' knowledge and skills. The tasks and products themselves become secondary attributes. Consequently, when cost-effective animal health service is the objective, profitability rather than price is the motivator. Therefore any price that fairly distributes the benefits of animal health services between the producer and the veterinarian prevails.

■ The difference between these two structures is not as much operational as they are attitudinal. Therefore the change is more of an educational process than a structural process. Livestock practitioners possess a vast amount of knowledge, many skills and abilities, and the goodwill and respect of their clients. However, knowledge, skills, and respect become secondary attributes to price when cutting costs is the motivation before profitability. Veterinarians need to be educators in this process.

■ Farms and ranches exist on a continuum, and the differences between the extremes may be distinct and identifiable. However, many operations exist somewhere between the extremes and are continually evolving.

■ Livestock veterinarians require a mixture of skills beyond diagnostic and treatment abilities to remain viable practitioners. Veterinarians require skills that will enable them to identify at what point on the continuum their clients and potential clients are operating and how they are evolving. These skills are required because the techniques for serving clients will vary and be dependent on these factors. Such a strategy will allow livestock veterinarians to realize the greatest potential demand for veterinary medical services and products.

In summary, the implications for veterinary medicine are as follows:

■ Four major forces affect structural transformation in food animal agriculture: industrialization, globalization, consumerism, and food and environmental safety.

■ Food animal agriculture is diverging into two distinct markets: One market is characterized by large specialized animal production units in which livestock production is the operators' primary occupation and source of income. The second is characterized by small, less specialized animal production units. Food animal production may be ancillary to crop production, and farming may be a secondary occupation and source of income. Regional concentration of livestock herds is shifting.

■ Increased efficiency that causes increased production from fewer herds is especially evident in the dairy cattle industry and increasingly evident in the swine industry. Feedlot production is highly specialized; however, the beef cattle industry has a limited amount of vertical coordination in contrast to the broiler industry, which is less concentrated but has a high degree of vertical coordination.

■ Dairy producers are the largest users of veterinary and animal health products and services. Swine practitioners generate the highest individual revenue. Dairy cattle practitioners generate the highest percentage of revenue from livestock products and services, whereas sheep practitioners depend on pets and horses for more than 50% of their revenue. Beef and dairy practitioners generate about 90% of their revenue from bovine services. Sheep and swine practitioners generate about 25% of their revenue from bovine services.

■ Beef, dairy, and sheep practitioners generate more than 60% of professional service fees from technical services, whereas sheep practitioners generate more than 40% of professional service fees from consultative services.

■ Animal health and veterinary medical expenditures increased at a greater rate than all prices paid by farmers. The ratio of animal health products to services has increased, especially in large herds. Animal health and veterinary medical expenditures per animal decrease significantly as herd size increases. This implies that large herds generate less veterinary revenue for a given number of animals than do small herds (Gehrke, 1995c).

■ Producers perceived local veterinarians to be very knowledgeable concerning diagnostics, treatment, and reproduction, moderately knowledgeable in areas of herd management and nutrition, and the least knowledgeable in agribusiness and economics (Gehrke, 1995a).

■ Producers perceive veterinarians to be highly cost effective concerning reproduction, diagnostics and treatment, but less cost effective than producers themselves concerning herd management, nutrition, and agribusiness and economics (Gehrke, 1995b). The producers surveyed in 1994 perceived local veterinarians as less knowledgeable and less cost effective in reproduction, diagnosis, and treatment than producers surveyed in 1985. These results suggest underlying factors that could have negative impacts on future growth of demand for the services of veterinarians.

■ Veterinarians are considered first, second, or third contacts in all areas except agribusiness and economics. Livestock producers believe local veterinarians are important to their livestock operations. They have a high regard for, and a high level of satisfaction with the abilities of veterinarians.

■ Veterinarians rated themselves or consultative veterinarians as the most knowledgeable individuals in all aspects of livestock production. The ratings of veterinarians and producers were consistent regarding reproduction, diagnostics, and treatment but inconsistent concerning herd management, nutrition, and economics.

■ Veterinarians feel that they are important to most aspects of their clients' operations.

■ Veterinarians do not believe that producers consider them herd management consultants, contrary to the belief of producers. Therefore veterinarians may be missing opportunities to expand their practices.

Other Market Studies

Perceptions that producers and veterinarians have about herd health services are important. A survey of veterinarians' and producers' perceptions of herd health services in an area in Saskatchewan, Canada, with about 255 dairy farms,

Downloaded From Vet-eBooks.com

found that veterinarians overestimate their services in nutritional consulting and heifer rearing (Giger et al, 1994). The primary determinant of a producer's perception of being on a herd health program was the occurrence of regularly scheduled reproduction visits. Producers who perceived themselves as being on a herd health program also believed that they received more services in the other four main areas of production medicine (milk quality, nutritional consultation, infectious disease control, and heifer rearing). Producers who perceived themselves as being on a herd health program differed from those who did not. The former thought they received more advice and service in the major areas of production medicine than did producers who thought they were not on a herd health program.

Approximately 60% of producers who believed they were on a herd health program indicated that their veterinarian was rarely or never involved in the analysis of their herd records, an activity considered a prerequisite component of a herd health program. The use of the term "herd health" by veterinarians to describe regularly scheduled reproduction visits may explain the high proportion of herd health producers who indicated that their veterinarian was rarely or never involved in analysis of their herd records. The survey found that producers with a comprehensive herd health program, including analysis of records by veterinarians, were clients of two practices. This suggests that comprehensive herd health services are not readily available from all veterinary clinics in that area.

A survey of dairy farmers in England identified the principal characteristics of the farm and farmer that are likely to adopt a herd health scheme (Wassell and Esslemont, 1992a). Larger farms with better educated, more progressive-thinking farmers are more likely to have a herd health service. Those producers who do not have a herd health program feel they do not have the problems to justify the service and the extra cost and effort required. A survey of 566 veterinary practices with dairy farms among their clients found that the majority of the practices were very positive about the benefits of providing a herd health service. However, only one third was providing such a service, and most had attracted only a small number of clients. The size of the practice, in terms of the number of veterinarians and dairy farming clients, was the most significant factor in determining whether a practice was likely to run a herd health scheme, and the age of the veterinarians did not appear to have any effect (Wassell and Esslemont, 1992b).

Modern Marketing Strategies for the Promotion of Health Management

Persuading livestock producers to use health management services has been a challenge for veterinarians. Veterinarians must consider some basic modern concepts in marketing as an aid in promoting health management services. Modern marketing theory requires that veterinarians view themselves as an applied scientist–business person competing in the marketplace. A successful health management program depends on the development of an integrated marketing strategy. It should emphasize providing producers with benefits they desire from traditional veterinary services combined with the benefits desired from a health management program. This requires detailed planning of the health management program that the producer needs, based on good market research. Finally, a realistic pricing policy should be based on cost and demand. A professional and dignified personal approach to each client's needs is necessary to make producers aware of the existence of such health management programs. The personal selling process allows the veterinarian to determine a particular producer's goals, values, and needs so that the basic herd health program can be customized to that producer.

Veterinarians providing health management services to livestock producers must be "knowledge workers" who can help their clients sift through the steady stream of new information related to their enterprise and assist them in making the best decisions. The AVMA has developed a set of marketing strategy cards. Each card contains a single marketing activity (Clevenger, 1996). For each activity, the marketing objective is listed along with the resources needed to implement the activity, the probable consequences of doing it, and the amount of risk it poses to the practice. Because analysis of data from the 1995 market for food-animal services indicated a need to improve producer perceptions about the value of veterinary services, the strategy cards emphasize improved professional image, public speaking, and client education meetings.

Marketing health management services to food animal enterprises requires the following: (1) defining the veterinarian's mission to ensure that clients are aware of the new direction; (2) developing a structure that integrates the variety of professional veterinary services that are offered, including the development of objective criteria that can measure progress and results in a population; (3) identifying the resources now supplied by the veterinary practice and broadening them into a wider package of services and products, including computer programs for animal health and production; and (4) learning the skills of communication, persuasion, and negotiation.

Animal Health Economics

The traditional veterinarian views disease as evil, and often embarks on a career with a 'Superman' like determination to destroy it, regardless of how important it is. To the classical healer, economic considerations are secondary. The economist on the other hand sees animal disease as just one, and often an insignificant one, of a great spectrum of constraints to human and societal well-being that needs to be put into context, and sometimes seems to take pleasure in spoiling the veterinarian's fun.

(Perry and Randolph, 1999)

Principles

Economics is one of the essential components of animal disease control at all levels in society and in all corners of the world (Morris, 1999). Economics is concerned with the allocation of scarce resources to competing uses, thereby providing the greatest benefit to society. The resource to be allocated is commonly money, but other limiting resources (labor, land) can also be considered. The benefit can be interpreted in a number of ways, depending on the particular circumstances to which economic principles are applied. Both animal and human welfare benefit from the improvement of animal health. The benefits to animal welfare cannot be translated readily into economic terms, but the benefit to human welfare can be expressed to a large degree in economic terms; hence the merits of alternative activities can be compared. Most of the economic benefit can be expressed in monetary terms (e.g., more animal products available for sale, a higher price per unit of product, lower production costs), but some elements cannot be valued so easily in monetary terms (e.g., reduced risk of human infection with zoonoses, increased work capacity of animals in crop production and transport, and increased availability of animals for cultural purposes).

The scientific foundation for the discipline of animal health economics was described in the early 1970s by Morris in Australia and Ellis in England (Dijkhuizen et al, 1995).

Downloaded From Vet-eBooks.com

They successfully introduced a simple but essential economic principle in making veterinary decisions: disease control input should be increased to the level at which the cost of an additional input equals the return from the additional output. This so-called *equimarginal principle* can be considered a fundamentally different approach from the earlier and more common opinion of disease control being an all-or-nothing situation.

Animal health economics is a discipline that aims to provide a framework of concepts, procedures, and data to support the decision-making process in optimizing animal health management (Dijkhuizen, 1992). Controlling the costs of production is critically important in modern livestock farming. Improving animal health and fertility is essential in achieving efficient and economically rewarding production. Current veterinary services are evolving to meet the need for service directed to the needs of farmers through planned disease prevention and control programs and management for optimal health. The application of these services is rarely an all-or-nothing situation. Usually several measures or programs are available, each of them offering a different degree of protection and requiring a different level of investment. Determining the optimal input level, therefore, is to a large extent a matter of economic decision making. This is not only the case for the individual livestock owner, but also for a national government that must determine the optimum policy against specific infectious diseases.

In animal health economics, the relative merits of different approaches to improving the health of an animal population are evaluated in order to make the best decisions on the allocation of disease control resources. The focus of the evaluation is on the *marginal* or additional benefit of intensifying disease control by a small degree, until an economically optimum strategy is identified. This point is reached when the increased benefit achieved by a further small increase in disease control effort is exactly balanced by the costs of achieving that improvement. Up to that point, additional investment has produced a positive net economic benefit.

Economic analysis is not a form of financial accounting. The primary strategy is to rank alternative disease control measures in order of the merit of each alternative and to make the best decision, not to calculate the exact monetary value. A fundamental characteristic of economic analyses is that the analysis is never entirely complete. The aim is to make the best decision given the available information.

The initial applications of economics to the field of animal health centered on the assessment of the total productivity losses associated with a given disease in order to provide a monetary figure reflecting how much the disease costs. These efforts reflected a need by veterinarians to demonstrate the importance of the disease in order to justify their research or development activity and give an indication of the potential benefits that might accrue in the absence of the disease. However, with all diseases, it is often unrealistic to present the total cost of a disease as if that figure can be saved. Disease eradication, the means of saving total losses, is only a realistic option under a very limited set of circumstances and for very few diseases. For example, among the parasitic diseases, most of which are endemic and in which the environment plays a key role in supporting development stages, eradication is rarely an option. Thus the determination of total losses has severe limitations as a useful decision support aid.

Economic Losses from Disease

The claim that a particular disease of food producing animals in a herd or region is responsible for large economic losses may indicate that the disease is responsible for impressive losses. However, the results cannot be used for making decisions about research priorities or funding control efforts. It is generally assumed that under the principle of diminishing returns, the marginal cost of control will rise as disease is reduced. The responsible decision maker would need to know how much control can be envisaged for a disease before the threshold is reached at which pursuing control is no longer physically or financially reasonable. That is the essence of impact assessment. Moreover, the decision maker must be convinced that pursuing control of a disease is the best use of scarce resources and must be able to consider the trade-offs made when funding efforts for one disease versus another, requiring yet additional information (Perry and Randolph, 1999).

The effect of animal diseases in a given production system is to reduce the efficiency with which inputs are converted into output-decreased productivity. This effect can result either by decreasing the value of outputs for a given level of inputs or by requiring a higher level of inputs to achieve a given level of output, or both (Rushton et al, 1999). There are various mechanisms by which disease affects animal productivity. Losses may be direct or indirect. The direct reduction in productivity caused by disease can result in losses that are clearly visible to the farmer. These losses may include the following:

- Death of affected animals due to diseases such as anthrax or blackleg
- Lower milk yield caused by subclinical mastitis
- Reduced feed intake because of lameness and inability to graze adequately

Examples of invisible losses include:

- Reduced pregnancy rate and calves not born, which represent unrealized income potential
- Failure to cull unproductive animals when appropriate
- The presence of endemic diseases such as Johne's disease in a dairy herd

Indirect losses include the following examples:

- Additional costs for treatment and control of clinical disease
- Use of outdated production technology
- Reduced or denied access to markets because of the presence of disease or political embargoes

The total cost of disease (C) is the sum of the production losses (both direct and indirect) (L) , and control expenditures (E) (Rushton et al, 1999):

$$C = L + E$$

In addition to the economic impact, diseases and intensive livestock enterprises can affect animal and human welfare. Faced with this complexity, it is not surprising that the economic implications of animal diseases and the control of animal disease are understudied.

The direct costs associated with 30 different endemic diseases of farm animals in Great Britain have been estimated (Bennett et al, 1999). The spreadsheet models and supporting documentation can be accessed at http://www.rdg.ac.uk/AcaDepts/ae/AEM/livestockdisea/ (accessed January 29, 2001).

Economic Modeling Techniques

The four most common economic modeling techniques are *partial budgeting, cost-benefit analysis, decision analysis,* and *systems simulation,* all of which can be applied on three levels of veterinary decision making: the animal, the herd, and the national level (Dijkhuizen et al, 1995). There are considerable differences between published economic

Downloaded from Vet-eBooks.com

evaluations and the losses from one and the same disease. These differences may be due to the structure of the farming system, the disease-related loss-making factors that are taken into account, and the way these are calculated (Rougoor et al, 1996).

Decisions can be made at three levels: the animal, herd and the national level (Dijkhuizen et al, 1995). At the individual animal level, decision-tree analysis is most often used to decide whether or not to treat an animal. The analysis has traditionally included probability distributions of possible outcomes. However, the technique itself cannot help the practitioner determine the economic value to include in case of premature disposal of the animal. Many applications include the slaughter value of the animal, whereas others choose to use the cost of purchasing a pregnant replacement, sometimes adjusted by the salvage value. One source has suggested that the following value be included: the value that equals the difference between (a) the income that the animal could earn during her remaining expected life, had the reason for replacement not presented itself (given normal probabilities of disposal because of other reasons) and (b) the expected income over the same period of time of replacement animals with normal productive qualities and normal probabilities of disposal (Dijkhuizen et al, 1995). This value is called the *retention pay-off (RPO)* and enables ranking of individuals within the herd on their expected future probability: the higher the RPO, the more valuable the animal. A value below zero means that replacement is the most profitable choice.

At the herd level, many trials have been done to investigate the economic value and attractiveness of health management programs. These programs are based on regularly scheduled visits to the farm, which this book describes in detail for each species or class of animals. The economic value of such programs is based on changes in disease incidence and improvements in performance using partial budgeting. A detailed economic analysis requires data from both the "with" and "without" health management groups, both by collecting data from "before" (b) and "after" (a) application of the health management program and by collecting data on farms participating in the program (P) and on comparable control farms (C). When available, these data make it possible to estimate the causal effects of the program more precisely. In its simplest form, the analysis is done according to the following formula:

$$(P_a - P_b) - (C_a - C_b)$$

Additional details on the economics of animal health in farmed livestock at the herd level are available (Marsh, 1999).

Economic analysis at the national level is not a simple addition of analyses as done at the farm level. The approach is entirely different and based on principles derived from "macroeconomics" (Dijkhuizen et al, 1995).

Animal health programs can provide a high return on investment because reduction of the impact of disease increases the efficiency of production, often without the need for additional inputs such as feed or labor (Marsh, 1999). Because the economic impact of most diseases that affect farm livestock is typically greater at the subclinical rather than the clinical level, animal health management often involves decisions regarding expenditure on preventive measures as well as the treatment of obviously sick animals. Most decisions in animal health economics at the farm level can be made by using partial budgeting, decision tree analysis, or cost-benefit analysis techniques. The use of economic surplus analysis, with preweaning mortality as an example, demonstrates the importance of improving livestock production efficiency in the face of international competition and how consumers gain from improved animal health (Ott et al, 1995).

The economic benefits of a neonatal calf health program can be evaluated using computer simulation of a multiple-year spreadsheet model, using economic and production variables (Larson et al, 1998). Actual economic performance data from a herd over a period of years can be compared with a projected simulation in which morbidity and mortality are decreased. A sensitivity analysis for the simulation model can also be applied. In a beef herd, for example, the mean per-cow increase in net income for the herd during a 6-year period for morbidity and mortality reductions of 20%, 40%, and 60% was $7.44, $14.93, and $22.42, respectively (Larson et al, 1998). Such a spreadsheet decision tool allows the producers to determine the economic value of a management program designed to increase the percentage of calves that remain healthy during the nursing phase, increase the number of calves weaned, and increase mean weaning weight as a consequence of decreases in illness and death of calves. By identifying primary areas of deficiency on a particular farm, management changes then can be ranked on the basis of economic impact.

Costs of Production in a Herd

For most food-producing livestock enterprises, making a profit is a major objective. This can be achieved by increasing production while maintaining the costs of production, or decreasing the costs of production and maintaining the level of production. Inputs include feed, water, fertilizer, vaccines, drugs, labor, fuel, interest costs on borrowed money, capital (land, animals, machinery), and management. Outputs include end products such as meat, milk, and wool. The costs of production can be reduced by using new and cheaper methods of production, including cheaper feed supplies or by increasing the efficiency of production of livestock products by controlling the effects of disease on animal populations. In most intensified livestock operations, in which profit margins are narrow, how much disease can be tolerated? The productivity of a livestock production system could be defined as follows:

$$\text{Productivity} = \frac{\text{Total value of outputs per unit of time}}{\text{Total value of inputs per unit of time}}$$

Veterinarians are becoming involved in the budgeting of livestock operations. A budget can be used effectively as part of ongoing monitoring to provide information on the profitability of the livestock production system. For example, a simple budget in the form of a projected income statement for a pork production profit center would include the breakdown per head sold, per hundredweight sold, and per breeding female place, which would provide an estimate of the overall profitability of the pork production enterprise. Profit is calculated as revenue minus expenses (Marsh, 1999). The details of budgeting and cost accounting are available in other standard textbooks of agricultural economics and in chapters dealing with each species. In dairy herds the costs of milk production should be determined on a regular basis. In the beef cattle industry the cost of weaning a beef calf is of major importance in determining profit and loss. In the feedlot industry the cost of daily body weight gain on a per pound basis is critical in determining profit and loss. Each individual cost item can be evaluated for its necessity and for whether a more inexpensive substitute is available of equal performance value.

REQUIREMENTS OF A HEALTH AND PRODUCTION MANAGEMENT PROGRAM

The three requirements for a successful program are a progressive livestock producer, an enthusiastic and competent veterinarian, and an animal health and production data and information system. An even more fundamental prerequisite is the establishment or growth of a satisfactory veterinarian-producer-client relationship. Through experience with the veterinarian, the producer becomes confident that the veterinarian can provide good veterinary service oriented to individual animal care and routine procedures. It is imperative that the veterinarian be knowledgeable and skilled in the diagnosis, treatment, and control of disease in the individual animal and in the herd.

Progressive Livestock Producer

The success of a herd health program depends heavily on the quality of a producer's management skills, including the desire and ability to comply with the recommendations of the veterinarian and other agricultural advisors involved. The identification of key farms who are potential herd health clients in a practice area is crucial to the success of a program (Wassell, 1995). The personal characteristics and attitudes that are desirable for a producer to adopt a successful health management program that can set an example for the rest of the community are as follows:

- *Leaders in the community.* These are the progressive producers whose opinions are valued by other producers. The producer must have a vision for the future and make a long-term commitment to effective and profitable livestock production. Continuous improvement to reduce variation and systems thinking and innovation are vital activities for success. Effective producers who are leaders do not allow entropy or the dissipation of energy to occur (Humble, 1995a).
- *Successful business people.* Business acumen is a highly desirable characteristic, especially if the producer has a good farm that is the primary source of income. The farm must be large enough to support a cost-effective health management program. These producers are aware of the principle of cost effectiveness and opportunity cost, and net profit from the farm is a primary objective.
- *Information-oriented people.* They recognize the need to keep and use animal health and production records. This is easily assessed by an examination of their records and how they use them to make decisions.
- *Stable, efficient producers.* They have good judgment and are recognized as "innovators" in the community (Fig. 1-2).
- *Knowledgeable producers.* These are producers who keep up to date with the farm literature and are interested in learning more about the modern aspects of animal health and production. They recognize the interactions among reproduction, nutrition, mastitis, milk production, and calf health management. They express interest in health and production management and appreciate the contributions that veterinarians can make, in addition to their traditional role in emergency veterinary medicine.
- *Producers who have not overextended their limit of resources in terms of finance and of labor or land area.* They are most likely to be able to make changes in management and scale of operations.
- *Producers whose inclination is to avoid taking risks.* They are natural enlisters in herd health programs. There are significant differences between them and high-risk takers in farming performance. Highly risk-averse producers may request veterinary services that can complement and improve management (Antle and Goodger, 1988).

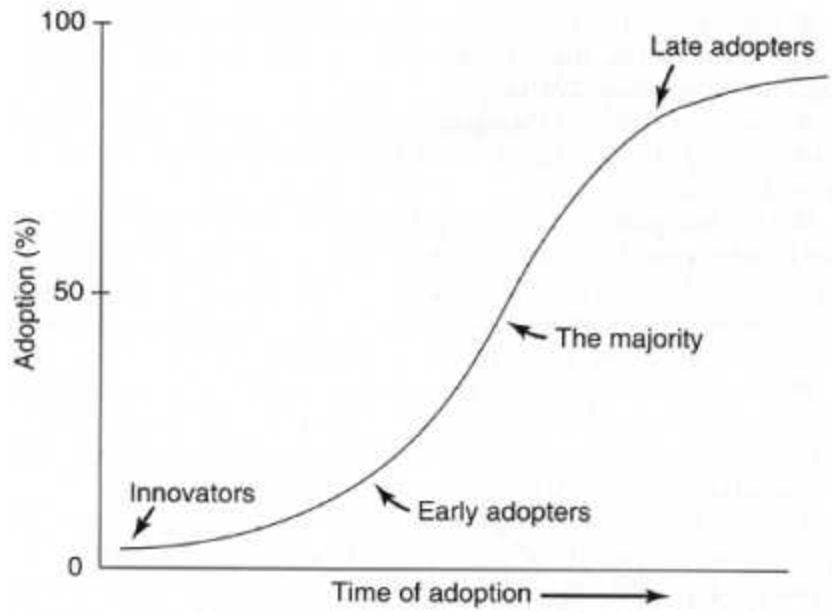

FIG. 1-2 Community adoption curve.

The development of a situation in which producers are committed to a herd health program requires two stages. The first is to convince them to begin by establishing a bond of confidence between the producer and the veterinarian, by determining that there is a problem in the herd that is likely to be responsive to a cost-effective control program, and, if necessary, by beginning the program on a partial basis (Wassell, 1995). For example, starting a program to improve reproductive performance or udder health and milk quality, and delaying action on other problems until obvious results are obtained, constitutes a partial program.

Herd health management programs need to be viewed from the perspective of the livestock producer's decision-making framework. The producer's goals and objectives must be considered first. The producer's resource situation may be a primary determinant of feasible herd health alternatives. The role, nature, and size of livestock enterprises impose varying degrees of limitation on the type and scope of a herd health management program that is economically feasible, workable in practice, and acceptable to the livestock producer.

Having established a program in a herd, the challenge for the veterinarian is to maintain it. A successful program has the following characteristics, which are attractive to progressive producers:

- The simplest data recording system possible. A producer's natural inclination is to avoid paperwork, especially large sheets of it showing many columns and figures. Data such as milk test results may already be provided on a regular basis but are not being used. The producer's observations should be restricted in scope, if possible, to the most important data. Also, these should be transcribed, collected, and entered into the database by proficient data handlers.
- The quickest possible turnaround time for analysis of data and reporting back to the producer. Instant turnaround by computer printout or visual display is most satisfying. Reporting back in numerical terms is usual, but, if the results can be expressed in financial terms, they have more meaning to the producer. The veterinarian's use of portable laptop computers and spreadsheet programs during farm visits provides the opportunity for rapid data analysis and the generation of useful information.
- A data analysis system that gives early warnings of impending deviations of production performance or disease prevalence from set targets and goals.

Downloaded from Vet-eBooks.com

- The introduction into the production and disease control systems of the most up-to-date technical information as soon as it becomes available.
- The creation of a database of information accumulated from many other farms to serve as a realistic guide to targets of performance.
- The calculation and preparation of anonymous inter-herd comparisons to indicate to producers where they stand with respect to performance in a variety of parameters and in contrast with peers. The intention is to motivate producers to consider how production can be improved.
- The promotion of exchange of information among producers about modifications of techniques, problems with existing techniques, and developing needs by conducting group meetings at intervals of 6 months to 1 year.
- Visiting the herd regularly, punctually, and for a sufficient time period to allow discussion of all management areas and problems. In beef cattle or sheep operations, where farm visits are less frequent, the maintenance of surveillance must be less personal but can be complemented by written reports at intervals between physical visits.
- Ensuring that farm staff, especially managers and partners, are included in the progressive atmosphere of the program. Inclusion of these people is critical because they are responsible for putting the recommended procedures into practice.

These parts of a total program are displayed in Fig. 1-3. They all encourage motivation of the producer to continue with a health management program. They also impose an acceptance of responsibility by the veterinarian to provide the necessary input, to keep on providing this input, and to be financially responsible if the wrong advice is provided.

Enthusiastic and Competent Veterinarian

A successful health and production management program depends heavily on the enthusiasm and competence of the veterinarian providing the service. Most veterinarians who are active in herd health began their careers in large animal practices, which provided primarily emergency veterinary service on an individual animal basis. As they developed sufficient experience and confidence with their clinical skills, they directed their interest toward health management of the herd or flock. By providing herd health services to a few producers initially, they learned about the importance of integrating health and production management. Veterinary associations and colleges responded to the continuing educational needs of these veterinarians by providing conferences and workshops that dealt with various aspects of herd health in each of the food-producing animal species. Gradually, these veterinarians expanded their services to the point where many now spend most of their time providing herd health services. They were self-taught and sought out as much information as they could find to assist them in developing herd health programs for their clients. Much was learned by careful observations of animal health and production techniques on some farms, which could be transferred to other farms. These experiences indicated targets of performance that could be applied to farms beginning a herd health program. These veterinarians were convinced that they had a vital role to play in cost-effective health management and production. They were production-oriented clinicians who placed more emphasis on the management factors that promoted optimum health and production than on the treatment of disease.

Veterinarians who serve the food animal industries have a general background in veterinary medicine combined with knowledge and skills in animal production, animal disease, production economics, systems analysis, and information management. They are specialists in the sense that they have a thorough understanding of a particular livestock species or class of livestock, and of the industry with which they work. The efforts of these specialists in production-oriented health management are directed toward the livestock enterprise and not merely the individual animals. They can provide producers and managers with information and advice on all aspects of the livestock components that influence health, productivity, and profitability. A farm information database that contains relevant data on health, production, and environmental factors is a necessity in order to make data-based decisions. The veterinarian must be able to analyze production records and identify the areas of the production cycle that need further investigation.

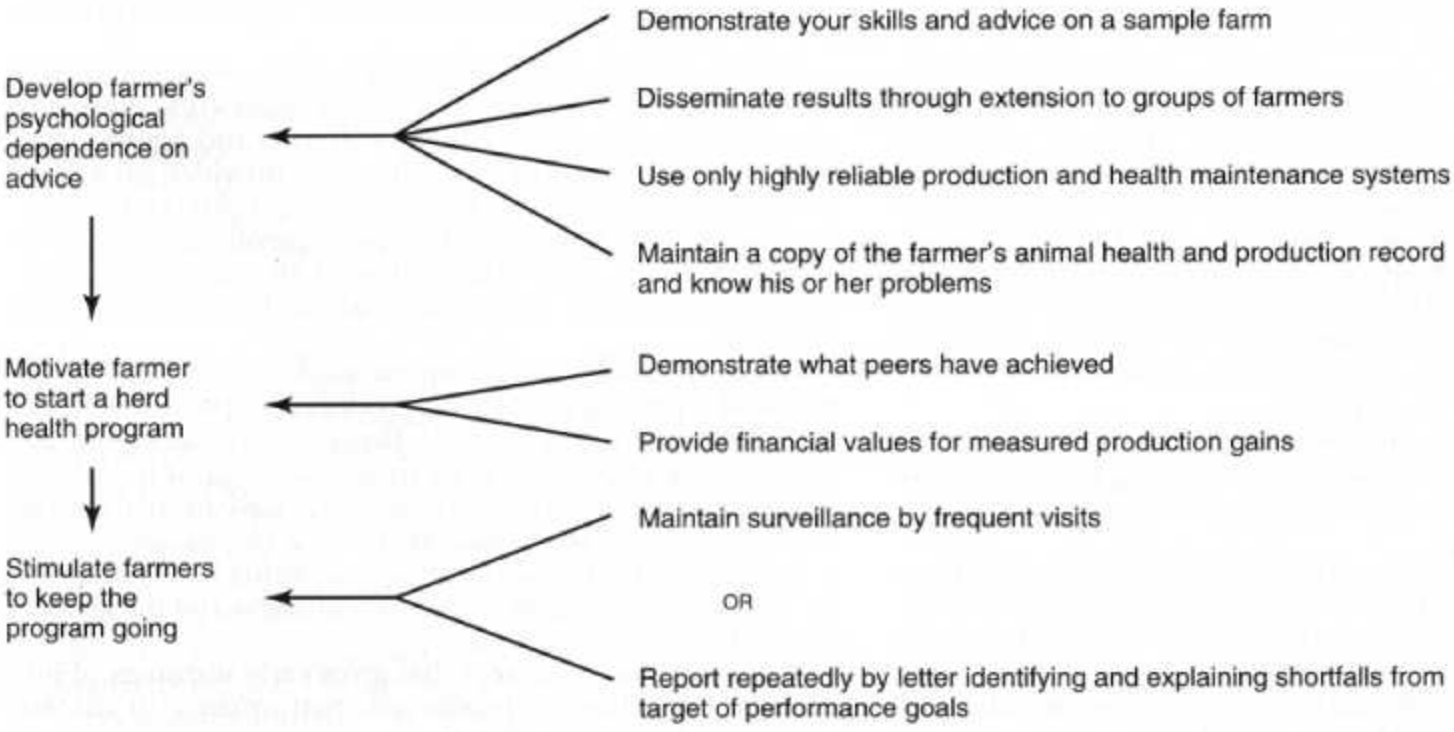

FIG. 1-3 Converting farmers to a herd health service.

Downloaded from Vet-eBooks.com

Those working with a number of similar farms can draw inferences from one set of production and management circumstances and use them to help explain or predict circumstances on another farm.

Livestock producers are seeking information from veterinarians on how to manage their individual enterprises and maximize profitability. They are interested in specific information on nutrition, housing, genetics, drug therapy, vaccinations, use of estrous synchronization techniques, and sanitation procedures, to mention some examples. Producers need the assistance of unbiased experts, like veterinary species specialists, to use the highly technical information that is available in order to make traditional management decisions. Producers turn to veterinarians to relate the vast amount of information to their particular enterprise. This means that these veterinarians need good verbal and written communication skills, which can be acquired with practice. It means spending large amounts of time analyzing records and writing concise reports, which are sent to the producer. A broad liberal education is an asset.

Species and Industry Specialists

Veterinarians who provide the services just mentioned have to become knowledgeable about a species or class of livestock and about the economics of production, clinical epidemiology, nutrition, housing and environmental management, reproductive performance, control of infectious diseases, and marketing aspects of the industry with which they work (Pritchard, 1989b). They should be committed to the role of the veterinarian in production-oriented veterinary medicine as species specialists (Blood, 1979; Radostits, 1989). The need to provide a broadly based, totally integrated, planned animal health and production management veterinary service should be a high priority for them and their practice. As multiple-person practices become more common; they allow individual veterinarians to specialize in a species or class of animal and to spend the time necessary to provide a competent service that is based on reliable health and production information. *The veterinary practice must be able to make a long-term commitment to providing a health management service.*

Problem-Solving Skills

Problem-solving skills are a major asset in learning and practicing health management. Veterinarians must be able to identify the problem; access a body of relevant knowledge from personal memory and experience, from a consultant, or from textbooks, journals, or computerized databases; apply the information to the solution of the problem; and evaluate the response. Keeping up to date with the veterinary and agricultural literature related to a species or class of livestock is a necessity and a challenge. Veterinarians generally find it difficult to be informed about new and useful information in the published literature because clinical practice usually takes priority over reading journals and filing articles for future reference. A personal library in which articles can be stored and retrieved quickly is a necessity. On-line computer searching of the literature to obtain the latest published information needed to solve a problem is now a reality. Veterinary colleges and practitioners will need to develop a variety of important competencies for lifelong learning (Stone et al, 1992).

Clinical Epidemiology

Clinical epidemiology is an integral part of health and production management and is an important part of the education and skill of veterinarians in food animal practice. New approaches to animal health problems include more observational studies, which interact with the disciplines of sociology, economics, and mathematical analysis (Davies, 1985). In the past, the lack of herd level expertise contributed in part to the lack of demand for veterinary services by livestock producers. Veterinary graduates were educated to deal with the individual animal but were not prepared to solve herd-level problems. As a result, many herd health recommendations were based on extrapolations from traditional individual-animal medicine. A major challenge for the veterinary profession is establishing expertise in herd-level decision making based on appropriate comparisons of herd-level treatments among sufficient numbers of farms. Clinical epidemiology can be used to conduct clinical and field trials, to test the efficacy of vaccines or a new drug, and to determine whether a particular herd needs a dietary supplement because of a suspected nutrient deficiency in the area. For example, the components of swine production—genetics, feeds and feeding systems, housing, record keeping and analysis, disease prevalence, and production scheduling—are constantly changing. Ideally, to remain current with these changes, a swine practitioner needs rapid access to the latest, well-reasoned, and scientifically supportable facts. However, commonly they are faced with the difficult task of differentiating scientific fact from huge volumes of testimonials and anecdotal accounts (Straw, 1997).

Computer Literacy

Computer literacy is a necessity for any veterinarian providing health management services to the food animal industries. Computers can be used to analyze health and production data, determine the response to treatment in feedlot cattle, transfer data from central data banks (such as the Dairy Herd Improvement Association) to the veterinarian's office, help formulate rations, access literature from computerized library databases, and prepare regular client newsletters and herd health reports. The use of portable laptop computers allows for the collection and analysis of data by the veterinarian during the farm visit so that the producer can have a quick summary of performance, ration formulation, and other computer outputs on the same day as the farm visit. This also allows the veterinarian to demonstrate to the producer the time it takes for the collection and analysis of data and to determine appropriate charges for the service. This is in contrast to the practice of the veterinarian analyzing the data back in the office, with the producer not fully appreciating the effort involved and thereby being reluctant to pay for the service.

Postgraduate Certificate Programs in Food Animal Health Management

Veterinarians interested in herd health have traditionally done emergency veterinary work for a few years and gradually increased their expertise in herd work by self-directed learning and by working intensively in several herds over a period of years, learning by experience. Practical experience has been combined with attendance at continuing veterinary education short courses, which concentrate on the health and production aspects of a species or class of livestock, such as dairy health management. The veterinary profession and veterinary colleges have traditionally accepted that specialization occurs following graduation and entry into private practice. However, the growth of well-qualified, specialized veterinarians has been slow, partly because of an insufficient number of quality formal postgraduate training programs suited for the veterinary practitioner who cannot

Downloaded From Vet-eBooks.com

afford the time or the financial resources to enroll in a conventional postgraduate program of 2 or 3 years' duration.

Some formal postgraduate courses in production-oriented health management in each of the species are now being offered by veterinary colleges and veterinary associations. The Post-Graduate Committee in Veterinary Science of the University of Sydney in Australia has offered highly successful refresher courses in health and production management for each of the food-producing animal species. The courses are several days in length, and lecture notes are made available at the course. The Australian Veterinary College of Veterinary Scientists offers memberships and fellowships by examination in almost any species selected by a candidate. Studying for the examination and becoming a member or fellow of the college provides a camaraderie that serves to promote and encourage communications and improved practice standards.

At its annual conference, the American Association of Bovine Practitioners now offers about 20 preconvention seminars on all aspects of health and production management of dairy cattle, beef cattle herds, and beef feedlots, including clinical epidemiology and quantitative methods for veterinary practitioners. Because the emphasis in these seminars is on small group teaching, enrollment is limited and they are usually oversubscribed, which indicates that practitioners recognize the need for specialized knowledge and skills. The American Association of Swine Practitioners also has an annual continuing education program for swine practitioners. The Royal Veterinary College of Veterinary Surgeons in the United Kingdom certifies practitioners by examination in swine medicine and production. The American Board of Veterinary Practitioners offers certification by examination within a food-producing animal species. The objective of the board is to promote species-oriented clinical practice as a specialty in the veterinary profession. It encourages excellence and advanced certification among practitioners, which should raise the standards of practice. The examination requires that the candidate have a multidisciplinary understanding of the health and production of a particular species, which fits well with the knowledge and skills required for a food animal veterinary specialist.

Certificate programs are a developing area of continuing education that will become much more important in the future as a means of ensuring continued or improved competency for practitioners. In general, certificate programs are structured, intensive continuing education programs designed to meet specific needs for a particular audience (Chenoweth, 1996). These programs attract individuals who are not necessarily interested in graduate degree programs, yet desire more intense training than that usually provided through conventional continuing education programs. Certificate programs focus on a specific area or need and are designed for individuals with at least 2 years of experience in clinical practice.

In 1990, at the Ontario Veterinary College in Guelph, Ontario, the Dairy Health Management Certificate Program was begun for dairy practitioners. It is a postgraduate program for dairy practitioners who desire to increase their expertise in dairy health management. The program extended over a period of 2 years and consisted of 13 modules, each 3 days in length, during which lectures and seminars were presented. Small-group problem-solving exercises based on actual dairy farm health and production problems were emphasized. Topics included monitoring of animal health and production, clinical epidemiology, nutrition, mastitis control, reproductive performance, control of infectious diseases, environmental management, rearing calves and herd replacements, genetics improvement programs, milk quality control and residue avoidance, economics of milk production, and implementation of health and management services. The participating veterinarians concluded that the program was successful and recommended it as a model for postgraduate education programs for veterinary practitioners wishing to specialize in a species or class of livestock.

The Pennsylvania Dairy Production Medicine Certificate Program began in 1991 and graduated its first class of dairy cattle practitioners in 1993 (Moore et al, 1996). The curriculum consisted of 10 modules, each 2 to 3 days long, devoted to topics of dairy production medicine. The effect of participation by veterinarians on herd performance and management practice of the herds serviced by veterinarians indicated a positive effect of the program. At the end of the study, treatment herds were three times more likely to review herd performance with their veterinarian and monitor heifer growth, and two times more likely to set goals and conduct adequate estrus detection than were control herds. In dairy herds serviced by participating veterinarians, the mean age at first calving decreased and the prevalence of many good management practices increased compared with herds served by veterinarians who did not participate in the program. Management practices that require inputs of time or money, such as estrus detection, culturing for mastitis, tape-weighing heifers, and body condition scoring are less amenable to change, and prevalence of these practices in control herds did not change over the course of the study.

Food-producing animal practitioners are now more business-oriented than veterinarians have been in the past even though most veterinary graduates do not have any formal education or experience in the business management of a veterinary practice or a livestock farm. Veterinarians tend to look on themselves as professionals first and as business people second, or not at all. As the emphasis on livestock farms shifts from increasing food production to business management, it is necessary for veterinarians to have some business management skills if they are to be accepted as advisors.

Undergraduate Veterinary Curriculum

There is now much interest in the content of the undergraduate veterinary student curriculum and in the postgraduate continuing education programs, which are necessary for preparing veterinarians to provide herd health services to the food animal industries. The undergraduate curriculum of most veterinary colleges has provided a broad-based veterinary education in the preclinical and clinical sciences. At least one veterinary college (North Carolina State University, College of Veterinary Medicine) has provided an active learning program for undergraduate students to integrate production medicine with the veterinary curriculum by providing an animal teaching unit for students to gain hands-on experience with commercial herds of animals in a farm setting (Oxender and Harrington, 1992). The students work in the herds on a regular basis and gain experience in population medicine and animal production. The student learning objectives include the ability to perform many clinical skills and to understand some elements of health maintenance and animal production.

Historically, veterinary graduates have practice-entry knowledge and skills for general, small, and large animal veterinary practice. With some exceptions, there has been limited opportunity in the undergraduate curriculum for students to concentrate their studies and clinical experiences in one or a few of the preferred domestic animal species. In addition, most veterinary colleges do not have a large enough clinical caseload to provide sufficient on-farm experience for students who might choose to focus their efforts on a single species or industry. Also, the traditional residency–board specialty program, at least in the United States, has been

Downloaded from Vet-eBooks.com

very much discipline oriented, not species-industry oriented. There is a need for formal postgraduate residency and degree-granting programs in a species specialty such as swine practice, beef cow-calf practice, and dairy cattle practice.

Veterinary education programs to meet societal needs of the 21st century have been well described (Pritchard, 1989b). In essence, veterinarians should have a broad-based liberal general college education in subjects such as languages and communication skills, art or esthetics, history, human institutions, nature, science, mathematics and quantitative problem solving, psychology, and social studies. Individuals with such broadly diverse backgrounds and interests are more flexible, creative, adaptable, and active in community affairs and better able to overcome personal crises. The professional veterinary curriculum should provide students with the essential information, skills, behaviors, and attitudes that should be possessed by a veterinarian. The goal of the professional curriculum should be to develop an understanding of the principles of biology as they apply to animal health and diseases (and their prevention and control in animal species of importance), and to develop clinical skills in the application of this information to the solution of animal health and production problems. It suggested that the principles of health management courses in veterinary curricula could be taught using the problem-solving approach (Goodger et al, 1994). Students are given examples of real life clinical problems that must be defined and explored, and action plans that must be described, for solving the problem, including implementation and evaluation. The focus of the educational process should be on the acquisition of skills for finding and using information to solve problems. In addition, the necessary behaviors and attitudes of the veterinarian should be emphasized.

It has been suggested that the four essential components of a veterinary education for the 21st century are as follows (Thornburg, 1992):

- Broad-based education
- Critical thinking skills
- Diagnostic competency
- Desire for lifelong learning

Among the recommendations of the PEW National Veterinary Education Program's Future Direction in Veterinary Medicine was that, in their education, veterinarians develop "skills in oral and written communication" in the management of information and in business and management. Communication is more than just the ability to write or speak well. Communication is about the process of respectfully interacting with oneself and others and is an exchange of information, feelings, and values. It includes intrapersonal communication (self-understanding, self-evaluation, and reasoning) and interpersonal communication (interaction with others, relationships, and self-disclosure). Through interpersonal communication, relationships are started, maintained, or destroyed. Good communication thus involves an understanding of self-awareness, self-esteem, feelings, and emotions, and the development of listening skills and the willingness to disclose oneself truthfully and freely. Good communication also requires an understanding of the principles of language and verbal interaction, including barriers to this interaction, principles of language of nonverbal communication (body language), and interpersonal communication and relationships (relationship development and deterioration, improvement of interpersonal communication, conflict management, interviewing skills). Veterinarians must learn about group and organizational communication dynamics and how to enhance effective communication in these contexts. Development of these additional skills need not be left to chance. They can be taught by people trained in the area and could be part of a management and interpersonal skills course for veterinary students. The time has come when veterinarians should be expected to graduate from all veterinary colleges with a reasonable understanding of the basis of communications (Prescott et al, 1994).

In the traditional clinical instructional program of most veterinary colleges, the student was required to spend some time in each of several different clinical rotations, which included both small and large animal species. There was insufficient opportunity to obtain in-depth knowledge in any particular practice subject. By trying to get some clinical experience with each of the domestic animal species, veterinary students did not get enough clinical experience with any one class or species of animal, which would have given them the confidence needed to provide quality veterinary service for a particular species in a clinical practice situation. On the day of graduation, each graduate was essentially a generalist. Only after graduation, and by entering a practice in which it was possible, could the veterinarian pursue a personal interest in the clinical veterinary medicine of a species or class of animal. There was no flexibility in the curriculum that allowed students to explore an area of interest.

Core-Elective Veterinary Curriculum

The core-elective programs, now being considered and instituted by many colleges, permit students to focus interest and expand their knowledge of certain branches of veterinary medicine. It is now proposed that the clinical instruction program permit the student to acquire an advanced level of clinical understanding and skills with a single species or class of animals by selecting such a clinical track at some time during the last 2 years of study. This would allow the student to achieve a higher level of clinical competency within the 4-year professional curriculum. The electives would have to be as rigorous as the rest of the curriculum, and the development of scholarly electives should be a challenge for the veterinary faculty. Species selection could come early in the curriculum to allow a maximum concentration during the 4-year period. Not every veterinary college would be able to provide clinical instruction in every species because they would have neither sufficient clinical practice nor the faculty to support the undergraduate and graduate teaching programs. However, if each veterinary college in the United States and Canada were to develop one or two centers of clinical excellence based on the opportunities currently available in their area, such centers would attract undergraduate students worldwide who desire in-depth clinical instruction in a food-producing animal species (Pritchard, 1989a). For example, if the colleges in the major swine-producing states were to develop such a teaching center with clinical swine specialists, the students interested in swine production would receive the education and experience required to become a swine specialist much earlier, before graduation, which would be a comparative advantage when entering practice. These are exciting prospects. The educational process will have to become more flexible to allow students greater choice with current DVM programs and from production animal expertise in other programs and institutions (Chenoweth, 1996; Hubbell and Shaffer, 1998).

To provide quality undergraduate and graduate education in food-animal health management, the veterinary profession and veterinary educators must also give research and education a higher priority than currently is the case (Cornelius et al, 1993). This will require a change in the culture of the profession and in the attitudes and practices of veterinary medical educators. Veterinary medical colleges must increase their research effort, and veterinary investigators must participate more fully in the nation's competitive, grant-supported, high-priority biomedical,

Downloaded from Vet-eBooks.com

environmental, and agricultural research agenda. Strategies must be developed to enable clinicians aspiring to academic careers to obtain solid research training in addition to clinical skill training obtained in residencies. Veterinary college clinical faculty must be species specialists who work in a real-life teaching clinic with an adequate clinical caseload or an adequate number of farms being serviced by the veterinary teaching hospital.

With the decline in clinical caseloads in the food-animal sections of veterinary teaching hospitals of veterinary colleges, the alternative of providing clinical experience to students by sending them into private veterinary practices as externships has been instituted in some situations (Dartt et al, 1997). Practice-based ambulatory rotations can be a good alternative to existing university-based ambulatory rotations for undergraduate students (Dartt et al, 1997). However, most of the emphasis was on clinical procedures (physical examination, surgery, general medicine), with limited emphasis on herd health management. Providing a comprehensive clinical education and experience in health management of any of the food animal species will require herds to be visited on a regular basis, data to be collected and analyzed on a regular basis, and recommendations to be made and results monitored on a regular basis. Such an experience requires sufficient time, mentoring by experienced clinicians, time and resources for library searching, and effective feedback. It is doubtful such a teaching and learning experience can be provided in private practice.

Animal Health and Production Data and Information Systems

Principles

One of the most important components of any successful herd health program is keeping good records that can be used to monitor animal health events, levels of production, and the incidence of disease. A simple, reliable system of recording animal health events and production performance is a fundamental requirement for a successful herd health program. Without recording, the analysis of productivity involves guesswork, and the recommendations for improvement cannot be made with confidence. Crandall (1980) said, "When performance is recorded, performance increases; when performance is reported, performance is accelerated." The records system involves all components, from the records containing raw data to the summaries of animal health and performance. Many different systems are available, but the fundamental requirements include the following:

- Positive identification of the individual animal or groups of animals is a necessity. For example, the Canadian Cattle Identification Program began January 1, 2001. The program involves the individual identification of all cattle that move beyond their herds of origin with approved ear tags bearing numbers that are unique to each animal. More information is available at www.cattle.ca/ccia.
- The system must be simple to use and understand.
- Only animal health and production data considered necessary to assess herd performance are monitored and analyzed. The types of data collected vary among species and classes of livestock, but clearly established standard terminology should be used to avoid confusion and to allow comparisons to be made among cooperating farms.
- The system must be structured so that the data are easily collected, gathered, analyzed, summarized, and available to the producer as soon as possible after the herd visit of the veterinarian.
- The veterinarian should maintain a file of each summary report available to the producer.
- In the simplest form of record keeping, the data from individual animal cards or from groups of animals are collected and analyzed regularly, and summaries of herd performance are reported. In small cattle and swine herds, the manual handling of records is satisfactory but can be time consuming. The types of records used vary considerably, depending on the class of livestock and the status of the herd health program. For example, in the simplest and most common form used in dairy herds, there is an individual lifetime card for each cow. All events of the reproductive cycle and incidents of clinical disease are recorded on the card when they occur. At regular intervals, monthly or less frequently, the veterinarian analyzes the data and prepares a summary of the reproductive performance and disease incidence. This type of individual-card manual analysis system can be successful for small, 50- to 80-cow dairy herds. Manual systems have been satisfactory, particularly with the development of new work sheets and calculation aids for the calculation of herd indices. Similar manual systems have been used successfully in beef breeding herds, swine herds, and beef feedlots.

As livestock herds become larger and production methods more intensive, producers become more cost conscious and require the rapid analysis of a wide spectrum of production data, which cannot be performed easily using manual methods. This has led to the use of the computer, which can provide useful performance statistics for decision making on a daily basis. The computer is "automating" the eyes of the producer. The computer is able to store a large amount of data about a large number of individuals. It has the capacity to analyze and integrate current data with historical data and provide a summary of up-to-date performance. It can be programmed to compare actual performance with preset targets of performance and farm goals. The computer can prepare action lists, which advise when certain events will occur or when certain procedures should be performed. It is now possible for the computer to take over the entire chore of record keeping and to provide summaries of performance as frequently as necessary. The farmer needs to make only the most elementary records of observations.

The computer has had a major impact on the development of efficient, modern livestock production. Much of the progress in animal breeding programs in cattle and swine has been made using the computer to analyze genetic merit. Initially, the information from the farm was mailed to the computer center and processed by a mainframe computer, with the report mailed out to the farm. A major problem with this bureau system was the long turnaround time—as long as 2 weeks or more—which often rendered the information obsolete. The introduction of farm-located terminals linked to the central computer by telephone has eliminated this problem. The development of microcomputers now makes it possible for farmers to own and operate a computer completely independent of any outside agency. It is obvious that on-farm computers can be used extensively for analyses of farm accounting, crop production, and livestock performance on individual farms. Veterinarians providing a herd health service must use all the production information that is available from the farm programs. If this is unavailable, computer programs should be developed that are located and operated in the veterinarian's office. The data are sent to the office on a regular basis and processed, and the results are returned to the farm. In this way, both the producer and the veterinarian maintain a record of the health and production of the herd.

In general terms, the flow of data and information in a herd health program participating in a bureau system of data and information management can be represented diagrammatically (Fig. 1-4). The data are collected from

Downloaded from Vet-eBooks.com

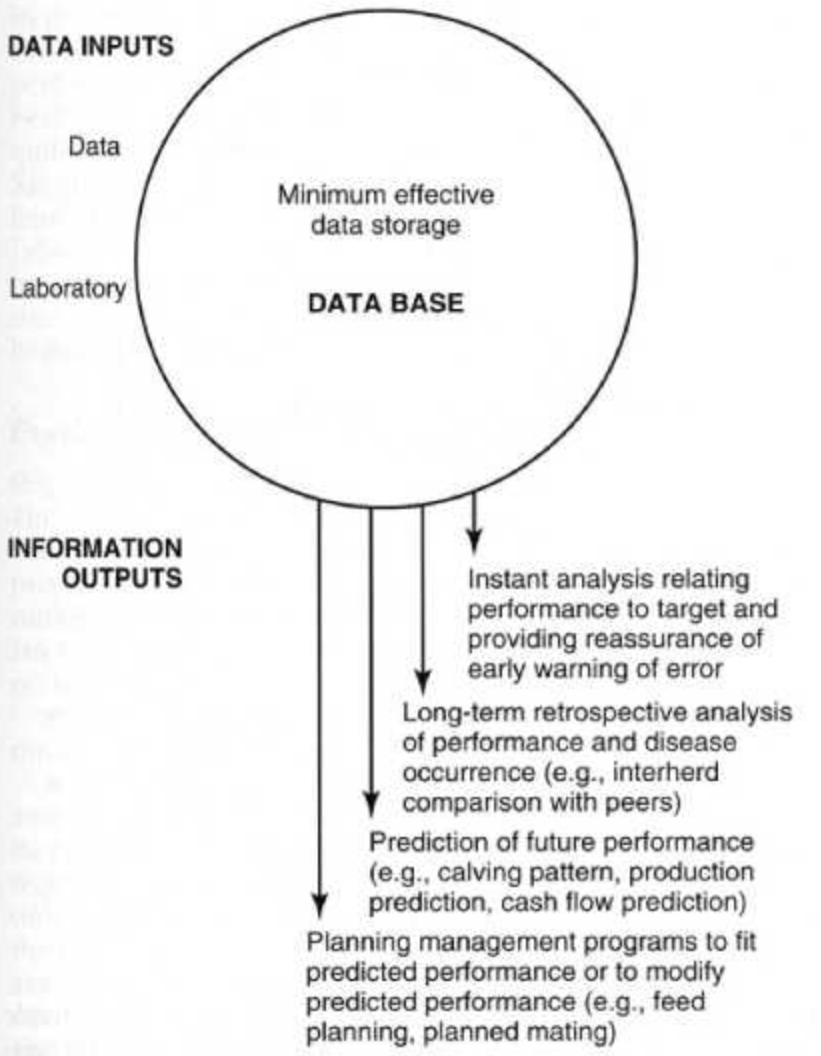

FIG. 1-4 Flow of data and information in a health management program using a bureau system of data collection and analysis.

available sources on a regular basis and entered by codes into the computer, which analyzes the data and produces useful information. The veterinarian must then interpret the information and make recommendations for action to improve performance. The results of the action to improve performance are monitored over the next few farm visits and the cycle is repeated. It is a constant, self-analyzing surveillance system. For each action there is a measurement, and for each period of monitoring there is either more action or a decision that no action is necessary. The targets of performance can be incorporated into the computer program and compared with actual performance. An examination of the computer printout for the period indicates the areas in which shortfalls have occurred.

As shown in Fig. 1-4, data can come from several sources. To maintain the program's profile of economy, and to use information as efficiently and inexpensively as possible, it is necessary to use data already accumulated for other purposes. For example, data from the Dairy Herd Improvement Association (DHIA) services should be directly available. Use of this material can be of considerable economic benefit, especially if it is already computerized and in a compatible language. Only data that are critical to the assessment being undertaken should be collected. It is easy to collect enormous amounts of data that are irrelevant or redundant. The sole purpose of the program is to perform every part of it with the greatest economic efficiency. This applies to data collection and analysis as much as it does to the veterinary part of the program.

The data obtained from participating herds and flocks can be accumulated into a data bank. From this bank, performance levels can be estimated and targets set. This information usually comes to the data bank as a monthly return on a structured report form. It is desirable to accumulate as much basic and detailed information about the relevant animal species and industry as possible. For a practicing veterinarian this may be, although not necessarily, limited to disease incidence and reproductive performance. For a species specialist, the expertise extends into the fields of nutrition, breeding programs, and housing. A collaborative effort with an animal husbandry adviser can complement the service.

Centrally Located Animal Health Data Systems

An example of a central animal health and production database is the Animal Productivity and Health Information Network (APHIN), which has been established at the Atlantic Veterinary College, University of Prince Edward Island, Charlottetown, Prince Edward Island, Canada (Dohoo, 1992). More information is available at www.aphin.upei.ca/index.htm. The network consists of a number of microcomputers linked to a central database. The microcomputers are on farms, in veterinary practices, in the processing industries, in the veterinary diagnostic laboratories, and within the veterinary college. Health and production data from these various sources are entered into the system using the microcomputers, which are linked to the central database by long-distance telephone lines. The function of the central database is to collate, analyze, and summarize the data it receives. Dairy, swine, and beef herds are participating in the program. The central database prepares summary reports of animal health and productivity of all participating herds, which remain anonymous. In addition, reports are generated for individual farms. Only individual producers are able to grant written permission for access to the identification data associated with their farm. The major advantage of this system is that it allows producers and veterinarians to see what health and production performance values are being achieved in the population of animals at large and to compare them with those of individual producers. Such comparisons can serve as a powerful motivating force for producers to improve the efficiency of livestock production. The pattern of flow of information is illustrated in Fig. 1-5.

A computer system for collection of animal disease and related data was begun in 1985 by the Directorate of Veterinary Services in Namibia. The nationwide system consists of detailed disease and herd health data from field veterinarians, disease and related data (such as grazing and animal condition, vaccinations, and farmer treatments) from animal health inspectors, laboratory results and investigations, and abattoir data (Hare and Biggs, 1996). In addition, a socioeconomic component has also been added. It is anticipated that epidemiological studies will be performed using the data.

National Animal Health Databases

Another network is the National Animal Health Monitoring System (NAHMS), which began in 1983 in the United States. Its purpose is to collect, analyze, and disseminate data on animal health, management, and productivity across the United States (King, 1985). NAHMS conducts national studies to gather data and generate descriptive statistics and compiles statistics and information from data collected by other industry sources.

The data for all the food producing animal species is available from the Center of Animal Health Monitoring (CAHM) at www.aphis.usda.gov/vs/ceah/cahm.htm.

The details of the information collected from representative farms are presented elsewhere in this book. The design and implementation of the United States NAHMS 1995 National Swine Study is available (Losinger et al, 1998).

Downloaded From Vet-e-Books.com

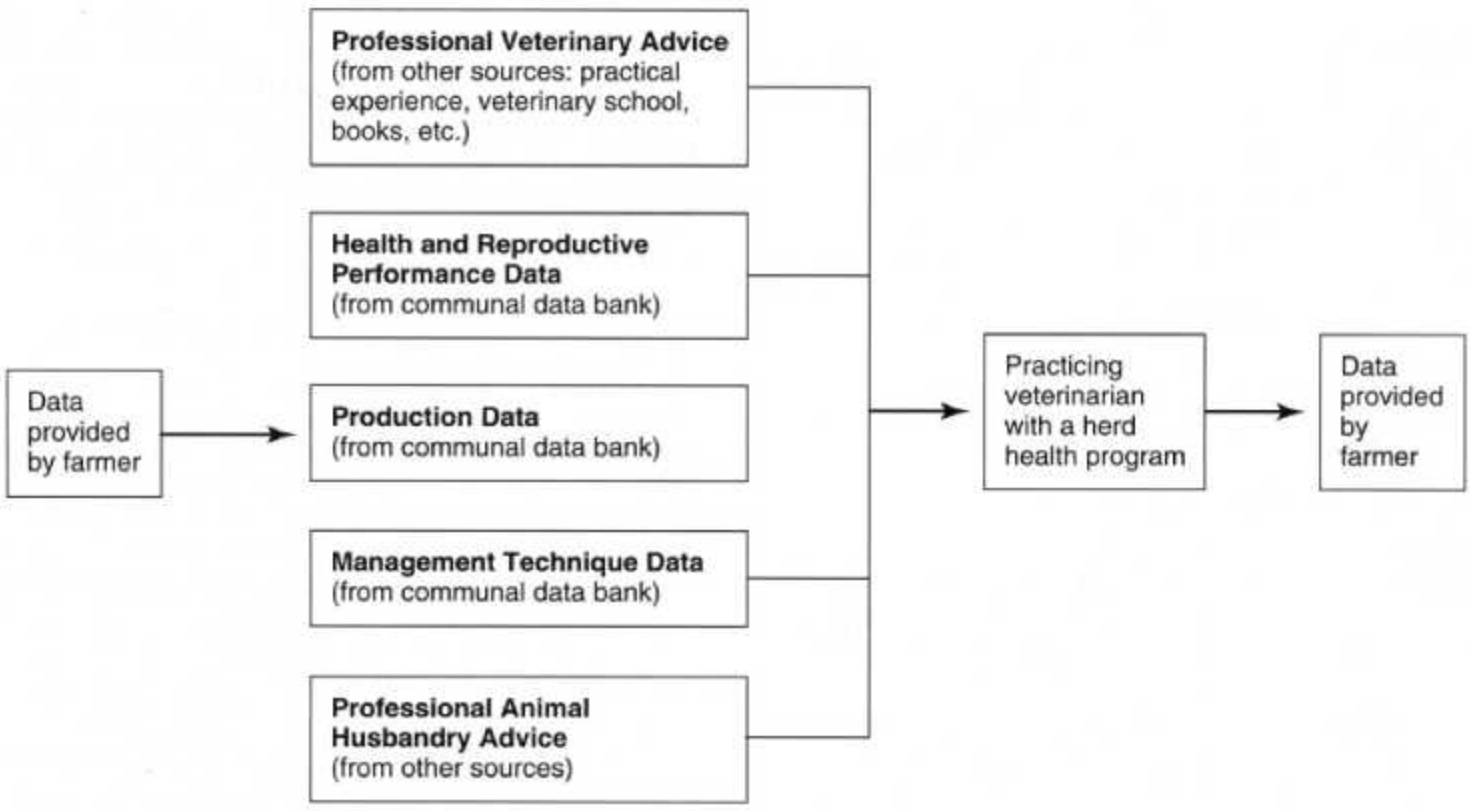

FIG. 1-5 Various sources of data in a health management program using a bureau system of data and information management.

Animal health and disease information systems are important nationally and internationally. The ability of animal agriculture to use information for strategic market advantage is at the center of domestic and international trade competitiveness. As increased demands are placed on animal producers to provide safe, wholesome products for domestic and international markets, real-time knowledge of the national herd is becoming essential (Miller et al, 1994). Countries that develop national-herd information management strategies, and especially those that do so first, will have a decided advantage in the international trading area. At a national level disease control can be viewed as the function of a large regulatory system comprising subsystems represented by states or provinces. Data collection begins at the individual herd level. A national regulatory system also can be viewed as a hierarchic arrangement of state and federal regulatory subsystems and sub-subsystems. At the top of the hierarchy is the strategic planning level, where decisions are made that establish the direction for a national disease-control program. An example of a national information management strategy is the control of pseudorabies in swine in the United States. In 1989 a 10-year effort to eradicate the disease from the swine population in the United States was initiated. It is nearing completion in 2001. To assist states in tracking pseudorabies and program-specific information and compiling quarterly and annual pseudorabies progress reports, the USDA, Animal and Plant Health Inspection Service, and the National Center for Animal Health Information Systems developed the Pseudorabies Monitoring System. This system, which is being used in 21 states, is the only regulatory disease-management software currently in use that allows data sharing among multiple states and the federal government.

International Animal Disease Data Systems

The Office International des Epizooties (OIE) has been developing a world animal health information system to collect and disseminate animal disease information to OIE member countries, to alert countries threatened by epidemic outbreaks, to strengthen international cooperation on animal disease control, and to reduce barriers to the international trade of animals and animal products (Miller et al, 1994). The lack of a standardized information technology management strategy has resulted in state and federal information systems evolving separately, rather than in parallel. The absence of an information management strategy may eventually affect regulatory program management, epidemiologic research, and domestic and international trade.

In Europe, with the introduction of the single market in 1993, all veterinary border checks were abolished and free movement of animals became possible throughout the European Union. A conceptual framework has been described for national identification and recording systems, especially for the control of highly contagious disease in pigs (Saatkamp et al, 1995). Electronic identification and monitoring systems could be an especially important tool in improving collection and subsequent use of information in future animal production.

Analysis of Data

After the animal health and production data are collected from the farm, they must be transferred to and incorporated into the previously collected data and analyzed periodically. The data must be stored and retrieved easily and economically. A variety of codes can be used that simplify data handling. Manual systems are satisfactory for small herds, but, as herds become larger, the computer becomes necessary to minimize the number of errors and to obtain rapid analysis of the data. The most important aspect of the analysis of the data is the selection of the most useful indices or parameters that are required to monitor performance accurately. Following analysis of the data, reports containing useful information and recommendations are prepared and sent to the farmer.

Some studies have found that veterinary practitioners had difficulty motivating farmers to adopt herd health schemes

Downloaded from Vet-e-Books.com

in part because they were unable to demonstrate the financial advantages. Being able to demonstrate the current herd performance and the potential financial advantages of herd health schemes to farmers before they will take them up requires a certain amount of data on which to base the analyses. Sampling the data from 40 cows from large commercial herds (about 200 cows) and 20 cows from smaller herds (about 100 cows) allows the cost of poor performance to be estimated sufficiently accurately to determine whether further computer-assisted investigation is warranted (Chamberlain and Wassell, 1995).

Periodic Reports to the Producer

Regular reports must be prepared and sent to the producer. The reports are provided after each visit. Portable laptop computers now provide the opportunity for veterinarians to prepare a report directly on the farm during the visit. The number of reports depends on how frequently the veterinarian visits the herd as part of a herd health program. The reports contain the following types of information:

- A list of clinical examinations and treatments carried out as a record of events.
- An updated list of the individual animals, or groups of animals, depending on how they are handled in the particular program. This list includes all data relating to the disease, reproductive performance, and preventive procedures for the unit; it also enables each animal's (or group's) history for the immediate past to be reviewed. A lifetime history also is available on request for producers who require this information to make decisions on culling and to provide a health and production record at the time of sale.
- An analysis of the parameters used to evaluate reproductive efficiency and the waste caused by mastitis and other diseases. This is accompanied by the levels of performance proposed as targets and provides an opportunity for the veterinarian to comment on whether performance is good or suboptimal. It is important that sufficient flexibility be retained when assessing changes in performance indices. For example, with bulk milk somatic cell counts (SCCs), which fluctuate significantly from month to month, it is usual to wait until a 3-month rolling average continues at a high level before raising an alarm.
- Recommended actions. These are recommendations arising from other programmed reminders for that particular time of the year or reproductive cycle, or from the interactive part of the computer program. Based on the data that have already been provided to it, the computer identifies those cows that have had a poor reproductive performance, a poor production record, or serious disease incidents. These cows can be considered with a view to culling some of them. Similarly, the computer can identify the cows to be dried off and the dates on which this should be done, cows to be bred, and cows to be examined for pregnancy or abnormal reproductive function.
- Predicted production events. This is a developing and vital segment of the program. The producer can preplan a calving or reproductive pattern for the herd or flock. Armed with a knowledge of the reproductive performance status of the herd, the computer program can then advise when individual cows should be bred to conform with this pattern. Similarly, it is then possible, knowing the reproductive data, to predict what the milk production will be at particular times and to predict the feed requirements week by week. All of these functions are performed by modern programs. Producers receiving this advice can plan their feed program 6 months in advance. This gives them time to plant a crop, boost pastures with nitrogen fertilizers, acquire more land, and cull more cows.
- Cash flow predictions. These may also be included. An annual report may be prepared as a retrospective summation of the other reports that have already been provided for the year. This is the opportunity for a major review of the performance of the herd for the year and for an interherd comparison for a local group, with an annual meeting of participants to discuss progress and performance. The annual review of the herd needs to be done in conjunction with an updating of the herd profile.

General Advice

This is advice that does not originate from the monitoring program. It relates primarily to those actions that the producer must take regularly during the year. The action is generally directed at the prevention of specific diseases and the maintenance of production. Some of the actions are stimulated by events in the reproductive cycle. For example, cattle may need to be vaccinated for certain infectious diseases before breeding, ewes may need to be vaccinated for enterotoxemia in late pregnancy, and cows that are susceptible to milk fever need to be treated prophylactically close to the day of calving or need to have their diet formulated to minimize the disease.

The range of the recommendations is not universal for every farm and depends on the prevalence of disease in the individual herd and in the area. What veterinarians recommend depends on their knowledge of these matters and on their expectations of bad seasons or bad years of particular diseases, often according to the climate and the availability of feed. Also, the recommendations are affected by the need to remain cost-effective. For example, it may be financially more beneficial on some farms, in some years, to restrict the supplementary feeding of ewes, normally done to avoid pregnancy toxemia, because the expected prevalence may not warrant the additional expense.

The general advice just described can be sent by electronic mail at strategic times of the year, without the necessity of visiting the farm. In addition, a formal report along new information and techniques may be included and in the form of a newsletter to the veterinarian's clients.

COMPONENTS OF A HERD HEALTH MANAGEMENT PROGRAM

The components of a program include regularly scheduled farm visits by the veterinarian, good farm management by the producer, the recording and analysis of animal health and production data, and the provision and coordination of advice by the veterinarian. There must be a long-term commitment to continuous improvement to reduce unnecessary variations in production. The management styles of the producer and the veterinarian must include systems thinking and innovation, and there must be a vision of the future. All efforts must be directed toward the goals of the producer.

The success of the program depends on the competence of the veterinarian, the level of management of the producer, the reliability and adequacy of the records, and the competence with which the veterinarian provides advice and follows up the results of that advice. The veterinarian must become involved in analyses of the costs of production, income statements, and a breakdown of production costs (Marsh, 1999). A major determinant is the extent to which the producer complies with the advice of the veterinarian and adopts the recommendations of the veterinarian.

The veterinarian should identify the objectives of the producer before beginning a program. A clear picture of the production objectives, compared with actual performance, often identifies the presence of problems that have interfered with performance.

Downloaded from Vet-eBooks.com

The initial stages of any program should concentrate on solving obvious disease or production problems for which there are some obvious and reliable solutions. When these problems are resolved, attention can then be given to evaluating the health and production status of the herd and to the identification of other economically significant problems. Gradually, over a period of 2 to 5 years, the veterinarian becomes acquainted with the herd and its characteristics and areas where additional effort should be directed to improve health and production. It is a gradual, evolutionary process.

The continuous improvement of health and production of a livestock herd requires planning, implementation, and evaluation, and it is an ever present challenge to the veterinarian. Some principles need to be followed that are generally applicable to most situations. The Shewhart Cycle has been recommended as a set of guidelines for continuous improvement of food animal practice (Humble, 1995b). It is also known as the Plan-Do-Study-Act (PDSA) Cycle and is an adaptation of the scientific method; the cycle provides a means of planned experimentation for problem-solving and continuous improvement of products or processes. The cycle is used to increase knowledge about a product, process, or service and to provide a systematic way of accomplishing change. There are five stages:

Stage 1: Generation of an idea. Someone has an idea about improving a health management strategy. It may be for improving calf health, control of mastitis, weaning of calves, or control of any endemic disease in a herd.

Stage 2: A plan. All known variables are considered and a decision is made about what will be compared, tested, or studied. Animal health consultants, livestock producers, farm managers, and employees should meet to review everything known about variables and confounding factors. All employees can be useful to the process, and they should be asked to contribute thoughts and ideas during the planning stage. This stage can serve as the basis for establishing a team approach for problem solving. The goal is continuous improvement.

Stage 3: The "do stage." In this stage, the test, the comparison, or trial is performed, preferably on a small scale. Management must ensure that the procedures outlined in the plan are performed correctly.

Stage 4: The information is collected and analyzed. Did the test or trial go as planned? What was learned? What do the data indicate? Were there improvements in performance? What problems were encountered? What unexpected variables were encountered during the trial? Is it possible to elucidate more important variables that contribute to performance? Was anything learned about people and teamwork? Which individuals contributed most to understanding the problems encountered during the study? Effective feedback from all people involved is crucial (Palazzolo, 1997).

Stage 5: Acting on the information. Three decisions can be made. First, adopt the change. Second, abandon the idea and start over. Third, modify the plan and run the trial or test under slightly different conditions.

Frequency of Visits to the Herd

The most common aspect of any herd health program is the regularly scheduled visit to the herd or flock. The frequency of visits depends on the class of livestock, the size of the herd, the prevalence of disease, the existence of particular disease problems, the level of risk aversion of the producer, and the length of time the herd has been on a program. Monthly visits are common for year-round calving dairy herds with fewer than 100 cows. Weekly visits become necessary for large herds. For large dairy herds, some veterinarians travel long distances to get to the farm and then spend long periods working through the various aspects of the herd. Four yearly visits are common for commercial beef herds, and weekly or daily visits are usually necessary for beef feedlots with a total capacity of 5000 or more head. For 100-sow, farrow-finish swine herds, monthly visits are common.

The traditional practice of regularly scheduled visits to the herd is becoming inadequate for some herds. Once a veterinarian becomes involved with the health management of a herd, it may be necessary to visit the herd as often as required to initiate and complete certain strategies and tasks. This means that veterinarians should direct the animal health and production management programs and visit the farm as often as necessary to achieve the level of animal health and production desired. When disease or production problems occur, it is the responsibility of the veterinarian to visit the herd as often as necessary until the problem is resolved. This may be followed by less frequent visits to the herd and by telephone contacts with the owner to ensure that the problem has been resolved and that progress toward optimum health is being made. Failure of the veterinarian to maintain contact with the owner concerning health and production problems has been a weakness in some health management programs. Veterinarians must show producers that they are concerned about the health and production of the herds for which they provide veterinary service.

Activities During the Farm Visit

The veterinary activities conducted during each visit are similar for each species or class of livestock, but the specific activities vary according to the class of livestock, the season of the year, and the length of time the herd has been on the program.

The primary purpose of the farm visit is to organize and concentrate the veterinary activities into a regular schedule to ensure that they get done. There are several animal health and production activities that occur during the production cycle of each animal. A major objective of the visit is to determine the actual performance of animal health and production, compare it with targets of performance and farm goals, and decide which performance index is abnormal. The veterinarian then attempts to determine the cause(s) of the shortfalls in health status or production and formulate cost-effective corrective action (see Fig. 1-1). The regularly scheduled farm visit is also part of a surveillance system designed to detect or predict animal health and production problems before they become economically significant and to indicate the corrective action necessary. Under ideal conditions, each visit should provide a summary of the animal health and production status, the reasons for failure to achieve certain targets of performance, and recommendations for corrective action. For some parameters of performance, the data are available directly from the records or from the computer printout of the DHIA services in the case of the dairy herds enrolled in such milk recording and herd performance monitoring programs. Examples include milk production per cow, SCC, butterfat and protein percentage in milk, average number of pigs born alive per sow, and average number of pigs weaned per litter. In a beef feedlot, for example, with a computerized animal health and production monitoring system, the computer provides daily summaries of morbidity, mortality, treatment response, and number of repeat treatments, and it identifies pens of animals that are on the verge of an epidemic of acute undifferentiated respiratory disease that should be examined more closely. For other parameters, the veterinarian has to carry out certain

Downloaded from Vet-eBooks.com

diagnostic procedures, such as pregnancy diagnosis, to obtain the information.

Some examples of specific farm visit activities follow.

Surveillance of Reproductive Performance

In breeding herds, a major emphasis is on surveillance of reproductive performance. For example, in dairy herds, which calve year-round, at each monthly visit all cows bred more than 35 days earlier are examined for pregnancy by rectal examination. The cows to be examined are identified by review of the individual cow records or by the use of a computer. Regular pregnancy examinations can identify nonpregnant cows as soon as possible so that early intervention can be taken. In dairy herds, prospective serology and analysis have been used in the diagnosis of abortion on a herd basis (Thurmond et al, 1990). In beef breeding herds, the bulls are examined for breeding soundness before the breeding season begins. Pregnancy examinations are performed only once annually, preferably in early pregnancy and usually following a short breeding season of 42 to 60 days. In swine herds, reproductive performance may be monitored regularly by pregnancy examination through the use of an ultrasound pregnancy tester, monitoring of the number of sows that return to heat 3 weeks after breeding, and the number of pigs born alive per litter. Similarly, sheep can be examined for pregnancy through the use of an ultrasound pregnancy tester and decisions made about feeds and feeding throughout the remainder of pregnancy to minimize the incidence of pregnancy toxemia and to ensure a high survival rate of lambs.

Monitoring and Analysis of Production Performance

The production of livestock and their products can be monitored on a continuous basis and the data used as indicators of performance. The parameters include average daily milk production, butterfat test, average daily body weight gain in feedlot cattle, closeout financial data in feedlot pens, days to reach market weight in pigs, feed efficiency in feedlot cattle and finishing pigs, and grades of carcasses at slaughter. The causes of culling, especially in dairy herds, is an important part of the evaluation of herd performance and the major causes of economic losses (Esslemont and Kossaibati, 1997). More details of monitoring are presented in Chapter 3.

Breeding Programs and Genetic Selection

Some veterinarians have become involved in providing regular advice on breeding programs and the selection of breeding stock in dairy herds, beef breeding herds, swine herds, and sheep flocks. This requires the development of expertise in pedigree analysis and the monitoring of performance indices. These activities are enhanced with computer technology. Chapter 8 deals with the role of the veterinarian in culling and genetics in dairy cattle herds.

Monitoring of Nutritional Status

The feeds and feeding program have a major influence on reproductive performance, growth rate, and milk production and must be monitored regularly. The veterinarian must be aware of any changes in the feeding program that have occurred since the last farm visit or that are intended in the near future. On breeding farms, there are several different age groups of animals at different levels of growth and production. This requires close surveillance to avoid undernutrition or overnutrition. Scoring of the body condition of dairy cattle, beef cows, sheep, and swine is becoming commonplace as an indicator of the adequacy of the diet. Veterinary clinical nutrition is now a veterinary medical specialty that should provide new and useful information for the practitioner working with a particular species or class of food animals (Remillard and Thatcher, 1988). The American College of Veterinary Nutrition also provides consultants in veterinary nutrition who can be called on for advice in solving nutritional problems. An experienced and competent nutritionist should be consulted to assist with complex nutritional problems.

Clinical and Pathologic Examination of Animals

On a herd basis, there are usually some animals affected with clinical disease that the farmer has identified. They should be examined and the necessary laboratory samples taken to obtain a definitive, causative diagnosis. In beef feedlots and swine herds, necropsy examination of animals that have died naturally or in selected clinical cases is a common practice in order to obtain a diagnosis. Necropsy information is an integral component for monitoring feedlot disease and designing rational preventive and therapeutic feedlot animal health strategies.

Computer imaging technology using a digital video camera can be used to facilitate the capture of feedlot necropsy data (Wildman et al, 2000). A trained technician follows a written protocol for prosection of each dead animal, capturing necropsy images as appropriate. The images are electronically transferred to a central site for veterinary interpretation and diagnosis. The veterinarian generates a necropsy report and transfers it to the originating feedlot to update the computerized animal health record-keeping system. Comparison of the necropsy diagnosis made by a field veterinarian with the diagnosis made by two veterinarians in the office receiving the images found that the digital necropsy images agreed with the gold standard diagnosis, on average, 95% of the time. When disagreement occurred between the off-site and on-site diagnoses, it was related to image quality rather than interpretation of the gross findings. The images are stored temporarily on an office server and are archived periodically to CD-ROM for permanent storage.

Analysis of Disease Occurrence

The records of all clinical diseases that have occurred since the last visit should be examined. The diagnosis, course of the disease, morbidity and case-fatality rates, treatments used, and response rates should be determined. The veterinarian should attempt to determine the cause or risk factors retrospectively from the evidence available and to prescribe advice on the treatment and control of future cases. This includes identification of risk factors that may have contributed to the disease.

In swine herds, producers may be unable to discriminate accurately between stillbirths and dying soon after birth. Without validation of data-recording accuracy, retrospective and prospective studies using producer diagnoses of causes of death in suckling pigs are likely to be invalid (Vaillancourt et al, 1990).

In dairy herds, the effects of the major health problems on the length of productive life, defined as the number of days between date of first calving and date at culling or death, has been used as a suitable measure of longevity (Beaudeau et al, 1995). The probability of a cow being culled increased in early and late stages of lactation in older cows, in low-producing cows, and in cows with poor reproduction performance. Mastitis before the peak of lactation or during the dry period increased the risk. Teat injuries and

Downloaded From Vet-e-Books.com

nontraumatic udder diseases had a large influence on longevity. These survival analysis techniques offer dairy farmers intuitive tools to predict length of productive life that may help them make culling decisions (Beaudeau et al, 1995).

Mass screening of livestock sera can be used for monitoring antibodies against infectious diseases (Behymer et al, 1991).

Routine Elective Activities

In some programs, veterinarians perform certain routine activities at strategic times. These include vaccination, administration of anthelmintics, aborting feedlot heifers, dehorning, castration, foot trimming, and other minor surgical procedures, such as spaying beef heifers. If veterinarians are not performing these procedures, they should at least be aware of when and how they are being performed. However, many producers prefer to employ their veterinarian for these tasks, which provides an excellent opportunity to get on the farm and make observations about the performance of the herd.

Examination and Discussion of Records and Reports

All production and disease reports, and relevant marketing and economic information, should be interpreted and recommendations made for corrective action, if necessary. The results of the previous herd health visit should be discussed with the farmer. The results of recommendations made on previous visits should be assessed and changes made. This requires that the veterinarian bring to the farm a current client file that contains the results of herd health visits, necropsy reports, feed analysis reports, and recommendations that were made for the previous few months. The information may be readily available in summary form on the on-farm computer. There are always some problems with the accuracy and completeness of the records, and these should be corrected each month.

Emergency Farm Visits

Emergency farm visits are independent of the programmed visits. However, the nature and amount of emergency veterinary medicine necessary in the herd are relevant to the overall herd health program. Every disease incident treated by the farmer or the veterinarian should be recorded. At each farm visit, the diagnosis, treatment, and control of the diseases encountered are discussed. As producers treat a greater percentage of the commonly occurring, easily recognizable diseases, the veterinarian is called to the more difficult cases for which the diagnosis is not obvious or that did not respond to therapy given by the producer. These require increasing emphasis on a careful and thorough clinical examination, making a rapid and accurate clinical diagnosis, and providing recommendations for treatment or slaughter for salvage. In some cases, euthanasia and necropsy may be indicated in order to arrive at a diagnosis.

Investigation of Outbreaks of Disease and Crisis Management

Outbreaks of disease should be investigated as soon as possible by means of a carefully planned clinical and epidemiological examination of the herd (Hancock et al, 1988). The investigation should include the clinical examination of affected animals and the submission of appropriate laboratory samples (Lessard, 1988). Detailed recommendations for treatment and control should be reported in writing to the farmer and a copy of the report retained by the veterinarian for future reference. Many veterinarians have not been proficient in this aspect of herd medicine. Some reasons include allowing a busy schedule of emergency visits that seem to take up much or all of the time (thus not leaving any time to do the herd investigation) and the frustrations of the detail and rigor of a proper disease investigation on a herd basis. However, if veterinarians take an interest in the problem and consult with specialists from diagnostic laboratories, universities, and industry, such field investigations can be rewarding, new insights into health and production can be discovered, and problems can be solved. Producers then are willing to invest the costs involved. It is imperative that the veterinarian provide a detailed report of the investigation that explains the problem, present the clinical and laboratory findings, explain the risk factors that were involved, and outline how the problem can be controlled or minimized in the future. Details of herd investigations are outlined in Chapter 5.

Consultation by Telephone

A significant amount of consultation can be done by telephone and may consume a large amount of the veterinarian's time. Many practitioners now have telephones in their vehicles, through which they can be contacted by producers who wish to ask a question about a clinical case or a herd problem. Such communication should be encouraged. Producers must not be reluctant to telephone their veterinarian to discuss a problem. Recommendations for the treatment and control of herd problems may be given over the telephone, provided that veterinarians are confident they have sufficient knowledge about the particular problem from previous visits to the farm. However, all major recommendations should be recorded and followed by a written report to the farmer. This is particularly important when prescriptions for mass medication of feed and water are given by telephone. A computer equipped with a modem can be used by practitioners to access information from large databases and to send information and recommendations to producers. Effective communication and presentation of information in a format that the producer can understand are vital.

Meetings with Participating Producers

A valuable aspect of any health management veterinary service is the convening of regular meetings of participating producers, either individually or in groups, to discuss the results of performance of the herds. Actual farm records of animal health and production can be presented anonymously, and individual producers can compare their performance indices with those of others in the anonymous group. The high levels of performance can be used as targets of performance that are possible under local conditions. This should provide a stimulus to producers with suboptimal levels of performance to establish farm goals and to explore methods of improving performance in their herds. Meetings must be planned carefully with clear objectives. Veterinarians providing service to large livestock operations now meet regularly with the farm staff to discuss health and production problems.

Many practices are now sponsoring extension education programs for their clients. Typically, a few extension type meetings of several hours in length will be held annually. Invited specialists will present lectures and demonstrations on topics such as housing and handling facilities for dairy herds, lameness in dairy cows, policies for culling dairy cows, calf health, record keeping systems, uses of antibiotics and pharmaceuticals in swine herds, vaccination programs for dairy and beef cattle herds, mastitis control, and breeding programs and calving management in beef cattle herds.

Downloaded From Vet-eBooks.com

The more knowledgeable producers become about the science of health and production management, the more they will consult with their veterinarian.

Provision of Drugs and Vaccines

Drugs and vaccines to be used in the herd are commonly supplied by the veterinary practice. Some practices supply the products at a reduced gross margin of profit as part of the health management program. This may encourage the producer to purchase the supplies from the veterinarian, who can provide recommendations for their use and is also then aware of the drugs and vaccines being used in the herd. The ethical marketing of drugs to livestock producers is a controversial subject (Upham, 1993). Some veterinarians actively promote the sale of drugs and others do not. Those who are involved assume the liability associated with their use. In some jurisdictions, the veterinary act stipulates that a veterinary-client relationship must be established before the veterinarian dispenses drugs to a livestock producer. This means that the veterinarian must have first-hand knowledge of the herd and the animals that are being treated.

Drug Residue Avoidance

Residues of therapeutic and production-enhancing drugs in meat and milk and other animal by-products derived from domestic animals are now a topic of considerable concern in all aspects of the food-producing animal industry. Producers and the national organizations that represent them are being confronted by consumers who are increasingly aware of the potential for drug residues in meat and milk. Veterinarians are also facing a dramatic change in attitude and behavior concerning drug residues as a result of the therapeutic and prophylactic use of drugs. Until recently, veterinarians did not pay sufficient attention to ensuring that the producer adhered strictly to the withdrawal period for milk and meat from animals treated with a variety of drugs. The dominant cause of drug residues is failure to observe withholding times. Veterinarians have a major responsibility to ensure that their producer-clients are aware of the regulations regarding the use of drugs in food-producing animals. Each drug used in a species or class of animals must have been approved for use by the agency responsible for such approval. Use of the drug at a dose higher than approved or in a species not approved constitutes *extra-label use*, which requires special considerations. The Food Animal Residue Avoidance Databank (FARAD) is a computerized database that compiles information into one source on veterinary drugs used in livestock production (Sundlof et al, 1986). This can be used to obtain information on the pharmacokinetics of drugs, the regulatory information on tolerance and legal levels of chemical residues in animal products, and the allowable concentrations of drugs in the feed. The objective of FARAD is to reduce the incidence of residues in animal products by educational methods rather than by regulations alone.

A 2-year investigation of dairy farms by the U.S. General Accounting Office pertaining to the nation's milk supply found a total of 82 drugs known or believed to be used to treat lactating dairy cows on dairy farms. Of the 82 drugs, 52 were not approved for use in lactating dairy cows, and 33 of the 52 were not approved for use in food animal species. A national survey of veterinarian-initiated drug use in lactating dairy cows in the United States found that drugs used or prescribed most to treat lactating dairy cows are antibiotics, followed by antiinflammatory drugs and tranquilizer or analgesic drugs (Sundlof et al, 1995). Next to antimicrobials and xylazine, the nonsteroidal antiinflammatory drugs (NSAIDs) were prescribed most frequently by dairy practitioners. The survey indicates that the majority of unapproved drugs prescribed by veterinarians are nonsteroidal antiinflammatories and analgesics or tranquilizers, all of which are intended for humane purposes to reduce pain.

In a study performed by the Food Safety Inspection Service Residue Violation Information System of violative chemical residues in U.S. beef from 1991 to 1993, most of the animals found to have violative residues were bob calves and culled cows. In bob calves, neomycin was the most frequently identified violative chemical, followed by tetracycline, gentamicin, oxytetracycline, and penicillin. In culled cows, penicillin was the most frequently identified violative chemical and was found most frequently in combination with other chemicals in cows with multiple violative residues (Gibbons et al, 1996).

Animal Welfare and Animal Rights

Animal welfare became an important veterinary issue in the late twentieth century. For many years, the goals of livestock production have been increased total production by genetic and environmental means and increased efficiency of production, especially in terms of labor and space. However, the use of animals for the intensive production of meat, milk, and wool has spawned concern in the minds of some people (Swanson, 1995). There has been increasing interest in and concern about the welfare of animals used for agricultural production. This growing concern has been mainly in evidence in the higher income countries and has been linked very closely to the public image of "factory farming" involving animals kept in confined conditions. Concerns about farm animal welfare vary widely between individuals, across societies, and over time. Within the European Union, there is increasing debate about the need for further legislation to safeguard the welfare of farm animals (Spedding, 1994). The importance of animal welfare in Europe is illustrated by the participation of all European Community member states as contracting parties to the Council of Europe Convention for the Protection of Animals Kept for Farming Purposes (Spedding, 1994). Consideration of farm animal welfare has been incorporated explicitly into European Union agricultural policy along with environmental considerations that state the need to "preserve and improve the natural environment and animal welfare by preventing undesirable intensive farming." Far-reaching legislation concerning food animal production has been passed, much of it clearly giving value to the animal's perceived quality of life, even if it means subordinating requirements for efficiency of production (Crook and Heider, 1994). In the United States, there is evidence of a growing awareness and concern about farm animal welfare issues similar to that experienced in the northern countries of the European Union and Scandinavia. Contingent valuation or the willingness of people to pay to support developments intended to improve the welfare of farm animals has been explored (Bennett and Larson, 1996).

Animal welfare advocates are concerned about the well being and comfort of food-producing animals. Animal rights activists believe that animals have the same rights as humans and should not be used as food-producing animals.

A major overall concern of animal welfare interest groups is the humaneness of intensive animal production, in which animals are kept under confined, high-stocking-density conditions. They object to animals' having no opportunity for exercise and being fed high-nutrient diets so that they can grow quickly and efficiently and reach market weight in the shortest time possible. Although intensive livestock production is perceived as being stressful to the animals

Downloaded From Vet-eBooks.com

involved, there is little documented scientific evidence to support this belief. In fact, there is a strong case to be made for the association of optimum animal production with good animal welfare principles. Some activists believe that intensive livestock production is associated with an increase in the incidence of infectious diseases. There is concern about how veal calves are housed in individual stalls and fed milk, with no access to roughage. The well being of gilts and sows tethered in individual stalls or crates with no access to exercise is questioned. Individual sow crates probably will be banned in certain countries in the near future. This subject is presented and discussed in more detail in Chapter 15 ("Swine Health Management"). The veterinary profession has been remarkably inactive in the field of animal welfare. This is ironic and unfortunate because the promotion of improved health (a major welfare consideration) is the greatest single contribution that veterinarians can make in livestock production. The reluctance of the profession to address the concerns of humane societies has impeded progress toward a greater understanding of animal welfare issues, as has its ability to communicate the positive welfare implications of veterinary contributions to reduced animal disease and stress. Clearly, a reassessment of attitudes toward manipulation of animals for human use is necessary (Murray and Ward, 1993).

Some countries have established codes of welfare for farm animals, which define acceptable standards of welfare in terms of the five freedoms: freedom from malnutrition; freedom from thermal or physical discomfort; freedom from injury and disease; freedom to express most normal, socially acceptable patterns of behavior; and freedom from fear (Webster, 1987). Agriculture Canada has published recommended codes of practice for the care and handling of specially fed veal calves, of beef cattle, and of pigs. In other cases professional and industry groups are also taking the initiative to develop codes of welfare for their animals.

A distinction must be made between "positive welfare," which is the aim of the Farm Animal Welfare Council, and the avoidance of cruelty, which is illegal. "Positive welfare" for the Farm Animal Welfare Council is based on trying to achieve the "five freedoms" for farmed animals. Public feelings about cruelty certainly would be much stronger than feelings about failure to achieve all five freedoms. The food animal veterinary practitioner is considered by those outside of the profession as the ultimate advocate for animal well being. This position requires that practitioners provide leadership in the development and implementation of acceptable humane standards in farm animal agriculture (AVMA at Work, 1994).

Farm animal welfare problems arise during handling, transport, and slaughter of livestock (Grandin, 1994). The single most important factor that determines how animals are handled is management attitude. Operations with humane livestock handling almost always have a manager who insists on humane handling, and operations with poor handling almost always have lax management or a manager who actually participates in animal abuse. Animal handling in feedlots and packing plants has improved in the past 15 years. Rough handling is the most important welfare problem and is a major cause of injuries, bruises, and stress. Handlers and managers need to learn livestock behavior principles so they can move animals quietly and efficiently. The maintenance of high handling standards requires sustained management commitment to continual incremental improvement of procedures. The transportation of animals from the farm to the slaughter plant must be accomplished with consideration of factors such as preventing stress during loading and unloading, avoiding overloading, and providing rest and feed stops at regular intervals for long trips (Grandin, 1994).

Nonambulatory (downer) cattle are a major problem, and veterinarians must provide leadership in the handling of such animals. In most jurisdictions legislation exists involving the handling and disposition of downer animals (Grandin, 1994).

It behooves veterinarians who provide health management services to livestock producers to be aware of the animal welfare aspects of the production process and to incorporate management changes that can meet the welfare standards being developed. Veterinarians should feel morally obliged to make livestock producers aware of infringements of practices of acceptable animal welfare. Veterinary colleges are now including animal ethology in the curriculum, ethologists are being appointed to faculty positions at universities, and research projects in animal behavior designed to answer some of the questions about intensive livestock production are under way. The intensive production systems in which livestock are being raised have provoked both scientific and public debate. Definitions of animal welfare/well being are not precise and will continue to evolve based on social and scientific information (Swanson, 1995).

Prevention of Zoonoses

The prevention of zoonoses (infectious diseases of animals transmissible to humans) is a responsibility of the veterinarian. There are well-known zoonoses that occur in each of the domesticated food-producing animal species. Over 150 zoonoses are recognized worldwide, with at least 40 having significance as occupational diseases in animal agriculture (Donham, 1985). In addition to direct human health disease, agricultural zoonoses are a major economic drain on the animal protein industry. Zoonoses are less common in developed countries, where there is improved nutrition, improved public health measures, and better environmental sanitation. Zoonoses are often not diagnosed or are misdiagnosed because the clinical signs are not pathognomonic. Also, there is a lack of awareness among physicians regarding the occurrence of the zoonoses.

High-risk groups for the zoonoses are those that have greater than average contact with animals, including farm workers, abattoir workers, veterinarians, and visitors to farms. Visitors to dairy farms should not be allowed to drink the raw milk from the bulk tank because of the risk of infectious disease. In some instances the zoonotic disease occurs in an animal and the infection spreads to humans on the farm or is transferred by the milk or meat to consumers at large. In other situations animals are inapparent carriers of infections and pose a health hazard for humans. For example, infectious agents such as *E. coli* 0157:H7 do not usually cause clinical disease in carrier cattle but may infect humans following the ingestion of inadequately cooked ground beef contaminated with the organism. The veterinarian must be aware of the occurrence of these infections and alert members of the farm family of the potential for human infection, which requires appropriate preventive precautions.

Foodborne diseases such as salmonellosis and campylobacteriosis from beef and poultry, beef tapeworm, toxoplasmosis from pork, and trichinosis constitute a major public health concern. In addition to illnesses and deaths, they account for the loss of billions of dollars annually in lost productivity because of absenteeism from work. Control of these diseases is becoming a significant activity for veterinarians providing health management services and for those in meat inspection. Reducing the incidence of these diseases requires an effective public health education program, the establishment of regulations requiring pathogen-free animal

Downloaded From Vet-e-Books.com

feeds, and the adoption of industry production standards designed to reduce the risk of infection to unwary consumers. Veterinarians should consult with public health officials when agricultural zoonoses are suspected on livestock farms with which they work.

Bovine Spongiform Encephalopathy

The recognition of BSE in England in 1985 and the potential risk that the beef could be the source of the agent causing variant Creutzfeldt-Jakob (vCJD) disease in humans was one of the most important zoonotic concerns in many years (Bruce et al, 1997) There is evidence that the biological and molecular transmission characteristics of vCJD are consistent with it being the human counterpart of BSE (Hill et al, 1997; Phillips, 2000).

Environmental Toxicology and Ecosystem Health

Environmental toxicology encompasses the study of a wide array of chemical contaminants and toxic effects on species ranging from humans to other vertebrates, invertebrates, plants, protozoa, bacteria, fungi, and viruses (Beasley, 1993). Ecotoxicology, a subdiscipline of environmental toxicology, is the science of toxicants in environments and their effects on living organisms, including interactions among organisms and with the environment.

Ecosystem health aims to provide a suitable environment to support human populations and maintain biological diversity. The goals of ecosystem health practitioners are often achieved through the equivalent of health management programs. Monitoring ecosystem health by using parameters currently used by classic ecologists, as well as those of conservation biologists, veterinarians, plant health specialists, geneticists, and others, will be essential to prevent problems before they become widespread. As in the production paradigm of food animal health management, conserving inputs and providing what is needed for optimum health is the ideal mode for ecosystem health management. It will also be necessary to include various types of emergency specialists able to deal with such problems as chemical spills, exotic species invasions, exotic diseases, and problems facing threatened and endangered species. Food animal practitioners are now becoming involved in improved productivity and wholesomeness of food of animal origin through better air and water quality, nutritious diets free from harmful contaminants, proper disposal of animal wastes, and specific disease-monitoring and prevention programs. Because food animal practitioners provide regular on-the-farm consultation, which increasingly involves management decisions, and because of their knowledge of infectious agents and toxic chemicals, they already assume a role in farm ecosystem protection. As agricultural policy becomes more attuned to environmental concerns, and as concerns with regard to urban, suburban, and home environments increase, at least some astute veterinarians will expand on their current expertise as knowledgeable environmental consultants for the animal-owning public. Concerns for environmental health may focus on the needs of the human population, domestic animals, and wildlife and may involve recommendations to avoid contamination of air, soil, water, and food. Environmental assessments will be performed on farm visits.

Veterinarians are now becoming involved in evaluating the potential adverse effects of environmental pollution on livestock and human health. Only recently have epidemiologic methods been used to study the potential effects of environmental contaminants from the oil and natural gas industry on livestock health and production (Waldner et al, 1998).

Food Safety

Foodborne diseases are an important public health threat internationally and nationally (Angulo, 1996). It is estimated that annually in the United States, 6 to 81 million persons become ill and 9000 die from foodborne disease. The epidemiologic characteristics of foodborne diseases in the United States are also changing. In recent years, several large multistate epidemics have occurred, caused by newly recognized pathogens including *E. coli* 0157:H7, *Listeria* sp. and *Salmonella enteritidis* (Potter, 1992). Some of these events are associated with changes in food processing from the "farm to the fork." When prepared properly foods derived from animal products are generally safe and wholesome. The federal and state departments of agriculture inspect and test animal products to help ensure that only wholesome, safe foods reach the consumer. As a result, meat and milk are among the safest and most wholesome food products that consumers can purchase. However, despite the combined efforts of people and nature to protect the food chain, microbial and chemical agents occasionally find their way into animal products (McCapes et al, 1991).

As a result of the emerging diseases just mentioned, food production, processing, and marketing increasingly are being influenced by concerns for consumer health (Heidelbaugh and Menning, 1993). There are increasing demands for reliable trace-back of food from consumer to producer, coupled with appropriate liability for consumer health. There are concerns for the costs of primary health care of ill patients and the lack of efficient use of health management of food-producing animals. The evolving human population is aging and more susceptible to foodborne diseases. The general population is increasingly aware that failure to provide safe food may be a general failure of government rules and regulations. Also, the potential for chemical residues in meat is a consumer concern that must be addressed. As a result, producers, through associations such as the National Cattlemen's Beef Association, the National Pork Producer's Council, and the National Milk Producer's Federation, have been urging expansion of stringent "on-the-farm" quality assurance initiatives and programs (Teske, 1992). The proper and responsible use of animal drugs and feed additives in food animals will continue to be an important issue for consumers and therefore all those involved directly or indirectly in animal agriculture enterprises. The perception by the general public that the food-animal industry is highly profit oriented creates considerable distrust in the system of food safety already in place. The expansion of international trade in food products intensifies the need for harmonization of food safety standards (Crawford, 1992b). The shortage of veterinarians who are qualified in modern food safety programs and management and the unwillingness or inability of veterinary colleges to prepare or inspire their students to pursue a career in food safety slow progress in the specialty.

Historically, veterinary medicine has provided national leadership for assurance of a plentiful supply of safe and wholesome foods of animal origin. Veterinary medical education and training provide the basis for this leadership and give the veterinary profession the unique ability to effectively participate in the full spectrum of activities involved in the production and consumption of foods of animal origin. These activities include live animal production, slaughter, processing, distribution, preparation, and consumption (McCapes et al, 1991). New developments in biotechnology will be used in food safety programs (Kopchick, 1992; Headon, 1994). New diagnostic techniques are now available that reduce the time necessary to identify food pathogens and their sources. Recombinant DNA technology

Downloaded from Vet-eBooks.com

may enable the development of recombinant proteins such as insulin, growth hormone, interferon, and recombinant vaccines. In the future, genetic modification of food-producing animals may allow modification of animal products to meet the consumer needs for healthy and safe food. Appropriate recombinant technologies may allow modification of animal products to better fit consumer needs for healthy and safe food. Current technologies used in animal production that modify or repartition animal growth yield leaner meat products with less fat. With emerging biotechnologies similar options will become available for beef and pork products. The generation of these types of animal products will require gene mapping and selective breeding, and the production of transgenic animals.

A symposium on food safety in 1995 presented the preharvest and postharvest food safety issues and discussed how various groups are responding to the changing epidemiological characteristics of foodborne diseases. The roles of veterinarians in promoting the safety of foods of animal origin are changing and will become a major activity in health management.

Preharvest Activities

The USDA has been monitoring animal populations from the farm through marketing, transportation, and preslaughter or processing preparation. These preharvest activities include preslaughter practices, animal health and well being, stressors, environmental conditions, feed and water, and vectors. Identification of the risk factors in preharvest activities that may contribute to foodborne diseases enable veterinarians to recommend practices that will improve food safety. Food safety begins at the point of conception of food animals on the farm, achieves greater attention at birth, and receives constant monitoring to the point of delivery at the dock of the food processor.

Postharvest Activities

Postharvest food safety issues include slaughter, processing, distribution, retail, and preparation (Sparling, 1996). The most important food safety hazard associated with raw meat products is contamination with bacteria, primarily *Salmonella* and *Campylobacter* spp. and *E. coli* 0157:H7. During slaughter of cattle, removal of the hide causes some aerosol contamination of the surface of the carcass with fecal contaminants. Such contamination has resulted in major improvements in processing, such as steam vacuuming to reduce the bacterial count on the surface of carcasses. Controlling the multiplication of bacteria during storage, handling, and preparation of food is a complex challenge. The presence of *E. coli* 0157:H7 in ground beef is now considered a food adulterant in the United States.

The National Milk Producers Federation of the United States has stated that there are three major milk safety issues facing the dairy industry: antibiotic residues, extra-label use of animal drugs, and bovine somatotropin (Barr, 1992). The Federation has taken various steps to assure consumers of safe and wholesome dairy products. A test sample of each farmer's milk is taken before it leaves the farm. Before a truck unloads its tank of milk at the plant, the tanker is checked for milk color, odor, and appearance; proper refrigeration; acidity of the milk; bacteria count; and milkfat content. The milk is also tested for antibiotic residues. If the milk fails regulatory or company standards, the entire tanker of milk is rejected. Consumers and activists are demanding zero levels of residues in milk. The most effective way to reduce animal drug residues is to minimize the need for animal medication unless necessary. To do that, dairy farmers must use an effective health management program. Veterinarians have a vital role in outlining explicitly the health management and production strategies to treat and control infectious diseases. When lactating animals require treatment, farmers must observe the milk withdrawal period established by the jurisdiction responsible for drug use. The National Milk Producers Federation and the AVMA initiated joint efforts in 1988 to develop the Milk and Dairy Beef Residue Prevention Program. This is a 10-point quality assurance program to help dairy farmers and veterinarians work together to improve the health of dairy herds, reduce the need for animal medications, and further ensure the safety and wholesomeness of milk, milk products, and dairy beef. Food animal veterinarians are the first line of defense on food safety and are capable of making the informed decisions necessary to protect human food safety while providing comprehensive health management advice to owners of food-producing animals.

Disease Surveillance

The National Center for Infectious Diseases at the Center for Disease Control and Prevention (CDC) has developed strategies for responding to emerging infectious diseases, several of which are foodborne diseases. The strategic plan collaborates with state health departments and numerous professional organizations. The plan emphasizes the need for improved surveillance, applied research, increased prevention and control efforts, and strengthened public health infrastructure as the essential elements for responding to emerging infectious diseases.

Hazard Analysis Critical Control Points

Many food industries have established hazard analysis critical control points (HACCPs) programs to assure food safety (Stenholm and Waggoner, 1992). The HACCP programs involve identification and monitoring of critical points in the food manufacturing processes. These programs place responsibility on industry to meet food safety standards, reducing the demand for government oversight in the food industry operation and increasing the impact of each regulatory inspection. In 1995, the Food Safety and Inspection Service (FSIS) of the USDA proposed sweeping changes in the meat and poultry inspection system, based on the National Research Council (NRC) Report of the Committee on the Scientific Basis of the Nation's Meat and Poultry Inspection Program (National Research Council, 1985). Inspected plants would be required to use a HACCP system. The FSIS established, for the first time, food-safety performance standards for pathogenic microorganisms that slaughter plants must meet, including the requirement for plants to conduct daily microbial testing to verify that the standards are being met. The FSIS public health mandate requires that the plant also work with the animal production, food transportation, distribution, and retail sectors to implement effective strategies and to ensure that the whole food delivery system, from farm to table, is working effectively to prevent food safety problems (Cross, 1992). The FSIS believes that HACCP principles can be used to structure voluntary national animal health programs that focus on pathogen reduction.

Meat inspection procedures in the European Community are being evaluated for their effectiveness in providing quality meat (Berends et al, 1993). It is suggested that neither the current nor the proposed revisions of antemortem and postmortem meat inspection procedures alone are insufficient, and that only integrated approaches, applied to each step of animal and meat production, will lead to better quality meat.

Food Safety in Veterinary Education

The public health importance of food safety has led to increased emphasis on food safety education in veterinary curricula and continuing education. There is a critical need for leadership capable of providing the public health-oriented management essential to food safety programs. The AVMA has made detailed recommendations to improve the safety of foods of animal origin (Heidelbaugh, 1992). Some veterinary colleges have established academic faculty chairs in food safety and veterinary public health (Crawford, 1992a). The veterinarian is the professional best prepared to provide the essential preventive medicine and public health oversight and integration of the many scientific disciplines essential to science-based programs for the safety of foods of animal origin (Heidelbaugh and Menning, 1993). The veterinarian can provide the essential preventive medical approach for food safety at all levels in the food-animal chain (farm, ranch, antemortem, postmortem, processing, distribution, and final preparation for consumption). Thus the veterinary profession has the responsibility to continue to provide specialty-educated veterinarians for their unique role in assuring the safety of foods of animal origin. The safety of foods of animal origin will continue to be important as technologies become more complex, international trade expands, restorative medicine costs increase, threats of foreign animal disease exacerbate, preventive medicine becomes more science based, risk assessment becomes increasingly the rationale for preventive measures, new diseases emerge, advances in molecular biology are implemented, environmental concerns intensify, and preventive medicine becomes the predominating form of medical science.

Antimicrobial Resistance in Food Animal Production and Public Health

A major question in the health management of food-producing animals is, "Does the use of antimicrobials in food animal production contribute to antimicrobial resistance in human medicine?"

Antimicrobials are used for the treatment and control of many economically important bacterial and protozoal infections of food-producing animals. They are also used as feed additives for growth promotion, which contributes to the economical production of wholesome beef and pork.

The various uses of antimicrobials in food-producing animals, especially in beef feedlot cattle and in swine herds, are presented in Chapters 4, 14, and 15.

Antimicrobial Residues in Food and Antimicrobial Resistance in Human Medicine

The potential risks from using antimicrobials in food producing animals are antimicrobial residues in meat and milk, and the emergence of antimicrobial-resistant enteric bacteria in animals that may be transferred to humans and cause clinical disease, which is difficult to treat because of antimicrobial resistance. Based on published information, there are no significant antimicrobial residues in beef that pose a human health hazard.

The problem of the increasing incidence of antimicrobial resistance in human medicine is commonly attributed to the subtherapeutic use of antimicrobials in the health and production management of food producing animals and to the overprescribing of antimicrobials by human physicians. The scientific medical literature and the public media attribute, with uncertain evidence, a significant part of the resistance problem in human medicine to the agricultural use of antimicrobials.

There is considerable concern that the subtherapeutic use of antimicrobials in food-producing animals causes the emergence of antimicrobial resistant bacteria (*Salmonella* spp., *Campylobacter* spp.), which may be transferred to humans who may develop clinical disease. Again, this may be difficult to treat because of antimicrobial resistance of the pathogens.

The 1969 Swann Committee Report in the United Kingdom, in response to concerns about an increased incidence of antimicrobial resistance in human and veterinary medicine, recommended that antimicrobials used in human medicine not be permitted for use as feed additives in food producing animals without a veterinary prescription. The banning of certain antimicrobials as feed additives did not cause a decline in the incidence of antimicrobial resistant bacteria in human and veterinary medicine.

From 1969 to 2000, several major expert committees examined the evidence that the subtherapeutic use of antimicrobials in the feed of food animals contributes to antimicrobial resistance in human medicine. All of the committees concluded that there is insufficient evidence to demonstrate a direct link between the use of antimicrobials in food animals and antimicrobial resistance in human medicine.

It has been difficult to trace the postulated steps from the use of the antimicrobial in the feed of animals to the emergence and transfer of antimicrobial-resistant bacteria to humans in whom it may cause disease. Those who argue that the use of antimicrobials in agriculture contributes to antimicrobial resistance in human medicine are unable to quantify the relative contributions to resistance made by their use in human and veterinary medicine. Several disease investigations in the 1980s claimed to have shown the link between the use of antimicrobials in farm animals and the isolation of antimicrobial-resistant bacteria from humans affected with salmonellosis. However, a review of the literature concluded that the evidence was incomplete for showing a direct link (Radostits, 1999).

Antimicrobial resistance is a major problem in human medicine, particularly nosocomial (hospital-acquired) bacterial infections in which the incidence of resistance has increased most dramatically because of the intensive use of drugs. There is general agreement in the medical profession that a major cause of antimicrobial resistance in human medicine is the overprescription of antimicrobials. Patients commonly expect physicians to prescribe antimicrobials for a wide variety of common infections for which antimicrobials are unnecessary. The failure of many human patients to comply with the prescription recommendations by not taking the complete course of the antimicrobials also contributes to the resistance problem. The incidence of antimicrobial resistance of several human pathogens has increased and continues to increase. Some multiple-drug-resistant strains of bacteria emerge in different parts of the world, persist for several years, and then disappear.

The people at greatest risk of developing clinical disease because of antimicrobial-resistant bacteria of animal origin are those already taking oral antimicrobial medication for a previous illness, immunocompromised patients, the young, and the elderly. Increased antimicrobial resistance is a problem in several pathogens that are not zoonotic; thus the resistance is unlikely associated with the use of antimicrobials in food animals but rather intensive and extensive use in human medicine. The most common and significant cause of disturbances in the normal intestinal microflora of humans is the administration of antimicrobials orally. Bacterial overgrowth and the emergence of resistant bacteria occur, which may lead to serious infections.

The use of antimicrobials deemed valuable in human medicine has been banned as growth promotants for livestock

Downloaded from Vet-e-Books.com

in some countries. However, banning their use in the United Kingdom in 1969 did not cause a decrease in the incidence of antimicrobial-resistant bacteria. In 1986, Sweden and Denmark banned the use of antibiotics as feed additives. In 1999 the European Community banned four antibiotic feed additives (virginiamycin, tylosin, zinc bacitracin, and spiramycin) as a precautionary public health measure.

Foodborne Illness

It is important to consider the circumstances of foodborne illness in humans in the context of any discussion of antimicrobial-resistant bacteria being transferred from animals to man. Meat and meat products are not bacteria free, and most foodborne illnesses are due to the improper handling of food and inadequate cooking. Moreover these bacteria may be pathogenic for humans whether or not they are resistant to antimicrobials. Thus the proper handling and cooking of food for human consumption must be given high priority.

The major foodborne pathogens are *Salmonella* spp., *Campylobacter jejuni*, and *E. coli* 0157:H7. Worldwide concern exists about the emergence of antimicrobial-resistant bacteria in the production of poultry, swine, and beef cattle production. However, the proportion of cases of foodborne illness resulting from antimicrobial-resistant bacteria is unknown. Foodborne illness in humans caused by the animal enteric pathogens is usually the result of the improper handling or inadequate cooking of ground beef and poultry. More than 90% of such human patients with foodborne gastroenteritis experience an episode of diarrhea and recover without the need for antimicrobials. The surfaces of beef cattle carcasses are contaminated with enteric bacteria immediately after removal of the hide during processing following slaughter. Fresh ground beef contains variable numbers of *E. coli* 0157:H7, some strains of which are highly pathogenic (*E. coli* 0157:H7), and rarely may be contaminated with *Salmonella* spp. Poultry is commonly contaminated with *Campylobacter* or *Salmonella*.

Little information is available on the prevalence of antimicrobial-resistant bacteria on the surface of beef carcasses. Major progress has been made in the last decade in the processing of beef carcasses after slaughter to reduce the microbial contamination of beef using the HACCP system.

Adequate cooking of meat such as hamburger eliminates all potential risks from bacterial contamination. Inadequately cooked beef hamburger is a major risk factor for infection with *E. coli* 0157:H7.

The Use of Drugs in Food Animals: Benefits and Risks

In response to growing public concern over food safety in relation to the use of drugs in food animals, the USDA and the Center for Veterinary Medicine of the FDA asked the NRC to form a committee to examine and review the benefits and risks associated with drug use in the food-animal industry (National Research Council, 1999). The NRC assigned the task to the Board on Agriculture, and the Committee on Drug Use in Food Animals was convened. The committee was charged with reviewing, evaluating, and making recommendations related to the need for drugs and their availability and accountability in agriculture, the benefits and risks to human health and food safety associated with food animal drugs, the development of food animal drugs and the process of approval of their use, and the emerging trends in animal health care and the availability of alternative management practices for raising food animals. In particular, the sponsors stressed the importance of evaluating the class of drugs known as antimicrobials.

The committee concluded that the use of drugs in the food animal production industry is not without some problems and concerns, but it does not appear to constitute an immediate public health concern; additional data might alter this conclusion. The greatest concern is associated with the use of antimicrobials in food animals in such a way that there is a potential for antibiotic resistance to develop in or be transferred to pathogens that can cause disease in humans. The report acknowledged that there may be a link among the use of antimicrobials in food animals, the development of bacterial resistance to these drugs, and human disease—although the incidence of such disease is low. A direct link among the animals fed antimicrobials, the emergence of antimicrobial-resistant pathogens, and their transfer to humans where they have caused clinical disease, which is difficult to treat with antimicrobials, has not yet been demonstrated clearly.

A substantial change in the human health risk posed by antibiotic use would affect not only how animal drugs are reviewed, approved, and used, but also how food animals are produced. It should be noted that antimicrobials are still effective for their intended purposes at the recommended dosages.

Bacterial resistance to antimicrobials will be the most important motivating factor in the development of new drugs to fight infections and in the modification of processes by which drugs are approved. Regulatory agency approval practices have improved in recent years and continue to do so. Reasonable balance in accountability, oversight, and veterinarians' access to alternative drugs has increased with the passage of the Animal Drug Availability Act (ADAA) and the Animal Medicinal Drug Use Clarification Act (AMDUCA) (Rhoda and Smith, 1999). However, those are only temporary solutions to a continuing problem.

Unless new antimicrobials become available, even the extra-label use of antimicrobials is expected to become ineffective. There is a great need to understand more clearly both the magnitude of the risk and the options available to minimize the risk while maintaining the benefits these drugs confer on agriculture. Constant vigilance in monitoring trends in antibiotic resistance in farm animals and humans is strongly encouraged.

New antibiotic drugs are needed to combat emerging animal diseases that do not respond to traditional drugs and thus threaten public confidence in animal agriculture and human medicine. Professionals in human health care should be concerned that they do not have enough specialty antimicrobials to treat resistant and emerging infections in humans, as should veterinarians. The question is, should newly discovered medications be held in reserve for human or animal use only? Antimicrobials should be available to treat specific human and animal diseases with proper accountability and oversight of the drugs used. Information gaps hinder the decision- and policy-making processes for regulatory approval and antibiotic use in food animals. A data-driven scientific consensus on the human health risk posed by antibiotic use in food animals is lacking.

The National Antimicrobial Resistance Monitoring System (NAMRS), which prospectively monitors changes in antimicrobial susceptibilities of zoonotic pathogens from human and animal clinical specimens, healthy farm animals, and carcasses of food-producing animals at slaughter plants, is in effect (Marano et al, 2000). The antimicrobial susceptibilities of indicator and zoonotic bacteria should be correlated with the use of antimicrobials used in the sampled herds.

There is a need for well-designed field trials to evaluate

Downloaded from Vet-eBooks.com

the effects of subtherapeutic antimicrobials in the feed of feedlot cattle on the susceptibility of enteric pathogens over the length of the feeding period. Control animals not being fed antimicrobials are also necessary. The antimicrobial susceptibility of the bacterial flora of the beef carcasses would also be determined at the time of slaughter and processing to determine the flow of the bacteria. It is important to examine the relationship between the use of antimicrobials and the emergence of resistant enteric bacteria and their dissemination at slaughter of the cattle and processing of the carcasses.

There is a need for risk communication between the scientists and the public to improve the understanding of antimicrobial resistance in food animals and how to reduce the risks of foodborne illness associated with the improper handling and inadequate cooking of red meat and poultry. Every effort should be made to explore risk reduction rather than risk elimination, which is not possible.

Based on the available information it is not possible to conclude with a strong argument that the subtherapeutic use of antimicrobials in the feed of feedlot cattle contributes significantly to antimicrobial resistance in human medicine. It is also possible that the probability of a cause-and-effect relationship is extremely low because of the complex nature of the events that must occur (Radostits, 1999). However, recent publications of expert committees from England (Advisory Committee on the Microbiological Safety of Food [ACMSF], 1999) and Australia (Joint Expert Advisory Committee on Antibiotic Resistance [JETACAR], 1999) concluded that the use of antimicrobials in food animal production leads to the selection of resistant bacteria that may be transferred to humans in food and cause human infections, which are difficult to treat. Human patients, physicians, veterinarians, drug companies, regulatory agencies, and food animal producers will have to address the issue. This will include the prudent use of antibiotics in human and veterinary medicine, improvement of food animal production practices, consideration of less dependence on the subtherapeutic use antimicrobials for the control of infectious disease, and the banning of the use of antimicrobials for growth promotion. The monitoring of antimicrobial resistance of animal and human pathogens will also need to be expanded.

Environmental Management

In geographic areas where animals are housed indoors or kept confined outside, management of the environment is a major determinant of health or disease. Much is now known about how environmental variables affect productivity of domestic animals. These include the following: (1) the adequacy of the ventilation of housed animals, (2) the daily fluctuations in temperature and relative humidity inside barns, (3) the quality of the air and the concentration of gases such as ammonia, hydrogen sulfide, carbon dioxide, and methane, (4) the comfort of stalls and pens, (5) the quality of the floor surface, (6) the manure disposal system, and (7) the population density of the animals.

The examples just listed are common ones, and there are many others. The methods of feeding and the amount of dust created by feeding systems may also have an important influence on respiratory disease. The method of cleaning and disinfection used in critical areas, such as the milking parlor and the milk house, and the quality of the bedding and ground surfaces where cows spend most of their time are important factors that can contribute to outbreaks of environmental mastitis in dairy cattle. The monitoring of these variables and how they affect productivity or contribute to disease is now a significant part of some health management programs. In the swine industry, pigs are raised indoors from birth to market, and ventilation, air quality, and the comfort of individual stalls for sows and the safety of farrowing crates for piglets are major considerations in swine health management programs. Housing quality and ventilation are considered to be important determinants of respiratory disease in growing and finishing pigs. Lameness caused by diseases of the feet is a major problem associated with floor quality and ground surfaces in dairy cattle confined indoors or in zero grazing systems. Enzootic pneumonia of housed dairy calves is closely related to the quality of housing and ventilation.

Clinical Research

Veterinary practitioners can serve an important role in the availability of new animal drugs by contracting as clinical investigators. Veterinarians who supply health management services to large herds have a particular advantage because of the existence of good record-keeping systems in such herds, and in most cases the owners are interested in the development of new drugs and vaccines. The provision of a health management service to livestock producers provides the veterinarian with an opportunity to do field research on food-producing animal farms. Because certain methods used for the treatment and control of diseases may not be applicable or economical on every farm, clinical research may be necessary on certain farms. Clinical field trials may be necessary to determine, for example, whether the diet of a certain herd should be supplemented with a nutrient such as copper or selenium to improve the growth rate of pastured sheep or cattle. A trial may be indicated to determine whether a vaccine is effective and economical in a feedlot situation or a beef breeding herd. Drug and vaccine manufacturers also need to conduct field trials on commercial farms under naturally occurring conditions, which provide an opportunity for the veterinarian to participate in the trial as a paid consultant. Clinical field trials must be well planned and designed scientifically so that the results can be analyzed statistically. This requires some knowledge of clinical epidemiology and statistics, and veterinarians planning to conduct field trials should collaborate with a veterinary researcher who can provide such assistance. The critical features of veterinary field trials have been described (Elbers and Schukken, 1995). A large potential exists for the use of randomized clinical trials in veterinary clinical research, especially in large herds (Lund et al, 1994). The basic features of the drug approval process in the United States and the important points for consideration when becoming a clinical investigator are available (Prater et al, 1996).

Animal Health Technicians in Health Management

Certified animal health technicians who are graduates of accredited training programs are a valuable resource as assistants in a large animal practice. They are able to do many of the routine elective procedures, such as dehorning, castration, and foot trimming, if these are part of the health management program of certain farms. In large animal practices that have clinical facilities for the intensive therapy of valuable animals, technicians are invaluable for the provision of intensive care, including intravenous fluid therapy. They can collect laboratory specimens, such as blood, milk, feed, soil, and water samples, which may be necessary as part of a control program or field study. They can assist with necropsies and the preparation of tissue samples for laboratory sub-

Downloaded from Vet-e-Books.com

mission. Technicians are excellent for the collection and preparation of animal health and production data for simple analysis or entry into the computer, if required. They can learn the use of some of the more commonly used computerized statistical programs for the analysis of data derived from field trials. Some technicians have been involved in information retrieval (of literature from the library), which is a valuable asset for the busy veterinarian. For large herds, regardless of the species, technicians can be collecting data and doing several different routine activities while the veterinarian is involved with veterinary diagnostic work. Technicians can be taught how to evaluate milking machine function to detect problems associated with mastitis. Large herds and feedlots have employed technicians to detect and treat sick animals according to a treatment protocol prescribed by the veterinarian. Technicians employed by a veterinarian and engaged in certain veterinary diagnostic and surgical techniques require veterinary supervision, as described in most veterinary acts. The training of personnel and monitoring of their performance is now becoming a major activity in dairy herds, and veterinarians will be required to provide the health and production protocols necessary to achieve optimum health and production.

COSTS AND BENEFITS OF A HERD HEALTH PROGRAM

Costs of Animal Health and Production Management

Health management veterinary services have many inherent costs. These include professional services on the farm; travel; drugs, vaccines, and other animal health supplies; the professional time required for the analysis of data and the preparation of reports to be sent to the producer; and telephone charges. There is little documented information on the total input costs of all veterinary services and supplies for the health management of herds of food-producing animal herds.

Traditionally, veterinarians have used one of three methods to charge for professional health management services. The most commonly used method is to charge for each professional hour the veterinarian is engaged in health management activities on the farm and in the office analyzing data and preparing reports. This is generally done for dairy and beef cattle herds, swine herds, and beef feedlots. A differential fee system may be used in which a higher fee is charged for skilled diagnostic work on the farm and a lesser amount charged per hour for analytic work done in the office. A second method is to charge a certain amount per head per unit of time (day, week, month, or year). In dairy herds, for example, the charge could be based on the number of lactating cows in the herd each month. In either system the veterinarian should outline in a written document the nature of the health and production management services that are to be provided, including the frequency of farm visits and the reports that are to be prepared for the producer. The time required for the preparation of reports is charged on an hourly basis, and an itemized account indicating all of the charges, along with the monthly herd health report, is sent to the producer. The costs of travel to and from the farm, telephone calls, and animal health supplies such as drugs and vaccines are additional. Animal health supplies may be provided by the veterinarian at a reduced gross profit by mutual arrangement with the producer. This may ensure that the producer uses the products that are prescribed by the veterinarian.

A contract method is used by some veterinarians and may be preferred by some producers. In this situation, the veterinarian agrees to provide a specified animal health and production service for a set professional fee per month or per year, which may include the provision of all services. The charges are usually determined on a per head basis and the contract can be renegotiated each year. Some contracts include a base professional fee plus a percentage of the increased profits made during the year. This provides an incentive to the veterinarian to promote high standards of health and production.

Veterinarians must understand that if they charge for advice, a written report must be provided to the client. The report is an extremely important document. Credibility is added when published articles supporting the recommendations are included in the report. Producers know that time was spent preparing the report and they are more likely to implement the recommendations. *Producers are reluctant to pay for something stated but are willing to pay for something written and documented* (Toombs, 1996). Veterinarians can use enterprise analysis to determine the value of their recommendations, thus allowing them to charge more appropriately for the services provided (Toombs et al, 1993).

A 1986 national survey of livestock producers in the United States obtained information on expenditures on veterinary services and animal health supplies (Wise, 1988a). Approximately 71% of beef producers used a veterinarian and spent an average of $315 (U.S.) per farm per year. Almost all dairy producers employed the services of a veterinarian or purchased animal health supplies from a veterinarian at an average of $1090 (U.S.) per farm per year. Only 59% of swine producers used a veterinarian for services or products, with an annual expenditure of $524 (U.S.) per farm. Approximately 78% of sheep producers used a veterinarian, with an average annual expenditure of $310 (U.S.) (Wise, 1988a). In general, owners of large livestock farms and ranches spent proportionately more on animal health products and less on animal health services than owners of smaller farms. Owners of large farms also spent proportionately less on veterinary services than did owners of smaller livestock farms. The relative amounts spent on the diagnosis and treatment of sick animals compared with the total amount spent on planned herd health programs were not determined.

The same survey sought information from food animal practitioners on the revenues from veterinary services and animal health supplies (Wise, 1988a). Approximately 62% of the average income of veterinarians was derived from professional services and 38% from sales of animal health supplies. Approximately 45% of professional service revenue was from sick animal services, 45% from well animal services, and 10% from consultative services. Income from consultative services including herd health programs, nutrition, and production analysis ranged from 5% to 7% for sheep and beef practitioners, respectively, to 11% to 24% for dairy and swine practitioners, respectively.

The amount of money spent on animal health services and supplies as a part of the total costs of production is low compared with other costs (Howe, 1988). Data from farm accounts indicate that veterinary services and medicines never exceed 2% of total farm expenditure, which is a minor proportion of total costs incurred by producers. However, this low cost does not necessarily mean that veterinarians can justify their services on the basis of the relative cheapness of their contributions, especially when compared with the increased production and financial returns that result from disease prevention and control. From an economist's point of view, the costs and benefits of veterinary services must be considered in the context of all other costs of the farming operation to determine whether the expenditure on veterinary services provides the best economic return to the farm.

A study of the veterinary and nonveterinary costs of

Downloaded from Vet-eBooks.com

disease in 29 California dairy herds participating in the NAHMS project from 1988 to 1989 revealed that the cost of disease prevention accounted for 11% of the total costs of all health-related expenditures (Weigler et al, 1990). From 1987 to 1988, in 60 beef cow-calf herds in Tennessee, the cost of preventive veterinary services accounted for 8.8% of the total cost of preventive actions, which included drugs and vaccines (New, 1991). Most of the costs in both studies resulted from the purchase of drugs and supplies to treat and prevent disease, and only a small amount resulted from professional veterinary services.

The economics of the rural practitioner market has been examined using the neoclassical economic theory as a foundation (Radke and Lloyd, 1996). There is a widespread belief that rural veterinary practice is undesirable because of the hard work, long days, inadequate professional income per hour, and poor self-image. There is a demand for rural veterinary service to the livestock industry, but a declining number of new graduates are entering rural practice. It has been suggested that one solution is to change the admission requirements to increase the number of graduates with a meaningful farm animal experience who may have a greater dedication to the farm community. However, such a mechanism to provide a stable market equilibrium would increase the welfare of consumers at the cost of rural veterinarians.

Economic surveys have indicated that all veterinarians, perhaps with the exclusion of those charging the highest prices, are operating in the inelastic portion of the demand curve for veterinary services (Radke and Lloyd, 1996). Since price and quantity are inversely related, a fee increase would normally decrease quantity demanded. With inelastic demand, the supplier's revenues will increase with an increase in price. At least one economic survey suggests that demand for the profession as a whole was unaffected by an increase in fees (Radke and Lloyd, 1996). The majority of veterinarians feel that they are underpaid relative to other professionals with similar postsecondary education. Large animal practitioners could move in the direction of solving the problem of inadequate remuneration and excess demand with one action: raising professional fees.

Raising fees appears to solve a number of the problems facing rural practitioners. Increasing rates would increase income, decrease supply, and decrease the number of hours worked. If demand still required more suppliers (veterinarians), profit in the market would be sufficient to attract and maintain employees or competitor veterinarians. With sufficient financial returns, an increased number of talented young people with rural backgrounds, who in the past have forsaken a career in veterinary medicine, would be stimulated to apply to veterinary college, thus meeting the desires of employers.

Social and Economic Benefits of Animal Health and Production Management

Social Benefits

The benefits of animal health management programs accrue to society as a whole. Disease in farm livestock has always been a problem of considerable importance to producers. The production of wholesome human food from animals is a major objective of livestock industries. Producers employ the services of many different professionals, pharmaceutical and feed companies, and government agencies to assist in achieving this objective. Because some diseases of livestock are infectious and can spread from farm to farm, and because zoonoses can adversely affect the human population, society also benefits from effective animal health management programs. Disease control programs benefit society by improving the quality and hygiene of food, public health, maintenance of trade in livestock, and increased awareness of welfare of animals.

Economic Benefits

The economic benefits derived from a herd health program have been the subject of considerable debate. When progress has been made and performance improved, it is difficult to identify which factor (or combination of factors) is responsible. A successful, comprehensive herd health program involves a combination of more effective management by the farm staff, the accurate recording of data, the use of new information, the introduction of specific disease prevention techniques, regular visits by the veterinarian, improved nutrition and housing, improved breeding programs, and other intangibles that are difficult to identify.

Four methods used to calculate the financial impact of veterinary services in beef cow-calf herds have been described: analysis of value of therapy; partial budgeting, standardized performance analysis-financial (SPA-F), and spreadsheet analysis (Toombs, 1996). The SPA is a major asset to cow-calf practitioners in the United States and is described in Chapter 13.

Enhancement of the profitability of the producer must be a primary objective of health management programs. The increased interest in applying economic principles to the analysis of veterinary services is an important step toward meeting this objective. Farm-level analysis of animal health economics is now being incorporated with animal health management. This involves selection of the appropriate analytic techniques and the use of economic parameters that adequately represent the actual situation on the farm. An important aspect of economic analysis is that management advice must be based on information that assesses the risk of loss from disease and the effect of animal health management practices. Without such information, it is difficult to assess the economic benefits of animal health management relative to other aspects of the farm.

The veterinary costs of a herd health program are part of the variable or optional costs of farming, such as those associated with feed, fertilizer, supplies, and services. Based on cost-benefit analysis techniques, the net return to the producer of money spent on veterinary services directed toward a comprehensive herd health program has been calculated for some specific disease control techniques, such as control of mastitis and improved reproductive performance in dairy herds. The net returns have been on the order of 200% to 500%.

Some indication exists that, as the level of performance improves, health costs decrease. Health costs are lowest in dairy herds with near-annual calving intervals compared with much higher costs in herds with longer lactation periods.

Agricultural economists contend that the economic analysis of disease control has been focused on an important but nevertheless narrow subset of economic problems (Howe, 1988). The economic analysis of disease control has centered on cost-benefit analysis, which is a form of simple accounting ratios. Economists are concerned more with the real resources (inputs) and real products (outputs) that underlie financial expenditures and receipts than with the money values themselves. Examples of real resources are veterinary manpower and animal health supplies, farm labor, buildings, machinery, land, breeding livestock, and feedstuffs. Examples of real products are milk, meat, eggs, and wool (Howe, 1988).

Economics is the study of the allocation and the use of scarce resources in production. This means that it may be more economically beneficial for producers to spend money

Downloaded from Vet-e-Books.com

on other aspects of the farming operation rather than on veterinary services. Thus the term "opportunity cost" is central to the appraisal of economic efficiency. The opportunity cost of using resources for one purpose is the return foregone by not using those resources elsewhere (Howe, 1988). If the potential alternative return is greater than that obtained from retaining resources in their present use, the resources should be reallocated. The effect of the reallocation is to benefit society. Economists may thus claim that the fact that expenditures on veterinary resources are more than covered by the consequent returns from healthier livestock may be good for farmers, but not for society as a whole. It all depends on whether there are higher returns to be earned from transferring those resource expenditures to other uses. It might be suggested that there is no good reason for animal disease to be controlled at all costs. This suggests that it may be necessary to define the economic optimum level of disease in a livestock population. From the producers' point of view, it would be that level of disease that is consistent with their welfare being maximized when each has allocated resources in the best possible way among all competing uses, such as disease control, crop production, bank investments, and building and equipment purchases.

From an economist's viewpoint, cost-benefit analyses have limitations in the economic analysis of animal health management. The analysis is useful for evaluating an investment when the returns, the investments, or both are spread over time. However, it does not indicate whether the investment being appraised was a sensible choice in the first place (Howe, 1988). When the veterinarian and the producer consider various options for the control of a specific disease, they are making choices. In a broader context, however, economics is also equipped to help identify a preferred option from all the possibilities for resource use. A comprehensive economic appraisal to support a policy decision should at least consider the consequences if other diseases remain uncontrolled as a result, or if resources for the control of other diseases are reduced. Thus the opportunity costs from allowing one course of action rather than another (e.g., vaccinate the animals or buy a new high-pressure sprayer for cleaning) must be taken into account. Cost-benefit analysis usually begins from the position that an objective, such as controlling a given disease, has already been determined, but it is important to be aware that the decision about whether the objective is worthwhile at all when compared with the alternatives has been preempted. In other words it is not a means for identifying the optimum or most efficient course of action.

The veterinarian must consider that there are circumstances in which disease can be controlled without the use of veterinary resources. Whenever disease can be controlled by more than one method, rational producers are expected to aim for the cheapest combination of methods possible for any given level of output. At one end of the scale, dependence on veterinary input is effective in keeping the incidence of disease at low levels. At the other end, the use of veterinary services can be minimized by adoption of the principles of disease control and by using all available resources more effectively. Between the two extremes, it may be possible to manage health and production by various combinations of veterinary and nonveterinary resources. That level should be the lowest cost combination of resources that should be sought; this is difficult if not impossible to identify by cost-benefit analysis.

Veterinary medical economics are presented in Chapter 2.

Aids to Management

An established operative herd health program with a reliable records system automatically leads to the development of several useful aids to management. In other words the program helps the producer organize the management of health and production. These management aids have been most successful in dairy and swine herds. One example is the development of action lists, which assist the producer in identifying when certain events occur or in determining which actions must be taken with particular animals. These animals are highlighted by the records system, which prompts the producer to perform the action when necessary. Some examples in a dairy herd include the identification of cows for reproductive tract examination (pregnancy diagnosis, postpartum examination, or infertility); the use of prostaglandins in postpartum dairy cows; cows to be dried off; cows due to calve; cows to be culled; an improved heat detection system using heat detection aids; cows for mastitis examination and the regular use of diagnostic tests, such as the California mastitis test; and cows to be examined because of a history of clinical disease.

Other aids to management include predictions of calving pattern, regular assessment of nutritional status of the animals and feed requirements, automatic milking parlor data recording systems, and cash flow. There are similar examples of aids to management in swine herds, beef feedlots, beef cow-calf herds, and sheep flocks. The central theme is that a health management program involves a system that alerts the producer automatically to pay more attention to the various points in the production cycle at which certain procedures need to be performed and when.

Continuous Assessment of the Farming Unit

The herd health program can be regarded as a recurring assessment of the farming unit as a functioning unit. The assessment can be used at any time as a check on the efficiency of a manager, herdsman, or business partner. The manager or managing partner can also use the assessment as justification for a change in shares in the proceeds. For a banker, investor, buyer, or seller, an annual report can provide evidence of biological and managerial efficiency to supplement a financial statement of profit and loss. In extension exercises, field days, producers' discussion groups, and meetings, the information provided in annual and monthly reports is most valuable because of the accuracy and local origin of the data.

Efficient Use of Rural Veterinary Practitioners

Rural veterinary practices have participated in governmental disease regulatory work on a fee-for-service basis for many years. The government benefited by being able to extend its surveillance and eradication programs. By using practitioners as part-time and casual employees, the government was able to remain flexible and relatively uncommitted for a significant segment of its work. Veterinary practices benefited by an improvement in their financial viability, partly because of added income but largely because the regulatory work could be programmed during parts of the year when emergency work was at a low level and practitioners tended to be underemployed. Eradication programs for brucellosis and tuberculosis provided most of this regulatory work for veterinarians. The success of these programs has brought about a marked reduction in the volume of this work available to practitioners and in the regular income that it used to provide. In veterinary practices in which work is seasonally distributed, such as beef cow-calf practice with the peak at the time of calving, herd health programs are a suitable alternative to governmental regulatory work. The reproductive program on which they are based is busiest in the slow season for emergency work.

Progressive and successful producers are able to integrate

Downloaded From Vet-eBooks.com

the information and advice that they receive from various sources and to make the appropriate decisions themselves. However, many other producers do not have this capability. Thus an opportunity was created for veterinarians to provide producers with a list of health management options, rank the alternatives, and recommend the best solution after making an objective evaluation of the herd using all the information available.

Veterinarians are situated in the advisory support system of livestock producers so that they are the most strategically placed to ensure that integration exists among the components of management.

FACTORS AFFECTING DEVELOPMENT OF HERD HEALTH PROGRAMS

Several factors have slowed progress toward the widespread adoption of effective health and production management techniques by producers and have retarded the delivery and marketing of those techniques by veterinarians to producers. Many producers are familiar with the economic consequences of clinical disease in animals but do not fully appreciate the existence of subclinical disease. Often they do not recognize that subclinical disease can impair productivity and, on a herd basis, can be a greater source of economic loss than clinical disease. They are also not fully aware of the economic returns that are possible by monitoring animal health and production accurately on a herd basis and by taking positive action to improve performance of the herd. Traditionally, producers were willing to pay for emergency veterinary services on individual, clinically ill animals. However, many producers and farm managers are still reluctant to pay for veterinary advice on health management and production when the results are not immediately obvious. Interviews with large-scale dairy farm operators have indicated that they perceive veterinarians only as primary providers of clinical services. Large dairy farms require an integrated approach to herd management, but the operators have not consulted historically with veterinarians for such comprehensive production-oriented management advice. Instead, they have employed the services of agribusiness industry representatives, including graduate agronomists, animal nutritionists, agricultural engineers, accountants, and other professional agrologists for advice on management and production, with emphasis on economics and how to reduce the costs of production.

Competence of Veterinarians

It has been suggested that there is a shortage of food animal practitioners who can provide profitable veterinary services to primary livestock producers. It is thought that this shortage may continue because of the shortage of adequately prepared graduates. "Food animal veterinary practice serves food animal producers and consumers and must respond to the forces that influence the clientele it serves" (Leman, 1988). Food animal practitioners need to be more knowledgeable in the areas of health, information, and farm management and must be effective communicators and good problem solvers. If they do not have these skills, herd health programs cannot be developed.

Veterinarians generally have few conflicts, with no vested interest, when giving advice about nutrition, proper facility design, and other general management issues. Thus this perception of the veterinarian as a clinician only deprives the dairy operator of an objective, integrated appraisal of herd health, management, and production. Changing this perception requires a restructuring of the curricula of many veterinary medical schools. The emphasis needs to be on courses in clinical epidemiology, health management on a herd basis, nutrition, and veterinary economics (Pritchard, 1989b). The general college education of the veterinary student should first provide a broad understanding of people, the natural and social sciences and the humanities, personal skills in communication, and the opportunity to pursue scholarly activities in areas of special interest. The professional veterinary curriculum should enable students to acquire the core of biomedical and veterinary knowledge, skills, values, behaviors, and attitudes that are essential to all veterinarians. In addition, entry-level clinical skills with at least one class of animals or species are of utmost importance. The veterinary curriculum should include equal emphasis on health and disease and on individual and population approaches to disease prevention and control; they should provide clinical experience in the care, husbandry, and management of the various animal species, as well as the management of disease (Pritchard, 1989b). Teaching strategies and methods should emphasize the development of the ability to find and use information rather than the accumulation of information as the primary objective of the professional curriculum. High priority should be placed on the acquisition of skills, behaviors, and attitudes that can motivate graduates to continue to learn and develop their competence throughout their professional lives (Leman, 1988).

The perception by the producer that veterinarians are not production oriented has been one of the constraints of more widespread employment of veterinarians as health management advisors. Much of the gain in preventive veterinary medicine in the recent past has occurred because of a change in the attitude of farmers toward a more financially conscious appraisal of their activities than they applied previously. Some of the change has been the result of better education generally, but primarily it has been an appreciation of the need to maintain a sufficient margin between costs and income in order to enhance their standard of living or simply to service their large financial commitments. Cost-effectiveness and benefit-cost analysis have become the important yardsticks, rather than winning at cattle fairs and shows or topping the prices at fat stock shows or wool sales. When this attitude about economic viability is applied to health and productivity, there is a tendency for technical services and advice to be used more to the mutual advantage of the service and the farmer. The trend toward the greater use of advisory services has been followed by a generally significant improvement in the standards of animal management and farming. This trend has been assisted by the disappearance of many inefficient farms, brought about by the cost-efficiency squeeze. In some areas the surviving farms absorb the others, and farm sizes have increased. In general, the larger the farm, the more demand there is for advice on the prevention of loss and for the development of planned health management programs.

Goals and Values of Producers

The goals and values of producers have been responsible for some of the slow growth of herd health. An analysis of the goals and values of a cross section of British farmers revealed that the smaller farmers place more stress on intrinsic aspects of work, particularly independence. Farmers with larger businesses, however, are more economically motivated and are more likely to seek and consider consultants' advice about health and production management.

The personal characteristics and attitudes of producers also influence livestock performance (Tarabla and Dodd, 1990). Favorable attitudes toward credit and risk, those who actively seek new information, good household structure, and high level of participation in voluntary farm organiza-

Downloaded From Vet-e-Books.com

tions have all been reported to influence farm performance positively (Tarabla and Dodd, 1990). In dairy herds a positive attitude toward milking was inversely related to SCCs and positively associated with milk production. This suggests that a positive attitude toward the correct application of management procedures is beneficial. A producer who is aware of and can understand subclinical mastitis is more likely to implement control measures that can influence herd cell counts and butterfat production. Educational efforts have been effective in implementing mastitis control procedures in commercial dairy herds.

Livestock producers have a high degree of confidence in their own knowledge and ability. They have typically had a lifetime of practical experience in addition to a college degree in animal science or agriculture. Producers commonly consider themselves the single best all-around source of information for making decisions affecting their farm (Straw, 1997; Wise, 1988d). Straw (1997) said, "Veterinary practice encompasses the art of dealing with people, the science of medicine, and the politics of combining professional ethics with business necessities." Producers are not an "easy sell."

The producer's attitudes and management practices influence livestock performance (Bigras-Poulin et al, 1984a,b). Some producers comply with certain recommendations regarding disease control that seem to be ignored by others, yet others do not keep records or, if they do keep them, may not use them. Interactions among attitudes and management practices suggest that attitudes act as effect modifiers on the relationship of management practices to herd performance (Bigras-Poulin et al, 1984a,b). This suggests that attitudes should be measured and considered before proposing management practices to improve performance. The level of compliance is a major factor affecting the development and success of herd health programs.

Record-Keeping System

Another important factor affecting the rate of development and the success of herd health programs has been the lack of reliable health management records that can be analyzed regularly. The success of a herd health program depends on the competence and enthusiasm of the veterinarian, the management expertise of the producer, and the ability of the program to demonstrate progress through improved performance. Only the records can help to document improved, cost-effective performance. When reliable records are lacking or cannot be analyzed easily, the veterinarian cannot demonstrate to the producer that progress has been made. With no clear evidence of progress, the producer may become disinterested in the program.

Economic Value of Animals

The economic value of the animal can influence the development of herd health. As the value increases, the need to reduce the risk of loss of the individual or its productive capacity increases. As the value of food-producing animals continues to increase, the need for diagnosis and treatment of individual sick animals increases. At the other extreme, when the economic value of animals is low, such as beef cattle and wool sheep, the treatment of individual animals is given low priority. There is a tendency for animal husbandry and management to be considered more important than specific health maintenance programs. The emphasis is on nutrition and reproductive performance. Disease control strategies, such as those for internal parasites, blowfly infestation, and footrot, are developed for application to all farms in the area rather than adapted to suit the circumstances or resources of a particular farm. For these reasons, planned health management programs for wool sheep and, to a lesser extent, for range cattle tend to emphasize production, with less emphasis on disease control. The opposite is the case in dairy cattle herds, in which both the capital value and the potential worth of the productivity of individual animals are high. Thus maximum veterinary intervention is usually requested. The risk of disease losses and the need for veterinary supervision are even greater in the large, factory-type farming units that are common in most developed countries (Watson, 1980).

Emergency Individual Animal Medicine

Emergency veterinary medicine and the revenue from the sales of drugs and vaccines have accounted for a large part of the gross and net revenues in well-established rural veterinary practices. In part, these revenues have contributed to the slow growth of herd health in some areas. In a study of the U.S. market for food animal veterinary medical services, approximately 62% of the veterinarian's revenue was attributable to professional services and 38% to veterinary product sales (Wise, 1988a,b). As long as veterinarians are making a good living from emergency veterinary medicine and prescribing and dispensing animal health supplies, there is little incentive to develop herd health programs. The fact that emergency work is satisfying to some veterinarians and producers has further slowed progress.

Uncontrollable Factors

Health management programs may be affected by uncontrollable factors such as feed supplies, the market value of livestock, the prevalence of disease in the herd, and the diagnostic laboratory services available to the veterinarian. Large fluctuations in the supply of feed can cause major disruptions in performance. A marked decline in the market price of livestock can force farmers to invest scarce resources elsewhere on the farm. A sudden, unexpected epidemic of an infectious disease can cause large economic losses, and the farmer may lose confidence in the veterinarian's ability to control disease.

Successful Health Management Veterinary Service

Some veterinarians may lack the experience and confidence necessary to provide a comprehensive animal health service that includes investigations of the nutritional status of the herd, housing requirements, reproductive performance, and other production-oriented aspects of the herd. However, veterinarians who give high priority to herd health can quickly develop a reputation as herd health specialists who can provide an integrated, production-oriented, preventive veterinary service. A busy veterinary practice can also schedule herd health work during those periods of the year when there is insufficient emergency work to support the practice staff financially. In this way the work can be balanced throughout the year.

The following factors are important in the provision of a full health management program to a livestock producer (Esslemont, 1995):

- Develop an enthusiasm.
- Become an expert in the service being provided both in veterinary matters and in communication.
- Learn the operation of the computerized recording system on a few pilot herds.
- Use those herds with which the producer is fully cooperative.
- Establish and record the farm background, objectives, tar-

Downloaded From Vet-eBooks.com

gets, aspirations, farm staff, and limiting factors.
- Understand the financial constraints of the farm.
- Be aware of and know who else is advising the farmer.
- Determine the daily operation of the farm using a checklist of every production procedure on the farm.

THEME OF THIS BOOK

The theme of this book is that the most important objective of food-producing animal veterinary practice is the maintenance and improvement of the efficiency of livestock production by the management of animal health. This involves several different but related activities and responsibilities, including the following:

- Providing the most cost-efficient method of diagnosis and treatment of sick and injured animals and returning them to an economically productive status, or to a point at which slaughter for salvage is possible, in the shortest time possible.
- Monitoring animal health and production of the herd on a regular basis so that actual performance can be compared with targets of performance; then the reasons for shortfalls in production or increases in the incidence of disease can be identified as soon as possible, so that appropriate and cost-effective action can be taken.
- Recommending specific, preventive veterinary programs for diseases that are risks in a particular environment.
- Setting up planned health management programs for individual farms, with the objective of maintaining optimum productivity through animal health management.
- Advising on nutrition, breeding, and general management practices.
- Encouraging livestock producers to maintain standards of animal welfare that comply with the views of the community.
- Promoting management practices to ensure that meat and milk are free of biological and chemical agents that can cause disease in humans.

CHAPTER 2

Quantitative Tools for Production-Oriented Veterinarians

BARRETT D. SLENNING

WHY BOTHER WITH THIS NUMBERS STUFF?

Most veterinarians enter the field because they enjoy working with animals and seem to do pretty well with the curriculum's emphasis on the basic sciences and the biological bent of physiology, anatomy, medicine, and related subjects. Had their main enjoyment been with mathematics, they would have become engineers, accountants, or statisticians. In fact, most practitioners dislike messing with numbers—balancing checkbooks, doing taxes, or putting together budgets—because it all seems so tedious, dry, and uninviting. For the most part that perspective is correct; mathematics does not have a lot of warm, fuzzy rewards to it. Of course, there is not a lot of excitement and joy in digging holes in the ground or cutting up pieces of wood, either. Yet dirt must be moved in order to garden, and wood must be cut in order to build a deck, so many people spend their weekends happily digging holes and cutting up wood. The same is true for number crunching; for production consultants, applied mathematics is a means to an end, not an end in and of itself. The numbers are worth bothering about if the end is a worthwhile one—and it certainly is.

The end most practitioners in production medicine attempt to achieve is the clients' better management of their animals in a consistently improving manner, so that they can reach their own goals of animal welfare, pride, profit, peer recognition, and financial stability. The old adage in business schools, "If you can't measure it, you can't manage it," applies to production medicine, for without some means of measuring health and productivity, there is no way to determine if the client's animals are benefitting. However, just knowing that clients' cows are producing more milk, or that their piglets are gaining more weight, is also not enough. A few decades ago practitioners could (or thought they could) justify their existence solely through biological arguments. They could run cultures and sensitivities to help a client decide which antimicrobial was the best for a certain bacterial pathogen. They could run serologies and help a client select the best set of vaccines to protect a herd. Those are biological arguments, pure and simple. But clients live not only in a biological world; their world has economic aspects and is not nearly as clean and certain as a set of *in vitro* lab results would suggest. Hence they need recommendations justified in more than strict biological terms. Practitioners must be prepared to answer some difficult questions:

- "Okay, Doc, this new vaccine seems to be better than the one I have been using. But is it better enough to be worth the extra costs of making a change?"
- "But what if the new processing program is only half as effective as you believe it will be, Doc?"
- "If I increase the amount of feed, I increase my costs, and my lender already says my costs are too high. How can I afford to make more money if I go broke in the process?"

To address such concerns, practitioners must become conversant with some quantitative tools. They need to understand how health and productivity can be measured and monitored and how to identify differences among groups of animals (epidemiology and statistics). They must be able to make sense of the uncertainty inherent in their information sources for making decisions and find ways to help clients put these factors together to make decisions about managing their farms (diagnostic test evaluation and decision theory). Practitioners need to have the skills to correlate significant health events and procedures with financial outcomes (economics). They must be able to dig through the literature to identify the nuggets of applicable and relevant information that exist (critical evaluation of the literature). Some of these topics are inherently quantitative, and others are only partly so. However, in total, they represent a set of analytical tools by which a production medicine veterinarian can influence the health of entire herds while attending to the financial well-being of the farms that own the herds.

This chapter introduces the aforementioned skills. "Epidemiological Considerations and Definitions" brings everybody up to speed with the jargon. "Statistics for Practitioners" looks at simple in-the-field techniques as well as more complex computer-based methods. "Diagnostic Test Evaluation" goes beyond merely reading test results to actually interpreting them. The "Economics" section presents some basic techniques in economics, from cost accounting through decision criteria. Much of this information comes together in the "Decision Therapy and Methods" section, in which I outline ways to help establish valid means of working through the uncertainties and outcome values derived from different courses of action. Finally, "Evaluating the Literature" briefly discusses issues of literature review, specifically where the literature is economic in nature.

EPIDEMIOLOGICAL CONSIDERATIONS AND DEFINITIONS

Overview

Epidemiology is the fundamental discipline involved with the study and measurement of health patterns over populations (Schwabe et al, 1977; Martin et al, 1987). Technically speaking, "epidemiology" is the study of health in humans. The branch that looks at health in animal populations is actually "epizootiology." Specific terms are used when focusing on birds ("epiornithology") and fish ("epiichthyology") (Martin et al, 1987), and terms exist for other species as well. For most of us, though, the only time these last three terms are of value is when we wish to be excruciatingly irritating to people at cocktail parties or seminars. Thus "epidemiology" is used in this chapter as the generic term for the study of health and disease over populations of any type of animal, human or otherwise.

Epidemiology is a process-oriented discipline. As with the earlier hole-digging analogy, epidemiology is a means to an end, not an end in and of itself. Being process oriented, it

Downloaded From Vet-eBooks.com

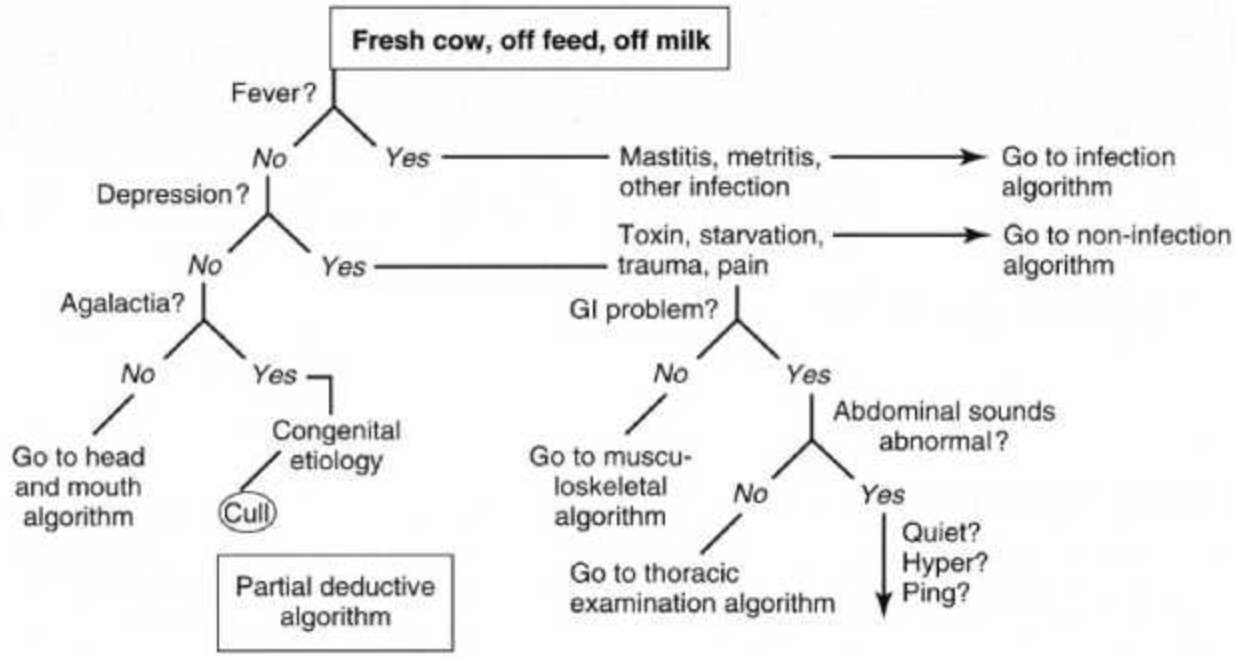

FIG. 2-1 Example of a diagnostic algorithm that could be used in a deductive process to diagnose a disease in an individual animal.

provides the practitioner with a conceptual "lens" through which to view the world and a formal set of tools by which some sense of that world can be made. The first lens-like aspect of epidemiology deals with how disease is approached differently when populations, as opposed to individuals, are discussed. This perspective affects what are seen as reasonable causes of ill thrift, what are determined to be possible avenues to ameliorate the problem, and the risk of failing to get back the costs of treatment. The second interpretive aspect of epidemiology can be considered in two parts: descriptive and analytical epidemiology. Descriptive epidemiology attempts to define the situations surrounding a disease event. Analytical epidemiology attempts to compare groups with and without disease. While they have different goals, they share many tools. The next section looks at how disease differs in the individual versus population perspective, and subsequent sections address the descriptive and analytical aspects of epidemiology.

Disease in Individuals Versus Groups

With a group perspective, the unit of interest becomes the group and not the individual. Because of this, it can become unclear in what is meant when a herd is or is not considered "infected" with a disease.

Infection can mean that at least one animal in the herd or group has evidence of the disease. This definition is usually reserved for diseases that are highly contagious to humans (brucellosis or tuberculosis) or other animals (equine infectious anemia), or for diseases that have, as their major impact, problems with import-export and animal movement. Examples of these are bluetongue and bovine leukosis in cattle, venereal diseases in nearly all species, and some respiratory virus infections for show animals. The lack of infection, or calling a herd "clean" in these situations, requires the demonstration of *no* evidence of disease in the herd.

In addition, infection can mean that the prevalence of the disease is above some threshold level. The threshold is often taken from a local or regional "expected level" or from an estimate of when a problem reaches economic significance. As an example of the latter, dairy herds with only occasional identifications of mastitis pathogens such as *Streptococcus agalactiae* are often considered "free" from an operational point of view. To be at such a low level, the herd is considered to be presumptively practicing good sanitation; risk of a blow-up is small. Chasing down the "last Strep cow" is not considered worth the time, effort, and money. A herd can be considered "negative" for these types of disease with evidence that the diseases do not exist, or at least exist below some established threshold level.

Disease Diagnosis in Individuals Versus Populations

Diagnosis in Individuals: Deductive

Diagnosis in individuals is deductive (i.e., goes from general signs to specific etiologies [causation]). When faced with an ill individual, the practitioner begins by making a list of "normal" comparisons (i.e., temperature, pulse, respiration, attitude). Each "abnormality" is a clue to the cause of the illness. Often a deductive process can be depicted as an algorithm, or series of questions. The answer to each question takes the examiner down an increasingly branching decision process as illustrated in Fig. 2-1.

In most cases the veterinarian can *deduce* the disease causation, or at least narrow it to a couple of choices, from the list of signs and symptoms. Hence, a cow as illustrated in Fig. 2-1, seen within the first few weeks of lactation and with poor appetite, gastrointestinal disturbances, poor attitude, and an audible "ping" in the left side of the abdomen, is very likely to have a left-side displaced abomasum.

Diagnosis in Herds or Groups: Inductive

Diagnosis in herds or groups is inductive (i.e., goes from specifics in a few individuals to generalities about the group). When a herd is performing at less-than-desired levels, the signs are rarely precise (Fig. 2-2). Again, in a dairy, the signs may be chronic milk loss and thin cows. All of the possible things causing those two signs could be listed, but the exercise would seem worthless after about 15 pages of data.

The four basics should be identified: who, what, when, and where. *Who* tells which animals are involved (young versus old, high producers versus low producers). *What* tells how the problem is signified (i.e., *what's* happening to *who*). Answering *when* the problem occurs (age, stage of production,

Downloaded from Vet-e-Books.com

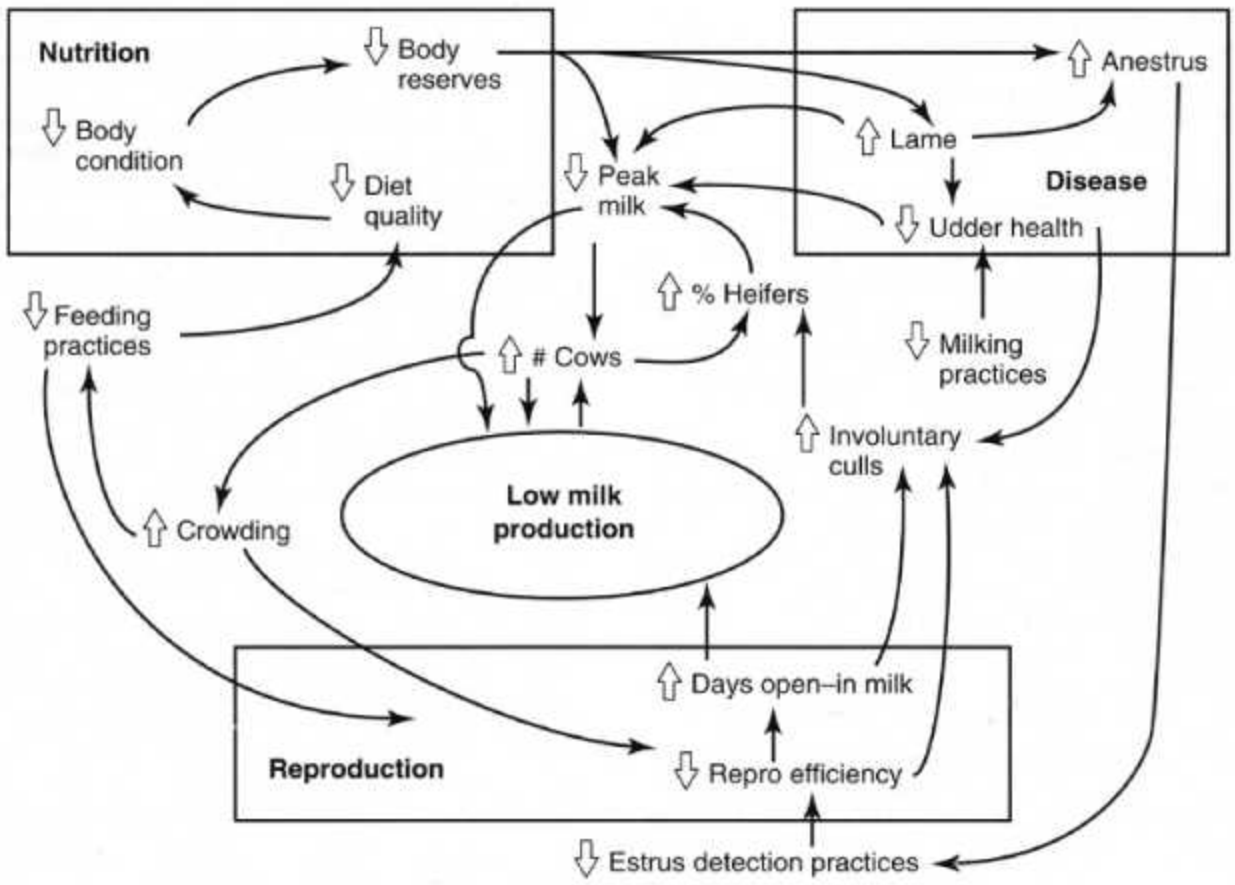

FIG. 2-2 Depiction of hypothetical low milk situation on a dairy farm with multiple factors affecting the problem in a network that is not amenable to a deductive algorithm for solution.

season, day of the week) helps to identify the dynamics of the process. *Where* the problem is most apt to occur (i.e., which pen, house, or farm) also offers clues into the type of transmission and etiology.

Is This "Individual Versus Population" Thing Going Anywhere?

Comparing disease definition and diagnosis for individuals versus populations leads to the realization that either model can color the perspective of what is happening and therefore what can be done. For instance, an exclusively individual animal focus would frame a question as, "What caused these cases to occur?" A population focus, however, might look at the same incident and ask, "What causes such a high number of cases in this herd?" On first reading, the difference might be considered purely semantic, but it is not. The individual perspective is looking for mechanisms, and therefore treatments, to affect high-risk individuals. The population perspective looks to shift the population's distribution of risk.

For example, in a situation in which a sheep flock was losing lambs to neonatal diarrheas, the individual perspective would focus on the sick lambs, find they had low plasma proteins, and interpret this as failure of passive transfer. Plasma transfusions or forced colostrum feedings might be instituted to decrease the likelihood of disease for high-risk lambings. The population focus, on the other hand, might concentrate on the lambing shed sanitation or prelambing ewe nutrition, attempting to improve hygiene and health for all the animals and thereby decreasing the incidence of disease across the flock. Of course, few people would actually look at a problem in only individual or population terms, but the example serves the point: How a problem is viewed influences how the tools that affect that problem are viewed.

This "individual versus population" perspective matters in terms of risk and level of reasonable investment. The individual focus places all the investment (time, effort, money, management) in the individual animal (i.e., only one animal benefits by a treatment); therefore the returns on that investment must be produced by that individual. If the required investment is greater than a reasonable expectation of what the animal could produce, the rational choice is to avoid making the investment. Further, placing all the responsibility for those returns on one individual also means that investment is lost if the individual is lost. The population focus, on the other hand, places the investment on the entire flock (i.e., each lamb born benefits from the treatment), so the needed return is carried by the whole flock (Galligan et al, 1993). Spreading the responsibility to more than one animal for paying back the investment reduces the risk that the debt will not be met.

Some segments of veterinary medicine are still almost exclusively in the individual-orientation camp (companion animal practice, for instance), whereas other segments have gone almost entirely to the population-orientation perspective (wildlife, aquaculture, poultry). Most of animal agriculture finds itself somewhere between the extremes, making it easy to forget to look at problems in both ways.

Data Types: Qualitative and Quantitative

Data are numbers—weights, counts, heights, speed—that are collected so that decisions can be made on normalcy of an animal or group of animals. Data alone are of little use. Only after they have been collated, and maybe transformed and organized, are they converted into information. As stated earlier, epidemiology is process oriented. Those processes are intended to turn data into information.

Data are classified into three general categories that are not always cleanly differentiable. The type of data used is important because different analytic techniques are appropriate for the different types of data. The two

Downloaded From Vet-eBooks.com

broad categories for data are either *qualitative data* (categories and ranks) or *quantitative data* (counts and continuous measures). A special case—*dichotomous data*—is discussed at the end of this section.

Qualitative Data

Also known as categorical or class data, qualitative data are generated when a variable or process can be grouped only into certain distinct classes or categories (hence the term *categorical*). The categories that are simply names are called *nominal data*. The categories that depict an inherent ordering among categories are called *ordinal data*.

Qualitative Data Type 1: Nominal Data. Classes such as animal breed or sex are nominal. They are names. Ranking Angus over Holstein over Zebu over Brown Swiss makes no sense. Likewise, the labels "gilt," "sow," and "boar" form a nominal classification. The quick test to check whether nominal data are being used is to change the names to something unrelated and see if information has been lost. For instance, if the "gilt," "sow," and "boar" set of classes was changed to "apple," "fork," and "shoe," nothing has been lost. The new names still differentiate the groups. Granted, "gilt," "sow," and "boar" are recognized as being swine, but changing them did not affect any ordering or ranking inherent in the class names. They are, therefore, nominal data.

Nominal data can be described as only frequencies, percentages, or counts. Averages mean nothing; saying the average animal is three fourths steer and one fourth cow is meaningless. However, saying a 1000-head farrow to finish hog farm has 25% sows, 15% gilts, 50% growing-finishing pigs, and 10% boars makes sense. Some statistical tests are designed to work with frequencies and percentages.

Qualitative Data Type 2: Ordinal Data. Qualitative categories may have an innate order or ranking quality to them. For instance, the following show an ordering tendency: beef cattle frame rankings of 1, 2, and 3; California Mastitis Test findings of negative, trace, 1, 2, and 3; and bird age classes such as poult, juvenile, and mature. However, there is no claim that a cattle frame size of 4 has twice the "frame" of a 2 or that the age difference from poult to juvenile is the same as the difference from juvenile to mature.

This is the distinction between ordinal data and true quantitative data: The ranks simply allow practitioners to "line up" the data points. No information exists on the relative distances between ranks. The quick way to see if ordinal data are being used is to change the classifications to "tiny," "small," "medium," and "big"—or any other series of descriptors (hot to cold, light to heavy)—and see if information has been lost. For instance, Dairy Herd Improvement Association (DHIA) records are often reported for cow age classes of "lactation one," "lactation two," and "lactations three and higher." If simple names such as "apple," "fork," and "shoe," were assigned, as used before for nominal data, the inherent ranking of lactation number would be lost. However, if they are called "young," "middle," and "adult," the ordering is maintained. This makes the classification ordinal in nature. Ordinal data can be reduced to nominal data, for instance, by describing birds by type of vaccine used (i.e., vaccine A versus vaccine B) and thereby removing the ranking information contained in measures of age category.

Ordinal data can be described as frequencies, percentages, and counts. Some *nonparametric* statistical procedures also exist that allow working with ordinal data and getting more information out of them than from nominal data.

Quantitative Data

Quantitative data are also known as *continuous* or *interval* data. The main characteristic of this class of data is that the thing being measured ostensibly could be measured always in a more exact manner; it is plausible to describe something as being partway between two classes. For instance, in agriculture the ages of females are often recorded as their age, in years, at the most recent parturition. In a goat herd, a set of five does could be listed as being 3, 3, 4, 6, and 7 years old. Had a more refined or precise measure been chosen, such as months of age at most recent parturition, those same five does might be listed as having ages of 22, 27, 46, 78, and 89 months. Technically, the animals' age could be measured in days (i.e., the oldest doe turned out to be 2719 days old at her last kidding) yet reported in years, thus giving a value such as 7.45 years or even 7.448219178082 years. It does not matter if the extra precision is useful (knowing a goat's age to 12 decimal places is of doubtful help), but it is plausible. In addition, the individual indices, such as 1, 2, or 3 years, must represent the same interval or distance for data to be quantitative. Therefore a goat that is 3 years old is considered equidistant in age from a 2-year-old and a 4-year-old. With equal intervals a calculation of average age of 4.6 years for the does previously mentioned makes sense. Doing this with DHIA parity ages would be an error. Whereas parity 2 animals indeed have had twice the parturitions as parity 1 animals, the fact that all animals parity 3 and higher together are combined makes this noncontinuous, and therefore an average would be in error. This equal interval quality makes continuous data different from ordinal data.

A special case of interval data is called *ratio* data. The added quality here is that there is, besides the ordering and distance properties of interval data, a meaningful zero point (meaningful in that a zero means the absence of the characteristic in question). Although the two commonly used temperature scales have a zero level, that zero is defined by convention, not as the absolute absence of heat. In both the Celsius and Fahrenheit systems, absence of heat occurs well below the designated "zero" point. The Kelvin temperature scale, on the other hand, has a meaningful zero point, since it is defined as the absence of energy. Therefore Celsius and Fahrenheit temperatures are not ratio scales, but Kelvin temperatures are. Measures based on counting, weight, age, and distance are ratio scales because a zero weight-age-height has meaning. In an interval (nonratio) scale relative magnitudes of difference must be described carefully because the "zero" level does not describe the absence of the character under investigation. Therefore a beaker of water at 80° C should not be described as being "twice as hot" as a beaker of water at 40° C. However, going back to the goat herd example, it makes sense to claim that an 8-year-old doe is twice the age of a 4-year-old doe.

Continuous data can be reduced to ordinal data or to nominal data. This is done all the time. Practitioners may measure pounds (or kilograms) of pig sold per sow per year (a continuous variable) yet run an analysis of average piglet weight gains by categorizing the females into "low producers," "moderate producers," and "high producers" (creating ordinal data) instead of by actual pounds of pig weaned per year. Also, the sow herd can be divided into family or genetic groups, making the classification a nominal category.

Continuous data can be subjected to the full armamentarium of statistical processes for description and analysis. The only thing that limits this is the distribution the data take, for most statistical tools make assumptions about the underlying distribution of the data being evaluated.

Qualitative or Quantitative: Dichotomous Data

A dichotomous variable has only two classes, such as yes-no, success-failure, or male-female. Some dichotomies are based on a natural ordering or preference. For instance, passing an examination is usually preferable to failing it. However, many dichotomies, such as gender, offer no natural reason for claiming an inherent ordering. Nonetheless, because there are two and only two categories, dichotomous data can be treated as ordinal, at least. Although a ranking may not be inherent, ranking female before male or male before female satisfies the mathematical requirements for ordinal data. In addition, since only one interval is to be managed, dichotomous data can be mathematically treated as interval data—even though the outcome may not make much logical or physical sense (i.e., average gender in a sheep flock may be 0.95 if the dichotomy were male = 0, female = 1, and the flock had 20 ewes for each ram). Hence, treating dichotomous variables best entirely depends on the questions asked and the nature of the classification. The mathematics is not a limit; the logic is.

The boundaries between ordinal and continuous are not as clean as many analysts would like to think. Some measures can be argued reasonably as representing one data type or the other. For instance, if steer carcass weight is categorized in units of pounds, it is obviously continuous. However, if carcasses are classified as either "big" or "small," the measure is just as obviously ordinal. What about weight classes in 50-kg increments or in 300-kg increments? What if they are just called "above average" and "below average"? At some point, even though the basic measure is continuous, categorizations are pushed from continuous to categorical types of data.

What about body condition scores in use in several species of animals? Some workers consider them strictly ordinal, because a condition score of 2 is not half the condition of a score of 4 and because a body condition score of 2.66788 claims a level of precision that does not exist. Hence, by this argument, body condition scores form an ordinal scale, not a continuous scale. Others, however, argue that this lack of multiplication is simply a consequence of a measuring tool that does not go to zero (i.e., makes the data type interval data but not ratio data) and that the intervals of the weight differences from a score of 2 to a score of 3, 3 to 4, and 2.75 to 3.75 are actually fairly constant in the standardized systems, which makes them appropriate for interval statistics. A cursory Medline* search for the *Journal of Dairy Science* over the period from 1994 through the first half of 1999 in which the term "body condition" was used either in the title or as a keyword (and were not review articles) yielded 11 citations. Of those, one study treated body condition as a strict ordinal variable in the analysis (Duffield et al, 1999), seven articles (five separate research teams) treated body condition scores strictly as continuous-interval variables (Ferguson et al, 1994; Hady, et al, 1994; Waltner et al, 1994; Domecq et al, 1995; Flamenbaum et al, 1995; Domecq et al, 1997a,b), and three articles (three separate research teams) reported or treated body condition scores as both continuous and categorical variables in the analysis (Waltner et al, 1993; Gallo et al, 1996; Heuer et al, 1999). Hence, it appears that reasonable people (as well as journal editors and reviewers) have agreed to disagree on the true nature of body condition scores.

*Medline, PubMed, National Library of Medicine, National Institutes of Health, Washington, DC. Available at: http://www4.ncbi.nlm.nih.gov/PubMed. Accessed October 12, 2000.

The apparent contradiction just mentioned is a false contradiction. The argument is not about the measurement of relative body condition but whether the measuring tool being used to capture body condition is precise enough to form continuous data. This is the crux of the debate: At some point, the ability to precisely measure something becomes so coarse that the resulting categories simply rank individual measures but do not give sufficient information to warrant the claim that a reliable absolute difference exists between classes. The argument does not stop there. In addition, the practitioner could ask reasonably if body weight, let alone body condition, is actually an accurate measure of total body energy stores. Technically, it is one part of the equation; estimates of the proportion of that weight composed of bone, protein, fat, gut-fill, and water should be available to accurately measure changes in body energy stores. But they are not. Even though body condition scores appear to be crude proxies of a somewhat useful measure, they have turned out to be quite helpful in making decisions about cattle rations and management, despite the inability to determine the most appropriate way to define the data.

Data Distributions: Not All Data Are "Normal"

Most people assume that if something is measured on a number of individuals (milk production in cows or starting salaries for new graduate veterinarians), the numbers are going to cluster around some value and trail away fairly evenly on both sides of the cluster. This is a decent working definition of a normal distribution: the typical "bell curve." But not all measures actually come in nice, clean, normal distributions. Some cluster at a fairly low measure and have relatively long "tails" that identify a few individuals with very high values. In standard graphical depictions, these kinds of data are described as being skewed to the right—the higher values on most charts move to the right. A distribution showing a long tail at lower values is "left skewed" for similar reasons.

Fig. 2-3 depicts actual Holstein heifer heart girths measured in centimeters. This is an example of how real data can take a basically normal distribution. It is not perfect, but for 39 measures, it is about as close as can be expected. A few

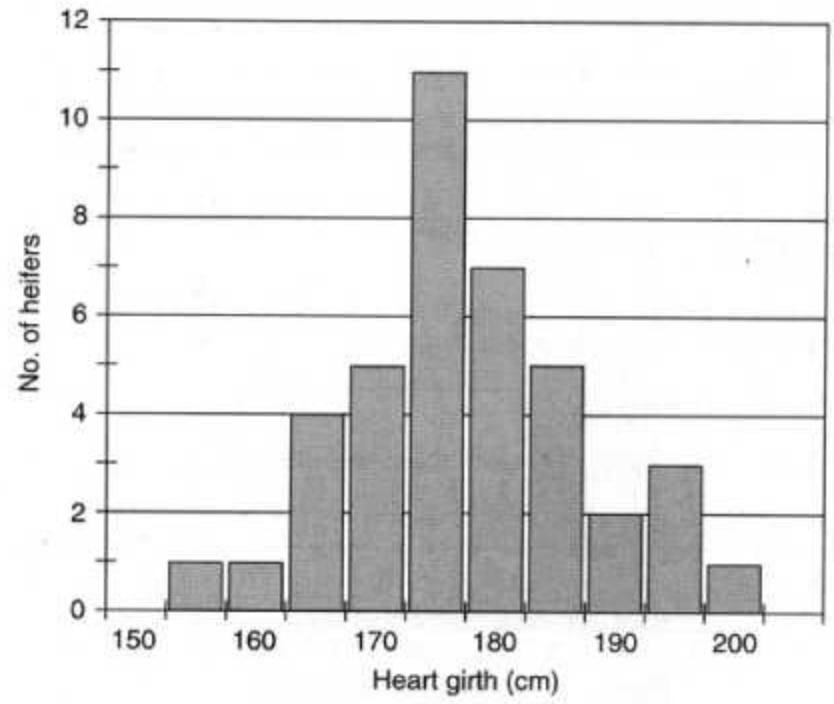

FIG. 2-3 Holstein heifer heart girths in centimeters. Example of relatively "normal" distribution from biological data. Average girth = 176 cm, standard deviation = 4.0 cm, median = 175 cm; count = 39.

Downloaded from Vet-eBooks.com

simple tests to determine whether a set of data is fairly normally distributed are as follows:

1. Mean and median are close to the same value. For the data in Fig. 2-3, the mean heart girth is 176 cm and the median is 175 cm.
2. Two standard deviations (SDs) above and below the mean do not exceed the actual distribution. For the data in Fig. 2-3, a 2 SD range beyond the mean is 156 to 196, well within the distribution's actual range of 153 to 198.

Fig. 2-4 illustrates a highly skewed data set, representing the time, in days, following weaning for a group of 671 sows to come into estrus. This is an example of "right skew" to the data. If the criteria just mentioned are used to determine whether a data set is normally distributed, this data set fails for the following reasons:

1. The mean for this data set is 28% larger than its median (6.4/5.0 = 1.28).
2. A 2 SD range above and below the mean exceeds the overall distribution (−5.4 to 18.2).

In addition, by going into negative numbers, the 2 SD range creates illogical values. Hence, with only the descriptive data, we recognize this data set is not normally distributed.

A general assumption can be made that biological data are often relatively normally distributed, whereas data in which people affect the outcome (e.g., management variables) are usually skewed. For example, Ruegg (1997) describes certain dairy data as being "often skewed" (days open, days to first service, age at first calving, somatic cell count, number of breedings) or as "usually normal" (days dry, fat corrected milk production, milk per cow per day, peak milk yield, pounds of fat or protein). Of course, this is not always true; both Figs. 2-3 and 2-4 would be considered "biological" data. When in doubt, the veterinarian should look at the data.

Other, more statistically robust, methods exist to determine if a distribution is or is not normal (Snedecor and Cochran, 1989). The terms used are *skewness,* which has been discussed in this section, and *kurtosis,* which refers to how "pointed" a distribution is; a highly kurtotic distribution shows little variability (hence, it looks very "pointed" in a graph), whereas a distribution that is not very kurtotic appears to rise and drop slowly (hence, it looks fairly flat and widely distributed). Statistical tests for skewness and kurtosis are not examined here; they are not used a great deal, and, as demonstrated in Figs. 2-3 and 2-4, often just looking at the data suffices (Altman, 1996). The reader simply should be aware that they exist so that, if uncertainty still remains, normality can be tested after the distributions are seen.

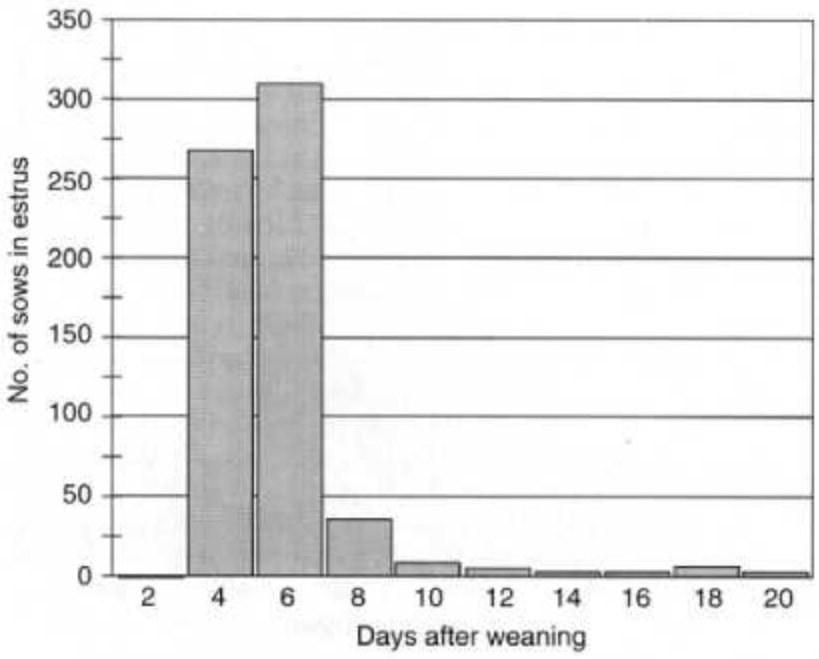

FIG. 2-4 Distribution of first estrus in sows following weaning. Example of highly skewed (right skewed) biological data. Average days to estrus = 6.4 days, standard deviation = 5.9 days, median = 5.0 days; count = 671.

RATIOS, PROPORTIONS, AND RATES

A program cannot be designed, a strategy operated, or outcomes of actions determined without measurement of the breadth and depth of a disease's hold on a population. Hence, a fundamental aspect of both the descriptive and the analytical realms of epidemiology is to quantify or measure the *occurrence of illness* in a population, for it is one of the first steps in understanding the disease being studied. Measurement of disease occurrence is an integral part of determining the impact of the disease in the population, the possible mechanisms of the spread of the disease in the population, and the possible implementation and effectiveness of any control programs.

This section looks at one of the major tools used in animal health, whether in descriptive or analytical activities: establishing occurrence of events in terms of ratios, proportions, and rates.

Ratios, Proportions, and Rates: Definition and Components

Ratios

A *ratio* is expressed as a/b (where "a" is *not* part of "b"), or "a" divided by "b," where "a" and "b" represent counts of two mutually exclusive groups. For instance, an animal cannot be both a "lactating cow" and a "steer," nor can an animal be both "diseased" and "nondiseased." When speaking about a ratio, the phrase "x *to* y" is usually used, indicating that "x" is not part of "y." A ratio is meant to relate the relative size or magnitude of the two exclusive groups. Some examples of typical ratios follow:

1. The feed conversion ratio for a swine-finishing farm is 2.4 to 1. For every 2.4 units of feed consumed, the pigs grew 1 unit. Note that a ratio need not be in similar units; the feed intake could be measured in calories of mix and pig growth as kilograms of meat marketed.
2. Of 314 piglets born in the last month, 15 were stillborn. The ratio of stillbirths to live births in the farrowing house was, therefore, 3:60, which reduces to 1:20. That is, for every 20 live piglets born in this house, 1 more was delivered dead. Again note the exclusiveness of the two frequencies; stillbirths cannot be live births.

Proportions

A *proportion* expresses a fraction in which the members of the group in the numerator (for instance, the number of animals with a disease or condition) are included in the group comprising the denominator (the population at risk). When speaking about a proportion, the phrase "x *in* y" is usually used, indicating that "x" is a part of "y." The difference between a proportion and a ratio is as follows: A ratio requires mutually exclusive categories, whereas a proportion requires one to be a subset of the other. A proportion cannot take on a value less than 0 or greater than 1, and it may be multiplied by 100 to give a percentage.

A proportion can be converted into a ratio (or vice versa) by subtracting the numerator from the denominator (or the reverse). However, this does not always make sense. For instance, in the pig feed conversion example just mentioned,

Downloaded from Vet-e-Books.com

combining feed intake calories with kilograms of marketed meat makes no sense. Typical proportions might be as follows:

1. The proportion of bulls in a cow-calf herd is 4/64 (i.e., 4 bulls out of a herd of 60 cows and 4 bulls), or 0.063. Multiplying this by 100 gives the percentage of bulls in this herd: 6.3%.
2. Of 26 mastitis cases on a dairy, 22 resulted in a full recovery, a proportion of 0.846. Therefore the percentage of mastitis cases that were "cured" was 84.6% ([22/26] × 100).

Rates

Rates are proportions that work with a specific time period. A rate shows the relationship between a group undergoing an event (e.g., disease or trauma) and a defined population at risk, both evaluated over a specified time period. The numerator is the number of affected individuals in a given time period, whereas the denominator is the population at risk over the same time period. The following could be a few typical rates:

1. In a cow-calf herd, 45 of 60 cows calved in the first 90 days of the calving season. The 90-day calving rate is 45/60, or 75%. In the terms mentioned previously, calving is the event of interest. In the given time period of 90 days, 45 animals underwent the event of calving.
2. A 2000 sow herd yielded 751 animals positive to porcine reproductive and respiratory syndrome (PRRS) on a herd test. The rate of seropositive animals on that day was 751/2000, or 38%. Here the time period is only 1 day; in fact, it is the time taken to blood-test the herd.

Rates and Ratios of Animal Health Importance

Prevalence and Incidence

Disease occurrence proportions, rates, and ratios either describe situations at a point in time (e.g., prevalence, as in the previous PRRS example) or describe events over time (e.g., incidence, as in the previous farrowing house stillbirth example above). It is easy to confuse them.

Prevalence describes what proportion of the population has the disease at one specific point in time, or the proportion of the number of cases observed compared to the population at risk at a given point of time. *Prevalence refers to all cases of disease observed at a given moment within the population at risk.* For example, suppose a veterinarian is asked to investigate a suckling calf pneumonia problem in a beef herd. The veterinarian finds 24 calves in the less-than-30-day age group on the day of the visit. Of these, 8 are showing signs of respiratory distress consistent with pneumonia. On this day in this herd, then, the prevalence of pneumonia in calves less than 1 month of age is 8/24, or 33%. Prevalence offers a "snapshot" or photograph of the disease state.

Incidence measures, on the other hand, describe the frequency of new cases that occur during a specific period of time. *Incidence refers to new cases that have occurred during a specific time period for the population at risk.* For example, if a practitioner goes to a goat dairy and finds that, from last month's visit to this month's visit, 7 mastitis cases arose out of the 35-head milking herd, the monthly incidence of mastitis in the milking herd would be 7/35, or 20%. Incidence, then, offers a "movie" of the disease state.

One reason why prevalence and incidence get confused is because, essentially, prevalence depends on both the disease incidence (the "flow" of animals from one state to another) and the average duration of the disease (how long an individual remains in the diseased state). A change in prevalence may be a result of a change in either incidence or duration. For a given incidence rate, the prevalence will be higher if the duration of the disease is longer. The prevalence is affected by the mortality rate of the disease, since this affects duration. A lower prevalence results if the disease is often quickly fatal, such as in rabies. However, in a chronic disease situation such as Johne's disease, improvements in case survival due to the implementation of a new treatment protocol could end up actually *increasing* the prevalence of Johne's, even if the incidence went down!

Fig. 2-5 shows how, at equal rates of transmission, the overall disease prevalence increases in an almost counterintuitive manner with increasing duration of disease in any individual. Hence, a better, successful, disease control program may well cause the overall prevalence of that disease to go up.

In epidemiology, the study of the flow of cases from the disease-free state to the disease state is the main area of interest. This is the definition of incidence. Incidence rates, therefore, rather than prevalence, are usually preferred in epidemiological studies because prevalence does not convey the true magnitude of the disease in the study population. There are several important, standard, incidence measures: *cumulative incidence rate, incidence density rate, attack rate,* and *case fatality rate.*

Cumulative Incidence Rate (CIR). The CIR is defined as the proportion of a fixed population that becomes diseased in a stated period of time, or the proportion of healthy individuals who get the disease during a certain period. The CIR is a measure of the average risk, that is, the probability that an individual would develop disease in a specified time period.

As an example, suppose on a swine farm the practitioner followed piglets for one 6-month period—one rotation on the farm. If, during this time, 144 piglets were born, and 36 fit the case definition of neonatal diarrhea, the cumulative incidence rate of the disease over a 6-month period would be 36/144, or 25%. This does not mean that 25% of the pigs are expected to be diseased, but that a piglet born on this farm has a 25% chance of getting neonatal diarrhea in the first 6 months.

Incidence Density Rate (IDR). IDR is a measure of the speed of disease occurrence in a population. It is defined as

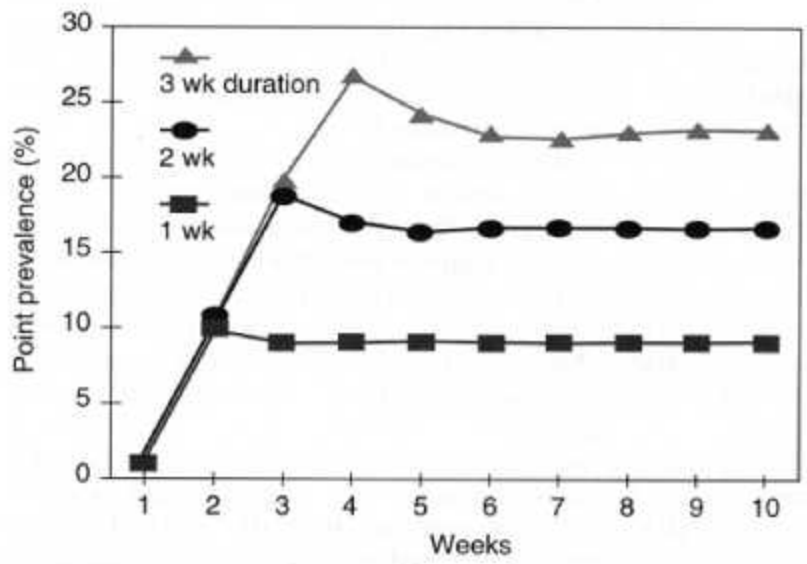

FIG. 2-5 Hypothetical model of a disease indicating how increasing the duration of clinical signs, in the face of no change in actual incidence, causes the prevalence of the disease to increase. This assumes no immunity or mortality from the disease, with a 10% incidence per week.

Downloaded From Vet-eBooks.com

the number of newly diseased individuals divided by the sum of the time periods of all individuals in the population who remain disease free. The denominator of the IDR is a combination term representing "person time," "animal time," or "population time" (animal years, calf months, piglet days, etc.); in other words, it is the sum of disease-free time for all the individuals in the population. This inclusion differentiates cumulative incidence from incidence density: *The cumulative incidence is a snapshot of the proportion of individuals affected, sort of an average risk of disease of a given period, whereas incidence density, because of its time sensitivity, yields a measure of an individual's risk, per unit time, of getting the disease within a period.*

For instance, in the swine unit mentioned previously, if the 144 piglets are followed over the first 4 weeks of life (instead of over the 6-month cycle), and none of them become sick, the denominator would be 144 × 4, or 576 piglet weeks. Half that number of piglets followed twice as long would give us the same 576 piglet weeks. So IDR can be used to follow different sized groups for differing times, and still provide comparable measures of disease risk.

The above example can be extended further. Suppose 36 piglets become ill in the first 4 weeks of life, so they could not be used in the denominator. The 108 nondiseased piglets would be fine—they contribute 4 × 108 weeks, or 432 total, to the denominator. Suppose 20 of the 36 became ill on day 10, and 16 became ill on day 18. The 20 would contribute 20 × (10/7) weeks of time (the term "10/7" is merely a way to convert 10 days into "x" weeks), and the 16 would contribute 16 × (18/7) weeks, or about 29 weeks and 41 weeks, respectively. Hence, the total piglet time in this study would be 432 + 29 + 41 weeks, or 502 total. Since 36 animals became diseased, the incidence density rate for diarrhea is 36/502, or 0.072 cases per piglet week. Over a 4-week period, then, each piglet has a 29% (4 × 0.072) chance of getting diarrhea. Table 2-1, option C, shows this calculation.

Calculations done the way just shown are a pain, to be sure. They are labor intensive and assume the farm has records that support that degree of precision. Many do not. What should be done? Estimates can be made.

Calculating Alternate Estimated IDR Population-Times. Suppose, for example, the farm previously discussed could not show with any real precision when the piglets became ill. Two methods that provide an estimate of time at risk are (1) taking a census of the population in the middle of the period and assuming that is an average weekly population, or (2) counting how many piglets existed at the start, how many existed at the end, and taking the average of those figures. Either way, those values are multiplied by the number of periods to get the estimates.

Option A in Table 2-1 shows the method of taking the middle-period census, which overestimates the incidence density by underestimating the total risk weeks. By averaging the starting and ending populations, the analyst underestimates the total incidence density by overestimating total risk weeks. In this example, neither estimate is too far removed from the actual calculation (option C). But this is not guaranteed to always happen; sometimes the estimates can be way off.

Attack Rate. Attack rate, another specific type of incidence measure, measures morbidity (illness) and is commonly used in outbreak investigations. It is calculated as the number of animals affected divided by the number of animals exposed. Attack rate is different from CIR because it looks only at the exposed group, not the whole population at risk. If calves in a veal barn have respiratory mycoplasmosis, the entire population is exposed, making the two calculations the same. However, if displaced abomasums following calving is sought, only the recently calved animals might be considered exposed, not every cow on the farm.

Here is an example of an attack rate: After 4 days of exposure to a diseased animal at a show, a group of 15 4-H steers suffered 6 cases. The attack rate would be 6/15, or 40%.

Case Fatality Rate. Case fatality rate, a specific type of incidence rate, is the proportion of affected individuals who die from the disease. In the piglet neonatal diarrhea example, if 3 of the 36 affected piglets died as a result of the diarrhea, the case fatality rate would be 3/36 = 0.083, or 8.3%. The case fatality rate is usually associated with the seriousness or virulence of the disease under study.

TABLE 2-1

*Example of Different Methods to Ascertain Incidence Density over 4 Weeks**

Time (wk)	Start Day	Start Pop	End Day	End Pop
1	1	144	7	144
2	8	144	14	124
3	15	124	21	108
4	22	108	28	108

A. Count at mid-period and multiply by number of weeks in period†

Mid-period	=	14 days		
Count at mid-period	=	124		
Count × 4 wk	=	496 total risk wk		
Incidence density	=	36/total risk wk	=	0.073
		Risk over 4 wk	=	**29.0%**

B. Take average of starting and ending counts and multiply by number of weeks†

Starting pop.	=	144		
Ending pop.	=	108		
Average pop.	=	126		
Count × 4 wk	=	504 total risk wk		
Incidence density	=	36/total risk wk	=	0.071
		Risk over 4 wk	=	**28.6%**

C. Count at risk days for all piglets and divide into number of cases†

Risk week for nondiseased	= 108 × 4	= 432
Risk week, disease @day 10	= 20 × (10/7)	= 29
Risk week, disease @day 18	= 16 × (18/7)	= 41
Total risk weeks	= Sum	= 502
Incidence density	= 36/total risk wk	= 0.072
	Risk over 4 wk	= **28.7%**

*Data: 144 piglets at start, 20 diseased on day 10, 16 diseased on day 18.

†Demonstration of three methods to calculate population time at risk for a swine neonatal diarrhea example. Options A and B are means of estimating population time at risk when the records do not allow for full accounting. Option C is the actual counting of risk.

Crude Versus Specific Ratios, Proportions, and Rates

Disease measures are often referred to as either crude or specific. *Crude* measures are derived from population totals (i.e., total animals lost, cases per year in a herd). They are relatively easy to compute and to explain and may represent the best data possible, but they ignore potentially important influences such as host or management factors. *Specific* measures approach the same topic, but they look at group breakdowns within the population (i.e., age-, sex-, or use-specific rates), limiting the view to only the special group of interest.

Crude rates should be used with care when herds or regions are compared, because for crude rates to work the underlying populations must be the same. This rarely occurs. For instance, suppose two southern U.S. dairies report cystic ovarian disease (COD) rates over the month of April. Herd A (an intensively grazed, grass-based dairy) reports a crude rate of 10%, whereas herd B (a confinement-reared dairy) reports 15%. Is herd A truly a "better" herd? Should the manager of herd B be penalized while the manager of herd A gets rewarded for their relative performance?

Suppose the grazing herd calves in late winter to take advantage of the spring grass growth, so the majority of breeding occurs in the spring. The confinement herd calves all year around to maximize its efficiency of facility and personnel use. Because of this, the majority of early breeding (i.e., without reproductive problems) animals in the breeding group for the grazing herd are accounted for in April's figures. The confinement herd, however, because of the distribution of lactation lengths through the herd, has "no problem" cows as well as "problem" cows. These are different stages of lactations and, therefore, different populations. Hence, the monthly crude figures do not tell much and could be misleading. A breakdown of the two herds by stage of lactation helps, as shown in Table 2-2.

The stage of lactation profile of each herd should be noted as greatly affecting the crude rate. Because most of the cows in the intensively grazed herd are in early lactation, the lower rate for that specific group predominates. The same group in the confinement-reared herd, however, has a lower specific rate for COD. However, since the confinement herd practices year-round calving, its lowest rate subgroup comprises only about half the total herd and has a much lower impact on the resulting crude rate.

The dissimilarity in the crude rates occurs because the unique demographic structures of the two herds confound the outcome, yielding rates that are misleading. Controlling for that demographic disparity by using specific rates allows for much better comparisons. Needless to say, when decisions are being made on where to apply program dollars and personnel, the importance of specific rates had better be recognized before effort is allocated! Two different populations exist here; crude rates should be avoided.

TABLE 2-2

*Comparison of Crude and Days-in-Milk Specific Rates for Cystic Ovarian Disease (COD) in Two Hypothetical Dairy Herds**

	Cystic Ovary Statistics (per 100 Cow Days)			
	Grazing Herd		Confinement-Reared Herd	
Days in Milk (DIM)	Count	Rate	Count	Rate
All (in April)	150	10.0%	475	15.0%
1-100	125	5.5%	238	4.1%
101-200	25	32.3%	237	25.8%

*The crude rates suggest the confinement-reared herd has nearly 50% more COD than the grazing herd. However, when stage of lactation is considered, the confinement herd can be seen to have a lower incidence of COD in both DIM categories. Therefore the grazing herd's predominance of cows in the lower DIM class gives the impression that it has fewer COD problems.

STATISTICS FOR PRACTITIONERS: HOOD-OF-THE-TRUCK FIELD TECHNIQUES AND COMPUTER-ORIENTED ADVANCED TOOLS

What Statistics Do: Some Definitions and Caveats

What Statistical Methods Do

The primary role of statistics is to document the existence and degree of difference in data. Statistics allow for separating the events in life that likely are due to chance from those events that likely are due to some action or characteristic of interest. Statistics as a discipline carries a great deal of mystique. It need not be that way.

Repeat Measures and the Unit of Interest

Assumptions in statistics should be approached carefully. Overstepping a basic assumption can invalidate a procedure. It is analogous to a practitioner allowing a set of blood tubes to sit on the dashboard of his or her vehicle for a summer day before submitting them to a lab. The laboratory assumes the specimen was handled properly; because it was not, the results will be highly questionable.

In veterinary medicine, caution should be used in instances in which *repeat measures* (i.e., using an animal as its own control) are used or in which the appropriate *unit of interest* is easily confused with another, inappropriate, factor (e.g., in a mastitis study is the "cow" or the "teat" the unit of interest?). Most statistical procedures assume that the groups being compared are independent. When repeat measures are used, they are not. Repeat measures occur when a difference in milk production on a dairy is sought after a ration is changed. The same thing is being measured, at a different time, on the same animals. Similarly, when a new vaccine is tested in two pens of 100 steers at a feedlot, and the vaccine is given to one pen but not the other, 200 separate units of interest do not exist. There are only two, because both the animals and the treatments are clustered in pens.

An *experimental unit* is the smallest independent component that could receive a separate treatment, and it often determines the smallest unit over which a study can be analyzed. Therefore, if the experimental unit (in the previous vaccine trial example, the experimental unit is the pen) groups individuals, the veterinarian cannot analyze to the individual level (McDermott, 1994). In such cases, with only one experimental unit and one control, no claim can be made regarding within-treatment variability and, hence, the statistical significance of differences observed between animals within either group.

Downloaded from Vet-eBooks.com

P-Values

The term "$P \leq .05$" is commonly used in describing the statistical significance of some finding. What does that mean? Basically, it means that a 5% chance exists that the differences described (or effect seen) could be due to entirely random variations in the data. Which level of "*P*" is best is up to the practitioner. There are a number of stories about where the infamous "$P \leq .05$" originated. I do not know which is correct, but none end with the choice being made for any scientific reason.

One way to look at statistical significance follows. Suppose two treatments are being analyzed. One is a successful standard treatment (colostrum feeding, for example), and the other is an experimental procedure (vaccinating the newborn, for example). This is truly a life-or-death situation, and the choice is to go from a successful procedure to an unknown one. In such a case, it is reasonable to require the new process to be obviously much better before the choice is made. Hence, choosing a .01 "*P*" value may be appropriate; quitting the standard treatment requires being sure the differences claimed in a research trial were not simply chance events. If, however, the choice is between two non-life-threatening processes, and the standard treatment is not that good, a much higher "*P*" value—say .1 or .2—could be chosen validly. The importance of the "*P*" value level is related to the importance of the decision.

Furthermore, the purpose should be remembered. If the work is intended to be published in *Science* or *Nature*, the practitioner had better have exceptionally low "*P*" values. Big-league academic journals tend to use them as an index of quality of work and relevance of outcomes. If, however, a decision is being made for a client, and that decision *must* be made soon, the practitioner may not be able to afford the often long time required to generate enough cases, data, or experience to get "*P*" values much below .2. A "*P*" of .2 means 80% certainty the effect is real; 4 to 1 odds are pretty good odds in real life!

Association Versus Causality

Statistics is an inferential discipline; its procedures identify associations that are not likely to be due to random chance. By no means, however, do they prove causation. Therefore small *P*-values should not be used to support the idea of causation. That is the responsibility of the understanding of the biology or flows of the situation under question. Even if a causal relationship exists, however, the statistical methods used do not explain which thing caused which. Again, this is a role for understanding of the system.

Imposing a false correlation between two variables can cause problems. For instance, when evaluating a clinic's profit, the practitioner may wish to standardize the figures by putting both income and costs on an in-clinic per square foot basis or on a per worker hour basis. This could make the resulting ratios falsely correlated (and therefore possibly show a relationship through ordered statistical processes or regressions) even if no underlying relationship existed.

Why Are Statistical Procedures So Complicated and Counterintuitive? Shortcuts and Assumptions

Anyone who is not a math wonk opening a statistics text is often immediately overwhelmed by the odd mathematics involved. All those symbols (Σ, $\surd$, n!) and Greek letters (μ, α, β, γ) combined with mind-numbing square roots, compound power functions, and multiple levels of parentheses and brackets are enough to put off anyone. But statistical procedures look that way because they are simply shortcuts. Most of the modern statistical theory developed in the late 1700s through the early twentieth century. In those times computation was expensive. In the 1890s a calculator was a human with a pencil and paper; a room of calculators was a room full of people doing nothing but arithmetic. People cost a lot to keep busy. To cut costs and make the system more time efficient, many of the early pioneers of statistical inference developed techniques that, if the underlying assumptions were true, yielded important descriptions of the data. These shortcuts became the modern set of statistical procedures for determining significance and for describing data. Like other shortcuts (such as in a complicated recipe for a soufflé), the final process or set of procedures hides much of the reasoning that went into the final product (Simon and Bruce, 1991).

All statistical tests come with assumptions—normal distributions, random selection of observations, independence of variables, to name a few—because those assumptions allow for taking advantage of the shortcuts. If those assumptions are violated, the shortcuts are handicapped. Sometimes the whole process is completely invalidated. It is analogous to the situation of running blood work. The problems inherent in mishandling blood samples are familiar; as mentioned at the start of this section, if a clot-tube is left on the dashboard of a vehicle over a summer afternoon and then submitted for a chemistry panel a few days later, the value of the results (if any are possible) will be limited. The laboratory analyses "assume" the sample was handled correctly. The laboratory can still check for glucose and liver enzymes, but if the laboratory's assumptions are violated, the outcomes are put in question. As long as the technician can shove the sample into the analytical instrument, some kind of outcome will appear; the test is ignorant of whether the assumed procedure in collection and handling was followed. The same is true for statistical processes. Plugging in numbers will lead to a result. Whether that result is meaningful depends on whether things were done correctly.

Choosing the Correct Procedure

Whereas a number of statistical procedures are feasible only when run on a big computer, and only then after a statistical consultant has organized the data, those procedures are not of much value in everyday, on-the-farm decision making. The statistical procedures demonstrated here fall into two categories:

1. Quick methods needing only pencil, paper, and a calculator, or what can be called "hood-of-the-truck" (H.O.T.) statistics. These are simple procedures requiring only that a couple of numbers be remembered. They have the potential to answer many statistical questions arising from veterinary-generated data.
2. More in-depth procedures suitable for computerized analysis. These procedures are readily available with current spreadsheet software and the many stand-alone statistics programs on the market. They tend to make more assumptions than the previous measures and require a bit more sophistication in setup and interpretation.

Data Form Determines Statistical Technique

Type of Data Determines Choice of Statistical Technique

Which statistical procedure to use and, hence, for which outcome to opt entirely depend on the type of data being used. Most veterinary data come as means with measures of variability, as counts and frequencies, or as "before and after" counts/frequencies. Each type of data has its own specialized analytical techniques.

Downloaded From Vet-e-Books.com

Data that come as *means and variability* include the following:

1. Average milk per cow per day ± 1 SD
2. Average work hours per week ± 1 SD, for large animal practitioners
3. The AI technician's average conception rate and standard deviation, over 1 year.

Data arriving as *counts or frequencies* include the following:

1. Proportion of Holsteins coming down with milk fever over a year's time
2. Percent of veterinarians with yearly net incomes greater than $60,000
3. Number of synchronized heifers responding out of a larger group

Data forming *"before and after"* measures could be as follows:

1. Herd average daily gain responses to changes in the ration
2. Client attitude scores following inception of a new in-clinic client management program
3. Rate of serological response after vaccination

"Hood Of The Truck" Statistical Methods

Rapid and Easy Statistics

This section looks at different techniques for testing differences between groups using the previous definitions of data type. The first three techniques fit the "hood of the truck" (H.O.T.) requirements. They must allow for answering a statistical question with a paper, pencil, and calculator—and allow for doing so without memorizing tables of numbers. The second group of techniques relates to more complicated procedures that are offered in spreadsheets and stand-alone statistical programs.

When Data Produce Averages

Z-test confidence interval for the difference between two means. Data in the form of averages and variability are among the most commonly developed data in medicine. Remember that to calculate an average, the data must be continuous data (interval or ratio), not ordinal or nominal. I have found most data concerning averages are best evaluated by using a *Z-test confidence interval* (Hamburg, 1983). The process is demonstrated in H.O.T. Stats Worksheet 1 (Chapter Appendix B).

Other ways exist to look for differences between means. However, H.O.T. Stats Worksheet 1 is about the simplest available. The biggest problem with most tests of means is that they require the data to be normally distributed. Practitioners in veterinary medicine often deal with small enough groups that they cannot claim normality. As the previous section explained, once a data set is determined to be nonnormal, using means and measures of variance to describe that data set is of questionable validity.

The trick to the Z-test confidence interval is that it tests for the *difference between means*. The data actually being tested, the differences between means, are the population that needs to be distributed normally, not the raw measures from which the means were calculated. *It just so happens that means of all kinds of distributions can be taken, one subtracted from the other, and the results can come out approximately normally distributed.*

Fig. 2-6 depicts two hypothetical populations of cows, one of which received a standard teat dip treatment, and the other of which was subjected to an experimental treatment. Whereas both distributions are highly skewed, with most animals in the lower somatic cell count (SCC) range, the animals in the standard treatment appear to have the "better looking" distribution.

Fig. 2-7 illustrates the distribution of differences between means of multiple samples from the two sets of cows depicted in Fig. 2-6. Sixty sets of 10 animals were randomly pulled from each population, and the SCC values for the experimental group were subtracted from the standard treatment group and averaged. The mean and median of this distribution are nearly identical, and a 2 SD distance from the mean (−406 to 35) does not exceed the actual distribution. This distribution fits the previous definition of a normal distribution.

Hence, the Z-test confidence interval statistic can be used to determine if one population has a different average SCC

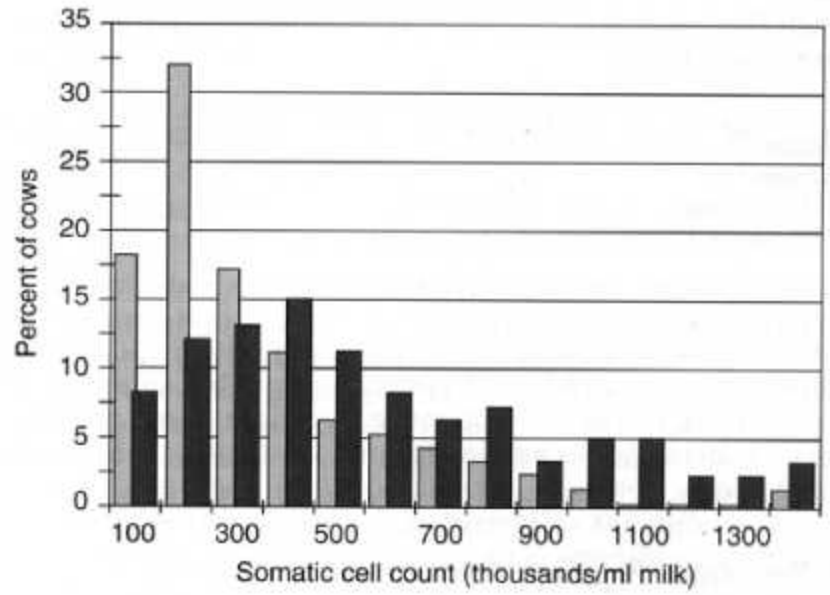

FIG. 2-6 Distributions of two hypothetical sets of cows by somatic cell count. The lighter bars represent those animals whose management uses a standard teat dip. The dark bars represent cows whose management uses an experimental teat dip. Both distributions are right skewed; however, the lighter bars appear to have the preferable distribution from an udder health point of view.

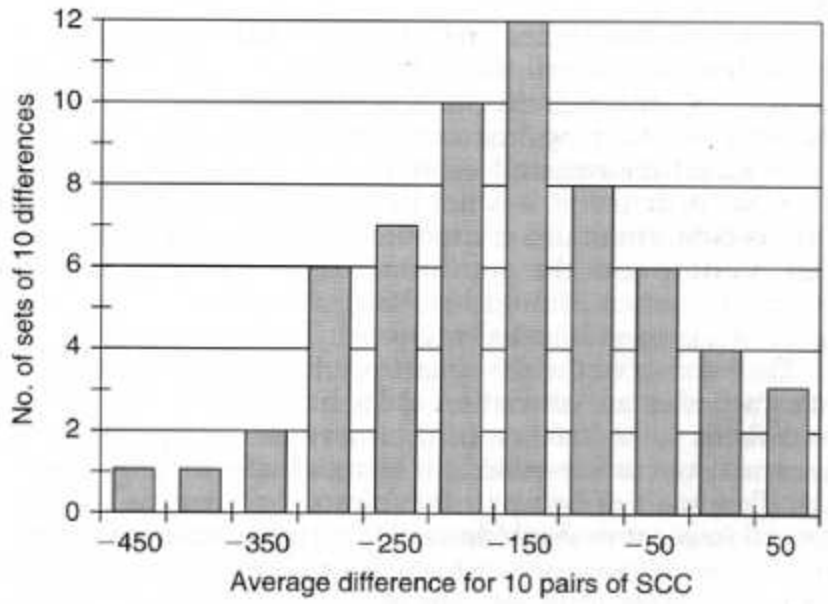

FIG. 2-7 Illustration of relatively normal distribution for the difference between two means, even when the underlying distributions are skewed. At random, 10 observations from each of the two groups shown in Fig. 2-6 were subtracted from each other (standard treatment − experimental treatment) and the differences averaged. This chart represents 60 repetitions of this subtraction and averaging. Mean = −186; standard deviation = 110; median = −180; n = 60. *SCC*, Somatic cell counts.

Downloaded from Vet-eBooks.com

than the other. The reader can run the math, but the results are shown below:

	Standard Dip	Experimental Dip
Count	100	100
Average	331	556
Std deviation	236	345

95% CI for difference in means = −230 to −220

Given these results (i.e., zero is not included in the interval), the practitioner can be at least 95% certain that the cows in the experimental group have significantly higher SCC than the cows in the standard treatment group. This difference is likely in the 220 to 230 SCC range. Therefore, based on these data, a client should not be recommended to use the experimental dip.

When Data Produce Frequencies or Counts

Chi-Square Test for Contingency Tables. Another common type of data encountered comes in the form of counts or frequencies. The observations can be from nominal, ordinal, or continuous types of data. Examples include gilts versus sows pregnant, proportion of teats dipped, or number of foals with good versus poor plasma protein levels.

"Count" data are best evaluated using a *chi-square for contingency tables*. The process is demonstrated by using a cattle example in H.O.T. Stats Worksheet 2 (Chapter Appendix C).

Small Sample Sizes and the Chi-Square Test. The requirement that no cell have a smaller value than 5 can raise difficulties. However, this limit is placed by the assumption that the "underlying," or expected, distribution follows a chi-squared distribution—sort of a right-skewed distribution. So, in actuality, it is not the observed data, but the expected data, that must contribute at least five items to each cell. So how does the practitioner figure out what the "expected" numbers should be? First, it must be understood what this process is actually testing.

The version of the chi-square test just discussed is evaluating whether an association exists between the row factors and the column factors. In the previous example, if there were no association—that is, if being a heifer did not change the likelihood of being in the "clean" or "metritis" class—*the cell frequencies should be roughly the same. In fact, since neither is more closely associated with being "clean," each would be expected to have about the same proportion as the grand proportion in the overall population. That is the definition of the expected values.*

Calculating the Expected Values for a Small Sample Size in a Chi-Square Analysis. Suppose a practitioner is working with a dairy client who has problems managing young stock. To help the client's heifer reproduction, the practitioner starts a two-injection, 11-day-interval, prostaglandin synchronization program on 24 heifers. Based on estrus detection, and by rectal palpation at breeding, the client says that only half the heifers responded (and implies the practitioner doesn't know what he or she is talking about). The practitioner visits the farm and wonders if the failure rate was due to a high proportion of thin heifers. A body condition score (BCS) is recorded for each animal in the group of 24, and the practitioner marks down whether the client classified them as being in estrus in the 3 to 5 days following the second prostaglandin injection. Approximately half the heifers appear to have had a BCS of 3 or greater, so that is used as the breakpoint in the analysis of whether being in the thinner group was associated with a higher likelihood of not responding to the prostaglandin program. The following table summarizes the findings:

	BCS ≥ 3	BCS <3	Total
Synchronized	8	4	12
Not synchronized	5	7	12
Total	13	11	24

The thinner animals apparently were less likely to synchronize than the heavier animals (approximately 36% success rate [4/11] versus 62% rate [8/13], respectively). The question, though, is how likely is this apparent difference due to random chance? The problem nicely fits a chi-square procedure, except for the fact that one cell (the "Synchronized" by "BCS <3" cell) has a value less than 5, which could invalidate the chi-square procedure. The expected value for that cell should be examined further, following the above argument.

If no association existed between BCS and synchronization, the proportion of synchronized heifers in both groups would be expected to be the same and, therefore, equal to the overall proportion of synchronized heifers (12/24 = 50%). Since 11 total heifers are in the "BCS <3" group, then 50% of 11, or 5.5, is the expected value for that cell. The other 50% are expected in the "Not synchronized" group. The entire table of expected values follows.

	Expected Values		
	BCS ≥ 3	BCS <3	Total
Synchronized	(0.5 × 13) = 6.5	(0.5 × 11) = 5.5	12 (50%)
Not synchronized	(0.5 × 13) = 6.5	(0.5 × 11) = 5.5	12 (50%)
Total	13.0	11.0	24 (100%)

Since the expected value for the "Synchronized" by "BCS <3" cell is greater than 5.0, it can be used in the chi-square analysis with this data. The following example, provided just to finish the analysis and to show another sample of using the chi-square, walks through the steps from H.O.T. Stats Worksheet 2, starting at Step 4 (Do the Math):

$$\frac{[(8 \times 7) - (5 \times 4)]^2 \times 24}{12 \times 12 \times 11 \times 13} = \frac{31{,}104}{20{,}592} = 1.51$$

The test statistic, 1.51, is less than the chi-square value for 80% confidence. A quick check in a statistics book or in Chapter Appendix A shows this test statistic falls between the value for 70% (1.07) and 80% (1.64). Therefore the practitioner can be at least 70% certain, but not 80% certain, that the lower BCS heifers did not synchronize as well as the higher BCS animals did.

Several authors (Fleiss, 1981; Snedecor and Cochran, 1989) argue that the limitation on cell sizes is likely too strict. Other rules of thumb are that no expected value be less than 1.0, and that over 20% of the actual cell values should exceed 5. Essentially, the smaller the sample size, the more difficult it is to defend *any* statistical procedure.

More Chi-Square Stuff: Statistical Significance Versus Magnitude of Effect (Odds Ratios). Just because something is statistically significant does not mean the overall effect is clinically significant. For instance, if the survival rate of piglets following a new neonatal diarrhea treatment were to be statistically better than that of a standard treatment, yet it improved survival rates by only 1%, the new procedure still may not be recommended. The 2 × 2 tables used in chi square analyses can be used to measure magnitude of effect. Magnitude of effect can be determined in two ways: the relative risk and the odds ratio (OR). The first is valid when dealing with an entire population (all the cows in a herd, for example), and the OR is best for dealing with a sample (a proportion of all the cows in a herd). For all intents and purposes, however,

Downloaded from Vet-eBooks.com

the OR can be used in either situation, so the next section focuses on this.

The OR from a 2 × 2 table is simply the result of dividing one diagonal product by the other. In the above synchronization example, it is the following:

$$OR = (8 \times 7)/(5 \times 4) = 56/20 = 2.80$$

This implies the higher body score group was nearly three times more likely to synchronize than the lighter body score group. Methods are available to construct a confidence interval around an OR, but they are not discussed here because they are relatively intensive computationally (and therefore do not fit the definition of a proper "hood-of-the-truck" procedure). Readers who are interested should refer to Fleiss (1981) for those methods.

When Data Produce Frequencies or Counts with Repeat Measures

Sign Test. The sign test is a simple means of addressing effects of treatments or programs when the same animals are measured twice (i.e., *repeat measures*), meaning the group comparisons are not independent. When the average daily gain on a group of pastured steers is measured before and after a worming treatment, the measures are dependent (i.e., fast growing steers from the previous month still tend to be the faster growing steers the next month) and therefore appropriate for the sign test. This can be used on any measure fitting a dichotomous class—yes-no, high-low, big-small, fast-slow, etc.—or anything that has a "better-worse" meaning. Therefore, continuous, ordinal, and even some nominal data forms work with the sign test. The process is shown in H.O.T. Stats Worksheet 3 (Chapter Appendix D).

The sign test assumes little about the underlying data structure. This makes running the test simple. However, some things are lost by simplifying matters. In the example, for instance, the *magnitude of change* in MEMP is unknown. Suppose that the cows that went up in milk production did so by 3%, and that the 26 cows that went down did so by 30%. The sign test would show that more went up than went down, but given the magnitude differences, the ration change should not be kept. Sometimes the best that data allow is a simple sign test, but bear in mind that ignoring the relative amount of change in each group could be an expensive mistake.

MORE COMPLICATED STATISTICAL APPLICATIONS: USING COMPUTER SPREADSHEETS

At Times, Fast and Easy Just Will Not Do

While the three "hood-of-the-truck" techniques cover most of the typical consultant's needs for quick and dirty decision making, they do not address all the questions concerning statistical data analysis. Only a few years ago the only statistical software available were stand-alone statistical programs that cost hundreds, if not thousands, of dollars and may have required programming knowledge to boot. These days any of the major commercial spreadsheets offer a wide array of statistical tests suitable for addressing many of the questions that production medicine veterinarians face. Several of these are discussed, following the same format as before; that is, they are categorized by the type of data being used—data arriving as means and measures of variance, as counts or frequencies, or as before-and-after types. Each of the three examples has a couple of twists, and an additional situation looks at determining if one variable is being driven by another (such as by looking at the association of weight gain and ambient temperature or if milk production and SCCs are related).

When Data Produce Averages: Two-Sample t-Test

When Data Come From Normally Distributed Populations and Independently Selected Samples

This section returns to the example in H.O.T. Stats Worksheet 1 in which the open heifers were believed to be lighter than the pregnant heifers. Suppose the practitioner actually got a list of the animals and their weights and took them back to the clinic. The values could be loaded into almost any of the modern spreadsheets and a statistical test run on them. But which one? When data came as averages with measures of variability, a reasonable test to determine the difference between means is the *Student's t-test*. One spreadsheet method of performing this test using the previous example of weight differences between pregnant and open heifers can be found on Spreadsheet Stats Worksheet 1 (Chapter Appendix E).

The Quattro Pro 8 t-test process, used in Spreadsheet Stats Worksheet 1, should be examined a bit closer. One point to expand on is the section in which a choice is given between *Two Sample with Equal Variances*, and *Two Sample with Unequal Variances* [Step II, B, 5 in the worksheet]. The question here is whether the two samples show significantly different amounts of variability. If they are different, the latter test should be used. Most spreadsheets allow the analyst to run an *F-test* to determine whether the variances can be considered equal. In most cases, given the rough values usually used in veterinary medicine, the two procedures yield essentially equivalent results. For the above example, the t-test procedure assuming unequal variances yields a "$P(T \leq t)$ two-tail" of .18—for all intents and purposes this is equivalent to the prior estimation of .2.

Another part of the process just mentioned is the section in which the analyst can choose <*Alpha*> or <*Difference*> values (Step II, B, 5 in the worksheet). The "Alpha" is simply asking for the *P*-value the analyst is willing to accept. The output will generate the t-value at this confidence level in the lines labeled "t Critical" for either the one-tailed or two-tailed tests. The "Difference" allows the null hypothesis to be changed; that is, whether the difference is hypothesized as zero or some other number. I recommend keeping the null hypothesis at zero; it is standard convention and relatively easy to interpret.

When Data Produce Frequencies or Counts

Two-by-Two Tables: Revisiting the Example of the Rate of Metritis in Heifers Versus Cows. This section returns to the example in H.O.T. Stats Worksheet 2, which examined a significant difference in the rate of metritis in heifers versus cows following a fertility examination at a farm. Frankly, it requires about as much work to run the 2 × 2 chi-square test using a spreadsheet as it does using the "hood of the trunk" techniques. However, the spreadsheet—Spreadsheet Stats Worksheet 2—is useful because it can run a larger chi-square than a 2 × 2 (Chapter Appendix F).

When Data Produce Frequencies or Counts with Repeat Measures, Paired t-Test

When Data Come as Averages in Pairs (i.e., Not Independent Samples) from Normally Distributed Populations. The sign test example used in H.O.T. Stats Worksheet 3 is reexamined in this section. Paired t-tests look at situations in which related items were measured: comparing

Downloaded from Vet-eBooks.com

right feet to left feet in a study of hairy heel warts in dairy cattle, looking at weight gain changes following addition of a mineral mix to a pen of feeder pigs, evaluating the impact of preventive medicine programs on several cow-calf farms and the returns to management. These all have some kind of a "before and after" feel. The process is demonstrated in Spreadsheet Statistics Worksheet 3 (Chapter Appendix G). The options for this test are the same as those for the *"Two Sample with Equal Variances"* t-test run in Spreadsheet Stats Worksheet 1.

When Data Produce Continuous Variables in Which One Variable is Likely Dependent on the Other

Sometimes events occur in which an outcome of interest is being "driven" by some factor or event. For instance, the practitioner may suspect a relation between the percent of gilts in a herd and average litter size or average weaning weights, may suspect an association between rainfall and SCCs, or may be told by a client that summer heat is causing decreased estrus detection rates. Is the relationship "real" or not? Is this a true association or just a chance observation? Statistics cannot tell about reality, but they can show the likelihood of that relationship's being due to chance.

Regression compares the variation in one quantity as a function of the variation in another. The outcome variable (average litter size, weaning weights, SCCs, or estrus detection rates) is the "dependent" variable, designated as "Y" in regression terminology. The variable suspected of driving the outcome (percent gilts, rainfall, or temperature) is the "independent" variable, labeled "X" in regression nomenclature.

Regressions tell how much of the variation in "Y" is explained by changes in "X." This is the "R^2" (called "R-squared") value; an R^2 of 0.4 means 40% of the variability in outcome "Y" is accounted for by the independent variable "X." These, however, are the minimal data derived from a linear regression. A few extra steps can help test whether the degree of association or correlation found, and whether the calculated effect, or slope of the line, is significant. The process is demonstrated in Spreadsheet Statistics Worksheet 4 (Chapter Appendix H).

Expansion of Spreadsheet Capabilities. Several third-party spreadsheet enhancement tools are on the market. In general, they operate as modules that allow spreadsheets to perform more complicated statistical analyses. Given the constant evolution of software packages, it makes little sense to go into the subject here. A number of user and support groups for various software or disciplines also exist. Interested readers are encouraged to explore these avenues, including searching the Internet for "spreadsheet statistics," for up-to-date information, software availability, and capability.

BEYOND SPREADSHEETS: STAND-ALONE STATISTICS PACKAGES

Commercial Statistical Software

Many commercial statistical packages exist. In general, they perform the statistical procedures listed in this chapter in a more complete and easier manner than the spreadsheet applications. Most also carry with them numerous diagnostic procedures that allow an analyst to do more and, therefore, to better understand the system being evaluated. For instance, one such program, Statistix for Windows (Analytical Software, Tallahassee, Fla.) was used to evaluate the linear regression problem of somatic cell code versus rolling herd average (RHA) in Spreadsheet Stats Worksheet 4. Figs. 2-8 and 2-9 show several output screens from the program.

Fig. 2-8 displays a typical set of output screens for the SCC code versus RHA problem. It displays the raw data (the window titled "C:\sccvsrha.sx"), a standard linear regression report plus analysis of variance (the window titled "Linear Regression - Coefficient Table), and an illustration of the regression line as it relates to the raw data (the window titled "Linear Regression - Simple Regression Plot"), along with confidence intervals for the prediction of the mean response (the narrow band) and for any single fitted variable (the wide band). Note that most of the data listed in the spreadsheet version are also listed here, except that Statistix uses a different test for significance for the constant. The analysis of variance table (the five-line table at the bottom of the window titled "Linear Regression - Coefficient Table") allows an analyst to gauge the significance of individual items in a multiple variable regression; that is, a regression in which more than one independent variable existed. In this simple case it does not add much to the analysis.

The graphic in the window titled "Linear Regression - Simple Regression Plot" draws the regression line through the data, plus it yields a 95% confidence interval around the regression line (the curved, fairly narrow band). This is useful for putting some range understanding into the regression evaluation. For instance, given these data, the analyst can be 95% confident that, should the herd achieve a reported SCC of 3.7 on several occasions, the average production will be in the range of 6060 to 6120 kg in terms of RHA. This is close to the actual average of the data points (average SCC for the 24 observations is 3.72) and corresponds with the narrowest 95% confidence interval for the mean. In either direction away from the mean, the confidence interval widens. This is a standard aspect of linear regression. More confidence lies in assertions about the center of the data sets, so that the further from the average of the data the analyst wishes to extrapolate, the less certain he or she can be about the actual results. The other confidence interval is the 95% confidence given for any single observation. Note the terms used here: Previously the "average response of RHA to changes in SCC" was discussed, whereas here the confidence in a one-time estimation is discussed. Because of individual month-to-month variability in production, the ability to predict any *single* response is much cruder than the ability to predict an average response, and therefore, the interval for a single prediction is much wider.

Fig. 2-9 depicts a second screen capture from the Statistix program. This one performs an important aspect of linear regression analysis, an aspect testing for some of linear regression's assumptions, called *residual analysis*. In essence, this analysis predicts a new production level for each of the listed SCCs, takes the difference from the actual RHA and predicted RHA, and submits this difference to analysis.

The residual analysis created three new variables: the predicted RHA values using the regression equation (RHAFIT), a standardized residual or measure of how far each prediction is from the actual RHA value (STDRES), and a t-test *P*-value for whether a single value is an "outlier" (OUTLIER)—the smaller the *P*-value, the more likely the observation is an outlier. Graphically, a plot of residuals should appear as a random pattern of points; should an obvious pattern exist (i.e., all the middle range residuals were above the zero line and the points on either side occurred below the zero line), the assumption of linearity or equal variation between the dependent and independent variable does not hold. In such a case, then, the analysis needs to be interpreted very carefully, if not redone using transformed data. The graphic in Fig. 2-9 shows no indication of a telltale pattern; the assumptions of linearity and equal variation hold in this data set.

The data table in Fig. 2-9 has one row highlighted, the row for case 18 (corresponds to the data point from "Jul-01"

Downloaded From Vet-e-Books.com

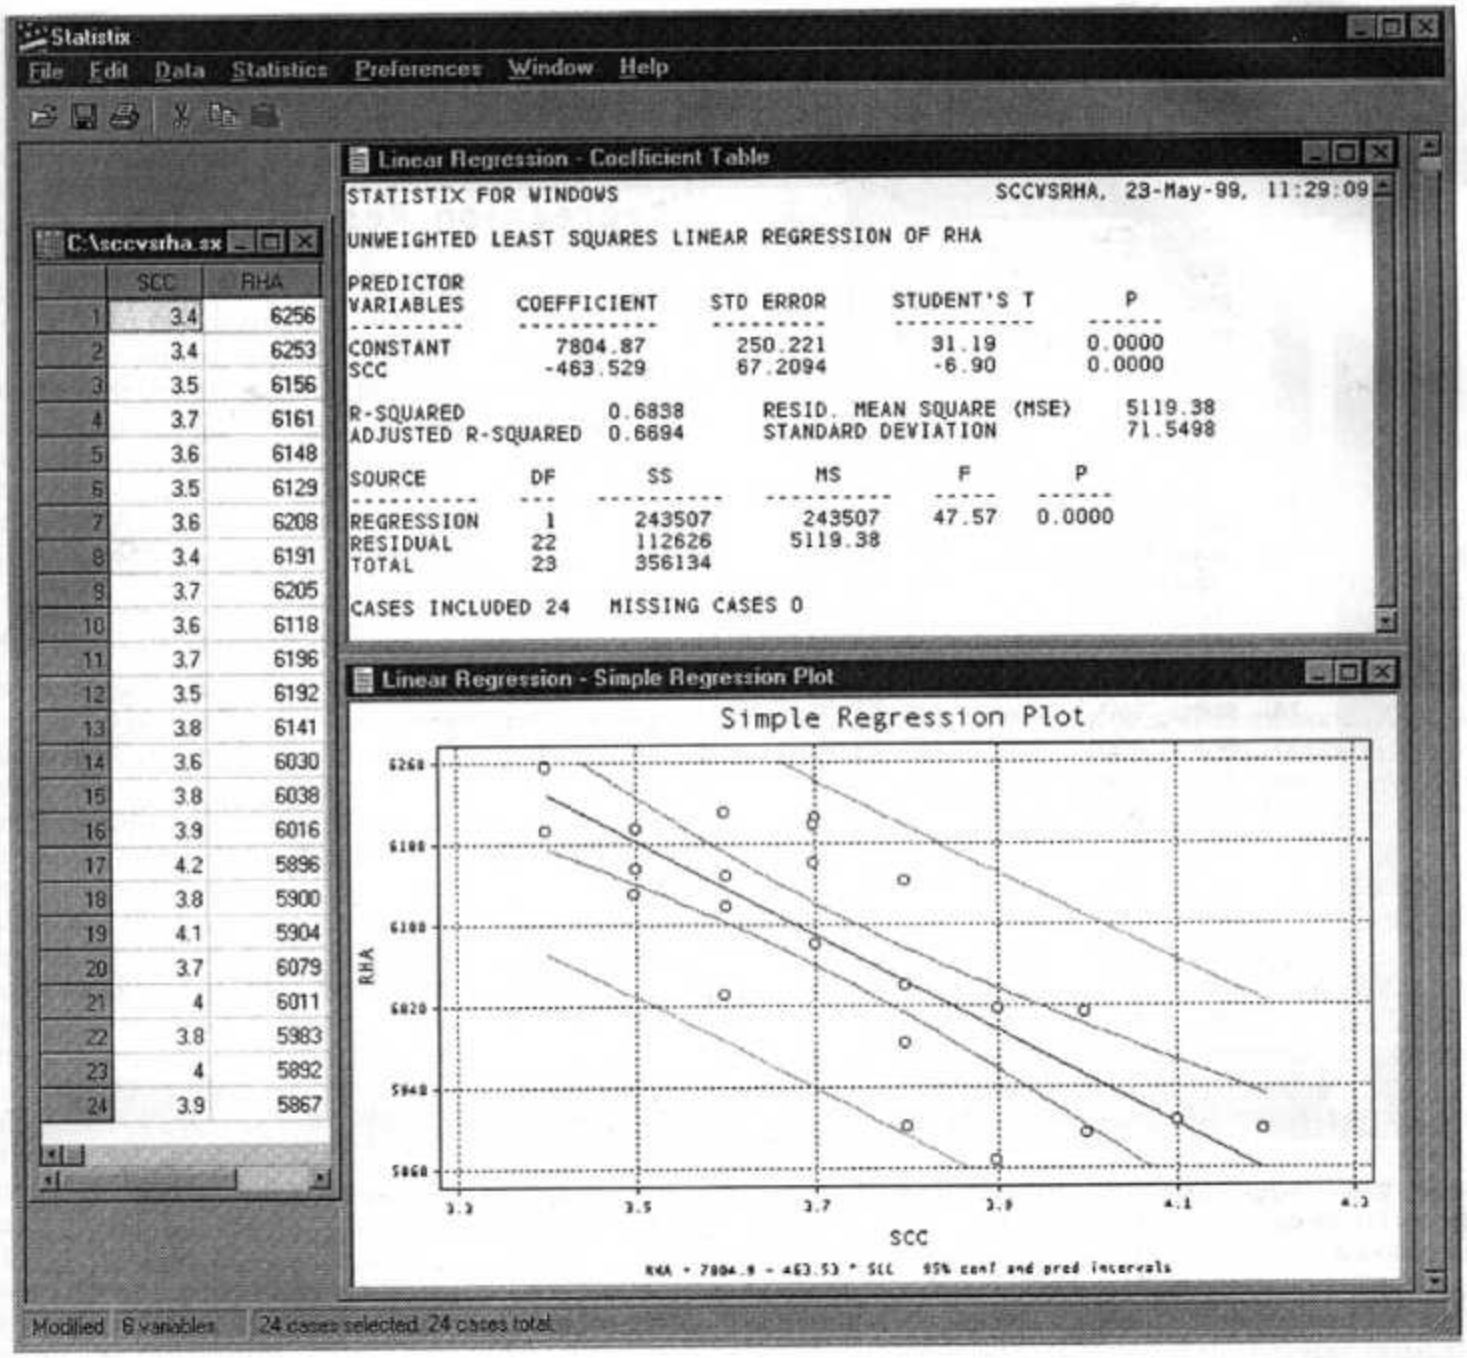

FIG. 2-8 Screen capture of typical output from a stand-alone statistics program (Statistix for Windows, Analytical Software) for the somatic cell code versus rolling herd average problem. The left window *(C:\sccvsrha.sx)* is the data listing. The top window *(Linear Regression - Coefficient Table)* is the linear regression report plus analysis of variance table. The bottom window *(Linear Regression - Simple Regression Plot)* displays a graphic of the linear regression and 95% confidence intervals for both the predicted (narrow band) and fitted (wider band) values.

in Spreadsheet Stats Worksheet 4). It has been highlighted because it is a potential outlier with a *P*-value of .04. Graphically, this is the lowest point in the chart, occurring midway between 6000 and 6080 on the x-axis and near −2.1 on the y-axis. The statistical test results in the "OUTLIER" column also identify cases 24 and 9 (the "Jan-02" and "Oct-00" data points) as potential outliers, with *P*-values of .06 and .10, respectively. Typically, the analyst would rerun the evaluation without one or more of these observations to see if the regression improved. Ideally, however, the analyst first would look for reasons why these data points should be excluded, other than their mathematical characteristics. For instance, if the "Jul-01" DHIA visit occurred the day after an equipment breakdown (i.e., the previous day's milking was 5 hours late), the analyst could feel there was support for removing that data point as an outlier. Likewise, if the "Jan-02" DHIA visit occurred during an ice storm, when the cows' exercise, feeding, and movement were drastically altered, the analyst might feel the data point were not representative of the herd's true abilities at that time. As a point in fact, for this herd, this is exactly what happened in both cases for the represented months.

Freeware Statistical Packages

Many organizations and groups offer "freeware" or "shareware" software, some of which can be quite sophisticated statistical packages. Perhaps the most widely used of the freeware packages is Epi Info from the Epidemiology Program Office of the Centers for Disease Control and Prevention (CDC) (Atlanta, Ga.). This package contains not only a set of statistical analysis modules covering a wide array of techniques, but a questionnaire developer, word-processing capabilities, a database module, a full on-line or printable manual, and potential connections to mapping and other surveillance software. While Epi Info is a registered trademark of the CDC, the actual software is available for free on the Internet at http://www.cdc.gov/epiinfo. Distributors include the CDC (Centers for Disease Control and Prevention, Division of Public Health Surveillance and Informatics,

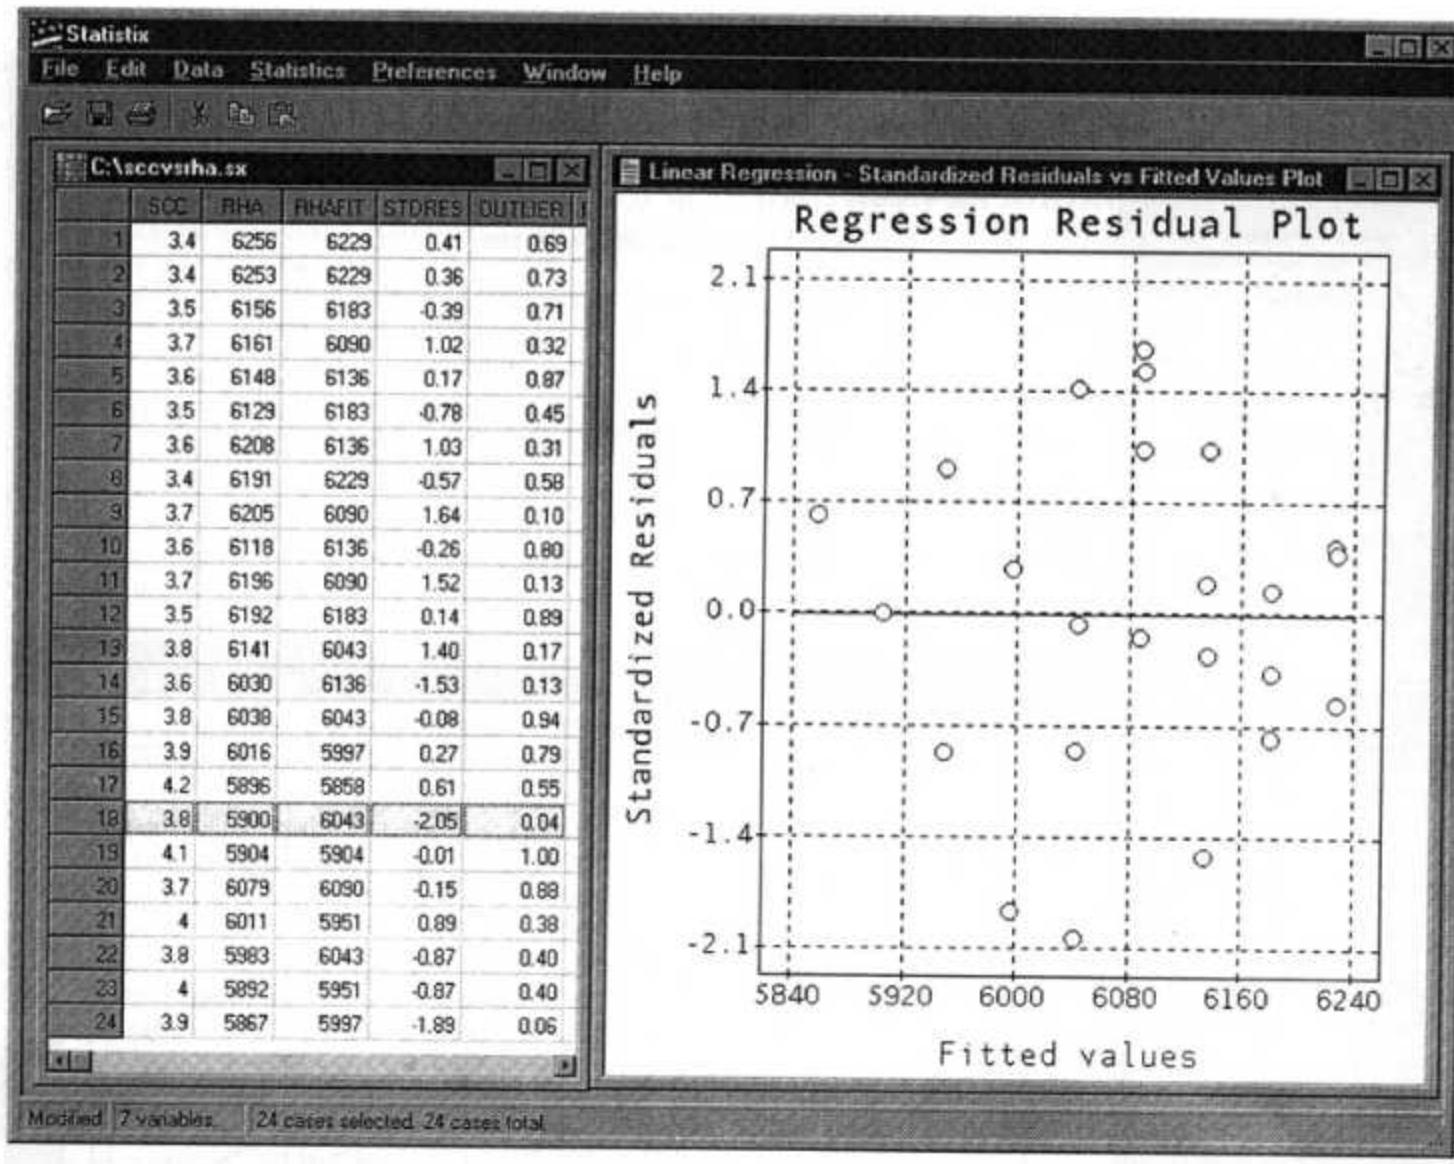

FIG. 2-9 Screen capture of typical output from a stand-alone statistics program (Statistix for Windows, Analytical Software) for the somatic cell code versus rolling herd average problem. The left window *(C:\sccvsrha.sx)* is the data listing, along with three new variables for residual analysis. Also shown is a graphical evaluation of residuals *(Linear Regression - Standardized Residuals vs Fitted Values Plot)*. The highlighted row (case 18) suggests that point is an outlier (value for column OUTLIER = 0.04) that may be overly influencing the regression. That point is the lowest point on the graphic.

Epidemiology Program Office, 4770 Buford Highway, MS K-74, Atlanta, GA 30341-3717), the World Health Organization (WHO), commercial vendors, translators, instructors in university and public health settings, and other public health professionals. A 1999 report (Harbage and Dean, 1999) documented that over 145,00 copies of the DOS version of Epi Info had been distributed, and its manual had been translated into 14 languages. Since 1994, the Internet has become a major means of propagation for this freeware, accounting for approximately two thirds of the copies known to be in existence.

As previously implied, Epi Info at time of writing is available in two versions: "Epi Info 6.04b upgrade to c" and "Epi Info 2000." The former is a DOS-based program that, in full, occupies approximately 15 Mb of disk space. The "upgrade to c" version contains a patch that corrects a problem in previous versions' Turbo Pascal compiler that produced a timing loop error on computers with processors faster than 200 MHz. In lay terms, that means that previous versions of the DOS program did not completely or reliably operate on anything but slower computers. For production medicine practitioners, the two major subprograms in Epi Info 6.04 are STATCALC and EPITABLE. These two modules allow the practitioner to enter data or summary information and quickly run a variety of statistical tests and statistical power calculations. The other version, Epi Info 2000, is a Microsoft Windows–based program that was first offered in mid-2000. In full, Epi Info 2000 occupies approximately 80 Mb of disk space. Its Windows format makes operating Epi Info 2000 more intuitive than Epi Info 6.04. However, the DOS version likely has more direct applicability to production medicine practitioners, because "2000" does away with EPITABLE and its ability to allow direct input of data without first generating an Epi Info data file. It still carries STATCALC (with its own ability to allow direct input of data without first generating an Epi Info data file), but the loss of the other module means that some of the quick utility of the DOS version is lost in the Windows version. However, Epi Info 2000 is easier to learn, is more adaptable, and likely will prove to be the dominant freeware statistical package for the coming decade or so.

DIAGNOSTIC TEST EVALUATION

Introduction

What is a Test?

A test is any device or procedure with the purpose of yielding information to help make decisions about a question or task at hand. In this wide view of what a test is, tests are performed anytime information is sought. Hence, whereas

Downloaded from Vet-eBooks.com

blood chemistries and bacterial cultures are recognized as tests, every assessment a clinician makes is, in truth, a test. For instance, when an animal's thorax is auscultated, the animal is tested with several criteria (sound quality, fluid lines, abnormal or missing sounds, etc.) that are believed to help differentiate normal from abnormal. When questions are asked regarding the history of an animal or herd, these details are used to rule in or out possible problems. Obviously, drawing blood for chemistries, hematology, or serologies are the same thing. In each situation, information is developed on how close the subject is to normality. The practical clinical value of a test, then, is based on its ability to provide information for making decisions. Not all tests are equal. Some have inherent biases in them. Some are not very repeatable. Not all tests are equal in differentiating normal from abnormal. A given test's weak points usually can be accounted for in analysis.

Reading Versus Interpreting Tests

Test strengths and weaknesses must be understood before moving from "reading test results" to "interpreting test results." Anybody can be given a sheet of test results, plus a sheet on where cutoff points are, and make decisions about the animals concerned. That is merely "reading test results" as if they were independent of everything else in the world. However, "interpreting test results" involves evaluating the test results given the underlying conditions—the likelihood of disease in the tested animals, the quality of the test itself—and using *all* the information at hand.

The next section looks at tests run in clinical situations. It starts with tests run on individual animals, before looking at tests applied over populations (the production veterinarian's main point of interest). The following points are covered:

1. Defining how all tests are uncertain
2. Looking into measures of test efficiency
3. Discussing how the disease environment (prevalence) affects test performance
4. Looking at how test efficiency affects performance when multiple tests are used on an individual and a single test is used on a population
5. Discussing the rationale in a screening-diagnostic testing strategy.

Sources of Uncertainty in Clinical Information

Variation in Data Quality

The general purpose of testing is to generate information that affects a future decision. The major way tests affect decisions is by allowing the decision maker to revise patients' probability of being diseased by separating a population into two or more groups, usually diseased and nondiseased. Four general characteristics of testing processes constitute the quality of information generated by tests: measurement errors, discrimination, accuracy, and precision.

Measurement Error. Instruments are not perfect, and the ability to manipulate the instruments varies. Difficult and exacting testing procedures are more prone to measurement errors, making the test less dependable. *Measurement errors* can be minimized by comparing a test's results against known standards. Laboratories do this by calibrating their instruments at regular intervals against known quantities. Many in-clinic tests now available are designed to be run in groups of three: the sample in question, a known positive, and a known negative. Such controls help minimize the chance of measurement error.

If a physical examination is actually a series of tests, how can measurement error be minimized? Clinicians recommend time and time again that findings on a suspect animal

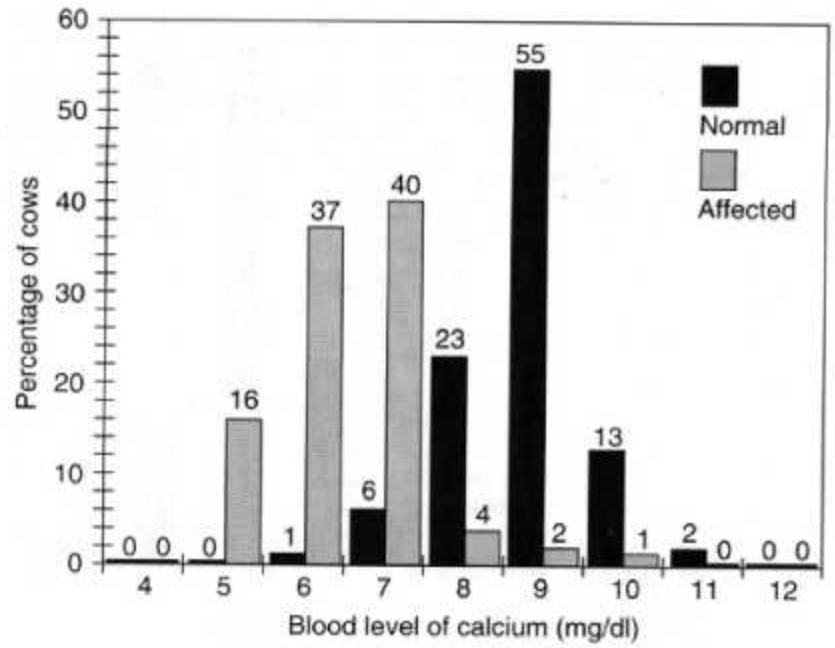

FIG. 2-10 Hypothetical distribution of cows from a study evaluating the relationship between blood calcium measures and clinical hypocalcemia. Some normal animals have low values of calcium, whereas some animals appearing affected with hypocalcemia have relatively high values. The degree of overlap indicates a test in which a perfect level of discrimination cannot be achieved.

be compared against those on a "normal" animal. For instance, when a clinician looks for radiographic abnormalities of a goat's tibiotarsal joint, he or she could take a few extra films of the opposite joint, using the animal as its own control. The same can be done in palpation of abdomens and joints, ocular examinations, auscultation, and any number of other common physical examination tests.

Discrimination. The term *discrimination* describes the ability of a *separator variable* (a threshold level of a blood chemistry, for example), exclusive of measurement errors, to separate one set of individuals from another. These separators are not exact. In Fig. 2-10, where should the line be drawn for blood calcium and milk fever? Regardless, a proportion of the individuals will be misclassified. For example, if the low end of normal is considered 8 mg/dl, 93% of both groups will be identified correctly. However, at the same time, approximately 7% of the affected animals will be incorrectly identified as also being "normal" (false-negative test result). If a higher limit is considered, such as 9 or 10 mg/dl, a higher proportion of truly hypocalcemic animals (98% and 99%, respectively) will be identified. However, increasing percentages of "normal" animals would be identified as potential hypocalcemia cases (false-positive results of >30% and 85%, respectively). There is a wide amount of individual variation; hence perfect discrimination between "normal" and "abnormal" cannot be achieved. By knowing this limit, often the choice of where to draw the line becomes one of practicality or economics, not physiology.

Accuracy. A test's *accuracy* pertains to the tendency of test measures to center around the actual, or true, value of that measure. Accuracy is difficult to ascertain, since it requires some standard measure against which to compare. Most errors in accuracy are systematic errors (for example, a blood glucose testing instrument is always 10 mg high) that lend *bias* to a test. A bias is simply a nonrandom directed error or a variation that is primarily in one direction, such as a thermometer that always reads either too high or too low. Inaccurate tests tend to shift a measure's distribution (Fig. 2-11), and therefore the measure's mean, to the right or left of the actual values. Inaccuracy does not,

Downloaded From Vet-eBooks.com

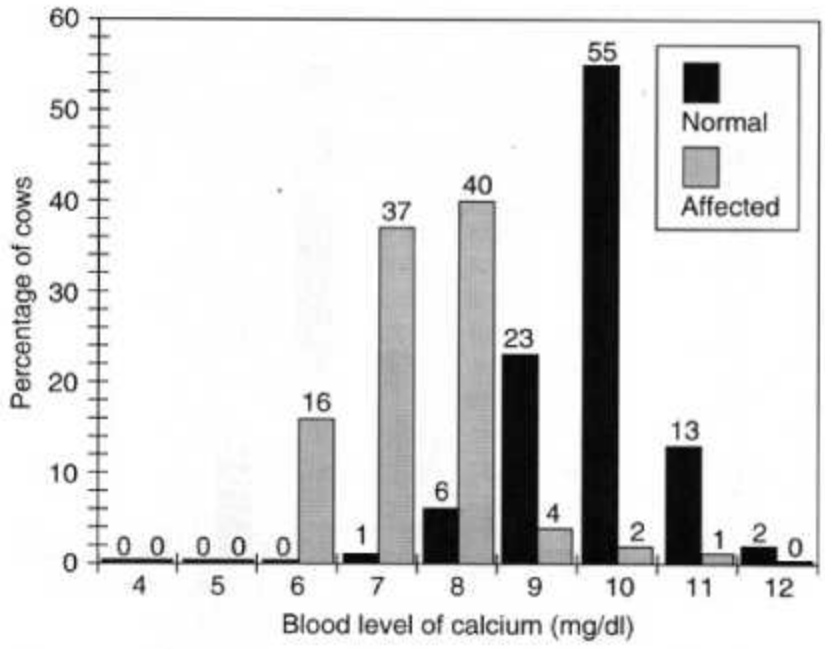

FIG. 2-11 Hypothetical distribution of cows from a quality control evaluation of a blood calcium–measuring technique. The two distributions, compared with those in Fig. 2-10, show a systematic upward bias of approximately 1 mg/dl. This does not change the test's ability to discriminate between the "normal" and "affected" populations; the difference between the central values is similar to that from the previous figure, and the dispersion stays the same.

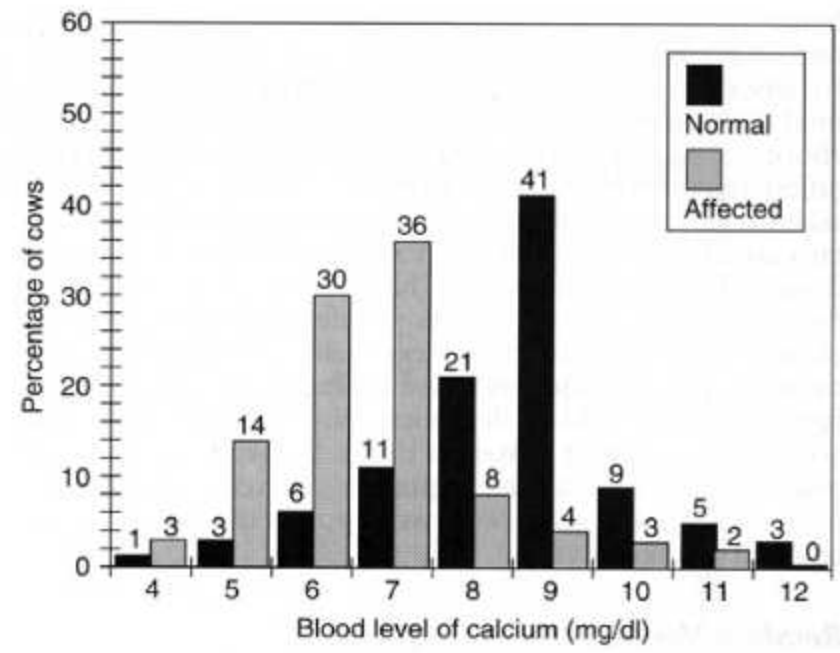

FIG. 2-12 Hypothetical distribution of cows from a quality control evaluation of a blood calcium–measuring technique. Compared with the distributions in Fig. 2-10, these distributions show a random bias. The centers of the populations are approximately the same; however, both distributions are flatter and wider than those in Fig. 2-10. This causes their amount of overlap to increase, decreasing the test's ability to discriminate.

however, affect the spread, or variance, of the distribution; if this instrument is known to measure 1 mg/dl too high, and the bottom end of normal is adjusted to an indicated 9 mg/dl, 93% of both groups again would be correctly identified. Hence, inaccuracy, in and of itself, does not change a test's discriminatory ability. When facing a bias, repeating the test does not improve the results. Improved calibration and changing tests are the only means to alter test accuracy.

Precision. The *precision* of a test, also known as *test reliability*, refers to the level of random variations in test results. Imprecision tends to cause a distribution of test results to have the same mean as the reference test's values but with a larger variance. Graphically, imprecision causes a series of test results to form a low, wide distribution curve compared with the reference distribution curve (Fig. 2-12). Imprecision in tests blurs discrimination lines because it increases the range of values over which the analyst is forced to name a category of results as being normal or abnormal. For instance, in this case, if 8 mg/dl is kept as the low end of normal, only 79% of the normal population (yielding a 21% false-positive test proportion) and 83% of the affected population (resulting in a 17% false-negative test proportion) would be identified correctly. Since the variation in imprecise tests is random, repetition of imprecise tests tends to give average results that approximate the true value of the index and therefore improve the confidence one has in decisions based on that information.

Measures of Test Efficiency in Clinical Decision Making

Definitions of "True" and "False" Negatives and Positives

Tests can be evaluated in terms of their efficiency at discriminating among groups of individuals. A dichotomous test, defined as giving results that register either "positive" or "negative" for some quality, can be used as an example. While tests that generate continuous results (i.e., liver enzyme levels) can be used, dichotomous results allow "either-or" clinical decisions to be made (either an animal is or is not treated). Hence, tests are often measured in terms of their dichotomous results as in a 2 × 2 contingency table. Fig. 2-13 shows a contingency table on the left comparing a hypothetical test (indicated as T+ and T−) with a state of nature (DZ+ and DZ−), and a table on the right explaining the terms used in describing test efficiency. From the contingency table data, information can be generated on some valuable efficiency index ratios (ratios that help determine whether a test is worthwhile). The "significance" of a ratio is the disease-relative probability value the ratio represents. For example, the sensitivity of a test is the probability of a test being positive, given the presence of disease. (The P(T+|DZ+) is an algebraic expression of this statement, where the "|" is read as the word "given.")

Sensitivity (SE) of a Test. The SE of a test is a measure of that test's ability to identify true positives, given that the tested group is truly positive. In a 2 × 2 table (as in Fig. 2-13), the SE is given by the cell signifying the positive agreements between the test and a gold standard divided by the marginal total of truly diseased animals. The higher the *sensitivity*, the better the test at pulling truly diseased animals from a group.

Specificity (SP) of a Test. A test's SP is a measure of that test's ability to distinguish true negatives, given that the tested group is truly negative; the cell signifying the negative agreements is divided by the marginal total of truly negative animals. The higher a test's *specificity*, the better the test at identifying nondiseased animals and leaving them be.

SE and SP are of limited usefulness by themselves because they each are calculated using only one side of the 2 3 2 table (i.e., either the state of nature diseased or the state of nature nondiseased side). The values desired (i.e., the likelihood that an animal a test labels "positive" is truly diseased) need to be calculated using both sides of the table (i.e., either the "total number of test positives" or "total number of test negatives"). This "vertical" alignment of SE and SP also means that neither is necessarily affected by prevalence of

1. Basic abbreviations

A. ***DZ+/– (state of nature)***	*Column depicts either diseased (DZ+) or nondiseased (DZ–) animals.*
B. ***T+/– (test results)***	*Row depicts either positive (T+) or negative (T–) testing results.*
C. ***TP (true positives)***	*Both Test and State of Nature indicate positive results.*
D. ***FP (false positives)***	*Test is positive, but State of Nature is disease negative.*
E. ***FN (false negatives)***	*Test indicates negative, State of Nature is positive.*
F. ***TN (true negatives)***	*Both Test and State of Nature indicate negative.*

2. Contingency table example and explanation of TP, FP, TN, FN

Assume you tested a 640-sow barn for some disease. 77 animals tested positive, and 563 tested negative. Unknown to you, 17 test positive animals are false positives, and 4 test negative animals are false negatives. In actuality, 64 animals were diseased and 576 were nondiseased. The testing program results could be displayed as the following:

TEST RESULTS

	DZ+	DZ–	
T+	60	17	77
T–	4	559	563
	64	576	640

EXPLANATION

	DZ+	DZ–	
T+	TP	FP	TP+FP
T–	FN	TN	FN+TN
	TP+FN	FP+TN	TOTAL

3. Definitions of efficiency index ratios

INDEX RATIOS	CALCULATION	EXAMPLE RESULTS		SIGNIFICANCE
A. PREVALENCE	(TP+FN)/TOTAL	64/640	= 10%	P(DZ)
B. SENSITIVITY	TP/ (TP+FN)	60/64	= 0.94	P(T+|DZ+)
C. SPECIFICITY	TN/ (FP+TN)	559/576	= 0.97	P(T–|DZ–)
D. FALSE POSITIVE RATE	FP/ (FP+TN)	17/576	= 0.03	P(T+|DZ–)
E. FALSE NEGATIVE RATE	FN/ (TP+FN)	4/64	= 0.06	P(T–|DZ+)
F. PREDICTIVE VALUE POSITIVE TEST	TP/ (TP+FP)	60/77	= 78%	P(DZ+|T+)
G. PREDICTIVE VALUE NEGATIVE TEST	TN/ (FN+TN)	559/563	= 99%	P(DZ–|T–)

FIG. 2-13 Basic setup of a diagnostic test evaluation table, using the contingency table convention to display test results. Index significance is read as the "probability of (event)." For instance, *P*(T+|DZ+) is read as "probability of an animal testing positive, given that it has the disease."

disease, as long as the prevalence does not affect the animals' display of characteristics used for testing. For instance, in the case in a neonatal gastrointestinal disease situation, often the higher the prevalence of the pathogen, the more it gets amplified as it passes from case to case, making the signs and symptoms more apparent as prevalence rises. In these types of situations, then, SE and SP of a test can change with prevalence. These cases are, however, the exception to the rule; SE and SP, being calculated using only the diseased or the nondiseased subgroups, are largely indifferent to prevalence.

The aforementioned is certainly not true for the *predictive values*. The "horizontal" alignment of the values of interest thus means that they *are* affected by prevalence. In general, then, the nature of a test (SE and SP) is not a function of disease prevalence, but its performance (predictive value of a positive test, predictive value of a positive test) is.

Prior Probabilities and Posterior Probabilities. In most situations the prevalence of a disease is called the *prior probability* of that disease occurring. This term is used because it is the probability of the disease occurring *prior* to any investigation or test being performed. As stated before, the purpose of a clinical test is to revise probabilities of disease. This is what the predictive value of a positive test (PVPT) and the predictive value of a negative test (PVNT) accomplish. The PVPT and PVNT of a test are *posterior probabilities* of disease. They are posterior probabilities because they come *after*, or posterior to, a test. They represent the revised probability of an animal's being diseased (or nondiseased). In general, the lower the prevalence, the worse the PVPTs and the better the PVNTs. The opposite is true for higher prevalences; PVPT improves and PVNT worsens. Most tests have their highest combined PVPT and PVNT somewhere in the mid-ranges of disease prevalence.

PVPT and PVNT are also asymmetrically affected by SE and SP. Fig. 2-14 shows predictive values over a range of prevalences from 0% to 100%, with SE held constant at 95% and three separate SPs (80%, 90%, 99%). Note the relationship of PVPT and PVNT with prevalence as described previously. Also note how PVPT is affected to a greater degree by changes in SP than is PVNT. Fig. 2-15 shows a similar graph, except that this time SP is held constant at 95% and SE varies from 80%, to 90%, to 99%. PVNT is evidently the more affected posterior probability when SE is the characteristic that changes. One way to remember this pattern is to think of SE and SP as elastic bands that pull the PV calculations toward the upper-right or upper-left corners of such a graph. As SE rises, PVNT is pulled to the upper-right corner. As SP rises, PVPT is pulled toward the upper-left corner.

Whereas, at first, it may seem counterintuitive that the test characteristic that determines a test's ability to correctly identify *diseased* animals (sensitivity) should most affect the posterior probability that registers confidence in *test negatives* (PVNT), the relationship makes sense with a moment's reflection. If, for instance, a test had a poor sensitivity, by definition it would incorrectly identify a number of diseased

Downloaded from Vet-e-Books.com

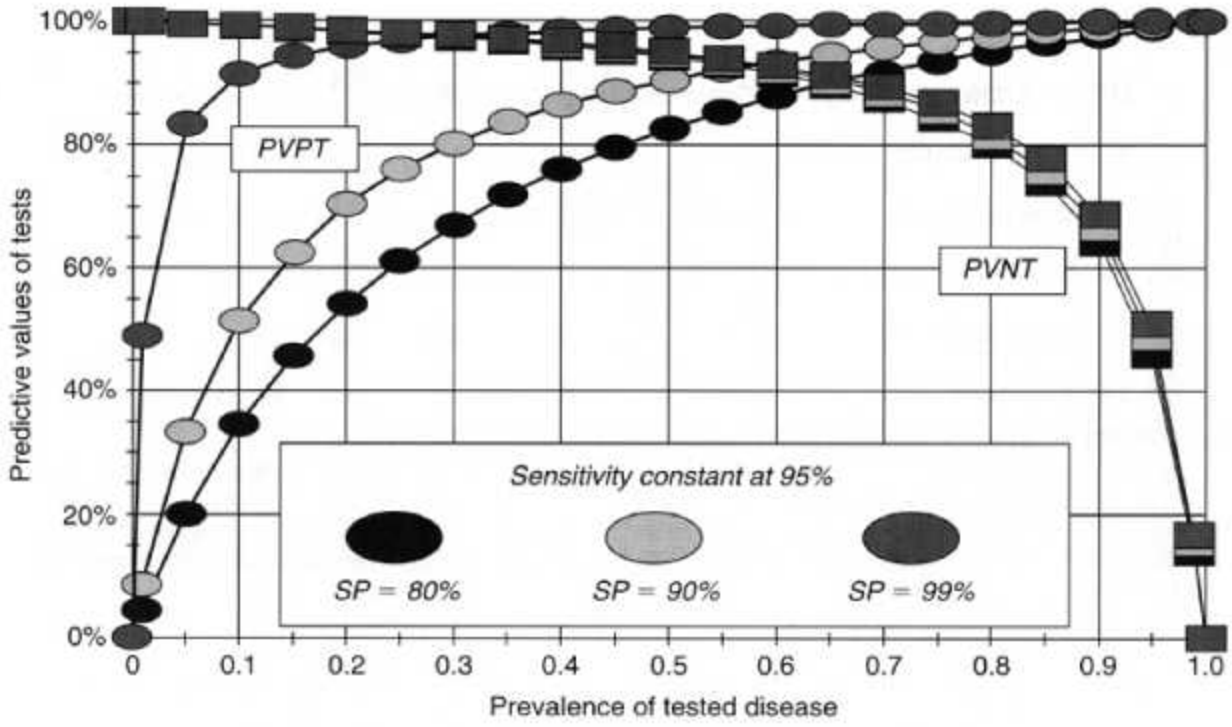

FIG. 2-14 Depiction of the effect of changing prevalence and specificity *(SP)* on the predictive values of a test. As prevalence rises, predictive value of a positive test *(PVPT)* rises and predictive value of a negative test *(PVNT)* drops, both in a curvilinear fashion. PVPT is apparently much more affected by changes in specificity than is PVNT.

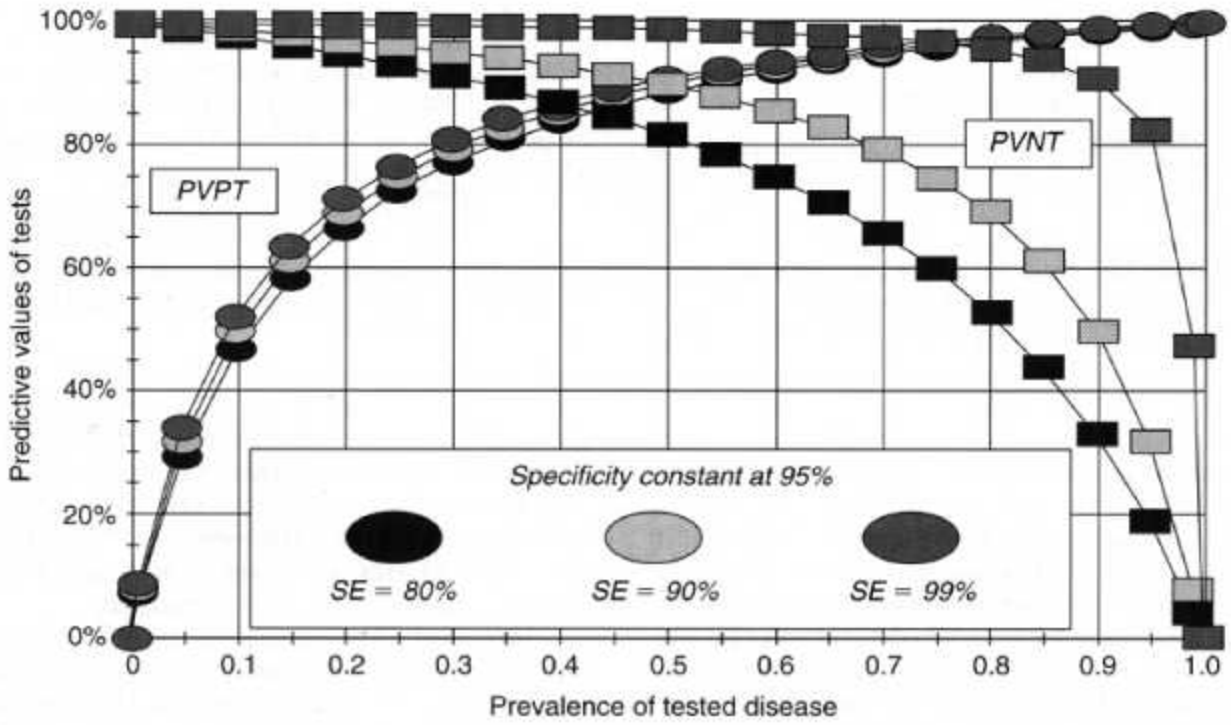

FIG. 2-15 Depiction of the effect of changing prevalence and sensitivity *(SE)* on the predictive values of a test. As prevalence rises, predictive value of a positive test *(PVPT)* rises and predictive value of a negative test *(PVNT)* drops, both in a curvilinear fashion. PVNT is apparently much more affected by changes in sensitivity than is PVPT.

animals as nondiseased—the false negative rate (FNR) will rise. Since the PVNT is calculated as the number of true negatives/(true negatives + false negatives), an increase in the FNR *lowers* PVNT (see Fig. 2-13 for review). For PVPT, the calculation is the number of true positives/(true positives + false positives)—as true positives increase, they cause an increase in *both* the numerator and denominator, dampening the change in the overall value of the proportion. The converse is true when specificity is the value that changes, making PVPT the most affected posterior probability.

Likelihood Ratios and Figuring Out the "Gray" Zones in Clinical Tests

Unfortunately, most tests are not perfectly discriminating; they each yield some proportion of false positives (FPs) and false negatives (FNs). The original hypothetical blood calcium data from Fig. 2-10 shows this. It is apparent that, within reason, any animal testing at or above 11 mg/dl can be considered "negative" (i.e., normal), because with this data set no affected animals achieved this high a blood calcium level. It is just as apparent that those testing below 6

Downloaded from Vet-e-Books.com

mg/dl can be considered "positive" (i.e., hypocalcemic). So at least an upper and lower boundary can be established on classification. The animals testing above 6 mg/dl and below 11 mg/dl, however, are another story; they cannot automatically be assumed to be either "negative" or "positive" without running the risk of misclassification. There is a way to rank these outcomes and give some probabilistic means of selecting any given animal's most likely class. It invokes what are called *likelihood ratios*.

A likelihood ratio (LR) is simply the ratio formed by dividing the proportion of the diseased population testing at some predetermined level by the proportion of the nondiseased population testing at the same level. Suppose that, using the data in Fig. 2-10, the analyst determines the LR for a blood calcium level of 9 mg/dl. In this example, 85% (55+23+6+1 = 85) of the unaffected group tested at or below this level, whereas 99% of the affected group (2+4+40+37+16 = 99) tested at this same level. The LR for 9 mg/dl would be 99/85 = 1.16. Thus affected animals are about 1.16 times as likely as unaffected animals to test at or below this level. The LR, then, is the odds that 9 mg/dl of blood calcium would be expected in an affected cow versus an unaffected cow. As another example, the LR can be developed for establishing a cutoff point for a blood calcium level of 6 mg/dl:

Proportion of affected cows with blood calcium ≤6 mg/dl
$= 37 + 16 + 0 + 0 = 53$

Proportion of unaffected cows with blood calcium ≤6 mg/dl
$= 1 + 0 + 0 + 0 = 1$

Likelihood ratio for 6 mg/dl $= 53/1 = 53$

This means that blood calcium results at or below 6 mg/dl are *53 times more likely* to come from cows affected with hypocalcemia than from cows not clinically hypocalcemic. The full 2 × 2 contingency table for a finding of 6 mg/dl would appear as follows (refer to Fig. 2-10 for data):

	Hypocalcemic	Normal	Total
Test positive (blood calcium ≤6 mg/dl)	53	1	54
Test negative (blood calcium >6 mg/dl)	47	99	146
Total	100	100	200

The LR, then, is actually the proportion formed from SE/FP, or SE/(1–SP). In this case, this would be (53/100)/(1/100) = 53/1 = 53 (refer to Fig. 2-13 for review as needed). Indeed, this is another means of calculating an LR. In this 2 × 2 table calculation, predictive values should not be generated, since the underlying proportion is arbitrarily set at 50% because proportions from two separate groups were used. However, in a herd in which hypocalcemia occurs in half the cows, this table *can* be used for predictive values. I pity the reader, and the reader's client, if this is actually the case.

Given the previous information, LRs can be calculated for all levels of blood calcium outcomes. Table 2-3 does just this. Inspection of this table should reveal an intuitive trend in LRs. As the cutoff value for the test is set at an ever lower level of blood calcium, the likelihood of achieving such an outcome from a hypocalcemic animal becomes much more probable. This fits with the knowledge that hypocalcemic animals have lower levels of blood calcium. The LR quantifies that relationship. The next part of this discussion shows how to use this new information in interpreting test results.

Using Likelihood Ratios to Improve Diagnostic Test Evaluation. LRs are used to develop posterior probabilities of an animal's being normal or abnormal. The method is simple; it often can be accomplished without paper. The logic behind it follows that the probability (or odds) of an animal's being diseased after test results are obtained is derived from the prior probability of the animal's being diseased, multiplied by the test's likelihood ratio. The equation form follows:

$$\text{Posterior odds of disease} = \text{Prior odds of disease} \times \text{Likelihood ratio}$$

This is written formally as follows:

$$\frac{P(DZ+|T+)}{P(DZ-|T+)} = \frac{P(DZ+)}{P(DZ-)} \times \frac{P(T+|DZ+)}{P(T+|DZ-)}$$

In terms of Fig. 2-13, this is equivalent to the following:

$$\frac{PVPT}{1 - PVPT} = \frac{PREV}{1 - PREV} \times \frac{Se}{FPR}$$

in which FPR is the false positive rate.

The prior odds of an animal's having the disease in question is formed by the following equation:

$$\frac{\text{Disease prevalence}}{1 - \text{prevalence}}$$

This is the "no other information available" position to take—if nothing else is known about the animal, its probability of disease is the overall population prevalence. This is not always the case, for an animal may be considered more likely than the underlying prevalence would suggest to have a disease after a close physical examination. For instance, in a certain dairy herd periparturient hypocalcemia may occur at a proportion of 1 case per 20 calvings (i.e., 5%). However, if a cow is examined that is 48 hours postpartum, has no signs of trauma or septicemia, is unable to rise, has cold ears, and appears depressed, she would seem to be at higher risk of being hypocalcemic than a random 5% selection would present. In essence, the physical examination changed the prior probability of 5% to a higher posterior probability—the physical examination is a true test.

If a test is to have the ability to revise probability of disease being present (the definition of test value), the *LR* must be different from 1.0. For the test in Fig. 2-13 the likelihood ratio is 0.94/0.03, or 31.33, indicating this is a useful test in revising disease probabilities. For the current example, Table 2-3 suggests that the blood calcium test is useful in differentiating diseased cows from nondiseased cows until the cutoff point is set at 9 mg/dl or higher—at those levels the LR for the test approximates 1.0 and is not informative.

Using Likelihood Ratios in Establishing a Single Cutoff Threshold for Normal and Abnormal. The simplest application of LRs is to help establish a cut-point for decision making. On one side of the cut-point the animal is classified normal, and on the other side it is classified as abnormal. Suppose the practitioner examines a cow and believes, given the presented signs and history, that it has a 33% chance of being hypocalcemic. Assume also that this test being discussed is a quick cow-side test. The result is that the cow in question has a blood calcium level of 7 mg/dl, just a bit below normal. How much more likely is the cow to be hypocalcemic and therefore a good candidate for calcium therapy? The LR and previous mathematical expression can be used to calculate it:

Posterior odds of disease = Prior odds of disease × Likelihood ratio
$= 33/67 \times 13.3$
$= 0.5 \times 13.3$
$= 6.7$

So, after the test is run, the posterior odds estimate for the cow's being hypocalcemic is 6.7:1. This can be converted to a probability. Refer to the discussion of converting ratios to

10	1	13	(0+16+37+40+4+2+1)/(0+0+1+6+23+55+13) = 100/98	1.02
11	0	2	(0+16+37+40+4+2+1+0)/(0+0+1+6+23+55+13+2) = 100/100	1.00
12	0	0	(0+16+37+40+4+2+1+0+0)/(0+0+1+6+23+55+13+2+0) = 100/100	1.00

*Table differentiates between affected and nonaffected animals for the hypothetical testing for blood calcium demonstrated in Fig. 2-10. The likelihood ratio expresses the odds that the test level would be expected in a hypocalcemic cow as opposed to a normal cow. Hence, a blood calcium value of 7 mg/dl is over 13 times more likely to come from a hypocalcemic cow than from a normal cow.
†Result of *na (big)* means that the arithmetic operation cannot be performed (cannot divide by zero); however, the analyst should be aware that the LR for this test level would be much higher (i.e., "bigger") than any value derived lower in the table.

proportions: Take the numerator and divide by the sum of the numerator and denominator (for 6.7:1 this comes to 6.7/[6.7 + 1] = 6.7/7.7 = 87%). Before the test, then, the probability that the cow was diseased was thought to be 33% in round figures. After the test is run, even though the results would often be considered as "borderline low," the confidence that the cow truly has the disease is now nearly 90%. Even at this moderately low level of blood calcium, a much higher proportion of hypocalcemic cows show such a result as opposed to normal cows. In other words, this worked because the test has, at 7 mg/dl, an LR much higher than 1.0.

What if the test result had been 8 mg/dl instead of 7 mg/dl? Insert the new LR for 8 mg/dl (3.2; see Table 2-3) into the previous expression:

$$= 0.5 \times 3.2 = 1.6$$

This yields a probability of the cow's being diseased of 1.6/2.6 = 62%. A relatively small move in blood calcium levels has lowered the confidence that the cow is hypocalcemic from nearly 90% to about 60% because the ratio of animals with and without hypocalcemia having such a blood level is fairly close. With this disease, the practitioner is most likely to go ahead and treat because the negative potential of treating the cow with calcium is low if she is *not* hypocalcemic. However, if the decision were not about intravenous calcium treatment, but about removing a teat or cauterizing a quarter, the practitioner might not be willing to proceed with treatment if there is a 40% chance the diagnosis is wrong.

Which is the better cutoff? 7? 8? Table 2-3 shows that over 90% of the affected animals fall in the ≤7 mg/dl range, and over 90% of the unaffected group fall in the ≥8 mg/dl range. Since percentages are being used here, these are equivalent to SE and SP. With a cutoff of 7 mg/dl, an SE of 93% and an SP of 93% result. Moving up to 8 mg/dl captures a few more unusual cases, but it also increases the FPs so that SE comes to 97% but SP drops to 70%. The best, overall test performance occurs with a cutoff of ≤7 mg/dl; animals falling in this range are over 13 times more likely to be hypocalcemic than not.

Using Likelihood Ratios to Help Make Decisions About Individual Animals by Dispensing With Either/Or Cut-Points. The previous argument, in the end, was decided by relative changes in SE and SP—the LR only clarified the magnitude of effect of changing the cut-point. The LR can be used in a much more powerful way, however, and that is to dispense with single cut-point decisions and move to a more substantial use of diagnostic tests that give quantitative results. The process involves establishing a true low-end cut-point, a true high-end cut-point, and setting up a range of LRs for the middle group. This process also uses SE, SP, and LRs to make the point.

Sackett et al (1991) use two terms that help in this activity: "SnNout" and "SpPin." *SnNout* is an acronym that represents the method for establishing a "rule-in" target level for any test: *"...if a sign, symptom, or other diagnostic test has a sufficiently high Sensitivity, a Negative result rules out the target disorder..."* Hence, most tests have a threshold at which test SE is so high that great confidence is gained in negative results and a disease is ruled out. *SpPin* addresses the opposite situation: *"...if a sign, symptom, or other diagnostic test has a sufficiently high Specificity, a Positive result rules in the target disorder...."* Hence, for most continuous outcome tests, a threshold also exists at which test SP is so high that any positive finding carries great predictive weight. These two rules can be invoked with the blood calcium data in Table 2-3.

If the practitioner is willing to miss 1% of each type of animal (affected and unaffected), the SE level for SnNout and the SP level for SpPin is 99% for each. Examination of Table 2-3 shows that an upper cut-point of ≥10 mg/dl captures 99% of the affected population (i.e., SE = 99%). Likewise, a lower cut-point of ≤6 mg/dl releases 99% of the unaffected population (i.e., SP = 99%). So any animal testing over 9 mg/dl is considered "normal" automatically by invoking the SnNout rule, and any animal testing <7 mg/dl is considered hypocalcemic automatically by invoking the SpPin rule. That only leaves animals that

Downloaded from Vet-eBooks.com

could test between these values: those at either 7, 8, or 9 mg/dl.

The difference in the approach here, as opposed to the previous section on establishing a single cut-point, is that the focus is no longer on estimating the population differences on either side of these single values, but how the two groups differ at each value. This is easily found from Fig. 2-10:

LR for animals at 7 mg/dl
= % affecteds/% unaffecteds = 40/6 = 6.67

LR for animals at 8 mg/dl
= 4/23 = 0.17

LR for animals at 9 mg/dl
= 2/55 = 0.04

Note the difference in what is being evaluating here, compared with the earlier examples. Any animal testing out at 7 mg/dl for blood calcium is 6.67 times more likely to be affected than not, and any animal testing out at 8 mg/dl is 17% as likely to be affected than not (i.e., odds are approximately 5/1 the animal is unaffected). Odds are better than 20/1 that an animal testing at 9 mg/dl is unaffected. The entire population is not being captured up to those levels, just the animals at those levels.

So how is the information previously mentioned clinically? Assume there is another down cow. Because of other clinical signs, the practitioner thinks the cow is only 10% likely to be clinically hypocalcemic. The hypothetical cow-side test is run. The rules of action are as follows:

1. If the test result is 10 mg/dl or higher, the cow is considered *not* affected with hypocalcemia and *not* treated
2. If the test result is 6 mg/dl or less, the cow *is* affected with hypocalcemia and *is* treated
3. If the test result is in between, the individual level LRs are used to calculate a posterior probability of disease and determine treatment

Blood test result	Calculation of odds of disease in example cow	Posttest probability
7 mg/dl	0.10 × 6.67 = 0.667:1	= 40.0%
8 mg/dl	0.10 × 0.17 = 0.017:1	= 1.7%
9 mg/dl	0.10 × 0.04 = 0.004:1	= 0.4%

If the prior probability for the cow to be hypocalcemic had been 67%, instead of 10%, the final posttest probabilities of hypocalcemia would have been approximately 82% for 7 mg/dl, 10% for 8 mg/dl, and 2% for 9 mg/dl. Had the prior probability for hypocalcemia been 90%, the posttest probabilities for 7, 8, and 9 mg/dl would fall out as approximately 86%, 14%, and 3%, respectively. The higher the initial estimate of the likelihood of the cow's being diseased, the more likely she is to be diseased after a test is run. Fig. 2-16 displays a histogram of the distributions from both affected and unaffected animals, marks the earlier rule-in and rule-out ranges, and shows the individual test level LRs.

What Does All This Individual-Animal Diagnostic Stuff Have to Do with Production Medicine? This "diagnostic stuff" defines a clear and repeatable means of establishing the rules regarding initiating treatment for any disease that is tested with a quantitative scale (as opposed to tests that yield qualitative "yes-no" results). A major role for production medicine veterinarians is in training their clients to use and operate treatment protocols. In modern animal agriculture, the veterinarian is less frequently being called on to treat animals; the client does this work more and more. The veterinarian accepts the responsibility for designing credible treatment protocols for the client to use. Evaluating diseases and tests for those diseases gives the consulting veterinarian a new tool in designing protocols to make the client's work efficient, to minimize wasted time and money in unneeded testing or inappropriate treatment, and to deliver better care to the animals involved. It also gives the consulting veterinarian a framework from which to evaluate new tests or diagnostic procedures.

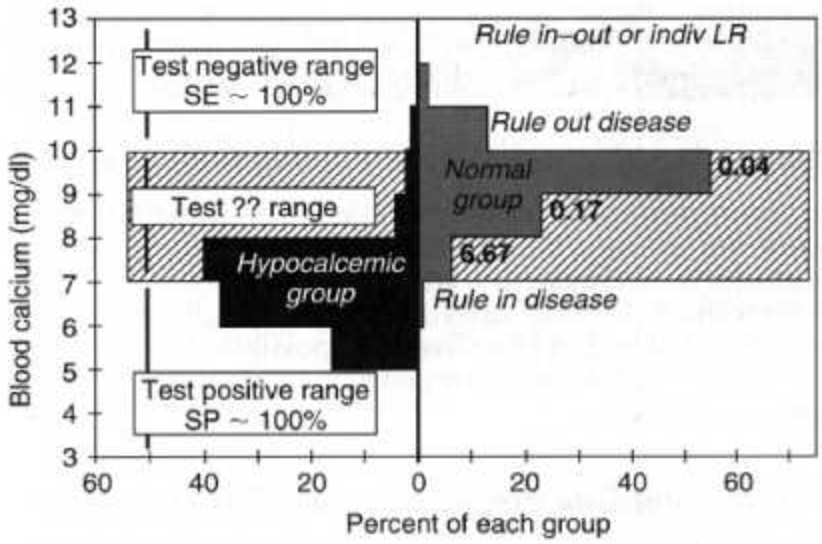

FIG. 2-16 Depiction of the interpretation and decision process regarding test outcomes for the hypothetical blood calcium example. The solid area histograms *(Hypocalcemic group* and *Normal group)* represent the populations listed in Table 2-3. Using the SnNout and SpPin rules (see text for explanation of abbreviations), the test positive and test negative ranges were established. The striped area demarcates intermediate test results (7, 8, and 9 mg/dl) that require use of the individual test likelihood ratios (LR) (ratio of the proportion of diseased animals testing at this level divided by the same proportion from the nondiseased group) and estimates of prior probability of disease to determine how to classify those animals. *SE,* Sensitivity; *SP,* specificity.

In the earlier case, suppose a veterinarian is designing the diagnostic and treatment protocol for a dairy to deal with hypocalcemic cows and this hypothetical cow-side blood calcium test. The veterinarian could design a process as detailed previously, or he or she might wish to depend more on the test, as opposed to the client's ability to create pretest probabilities. For instance, suppose the client's physical examination skills, and hence ability to estimate the probability of an animal's being diseased, were poor. After inspection of the effects that changes in pretest probabilities have on test outcome, the practitioner might decide to increase the rule-in and rule-out ranges because at a 90% prior probability of disease, a finding of 8 mg/dl results in a posttest probability of disease of 14%. This is not a high enough probability for most people to opt for treatment. If so, this means that the rule-out range is actually from 8 mg/dl on up and that only animals testing at 7 mg/dl are in question. This allows a diagnosis and treatment protocol to be designed based on the skills of the client, the type and nature of the disease, and the quality of testing methods. Should the client be better at physical examination, or should the client have more experience at working with the disease, the diagnosis and treatment protocol could be designed to allow for more client latitude (i.e., depending on the client's diagnostic skills) in classifying animals for treatment.

Should a new testing regime be made available, the veterinarian can apply the new test's capabilities to the same framework and determine if the new test will be an improvement on the client's operation by comparing its ease of use and ability to discriminate against the current process. In either case, whether designing treatment protocols or

Downloaded from Vet-e-Books.com

evaluating new tests, the veterinarian can use LRs, SpPin, and SnNout in building and adjusting individual protocols for each client in a repeatable, defensible manner.

Testing Populations Versus Testing Individuals

In production medicine the group is typically the unit of interest. For instance, batteries of tests are often done when an outbreak is investigated or when an import-export function is performed. In these cases multiple independent tests affect the likelihood of FPs. Given this possibility, the way tests are viewed needs to be revamped when they are applied over large populations.

Determining True Prevalence from Test Outcomes

Working with imperfect tests often means incorrectly estimating true prevalence, associating it with "apparent prevalence." To understand how to derive true prevalence is a useful skill in working with disease programs and less-than-perfect tests. For example, the practitioner may take a statistical sample of pigs on a farm, test them for pseudorabies, and then attempt to come to a conclusion about the herd's overall pseudorabies status. In cattle, the tuberculosis and brucellosis programs have similar processes. Practitioners are not always good at interpreting these test results in light of the tests' qualities. The problem, simply put, is the confusion about the difference between *apparent prevalence* versus *true prevalence*. For example, suppose a beef client, after having his 104 cow herd tested for brucellosis (using complement fixation as the only test), is informed that 41 animals tested positive (39% apparent prevalence). Is that the true level of disease in this herd? The true prevalence must be deduced. This is easily calculated by the following formula:

$$\text{TPv} = \frac{\text{APv} + (\text{Sp} - 1)}{\text{Sp} + (\text{Se} - 1)}$$

in which TPv is true prevalence and APv is apparent prevalence. If the Se and Sp of the complement fixation test are known, the true prevalence of the disease can be calculated. Huber and Nicoletti (1986) found the CF test's sensitivity to be 0.90 and its specificity to be 0.58. The APv has been determined already to be 39%. Plugging this into the equation gives the following:

$$\text{TPv} = \frac{0.39 + (0.58 - 1)}{0.58 + (0.90 - 1)} = \frac{-0.03}{0.48} = -0.06$$

Hence, given the previous test characteristics, a finding of 39% apparent prevalence suggests that the true prevalence is actually negative! Of course, a negative prevalence is nonsensical; it means that the disease is not present. With so many FPs resulting from the low specificity, the practitioner needs an apparent prevalence well above this level to feel confident that any of the identified animals are truly infected. As an aside, the complement fixation test is only *presumptive* in U.S. Department of Agriculture rules; it must be confirmed by a highly specific test. The reasoning behind this should be apparent now.

Running Tests in Series: Test Batteries

Often, when investigating a potential disease in an individual or when working up a group- or herd-level problem, practitioners take "test batteries." Some of the more common examples lie in running clinical chemistry panels. Reference laboratories offer the option of running a variety of panels, each specialized for either a species or suspected condition. For example, the standard "small animal panel" or "equine panel" is made up of approximately 15 different derivations. The "food animal panel" often comprises 16 individual tests.

The earlier discussion of test qualities (measurement error, accuracy, discrimination, and precision) suggests an interesting, if rarely considered, problem in running panels. Each test has a certain ability in differentiating "normal" from "abnormal" based on the specific characteristics of the method and processing. Depending on where the test lines are drawn, therefore, each test has a certain likelihood of misclassifying an individual. If the tests are independent (and some of them are not, making the following a little pessimistic), the probability of a panel's coming back with at least one "false-abnormal" finding is equal to the product of each test's likelihood of falsely categorizing a normal animal as abnormal. The ranges shown on most clinical pathology reference tables are the mean result from a significant number of seemingly normal animals plus or minus 2 SDs. When a normal distribution is assumed, this means that roughly 97% of all normal animals should fit in the range. Hence, the practitioner starts out knowing that 3% of all normal animals will not fit in the range (i.e., a 3% FPR). For some species the numbers used to develop normals can be quite small—with reindeer, for instance, the published normals probably are not as valid statistically as those for swine or cattle.

Suppose a baseline panel of five unrelated tests is run on an otherwise healthy goat. If the tests were completely independent, the probability that at least one test will yield a false positive is as follows:

$$P(\geq 1 \text{ FP} \mid 5 \text{ tests @ } 3\% \text{ FPR}) = 1 - (0.97^5)$$
$$P(\geq 1 \text{ FP} \mid 5 \text{ tests @ } 3\% \text{ FPR}) = 14\%$$

Hence, when an abnormal finding appears on an apparently healthy goat, there is a 14% chance of its being a red herring. If this were a testing program on five goats, there is close to a 70% chance that one of them will get an "abnormal" result. If the practitioner simply is looking at which animals may need closer scrutiny—that is, if it is being done as a *screening test*—there is little danger of an occasional misclassification. However, if the test is a test for *Brucella*, tuberculosis, or vesicular stomatitis, in which a positive test means the animal will be slaughtered and the farm or stable will be quarantined (bringing with it all the immediate and long-term financial, personal, and psychological losses), a misclassification can be disastrous. Thus practitioners should never make diagnoses based on tests alone.

Multiple Tests: Screening and Diagnostic Strategies

The previous examples looked at using a single test in a vacuum. Since practitioners do not operate in a vacuum, more than one test can be used. A technique that attempts to use the greatest strengths of individual tests is using tests as *screens* and as *diagnostic tests*. A screen, in the classic sense, aims to identify the maximal number of diseased individuals, at the expense of incorrectly identifying nondiseased individuals as diseased. In the terms used previously, a screen has a high sensitivity (low FNR). Its specificity is not a priority. A diagnostic test, therefore, is used on the population identified as positive to a screening test. It attempts to winnow out the screening test's false positives. Hence, a diagnostic test demonstrates a low FPR (high specificity).

The idea is to use the tests in situations that take advantage of each test's power, yet protect the population from the tests' weaknesses. Biologically the process offers the most efficient way to measure individuals' status within a population. Yet even this process is not perfect; trade-offs are made even when test situations are optimized. This trade-off

TABLE 2-4

*Hypothetical Set of Two Tests**

HI-SE STRATEGY

	DZ+	DZ−						
T+	32	14	46	SE	=	0.97	**Inaccurate results**	
T−	1	53	54	SP	=	0.79	Cull	14 (FP)
	33	67	100	PVPT	=	70%	Keep	1 (FN)
				PVNT	=	98%		

HI-SP STRATEGY

	DZ+	DZ−						
T+	28	2	30	SE	=	0.84	**Inaccurate results**	
T−	5	65	70	SP	=	0.97	Cull	2 (FP)
	33	67	100	PVPT	=	93%	Keep	5 (FN)
				PVNT	=	93%		

SCREEN STRATEGY: HI-SE, THEN HI-SP

	DZ+	DZ−		DZ+	DZ−					
T+	32	14	46	27	0	27	PVPT	=	100%	
T−	1	53	54	5	14	19	PVNT	=	92%	
	33	67	100	32	14	46	**Inaccurate results**			
							Cull	0	(FP)	
							Keep	6	(FN)	

*One test has a high sensitivity *(Hi-SE strategy)*, and the other has a high specificity *(Hi-SP strategy)*. Each test is run, by itself, on a group of individuals in which the group prevalence for the disease in question is 33%. Then they are run in series, using the standard "screening and diagnostic" test strategy *(Screen strategy)*; the highest SE test is run on the whole group and the high SP test is applied to those testing positive to the first. The end result of the screening-diagnostic strategy is that the dual test scheme displays the highest average predictive value compared with either test alone; it removes the false culls yet returns the most diseased animals back to the herd. *FN*, False negative; *FP*, false positive.

TABLE 2-5

*Continuation of the Process from Table 2-4**

SCREEN STRATEGY: HI-SP, THEN HI-SE (SP, SE)

	DZ+	DZ−		DZ+	DZ−					
T+	28	2	30	27	0	27	PVPT	=	100%	
T−	5	65	70	1	2	3	PVNT	=	92%	
	33	67	100	28	2	30	**Inaccurate results**			
							Cull	0	(FP)	
							Keep	6	(FN)	

*This time the two tests are run in the reverse order: the highest specificity *(Hi-SP)* test is run on the whole group and the high sensitivity *(Hi-SE)* test is applied to those testing positive to the first. The end result of the "reversed" screening-diagnostic strategy is the same as for the standard screening-diagnostic strategy from Table 2-4.

weighs the relative merits of minimizing false positives versus the false negatives. One, of necessity, will be higher than when at least one of the tests is used alone. The following example helps to illustrate this.

Assume a practitioner wishes to identify individuals with a communicable disease in order to cull them. Further assume there are two tests: one with a high sensitivity and a relatively low specificity, and the other having just the opposite. One of three testing strategies can be chosen, as shown in Table 2-4: (1) only the high sensitivity test ("Hi-SE"), (2) only the high specificity test ("Hi-SP"), and (3) the Hi-SE test as the screen and the Hi-SP test as the diagnostic test ("Screen strategy"). The 2 × 2 tables in Table 2-4 show the results of each strategy when used in a population with a 33% disease prevalence.

This is all great. The screen-diagnostic method yields a higher average PVPT and PVNT than either test alone. It wrongly culls fewer animals, too. However, it allows more diseased animals to stay in the herd. Plus it runs 46% more tests than either test alone.

Just for fun (this *is* fun, right?), what would happen if the analyst ran the screen-diagnostic strategy just the opposite (i.e., using the Hi-SP first and following with the Hi-SE)? Table 2-5 uses the same data as before, simply with the order reversed.

The outcomes are *identical!* This is actually a pretty intuitive result, since the test results are a matter of multiplying a set of efficiencies against the initial population and then following with a second set of efficiencies being multiplied against the result of the first multiplication. Since multiplication is order independent (i.e., 3 × 5 = 5 × 3), they should get the same answer. If, biologically, it doesn't matter how the screening-diagnostic test strategy is run relative to the comparative SE and SP of the involved tests, the strategy's order must be chosen based on other criteria.

Economically Choosing How to Run a Screening-Diagnostic Test Strategy. The choice depends on the relative cost of each test. The SE-SP strategy runs a total of 146 tests, with 2.2 SE tests per SP test (100, 46 respectively). The other strategy, SP-SE, requires only 130 tests total, with 0.3 SE tests per SP test (100, 30, respectively). These values can be placed into an equation, setting the one strategy equal to the other, and solving for the relative costs that fulfill the equality:

$$100\text{Hi-SE} + 46\text{Hi-SP} = 100\text{Hi-SP} + 30\text{Hi-SE}$$
$$70\text{Hi-SE} = 54\text{Hi-SP}$$
$$(70/54)\ \text{Hi-SE} = (1)\ \text{Hi-SP}$$
$$(1.296)\ \text{Hi-SE} = (1)\ \text{Hi-SP}$$

Algebraically, the rough break-even price ratio of the two is Hi-SP = 1.3 × Hi-SE. If the Hi-SP test costs more than 1.3 times the Hi-SE test, the SE-SP strategy should be chosen. If the Hi-SP test costs less than 1.3 times the cost of the Hi-SE test, the SP-SE strategy should be chosen.

Using System Efficiency Measures (Number Correct Versus Number Incorrect Classifications) as a Method to Choose Between Two Screening-Diagnostic Testing Strategies. The SE-SP strategy yielded over six correct calls for every incorrect classification (126 versus 20). The SP-SE method, though, achieved a greater than 15:1 (122 correct to 8 incorrect) ratio in correct to incorrect classifications. As in the prior example, a value could be placed on each test outcome (i.e., each false positive, false negative, true positive, and true negative). Then the opposing screening-diagnostic test costs could be compared against this valuation to select the optimal strategy.

With either type of analysis, choosing between testing strategies requires more than knowledge of test efficiencies, since they both involve economic methodologies. Not surprisingly, that is the next topic.

ECONOMICS

Economics has been defined as the science of allocating scarce resources between competing wants. It has also been defined as the hard science of the humanities and the astrology of the hard sciences. Both descriptions fit. As a discipline, economics has tried to explain things as different as human motivation and the market price of a wheelbarrow. The techniques it employs are used to evaluate the past, appraise the present, and predict the future. As a working tool it is not perfect in performing any of those three functions.

Both private and public practice veterinarians involved in agriculture live in a world governed by economics. Private practitioners' decisions and recommendations have economic impacts on their clients and the markets to which the clients sell products. Veterinarians involved in regulatory occupations can have major impacts on a county, a state, an industry, or even a country. As a result, it is important for both segments of the profession to have an understanding of economic basics.

The majority of the learning curve in economics is concerned with digesting the nomenclature of the discipline. The language is peppered with a variety of abbreviations such as APR, TP, MVP, IRR, and others. It also uses jargon such as *utility, opportunity cost,* and *marginal value* and differentiates between seemingly synonymous terms such as income, revenue, and profit. Lastly, it uses a graphical and mathematical means of proving and disproving points of contention. Luckily, most of the vernacular and mathematics is simply a shell over common sense and logic.

As a discipline, economics is most commonly divided into two major areas of inquiry: *microeconomics* (mainly concerned with firms or groups of individuals [often called "markets"]) and *macroeconomics* (study of the function of whole economies on the level of countries or continental regions; it attempts to account for all facets of an economy such as unemployment, inflation, and relations between countries or regions). Both microeconomics and macroeconomics deal with supply and demand and the interaction of producers and consumers. Therefore a great deal of overlap exists between the two. Government regulations (certainly a macroeconomic function) affect individuals and markets. Further, markets can apply pressures that cause macroeconomic changes (look at the impact foreign automakers had on U.S. economic policy and international trade programs of the 1980s and how the inception of the North American Free Trade Association has altered the local markets and businesses on both sides of the participants' borders), and market trends are often analyzed using macroeconomic techniques. Whereas macroeconomic factors determine the landscape in which veterinarians and their farming clients operate, practitioners do not strongly affect the macroeconomic factors. Therefore this section primarily focuses on microeconomics as it relates to production and production medicine. However, in agriculture, macroeconomic trends can never be far from mind.

Supply and Demand

Supply, in economic terms, refers to the quantity of some item that producers are willing to create at a certain price. In the U.S. economic system, supply is determined almost exclusively by price: the higher an item's value, the more apt it is to be produced. *Demand,* in economic terms, refers to the quantity of an item that consumers are willing to purchase at a certain price. The more something costs, the less of it a consumer will buy. The radio may report on supply or demand, but in most cases they do not provide the full economic description because all they usually refer to is quantity. Remember, to be economically meaningful, *both* the quantity and price are needed.

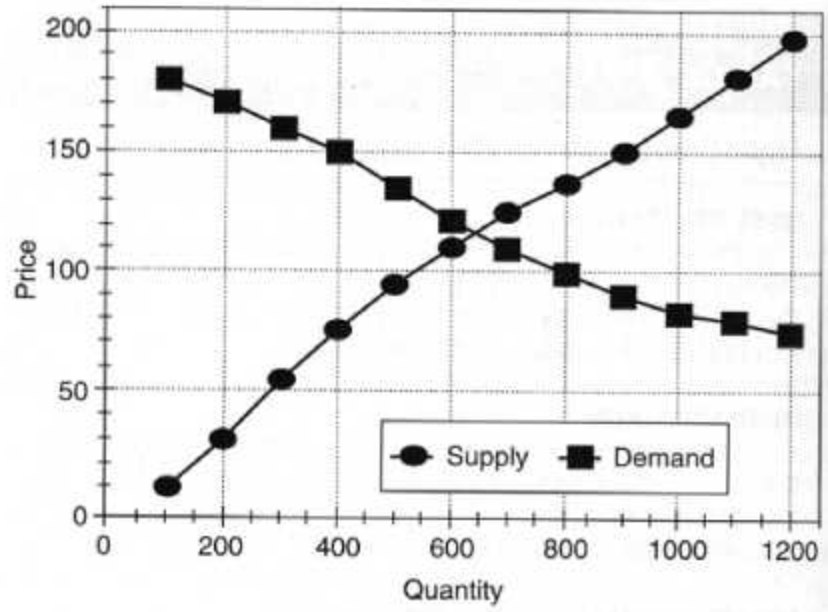

FIG. 2-17 Depiction of typical supply-and-demand response curves for a hypothetical product. As price of the commodity rises, more producers can afford to create the commodity, so supply goes up. Demand, however, decreases in the face of rising costs. The point where the two lines cross is the equilibrium point. This is the price and quantity combination where both supply and demand are satisfied. Left on their own, most markets move toward the equilibrium point.

Fig. 2-17 shows an example of supply-and-demand curves for some hypothetical commodity. They are increasing or decreasing curves, not merely straight lines. The point at which the two curves intersect is called the *equilibrium point* and is the price and quantity at which both curves are satisfied (i.e., supply equals demand). At other points along the curves, supply and demand are in *disequilibrium* and the market is unstable. This occurs often in the short run, but if left alone, prices will change such that equilibrium is once again reached.

In Fig. 2-18 the price shown as "A" is a disequilibrium price. At this point, to sell all the product, price must fall (the line connecting the two curves, points 1 to 2). Producers cannot afford to maintain this level of production, so they scale back (line connecting points 2 to 3). This low a quantity, however, does not meet demand, and price jumps (line 3 to 4). At this price, producers can afford to supply more, so quantity increases (line 4 to 5). This makes price drop, and the whole thing continues until equilibrium occurs once again. Adam Smith, the economist of colonial times, called this tendency for a market to move toward equilibrium an economy's *invisible hands.* The invisible hands are actually the summation of a number of individuals' decisions to produce and purchase a product. This pattern of economic behavior is referred to as the *cobweb theorem* for obvious graphical reasons.

Demand and Supply Analysis (Elasticity)

Different products have different shaped and sloped curves. Economists call the slope of a curve the product's *elasticity.* Elasticity of demand is a simple calculation referring to the relative change in quantity of a product demanded divided by the relative change in price. Supply elasticity looks to the change in quantity supplied divided by the relative change in price. If the slope is low (in most graphs such a line appears relatively flat), this is called *elastic;* it indicates that a large percentage change in quantity occurs when price changes only a little. If the change in quantity is low when

Downloaded From Vet-eBooks.com

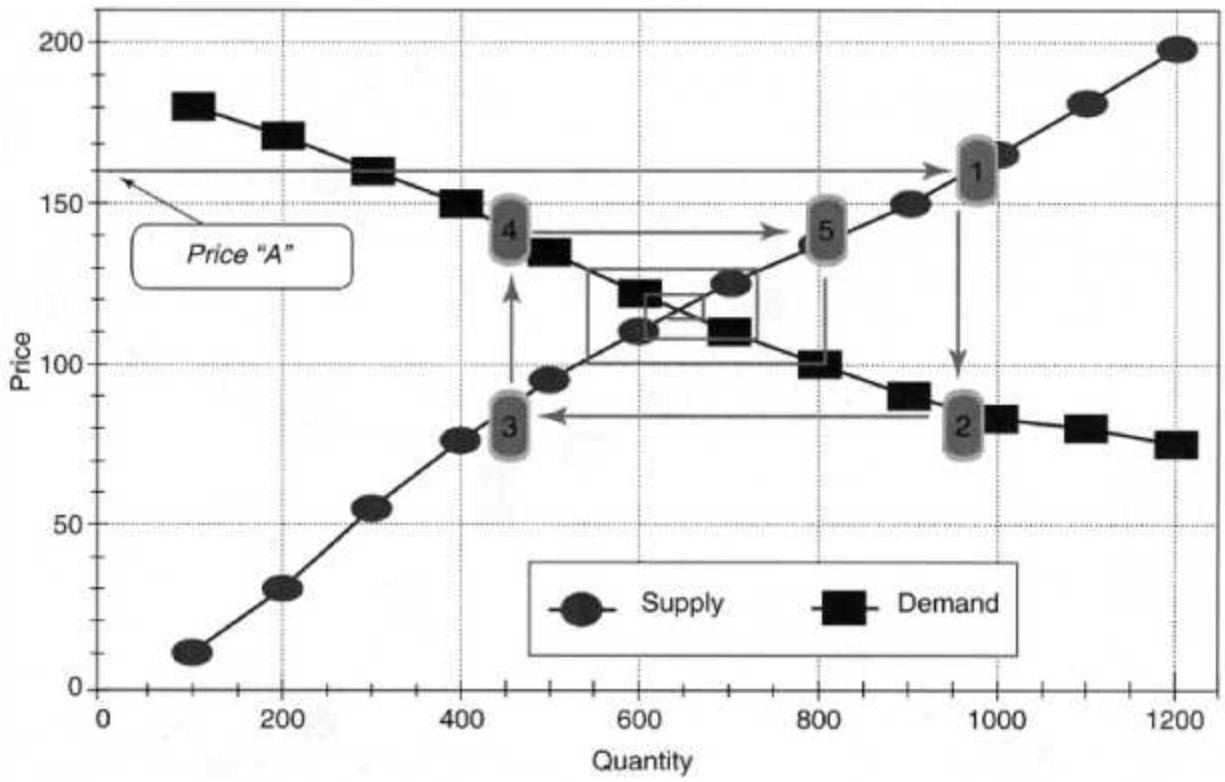

FIG. 2-18 Graphical display of the "cobweb" or "invisible hands" theory of market equilibrium. If price is set at a disequilibrium level *(Price "A")*, supply is greater than the quantity demanded *(1)*. This causes prices to drop to the point where demand will clear the market *(2)*; another disequilibrium price. This price, however, is below that which producers can maintain supply, so they scale production back *(3)*. Now supply is being outstripped by demand, so prices rise again *(4)*; yet another disequilibrium price, but closer to market equilibrium than before. At this high price more producers can operate in the market, so supply rises and once again exceeds demand *(5)*. This causes a continuation in the price-and-supply oscillation until the market settles at the equilibrium price and quantity, satisfying both supply and demand.

price changes a lot (in most graphs such a line appears relatively vertical), it is called *inelastic*.

Fig. 2-19 shows an instance in which supply is elastic (price changes approximately 100 units for a change in quantity from 200 to 1000) and demand is relatively inelastic (price changes approximately 200 units for the same change in quantity). This is an instance of market instability even at price equilibrium, since a minor fluctuation in price greatly affects supply (i.e., a small change in price results in a major change in quantity supplied), but it does not translate into a similar change in demand. This can set up a market, as Fig. 2-19 shows, in which prices oscillate wildly, causing the market always to be unstable. Hence, the producer is at risk. This situation is common for staple goods (bread, surgeon's gloves), low-risk actions (buying feed), essentials (semen for AI technicians, calcium solutions for dairies), and agricultural production in the short term. In these situations, market demand is relatively price sensitive, whereas production is not. Were the relationship reversed—that is, were supply inelastic and demand elastic—this would mimic the market for luxury items (yachts, caviar, jewelry) or risky endeavors (developing new products, starting new health programs).

Elasticity indicates a market's ability to react to changing times and conditions. As in Fig. 2-19, if both curves show inelasticity and elasticity, changes in market price can cause the market to "explode" as opposed to reaching equilibrium. Unfortunately, most of agriculture displays fairly similar short-term supply-and-demand functions, leading to farming's famous "boom and bust" cycles. Agriculture, particularly capital-intensive agriculture, can be quite prone to this unstable disequilibrium. For instance, once a sow farrows, there is little the producer can do to increase or decrease the number of piglets in the production system; if prices go up or down, the producer cannot change production to match. On the demand side, some products are quite elastic with price. For example, the demand for fishmeal may vary greatly if the price changes only a little relative to the price for other protein feed ingredients.

Production Function Analysis and Interpretation

To understand production, the reader, whether working in a veterinary practice, making widgets, working on the executive board of a zoo, running a laboratory animal resource center, or farming, must gain an appreciation for several dynamics of production. Understanding the relationship between costs, inputs, outputs, and returns provides a good idea how much of the product should be produced and if the producer can afford to expand. Fundamentally, understanding the costs of production allows for planning and realistically budgeting for the future.

Introduction to Production Functions: Total Revenue (Total Product)

Production functions are tabular schedules, graphs, or equations that relate a variety of costs of production with a firm's profitability. When graphed, they relate inputs to outputs and are called *production curves*. By convention, the units on the vertical axis are in units of returns (units of money, pounds of gain, eggs per hen) and the horizontal axis is in units of inputs (pounds feed, gallons of fertilizer, worker hours, units of money).

Fig. 2-20 depicts a production function developed from published feed requirements for growing beef calves at recent local North Carolina prices (National Research Council, 1996; North Carolina Department of Agriculture and

Downloaded from Vet-eBooks.com

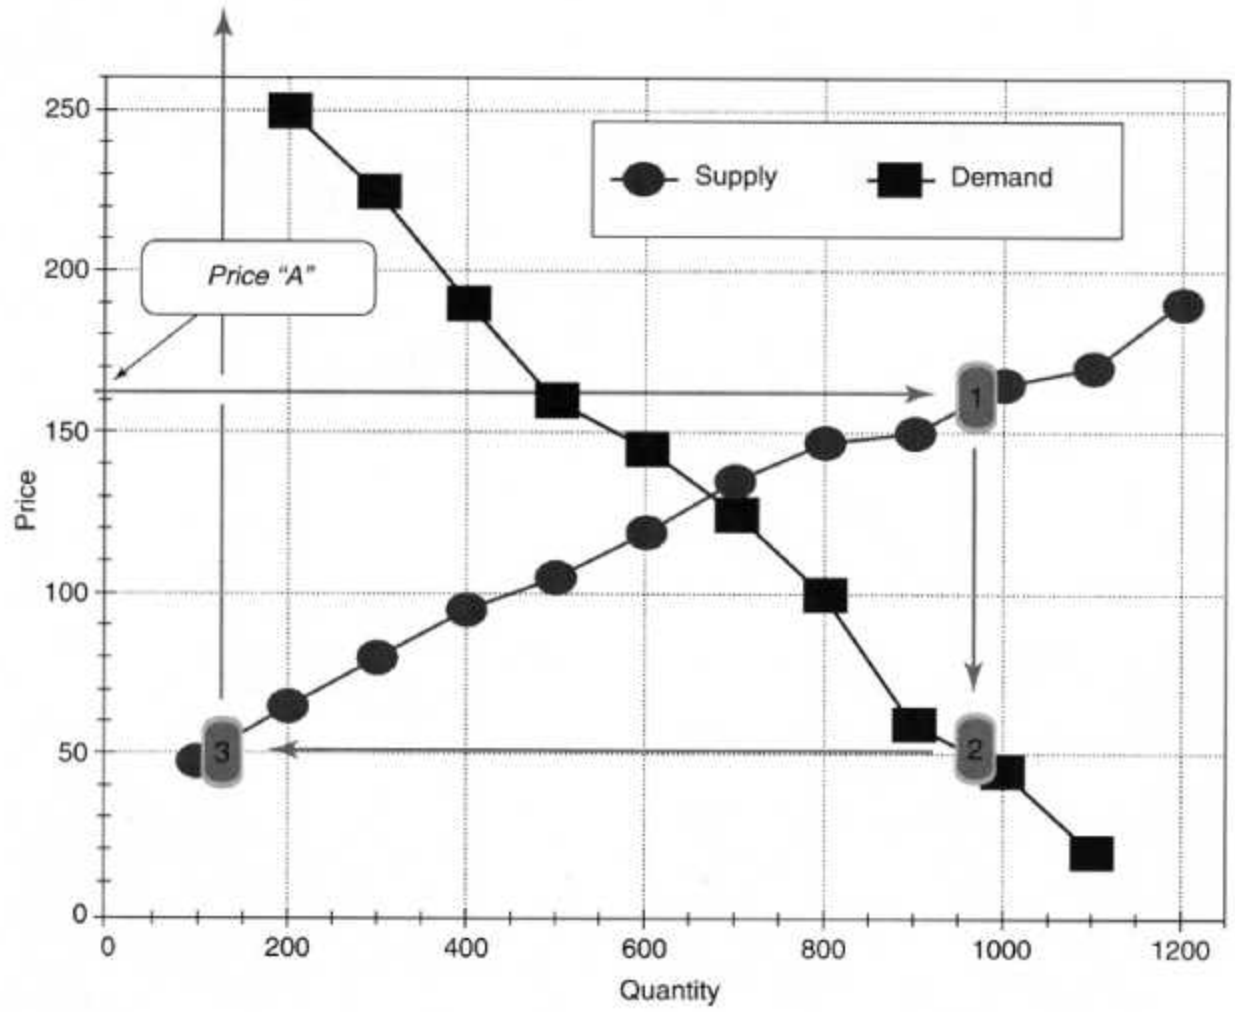

FIG. 2-19 Graphical depiction of a case in which supply is relatively elastic (horizontal orientation) and demand is relatively inelastic (vertical orientation). If price is set at a disequilibrium level *(Price "A")*, supply is greater than the quantity demanded *(1)*. Price drops precipitously because of the more vertical orientation of demand in this figure compared with Fig. 2-18, to clear the market at point *(2)*. This price, however, is much lower than that which producers can maintain supply. Only a few producers remain in the market, and supply then crashes *(3)*. At this extreme level of scarcity, price would need to skyrocket beyond the limits of the chart to cross the demand curve. As a result, disequilibrium pricing in such an unstable market causes the market to spiral out of control, establishing a "boom and bust" oscillation of prices and quantities.

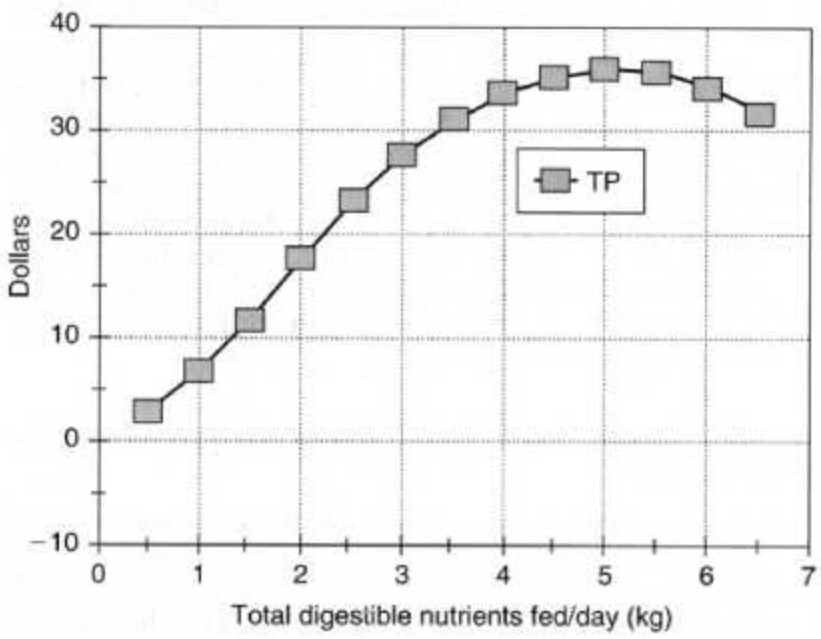

FIG. 2-20 Production function for raising beef steers in the North Carolina market (spring 1999). The total revenue or total product (TP) is the income expected by selling steers at market. The inputs here are feed inputs, measured as total digestible nutrients *(TDN)* fed per head per day. Note that the curve shows a slight sigmoid form from 0.5 to approximately 3 kg TDN. After that point it shows diminishing returns; adding more TDN/day yields a lesser return, until after 5.0 kg/day, returns actually decrease.

Consumer Services, 1999). It relates the income expected against the amount of feed given per animal per day, in units of total digestible nutrients (TDN). For the sake of this demonstration, the relationship has been smoothed out somewhat, but the trend is based on real data. *Total revenue* or *total product (TP)* is the overall revenue curve. It shows "diminishing returns," meaning that production is not a straight-line relationship with input. Like most TP curves, this one climbs quickly at the start, reaching a point of inflection somewhere at 2.5 to 3.0 kg TDN per day. After this it continues to rise but at an ever lesser rate. Finally, there is a point where, perhaps because the ration is too energy dense or requires too high a dry matter intake, the efficiency of production drops and the value of the next pound of gain becomes negative. This is a common finding; most activities reach a point of diminishing returns, whether they are time invested in studying, money spent on an old car, or number of beers consumed. After a point the "returns" on continued activity begin to drop. For this reason the practitioner needs to be aware not of *maximum* production, but *optimum* production. This requires knowing more than just the total output of a system.

Average and Marginal Product

One way to look at production is to evaluate the "average" production at each point on the line. *Average product (AP)* is

Downloaded From Vet-eBooks.com

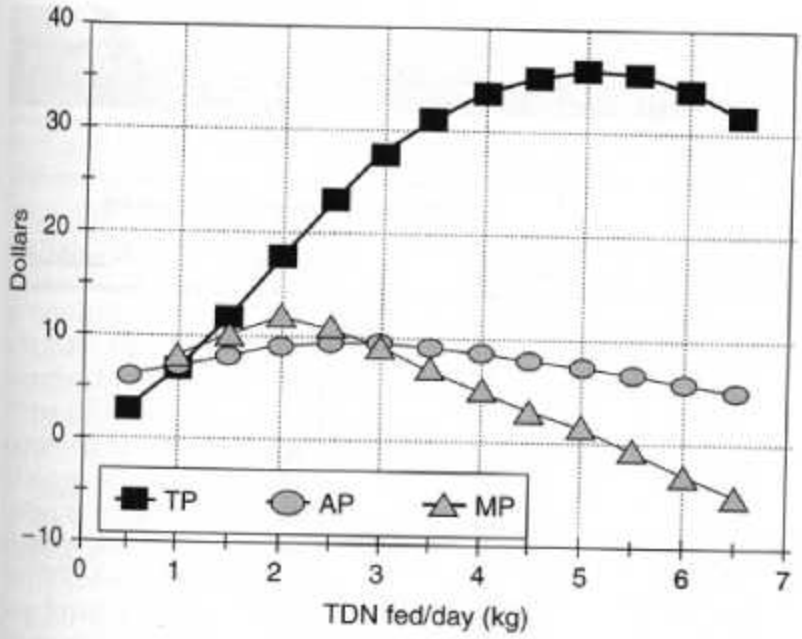

FIG. 2-21 Continuation of the steer beef production function analysis from Fig. 2-19. Here, average product *(AP; total revenue [TP]*/total digestible nutrients *[TDN]* input) and marginal product *(MP;* change in TP/unit change in TDN input). AP is an efficiency measure, whereas MP determines income for the last unit output. In this chart efficiency is maximized (i.e., AP reaches its highest) at approximately 3 kg TDN/day; however, the producer still can increase revenue by increasing TDN inputs until marginal product crosses 0 (i.e., the last unit input did nothing to increase revenue) at just over 5 kg TDN per head per day.

calculated by dividing TP by total units input. It is, then, the output per unit input for the production range. This curve for beef production is shown in Fig. 2-21. Note how the AP first climbs, then drops off. It reaches its peak at the TP-curve point of inflection. This is the point of highest average efficiency of the process. At the maximal AP, additional inputs lower efficiency but yield more income. Hence, maximal average return probably is not the most profitable production level. To get at profit, the analyst really needs to know not just where maximal efficiency lies, but at what point income is lost by increasing production. It makes sense that before that point, production would be near to being most profitable. The marginal cost of additional product is needed.

Marginal product (MP) is the incremental change in total product associated with a one-unit change in input. An example is shown as the other new line in Fig. 2-21. When MP is greater than AP, AP increases. MP and AP cross where AP is maximized. That is, any point of production beyond that level will be at a lesser overall efficiency. However, for a time after this point MP is still positive, it is still profitable to produce, even if it is at a lower per unit return. When MP finally goes negative, it no longer makes sense to produce more product—it no longer increases output. This occurs when the TP curve hits its maximum. Conceptually, it makes sense: If total income starts to fall, the value of each added unit of product must be *subtracting* from the overall income. That is, marginal values must be less than zero. Beyond this point it makes no sense to produce.

Stages of Production: Goldilocks Had the Right Idea

The TP, AP, and MP curves delineate three separate regions of production. *Stage I production* starts at the lowest production and ends where MP and AP cross: at maximal average efficiency. *Stage II production* ends where MP goes negative, where it does not pay to produce anymore. If a producer is at Stage I, additional input definitely will increase efficiency and profit. Hence, it makes no sense to operate at this low a production level. Any producer in Stage I should be working to move up to Stage II. A producer in *Stage III production* is lowering yield; total revenue is dropping. So it does not make sense to produce in Stage III. Stage II, then, is the rational region of production. Somewhere in Stage II is the optimal production level—money always will be lost below it and above it. Much like the story of Goldilocks and the three bears with their bowls of porridge, one stage of production is too hot (Stage I), one stage is too cold (Stage III), and one stage is "just right" (Stage II).

The value of staging production in the way just mentioned is that an analyst need not consider production ranges below maximal average efficiency or above where additional production cuts into revenue. Both usually can be calculated fairly easily, given that a few levels of production already exist. Staging, then, allows the analyst to concentrate on the area of production at which profit is at its highest. Of course, to find the maximal profit, the producer needs to look at *monetary costs,* not just units of input.

Costs of Production. Although production curves address units of input versus units of output, and these certainly can be put on a dollar-cost basis, there is more to "costs" than simply tallying inputs. Four costs are commonly discussed: fixed, variable, marginal, and opportunity. Fixed, variable, and marginal costs refer to the production process itself; opportunity costs relate to the costs incurred by choosing a nonoptimal action.

Fixed costs are those costs of an operation that do not change with level of production. They are incurred whether a farm is at maximal production or not; most still will apply even if the farm is not producing anything. Fixed costs can include mortgage payments, property taxes, insurance, equipment and building depreciation, warehouse rent, interest on capital, and management salaries. *Variable costs* represent those expenditures that increase with gains in production and decrease with drops in production. They are basically direct inputs into production, such as materials, seed, water, feed, labor, most power costs, and fuel. It is not, however, a straight-line relation with total output. This shows that, as in revenue, costs show variable returns to inputs. Remember that these definitions are time dependent. In the short term, such as a week or two, nearly all costs are fixed. However, as the time horizon increases, nearly all costs can be changed. *Marginal costs* are described in the next section. *Opportunity costs* are the costs of making a nonoptimal decision. Suppose a farm has the option of growing either winter wheat or barley. Historically wheat may be the best choice, but if this year a new brewery opens down the road, the local demand for barley (and hence its price) may rise. If the farmer chooses wheat, and barley returns $100 per acre more than wheat, that $100 is the opportunity cost of having chosen wheat.

Marginal Analysis. Just as the production functions show marginal products (the incremental increase in revenue by increasing production by one unit), the cost curves show marginal costs (the incremental increase in cost by increasing production by one unit). The relationship of marginal product and marginal cost determines a firm's optimal production point. Table 2-6 shows the production and cost schedule for producing cattle that has been used in this section. For this example a $5 per head per day fixed charge was attached to the production to cover taxes, mortgages, insurance, etc. Other costs were adapted from the current market data referenced earlier.

Marginal costs are the costs of producing one more unit of product. As defined before, marginal product is the revenue realized from one additional unit of product. Common

6.0	5.00	39.00	44.00	16.00	34.50	5.75	−3.00
6.5	5.00	48.50	53.50	19.00	32.00	4.92	−5.00

TDN, Total digestible nutrients.

*Optimal level of production can be selected as the level where Marginal Cost equals Marginal Product. In this table, optimal production occurs at or near 3.5 to 4.0 kg TDN per head per day (bold rows, circled values).

Data adapted from the National Research Council (1996) and North Carolina Dept. of Agriculture and Consumer Services (1999).

sense dictates that when it costs more to produce something than is given in return, it is time to stop. Until that point, however, each additional unit increases total profit, even if only a little. As seen in Table 2-6, it appears that at a quantity somewhere between 3.5 and 4.0 kg TDN input the marginal cost equals marginal product and is therefore the optimal level of production. This occurs well within the Stage II production, fitting the definition of the rational production region.

Most farms (or veterinary practices, for that matter) cannot perform constant and consistent marginal analyses of production; costs and revenues vary too much to make the effort worthwhile. However, they can identify fairly quickly Stage II production. A reasonable first step for a manager is to keep the firm's productivity in that range, since it is close to optimal. The better the records, however, the more apt an operation is to be able to identify an ever narrower range of production in which MC will equal MP and hence will be able to target inputs and outputs to truly maximize profit.

Where We as Veterinarians Err. (Or "Why did he drag us through all of this production function nonsense?"). A few moments spent looking at Fig. 2-21 and Table 2-6 will point to an error the veterinary profession, agricultural extension agents, and animal science researchers have been making for years: *Maximum efficiency is equated with maximum profit.* But the table and figure demonstrate that maximum efficiency results in the highest *average* return (somewhere around the $9.40 level, with 2.5 kg of TDN per day), not the highest *total* return (where AP is between $9.00 and $8.50 and TDN input is between 3.5 and 4.0 kg/day). *Therefore highest profit for an operation—whether a clinic or a farm, a car manufacturer or a restaurant—occurs at some point beyond maximal efficiency.* If a client is forced to maximize efficiency, the client is also forced into suboptimal profit regions.

Practitioners' health programs aim to maximize efficiency, as do the management programs and health goals and plans. Success of a program or management practice is often assessed by measuring "average daily weight gain," "herd-level income over feed costs," "average milk per cow per day," "income per worker hour," or "pigs weaned per sow per litter." These are measures of *average product* or efficiency, *not* measures of profit. They occur at the very beginning of Stage II production. Therefore, if a client stays at maximum efficiency, the client always will be straddling between rational and irrational (i.e., Stage II and Stage I) levels of production. Is that really where the client should operate?

Much to the practitioner's chagrin, and often against his or her heartfelt recommendations, clients often try to "squeeze" a few more feeders in a pen, or push the milking parlor "a little" beyond capacity. Practitioners should not be surprised when clients choose to operate at levels considered "inefficient"; they are maximizing profit just as they should. This is just a fundamental fact of production economics.

Costs of Animal Diseases

Overview of Disease Costs

Costs of animal diseases come in a variety of guises. There are the obvious *direct costs* of disease, such as medicine, treatment labor and equipment, and professional fees. These are out-of-pocket costs that are readily apparent and fairly easy to measure, but they often make up a minority of the disease's true costs. Other costs include *losses in production.* These costs of disease are more difficult to document. Diseases that cause morbidity also decrease feed efficiency, causing losses in production of meat, milk, eggs, and fur. However, debilitation also limits production of offspring and depresses genetic gain. These losses therefore must include not only the losses of production not realized, but also the losses in efficiency of what was produced. Animals provide economic value beyond that often considered within the bounds of agriculture, resulting in *nonagricultural losses.* In many parts of the world, disease costs are dominated by losses in labor or work performed by stricken

Downloaded From Vet-eBooks.com

animals (plowing, transportation, water pumping, grain grinding), by the loss of manure used for fuel (and the impoverishment of the environment when other fuel sources such as wood and ground cover are used instead) or fertilizer, and by the loss of liquidity (bartering potential and social status) and crop storage (feeding crops to animals converts that energy and protein to a form that the animal carries long after the crop is out of season) that animals provide for many people. Disease costs to *wildlife and companion animal populations* also can be great. Destruction of wild populations causes environmental degradation, allows foreign species to take root in an area, and can unbalance ecosystems. Companion animal losses, while often primarily accounted for in the direct costs of disease, also affect resource allocation (professional time and effort) that hinders other aspects of disease control. *Zoonotic disease losses* can be extreme. The losses of human labor, work efficiency, resource reallocation, medical expenses, and political support resulting from zoonotic diseases such as brucellosis, tuberculosis, and rabies cannot be overstated. Many of these diseases have, as their greatest costs, the expense of preventive programs and activities.

Details of Disease Costs

The direct economic losses from livestock diseases derive from biological losses. Measuring the financial losses can be approached using many of the same techniques used in biological epidemiology, with the addition of several factors specific to economics. Dollars, as well as morbidity and mortality, must be measured. Preventive and therapeutic inputs need to be included, as does labor. The concept of morbidity needs to include impacts on productivity and efficiency in addition to the traditional areas of subclinical and clinical disease effects.

The biological effects manifest themselves in a variety of ways: clinical, subclinical, carrier states, death. Each has its own economic impact. In addition to the economic toll arising directly from a disease, some economic impacts extend beyond a disease's biological effect on an individual animal or group. These include disease control activities, public health risks, genetic losses, impacts on management activities and the allocation of resources, limitations on marketing channels, reduced opportunity to enter into certain animal production activities, and the increased variability of farm output and efficiency (risk) and therefore reduced chance for survival of a farm or industry as an economically viable unit.

Direct economic losses to the production unit are the most obvious results of disease. These losses can be broken down into changes in revenues and changes in expenses (using the techniques derived from partial budgets). Disease control interventions have their impact by increasing revenues (or decreasing losses) or by reducing expenses. Some examples, with notes, are listed in Box 2-1.

Some points that are raised from the listing of disease and program costs deserve expansion. The costs of disease obviously depend heavily on current market conditions. The cost of a disease outbreak is greater when the market prices for animals are high than when prices are low because the relative value of the individual losses is greater. However, the overall financial picture of the farm on entering the disease losses is better in times of high prices. Therefore the outbreak may be more likely to bankrupt an operation when prices are low, even though the per animal costs are less.

Aspects of the disease and its losses undoubtedly are overlooked in the previous discussion and Box 2-1. However, no on-farm study approach to disease economics clearly provides answers to all of the aspects previously listed. In the example for pseudorabies in swine shown at the bottom of Box 2-1, on-farm studies can address the first seven to nine items and can provide some of the basic input data needed to do the calculations for items 8 to 14. The results can guide investigations and economic models that address items 15 through 20. Some items in this example (those dealing with trade or regional markets) require both macroeconomic and microeconomic evaluations to be complete.

Costs of Disease Control–Eradication Programs

Overview of Disease Control–Eradication Costs

Disease program costs can be broken into four large and overlapping categories. *Personnel costs* would include professional and lay staff. Costs of training, performing project related activities, and associated benefits are included here. Costs of *surveillance* are often great. Here, travel expenses, data collection, information processing and collating, reporting costs, laboratory expenditures, supplies, and administrative encumbrances are important. It should not be forgotten that surveillance involves both "seeing" and "telling." Many programs have high *compliance costs* associated with them. These can include costs of educating the public and producers (travel, personnel, supplies), administrative costs in monitoring and reporting program accomplishments, and the potential for indemnity payments as client compliance inducements. Lastly, a disease program analyst must include *costs of infrastructure* associated with a disease control program. These include, but are not limited to, purchase and maintenance of equipment (phones, data processing, communications, laboratory, vehicles), general supplies (paper, binders, uniforms), medication storage and transport, and general administration and oversight.

Again, many program costs overlap. Administration is mentioned several times, as are supplies and personnel costs. Partitioning such costs to various segments within a large regional program can be a daunting task. Much of the information needed for accurate cost accounting is, at best, difficult to generate for animal diseases. If you expand cost accounting into the wildlife and human loss arenas, the cost description becomes exceedingly complex and demanding because of the lack of hard figures and the general inaccessibility of much of the needed information.

Details of Disease Control–Eradication Costs

The costs of disease control are largely a function of the underlying structure of the group or organization running the program. For instance, the cost of a government level control program includes items and concerns different from that run by a veterinary clinic. A clinic is not likely to pay indemnities, yet needs to carefully account for its added costs in administering a program. With this in mind, here are a few added thoughts.

When accounting for personnel costs (especially in developed countries), the practitioner must be certain to account for benefits in salary considerations. Currently, an additional 25% to 33% in costs over salary can be expected to be incurred by an employer to cover benefits (health plans, medical insurance, retirement, etc.). Such costs are mandated by government fiat (local, state, or federal) and through private enterprise (labor unions and standards of practice).

Training costs have hidden expenses. Often practitioners do not take into account that training an individual in new skills requires taking that individual off his or her current job. This means either that job goes undone for the duration

Downloaded From Vet-eBooks.com

BOX 2-1

General and Specific Cost Considerations for General Animal Diseases and Specifics for Pseudorabies in Swine

CHANGES IN REVENUES WITH DISEASE CONTROL

1. Deaths avoided: estimating this can be difficult. A common approach is to take market values and deduct further variable costs needed to bring the animal to market. This is essentially a marginal costs exercise.
2. Improved weight gain–feed efficiency: for this, parameters to be economically relevant, costs of gain (feed costs) need to be assessed.
3. Increased reproductive efficiency: measuring the value can be a complex, situation specific task. It will be different for a commercial producer of terminal crosses versus a producer of breeding animals.
4. Increased milk, wool, eggs: the value is again a marginal analysis.

CHANGES IN EXPENSES WITH DISEASE (CAN GO UP OR DOWN)

1. Changes in feed costs
2. Drug, chemicals, vaccine costs
3. Veterinary services
4. Culling losses (commonly replacement cost minus salvage value)
5. Changes in physical facilities (should be their useful life if they are a major expense)
6. Downtime in the facility
7. Loss of genetic value (commonly handled by subtracting the value of a replacement animal with equal genetics)
8. Labor (can be difficult to capture; one approach is to ignore labor and then attribute any profit from a program as payment for labor and management efforts)

EXAMPLE: COST OF PSEUDORABIES IN SWINE

1. Dead pigs with clinical disease
2. Pigs dead of other disease, either via pseudorabies' sequelae or because management efforts directed at pseudorabies resulted in problems in other areas
3. Specific therapeutic measures against the disease or secondary diseases
4. Reduced litter size, abortion, or reproductive inefficiency
5. Reduced weight gains or feed efficiency, again either directly through the disease or because of management changes brought about by the disease
6. Costs for vaccination and preventive measures such as isolation and disinfection
7. Increased labor costs as a result of the disease
8. Loss from facility down-time during eradication or control (opportunity cost)
9. Loss of genetic stock, particularly in purebred or breeding stock production units
10. Lost value of product because of presence of disease
11. Loss of market for breeding or feeder pig stocks
12. New facility construction for herd repopulation
13. Costs for disease testing for eradication or control
14. Regulatory costs for surveillance and monitoring and control programs and administration
15. Increased risk and reduced attractiveness for swine production in regions known to have pseudorabies
16. Reduced entry into the swine business because of risks if pseudorabies enters a unit
17. Bankruptcy from reduced production or increased costs resulting in nonprofitability
18. Risk of bankruptcy to a profitable unit that cannot meet cash flow needs in the midst of a disease flare-up
19. Loss of export markets
20. Public health effects (not known to be important) or companion animal and wildlife effects (possible)

of the training (encumbering opportunity costs) or additional personnel must be hired or moved to cover that individual's activities (adding more personnel salary [often as overtime] and benefits).

Costs of infrastructure can be the limiting factor in program costs, especially when the unit of interest is a region or country. For instance, in a rinderpest and foot and mouth disease program run in Africa during the 1960s and 1970s, the costs and requirement for vaccine refrigeration capacity were enormous. Individual farms can face economically insurmountable infrastructure costs, though. For instance, a feeder pig respiratory problem may be largely due to poor waste management. Fixing this might require completely renovating the barns and waste control system—a huge cost that might not be warranted by any improved performance because of decreased respiratory disease. However, the infrastructure costs actually display strong competitive risk characteristics (see the earlier section "Is This 'Individual Versus Population' Thing Going Anywhere?" for review); hence they will benefit society (in the African example) or the farm (in the feeder pig respiratory disease example) in areas far beyond the control of mosquitos or pneumonia. This means that the actual costs of that infrastructure should be amortized over other parts of the system (society or farm) that benefit from its inception. Through such means of analysis expenses often can be justified that a single disease control result could not support.

Capturing What's Important

To understand the workings of any economic analysis, it is imperative to understand the basic foundations on which that analysis (indeed, *most* financial analyses) is built. Several aspects of technique are represented continuously throughout most economic analyses. These include some form of budgeting, or a means to list costs and returns. In addition, whenever programs or diseases have their effects over the long term, or the analyst wishes to account for relative financial or biological risks, most reports also take advantage of time discounting to the cash flows. An analysis that promotes a finding or a course of action also includes some decision criteria and occasionally considers several. Finally, most analyses attempt to put all the facets together

Downloaded From Vet-eBooks.com

into an overall indication of costs and returns comparisons between choices.

Other types of analyses exist, of course. Many get to levels of extreme complexity by using advanced modeling and statistical techniques. However, most are based on the processes just mentioned. Later sections look at other means of addressing problems.

Definition of "Partial Budget"

Though they are not often looked at in this way, budgets are economic models. A budget forecasts the future, creating a projection of costs and returns of some decision and its resulting actions. Everyone has created budgets. Some make them for household expenses, to qualify for a bank loan, or for costing out some project at work. The "partial" aspect can be a little tricky, but it is the facet of the technique that gives partial budgeting its power. In this instance, a *partial budget* attempts to include all parts of a problem that are related to a decision, but nothing more. For an element to be unrelated to a decision it must be unaffected by the decision and must not affect the decision itself. Many of the analyses used in animal agriculture are variations of partial budgets or take a partial budget and add in additional analytical techniques. All share the need to limit the analysis to essential items.

General Weaknesses and Strengths of Partial Budgeting. Because of the basic similarity of other techniques to partial budgets, it is important to understand how partial budgets work and where their strengths and weak points might lie. Deciding what belongs and does not belong in a partial budget sometimes can be difficult. Some basic guidelines exist. Again, anything that affects the decision or that is affected by the decision should be included. Usually, fixed costs are not included, since they are unaffected. Generally a partial budget does not attempt to account for risk or variability either, since the outcomes are assumed to occur precisely as computed.

The Family Vacation and Einstein. One thing to avoid in partial budgeting is the so-called Einstein effect. It is logically possible to tie nearly every item and event in the world to each other; some ties are just much more indirect than others. Practitioners of partial budgets suffer from the Einstein effect when they lose the perspective of being able to know when a tie becomes too indirect to count. The following few paragraphs show a ludicrous example of the Einstein effect.

Suppose you are taking a family trip and you need a budget. Certainly you need to account for meals and lodging costs. But what about new tires for the car? They might or might not be a part of the partial budget. Whether or not you go on the trip, you will eventually need tires, so you can't claim the tire acquisition will be the result of the trip—buying tires is unrelated to the trip because the decision is unaffected by taking the trip. However, if the tires are currently rotten, then the tires have to be purchased as a prerequisite to going on the trip. In this view, buying tires is related to the trip and should be included in the trip's partial budget, because the decision to purchase tires affects the ability to pursue the vacation.

What is the cost of taking the family car? One way to look at it would be to count the miles to be covered, divide by the average miles per gallon, and multiply by the cost of gasoline. You could add the cost of oil and coolant. Then again, you will be wearing out the vehicle by driving it, so a depreciation charge could be added to the trip, prorated by expected miles of life still in the vehicle versus what it will be worth at the end of the trip. What about insurance costs? You will be traveling long, exhausting miles in unfamiliar territory and increasing your risk of accidents, so an increase in insurance rates could be added. What if you sit in the car for too long and get a backache? What if it reinflames that old swimming injury, making it difficult for you to work when you get back? Then you'll lose some workdays and income.

What if your child chokes on a hamburger while riding in the car and has to go to the hospital because you also should have replaced the worn-out shocks when you did the tires? You will incur direct and immediate hospitalization costs and likely will see your health insurance rise in later years. What if, in your hurry to get your child to a doctor, you drive exceedingly fast, lowering the car's combustion efficiency and greatly increasing the vehicle's greenhouse gas emissions? That will increase your risk of skin cancer, possibly forcing you into an early retirement and increased old-age health costs.

What if you cause an accident while racing to the doctor, which is likely an increased risk because your back is already in spasms and you have exhausted yourself driving for so long in that constantly depreciating car? What if you kill someone in another car? Now your share of the societal costs in losing a productive member of the work force should be added, not to mention court costs and fines. What if that person were a brilliant Einstein-like child who was on her way to a major college whereupon she was going to make a discovery that would have led to a truly clean, environmentally sound, unlimited energy source for the world? Now how do you feel? Now how expensive was that trip?

That is the Einstein effect; watch out for it.

Parts of a Partial Budget: Solving a Problem with a Spreadsheet. A partial budget aimed at program evaluation essentially looks at two things: how a new program will change net revenues and net expenses. For example, a vaccination program might change revenues by adding weight gain efficiency and increasing the per unit value of the animals. That same program might change net costs by increasing vaccine expenses, decreasing sick animal costs, and decreasing morbidity. The budget then compares the revenue changes with the cost changes to give a net profit or loss. The following example helps put this into perspective and introduces the concept of sensitivity analysis.

Assume a client is looking at increasing profit by using intensive resource management (IRM) techniques (after all, it *is* what all the pundits are saying to do, and the pundits are always right). The data and assumptions are listed in Table 2-7. Essentially, this producer is above the North Carolina average in herd size and about average in historical weaning percentages and weaning weights. The prices vary, but they are in the ballpark for the southeastern United States. The literature (Lichtenwalner, 1996) suggests that intensive grazing allows stocking density to be increased by at least 10% to 15% on the same acreage of land, increasing the pounds of calf weaned per acre. Hopefully this translates into increased revenue, but it does not come without cost. The fencing needs to be established, maintained, and operated throughout the year. In addition, the pasture needs more intensive management. Is it worth it? This is a good problem to address with a partial budget. Again, the analyst needs to find out how revenues change and how costs change. Some physical factors will change: More cows are available, and they will have more calvings and (hopefully) wean more calves by going the IRM route. More fencing must be established and more pasture management must be scheduled. Financial factors will also rise; if the additional cows and fencing costs are financed, the interest charges will rise. And those new fences and pastures will not come free. So the analyst needs to account for all of this to make a good decision.

TABLE 2-7

Assumptions for the Integrated Resource Management Decision on Whether to Intensify Pasture Management

Number	Variable	Value	Units
1	Current cow-herd size	30	head
2	Current weaning percentage	80%	of total
3	Current weaning weight (avg)	218	kg
4	Expected weaned calf value (avg)	$1.43	per kg
5	IRM costs		
5a	Interest rate (compounded monthlly)	10%	per year
5b	Fencing (box, posts, wire, gates, water, labor)	$750	for pasture
5c	Life of fencing	5	years
5d	Seeding–fertilizer	$105	for pasture
5e	Life of seeding–fertilizer	1	years
5f	Percent of cow and fencing financed (period = life)	100%	of total
5g	Cost of replacement cow	$250	per head
5h	Lifespan of cow	8	years
5i	Cull value of cow	$125	per cow
6	IRM allows increase carrying capacity of:	10%	per unit area

IRM, Intensive resource management.
Data from Lichtenwalner R: Management practices for more profit, *Animal Husbandry Newsletter,* April 1996, North Carolina Cooperative Extension Service, and recent local prices.

Fig. 2-22 shows a spreadsheet that addresses the issue. It is in the basic format of partial budgets: List the changes in revenue and the changes in costs, and compare the outcomes. Some of the values were calculated as shown in the following chart (The numbers refer to the line or "item" number from Table 2-7; the equation numbers [e.g., EQN1] refer to the following relative equation listed here):

	Current System	IRM System	Equation No.
Physical units			
No. of cows	Item 1	Item1 × (1 + Item6)	EQN1
No. of calves weaned	Item1 × Item2	EQN1 × Item2	EQN2
Calves weaned (kg)	EQN2 × Item3	EQN2 × Item3	EQN3
Revenues			
Value of calf weaned	EQN3 × Item4	EQN3 × Item4	EQN4
Annual cull cow return	(EQN1/Item5h) × Item5i	(EQN1/Item5h) × Item5i	EQN5
Costs			
Yearly fencing costs	—	Item5b/Item5c	EQN6
Yearly added replacement cow costs	—	($EQN1^{IRM} - EQN1^{CURRENT}$) × (Item5g/Item5h)	EQN7
Annual interest (avg)	—	(See below)	—
Yearly pasture maintenance	—	Item5d/Item5e	EQN8

Calculation of "Annual Interest (Avg)" Charge. Calculate total finance charge over life of each loan and then divide by term of loan. Quattro Pro 7 or another Windows spreadsheet "@" function can be used for this. It is called "@AMAINT" (amortized accumulated interest). Syntax for the equation is as follows:

@AMAINT(Principal, Int, Term, n)

where *Principal* = initial loan principal; *Int* = periodic interest rate; *Term* = term of the loan, expressed in number of total payments; and *n* = number of payments made (must be an integer from 0 to term). For the two values needed, this translates as the following:

Fencing: @AMAINT([Item5b × Item5f],[Item5a/12],[Item5c × 12],[Item5c × 12])/Item5c

Cows: @AMAINT([{$EQN1^{IRM} - EQN1^{CURRENT}$} × Item5g × Item5f],[Item5a/12],[Item5h × 12],[Item5h × 12])/Item5h

The partial budget from Fig. 2-22 suggests that, given these inputs, the IRM choice will yield an annual increase in income of approximately $363, or roughly 5% per year more than the current grazing strategy. A 5% increase in income may not be worth the added trouble—remember, these are in terms of "returns to management and labor," meaning this income must pay for management's extra efforts. Maybe the hassle of daily movement of cows is not worth getting an extra dollar a day.

Sensitivity Analysis: How Wrong Can the Estimates Be and Still Allow for the Right Decision? Suppose the analyst decides the daily movement of cows, as described in the previous section, is worth it but still wonders about some of the assumptions. What about some of the numbers? What if the operator is unable to keep control of more cows in a more intensively managed situation? He or she may not get as high a proportion of cows bred. The weaning percentage or weaning weights might drop if the producer is unable to manage the grass as well as is assumed here. If that happens, what will that do to the decision? These are all questions for *sensitivity analysis.*

Fig. 2-23 displays a sensitivity analysis on returns to management in which the weaning percent was allowed to vary from zero to 100% and all other values were left alone. The spreadsheet was recalculated at each new weaning percent. Note how the returns line crosses the zero outcome value threshold at around a 40% weaning percent. This means

Downloaded from Vet-eBooks.com

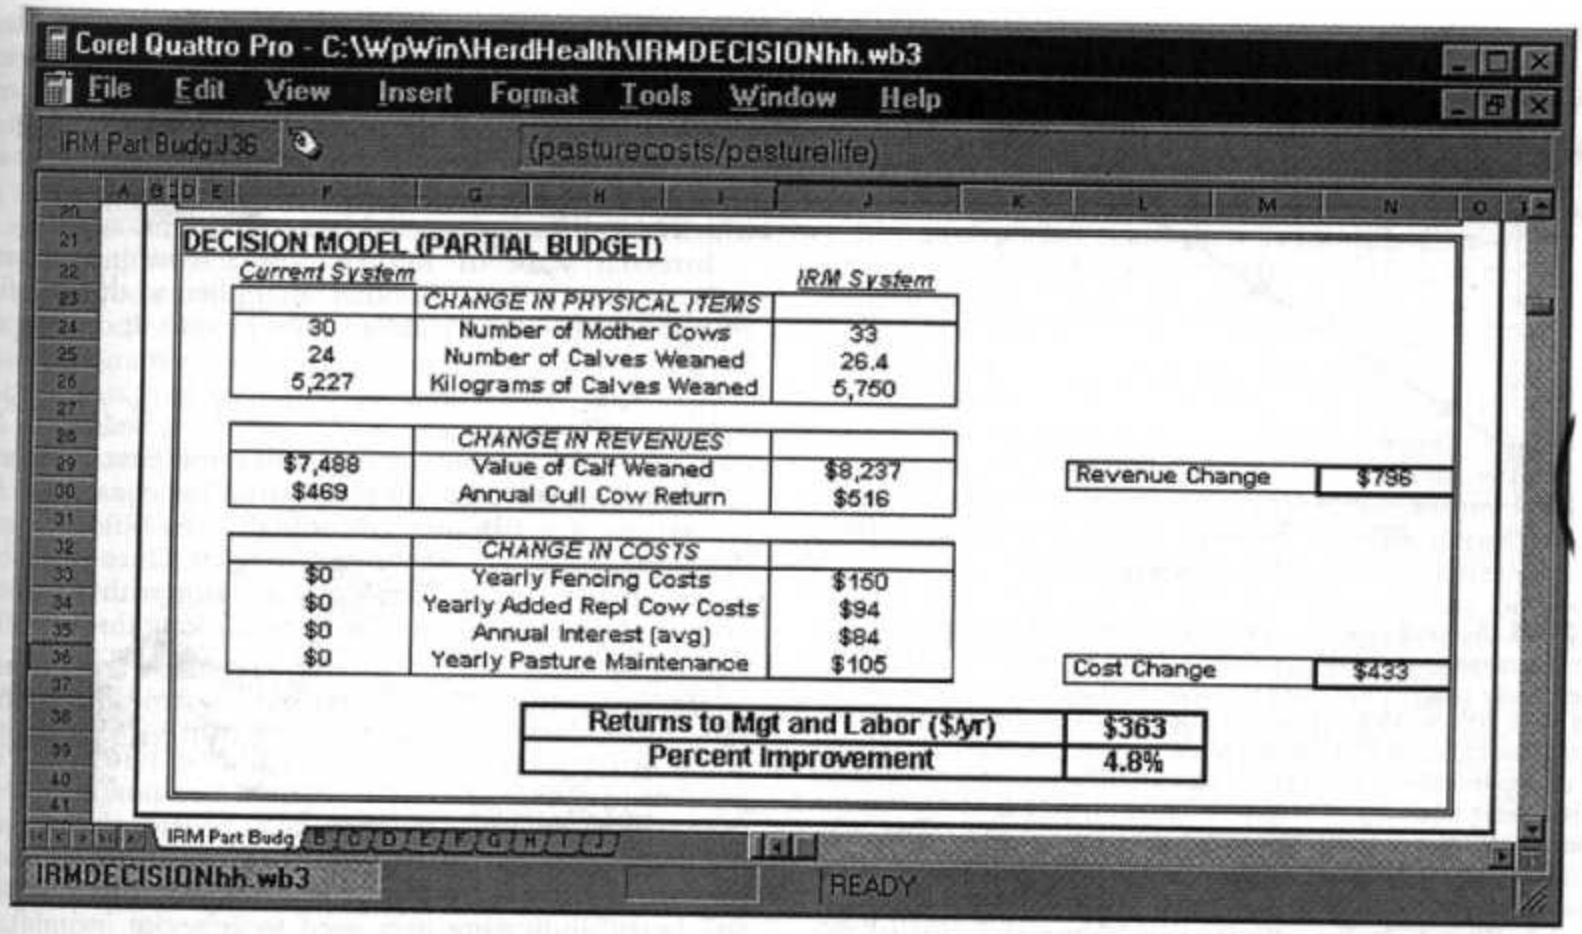

FIG. 2-22 Partial budget example for the Intensive Resource Management *(IRM)* problem, using Quattro Pro 8. See Table 2-7 for input data. The three sections on the left side of the window show, from top to bottom, the physical changes between the current and IRM systems, the revenue changes, and the cost changes. The summary changes for revenues and costs are listed on the right. At the bottom of the window is the difference between revenues and costs *(Returns to Mgt and Labor ($/yr)*, and a percent improvement in returns calculation. This model suggests that taking the IRM choice will increase returns by nearly 5%.

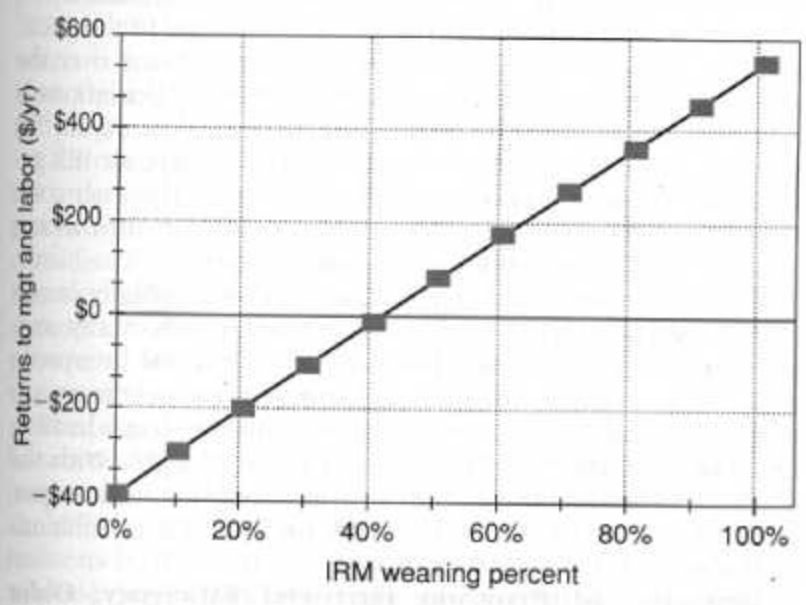

FIG. 2-23 One-way sensitivity analysis of the Intensive Resource Management *(IRM)* decision problem for weaning percent; all other values are per Table 2-7. The graph indicates that, even if the herd's weaning percent dropped by enacting IRM, the IRM program would still be optimal as long as the IRM weaning percent stayed above approximately 40%. The graph also suggests that if the herd were to improve its weaning percent from the current 80% to 90%, under IRM the herd's return would increase from approximately $363 per year to almost $500 per year.

that, all else being equal, switching to an intensive grazing program will pay, even if the weaning percent dropped to nearly 40%! Granted, the relative value of IRM drops as its weaning percent drops, but it is still the correct decision. This is a decision that displays a high degree of stability to weaning percentage—the likelihood of weaning percentage becoming this low is remote. Hence, the decision is a good one. Of course, to do it right, sensitivities would be run on other variables as well.

Suppose the client felt that the farm would support the high end of the increase in carrying capacity (i.e., a 15% increase versus the estimate of 10%). Would this increase the income sufficiently to make it more worthwhile? This can be shown if the value in Table 2-7, Item 6, is changed to 15%. With everything else left the same, the spreadsheet was rerun and showed the same basic analysis for changes in weaning percentages (Fig. 2-24). Increasing the carrying capacity to 15% (by 1.5 cows) approximately doubles the system returns at any given weaning percentage. Hence, this decision is critically affected by small changes in overall carrying capacity.

Time Value of Money

Present and Future Values of Money

The old adage states that "a dollar today is worth more than a dollar tomorrow." Anybody who has listened to the promises of deadbeat, no-pay clients knows this to be only too true. In financial terms a dollar received at some time in the future will have a *future value (FV)*, usually the face value of the money, and a *present value (PV)*, the discounted value of that future sum today. The difference in the value of that dollar between today and tomorrow determines the dollar's *discount rate (dr)*. This is usually a function of the *interest (i)* that could be accumulated if that dollar were invested today rather than tomorrow. As a result, money has a value directly proportional to when it is actually received.

Equations (for the Mathematically Inclined). The FV of an asset is equal to that asset's PV multiplied by some fractional discount rate over the given time horizon (number of

Downloaded from Vet-eBooks.com

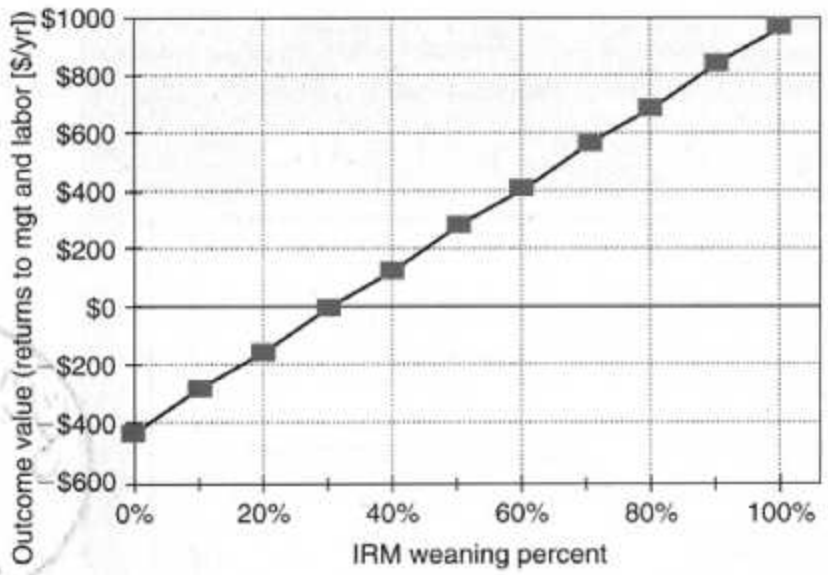

FIG. 2-24 Second one-way sensitivity analysis of the Intensive Resource Management *(IRM)* decision problem for weaning percent. In this sensitivity analysis the carrying capacity (Item 6 in Table 2-7) was raised from 10% to 15%; all other values are given per Table 2-7. The new analysis indicates that the increased carrying capacity will raise returns to approximately $700 at the current 80% weaning percentage. This is a near doubling of return on the project, indicating that the decision is sensitive to final carrying capacity.

periods). The discount rate is, in a sense, the reward the moneylender expects to receive for accepting the delayed payment.

$$\text{FV} = \text{discount factor} \times \text{PV} = (1 + \text{dr})\text{^no. of periods} \times \text{PV}$$

$$\text{PV} = 1/\text{discount factor} \times \text{FV} = [1/(1 + \text{dr})\text{^no. of periods}] \times \text{FV}$$

where the "^" sign indicates "taken to the power of."

As an example, what would John be willing to give Mary now if she promised to give him $100 in 1 year? If the yearly discount rate were zero, John should be willing to give Mary $100 right now ($100 \times [1/(1 + 0)\text{^}1]$). If John knew he could make 12% by investing that $100 over the same year, he would need to get $112 ($100 \times [(1 + 0.12)\text{^}1]$) just to break even (or to avoid an opportunity cost). If Mary held steady at only offering $100 in a year, John could only give her $89.29 ($100 \times [1/(1 + 0.12)\text{^}1]$) without incurring an opportunity cost on the transaction. In other words, for accepting the limitation of not having access to his $89.29 for 1 year, John would expect to be given $100. All modern spreadsheets, and most business calculators, perform time value of money calculations, so the above equations are not necessary to remember.

Net Present Value. *Net present value (NPV)* is a common decision criterion in economic analyses. The next section shows an example of calculating a cash flow's NPV. The NPV of a *one-time investment that yields a constant return* is simply the present value of that investment minus the current cost of that investment. This shows whether the opportunity is worth more than it costs.

$$\text{NPV} = \text{PV} - \text{required investment} = (1/[1 + \text{dr}]\text{^no. of periods} \times \text{FV}) - \text{required investment}$$

NPV calculations for investments showing *uneven but regular payments,* as shown by the following equation, can get quite complex to do by hand or calculator. Again, modern spreadsheets handle all the calculations needed. In this equation "V_x" indicates the difference in PV and costs in the time period "x." The equation is only the individual present values summed over the entire timeframe.

$$\text{NPV} = V_0 + V_1/(1 + \text{dr})^1 + V_2/(1 + \text{dr})^2 + \ldots V_n/(1 + \text{dr})^n$$

$$\text{NPV} = \text{COST}_0 + \text{PV}(\text{REV}_1 - \text{COST}_1) + \text{PV}(\text{REV}_2 - \text{COST}_2) + \ldots \text{PV}(\text{REV}_n - \text{COST}_n)$$

NPV calculations tell the analyst what discount rate is most appropriate for a cash flow. An NPV analysis, when applied to a program's cash flows, provides information on whether the program's cash flow exceeds that of the test discount rate. Also, NPVs are reported as either positive or negative to show which of the parties is realizing a gain and which is realizing a loss.

Internal Rate of Return. The *internal rate of return (IRR)* is the discount rate that, if applied to the cash flows of a program, would yield an NPV of zero. It can be calculated as follows:

$$\text{NPV} = V_0 + V_1/(1 + \text{IRR})^1 + V_2/(1 + \text{IRR})^2 + \ldots V^n / (1 + \text{IRR})^n$$

Finding an IRR is done by trial and error. First, select some discount rate, say 0%, and plug it into the equation. If NPV is >0, raise the IRR guess. Eventually, the IRR is narrowed down to a number generating NPV = 0. Once again, computer spreadsheets are capable of working with IRR calculations and prevent the headache of working through all the arithmetic.

There is a problem with some IRR calculations, specifically those dealing with cash flows in which values go up and down. For instance, if the practitioner purchases a large piece of equipment (a radiology unit, for example), the cash flow representing that purchase may be strongly negative in the first year (negative, because the practitioner had to fork over a lot of money for the unit), then may go positive for a few years (indicating it is used to generate income), and then may go negative again some time in the future when the cathode tube needs to be replaced. Such cash flows are notorious for leading IRR analyses astray because a very low interest rate and a very high interest rate usually can be applied to such cash flows and cause the net present value to go to zero. Because IRR calculations start with an educated guess, which of those two interest rates (and there may be more than two!) the algorithm settles on is due to the guess, not any special mathematical importance of one over the other. A second potential problem with IRR calculations is that they are indifferent to the direction of flow. In an IRR analysis, both the borrower and the lender have an IRR exactly the same; it doesn't matter which way the cash goes. Most businesses consider the direction of cash flow as important—IRR does not give that information.

For the reasons just listed, the NPV rule usually is recommended for deciding between investments. Many analysts, however, prefer IRR because of its ease of interpretation. It is indeed simpler in concept to get across to end-users, and as long as the project under consideration has a fairly even cash flow, they will be all right. With the ubiquity of financial calculators and spreadsheets, however, it is not asking too much to back up any IRR calculations with regular NPV determinations.

Measures of Program Financial Efficiency: Older Measures That Do Not Use Time Value of Money Calculations. Measures of financial efficiency are used to decide among competing proposals. The NPV and IRR indices just mentioned are two measures that use time value of money techniques. Not all criteria do. Older techniques for choosing among differing investment opportunities exist and are still used. They usually are variations on a *payback period scheme* or a *book-rate of return*. A payback period simply looks at the time it takes to recoup the start-up costs of a program. For example, if a program costs $100 to start, and that program pays back at $50 per year, the payback period will be 2 years (ignoring the time value of money). Payback periods, however, are ad hoc in their choice of a cut-off date; they ignore the long-term benefits and costs of a program and can be misleading if the analyst is not careful. Book rate of return looks at average percent returns and decides on pursu-

Downloaded from Vet-eBooks.com

ing an option by determining if it exceeds the return on a farm's portfolio of investments. In addition, book rate of return does not consider time value. Further, it looks at accounting valuations, not cash flows. Lastly, and this holds for both, the decision criterion is often arbitrary. A company may compare average book rates of return or payback periods against its current projects' values. As a result, successful producers with high rates of return on existing operations may reject good projects, and producers with low rates of return may accept almost any project. One last technique to measure program value is *cost efficiency*. This looks at costs to achieve some predetermined outcome, such as a certain level of disease prevalence or a proportional decrease in mortality. Cost efficiency is the only way to deal with programs whose returns are not quantifiable. It is shortsighted, though, since it is another form of payback analysis. Hence, it suffers from the same inability to look at outcomes beyond the predetermined endpoint.

Benefit:Cost Analysis: Using Time Value of Money, Efficiency Criteria, and Partial Budgeting

Definition of Benefit:Cost Analysis

Benefit:cost (B:C) analysis is the tool to use when looking at a program with high start-up costs and gradually accumulating benefits. Benefits are not always economic, however. Societal benefits from programs (increased public safety from animal-borne tuberculosis, for example) are difficult to quantify and simply may be listed in a qualitative fashion for consideration.

Several steps are common to most B:C analyses. First, the investigator must have epidemiological and economic data demonstrating the impact of the disease in question. Second, the biological and political feasibility of potential programs must be evaluated. For example, one way to get rid of PRRS would be to get rid of the national pig herd entirely—which is biologically feasible but not politically possible. Next, the analyst needs to evaluate the costs and benefits of the programs under investigation. This requires documenting the costs of disease, both direct and indirect; the costs of the program(s), both direct and indirect; social effects, both positive and negative; and an evaluation of the time horizon considered and the discount rate to be used (Hanson and Hanson, 1983). Fourth, the analyst needs to select the most appropriate decision criterion. Last, the exercise is incomplete until sensitivity analyses are performed on numbers that may be estimates.

The premise behind B:C analysis is that, for a program to be worthwhile, its long-term benefits should outweigh its long-term costs. As such, it is a form of partial budgeting. The difference is that B:C attempts to account for long-time horizons by discounting future costs and returns (i.e., time value of money) in establishing an overall program value. This requires understanding the time value of money and the effect of discount rates on program values. A variety of topics that go into a B:C analysis have been discussed. Time and space do not allow for a full example of the process. Instead this section looks at two programs, assuming that the partial budgeting aspect of the programs has been accomplished and that work can begin on the B:C part of the study. Table 2-8 assists in depicting this process of discount rates and B:C analysis.

Two programs are available. In total dollars the two are equivalent; however they show differing cash flows. Program A has a large cost for the first 2 years, then no costs. It returns a constant benefit over the time covered. Program B has lower early costs, but they continue for an extra year. Program B's returns increase throughout the program. The two columns titled "PV @ _%" list *time value conversion factors*. These convert a dollar given in the future at a certain discount rate. For example, at 8% interest, a dollar given 2 years from now is worth 85.7 cents (1/[1.08^2] = 0.857). At 12% it would be worth 79.7 cents (1/[1.12^2] = 0.797). Table 2-8 compares the two programs using two different discount rates, 8% and 12%.

In out-of-pocket costs, there is no difference—both cost $900 and yield $2100. Again, with out-of-pocket costs, Program A reaches its payback (i.e., recoups its costs) in year 3. Program B achieves payback in year 4 and so would be considered the lesser of the two using this criterion. If the decision between the two programs were based on PV of either the revenues or the costs, the decision would be a toss-up. The PVs of the revenues, at either discount rate, would favor Program A because it has the higher earlier values. However, if the decision were based on PV of costs, the decision would go to Program B because it has the lowest earlier costs. Although strict analysis of PVs for only revenue or costs is done rarely these days, the technique might be seen in older papers. Obviously, it is not advisable to do this.

If, as is more likely, the decision criteria were net present value, Program A is the choice at either discount rate. For Program A the NPV at 8% (819) is 20% greater than the NPV at 12% (683). For Program B the 8% NPV is 29% greater than the 12% NPV (723/559); the higher discount rate is "harder" on the program with returns increasing with time.

Based on B:C ratios, the two programs are essentially equivalent at equal discount rates. Both return, on discounted values, nearly $2 in revenue for each dollar invested. This is a good measure in that what it means is intuitively clear. The downside of B:C indexes is that they do not recognize magnitude of yield. For instance, had Program B's cash flows been 1/10 of those listed above, the program's B:C ratio would not change. If the decision maker could invest in 10 Program Bs, that would be fine. However, if only one Program B were available, the total cash return would be less with Program B than with Program A. Again, B:C ratios are indifferent to the magnitude of change.

Note what happens with IRR: Program A shows an IRR approximately 2.8 times as large as that of Program B! How can this be? Because of the cash flows' (i.e., Program A's earlier returns) responses to discounting, Program B's later, although larger, revenues are diminished enough to make its overall return less attractive compared with that of Program A.

The weight of the "opinion," then, seems to be toward Program A. It is favored by payback periods, NPVs, IRRs, and (although barely) B:C ratios, with all of this over two differing discount rates. The fact that the payback period favors the program may be of little interest, but it may help in selling a program to a producer. The fact that it returns its investment sooner than the other can be a powerful motivator.

The decision is not as easy with some programs (Rougoor et al, 1996). At times the criteria may disagree. In those instances the analyst can do either of two things: Pick the criterion that makes the most logical sense, or interpret the different outcomes as suggesting there is little financial difference in the programs. When this occurs, the analyst can use other, nonfinancial means of choosing among programs.

MAKING QUANTITATIVE CLINICAL DECISIONS

Statistical Significance Versus Clinical Significance Revisited

The H.O.T. statistics section on the chi-square test briefly touched on the difference between statistical significance and clinical significance by illustrating the use of the odds

Downloaded from Vet-eBooks.com

TABLE 2-8

*Example of Benefit: Cost Analysis**

Year	PV @ 8%	PV @ 12%	Program A Benefits	Program A Costs	Program B Benefits	Program B Costs
1	0.926	0.893	350	400	0	300
2	0.857	0.797	350	500	220	300
3	0.794	0.712	350	0	320	300
4	0.735	0.636	350	0	420	0
5	0.681	0.567	350	0	520	0
6	0.630	0.507	350	0	620	0
Total cash flow			2100	900	2100	900
Payback period			within 3 yr		within 4 yr	
PV	@ 8%		1618	799	1496	773
PV	@ 12%		1439	756	1279	721
NPV	@ 8%		819		723	
NPV	@ 12%		683		559	
B:C	@ 8%		2.0		1.9	
B:C	@ 12%		1.9		1.8	
IRR			128%		46%	

*Example includes the other decision criteria discussed before the section "Definition of benefit:cost analysis" in choosing between two programs. Program A yields constant benefits with a 2-year start-up cost. Program B yields increasing benefits and has its start-up costs spread over 3 years. Program A is clearly preferred when using either payback period, present value *(PV)* of benefits, net present value *(NPV)*, and internal rate of return *(IRR)* as the criteria. Program B is preferred when using PV of costs. The two programs essentially are equivalent when evaluated without time value of money calculations (total cash flow) and by benefit:cost *(B:C)* analysis (though B:C does slightly favor Program A). Note the IRR values (128% and 46%). It is clear that neither cash flow has anywhere near these levels of yield. These cash flows vary enough year to year to make IRR unreliable.

ratio to address magnitude of effect observed in 2 × 2 tables. The topic is now taken further with the introduction of new matters as well as more in-depth discussions of *P*-values.

Statistical significance versus clinical significance is an important relation to keep in mind. Everyone is aware that just because something is important statistically does not mean it also carries a clinical value. The difficulty lies in converting statistical outcomes to results that have intuitive meaning for clients and practitioners. The confusion between the two, however, deserves some attention, namely in making certain definitions are agreed on and some measures can be created that tie the two types of significance together.

The definitions of statistical significance and clinical significance are relatively straightforward, although sometimes they are easy to confuse. *Statistical significance* tells whether the conclusions drawn are likely to be true—the flip side of the classic *Type I* and *Type II* errors (declaring a difference exists when it actually does not or declaring no difference exists when one actually is there)—but gives no information regarding the degree of difference to expect if the experiment is run again. In terms of diagnostic tests (after all, the purpose of Type I and Type II errors is to "diagnose the truth" of the conclusions) the errors can be termed equivalent to sensitivity and specificity, as shown in Fig. 2-25. The diagram illustrates the four possible outcomes from a clinical trial testing the relative efficacies of two drugs. The columns indicate the actual, or true, state of affairs (i.e., Drug A is truly better than Drug B; Drug A is truly not better than Drug B), and the rows indicate the conclusions drawn from the clinical trial (i.e., the outcomes suggest Drug A is better than Drug B; the outcomes suggest Drug A is not better than Drug B). The upper-left corner cell indicates the outcome where there is a true difference, and the study identified it as such. The cell in the upper-right corner displays the outcome where there is no real difference, yet the study mistakenly identifies one as existing. The lower-left cell shows the outcome where there is a true difference, yet the study misses it. Finally, the lower-right corner signifies the outcome where there is no real difference, and the study correctly identified it as such.

The indices of study validity, α and β, then, are the complements of specificity and sensitivity, respectively. That is, α is the study's false-positive rate, and β is the study's false-negative rate. By convention, a "sensitivity" of 80% is accepted (i.e., somewhere in the Materials and Methods section of a typical report, the authors might say something to the effect of "...power is greater than or equal to 80%..."), and a "specificity" of 95% (i.e., in the same section, the typical manuscript might state "...significance was deemed to exist at the 5% level..." or something similar). The ability to "test" for the true difference in this hypothetical study is 8 of 10, and the ability to identify true nondifferences is 95%. But clinical tests are accepted (i.e., serologies, bacteriology, histology) with higher and lower false-negative rates and false-positive rates all the time—it depends on the situation. It makes sense, then, not to blindly accept or enforce an α of 5% and a β of 20% all the time.

Clinical significance shows the importance of the differences described—that is, the magnitude of effect observed—but gives no information whether the effect would repeat if we did the experiment again. Again, as shown in the H.O.T. statistics section on the chi-square test for contingency tables, tools to examine this are available. There are others.

Downloaded from Vet-eBooks.com

CONCLUSION DRAWN FROM A CLINICAL TRIAL	TRUE STATE OF AFFAIRS: Drug A is truly *better* than Drug B	TRUE STATE OF AFFAIRS: Drug A is truly *not better* than Drug B
Drug A is *better* than Drug B	**Correct (true positive)** *(1 − β = power)* Sensitivity	**Incorrect (false positive)** *(α = 1 − confidence)* 1-Specificity
Drug A is *not better* than Drug B	**Incorrect (false negative)** *(β = 1 − power)* 1-Sensitivity	**Correct (true negative)** *(1 − α = confidence)* Specificity

FIG. 2-25 Table (2 × 2) comparing the true state of affairs against a clinical trial's conclusions. This illustrates the similarities among the following: test sensitivity and specificity; α (alpha) and β (beta); study confidence and power; and true positives, false positives, true negatives, and false negatives. (Adapted from Sackett DL, Haynes RB, Guyatt GH, Tugwell P: *Clinical epidemiology—a basic science for clinical medicine,* ed 2, Boston, 1991, Little, Brown.)

For instance, if an analyst ran a clinical trial between two electrolyte solutions used for calf diarrhea in which "MagicLyte" gave twice the survival rate of "Cure-O-Lyte," and he or she did not state the statistical significance, or "*P*-value," of the study, another analyst would not know how likely the outcome would be to occur again if the test were rerun on a set of similar calves. If the statistical significance of the study were listed as $P = .33$, the odds are 2 to 1 that "MagicLyte" would, in a similar situation, prove better than "Cure-O-Lyte." That is, a 33% likelihood exists that "MagicLyte" performed best just from chance alone, and if the study were repeated, "MagicLyte" is more likely to result as the better solution. If the statistical significance of the study were $P = .01$, the odds are 99 to 1 that "MagicLyte," again, would prove better than "Cure-O-Lyte." That is, only a 1% probability exists that "MagicLyte" performed best just from chance. So, it is unlikely—*very unlikely*—that another, similar trial would disagree with this one.

The two types of significance—clinical significance and statistical significance—are related, therefore, by the fact that neither tells everything. *Statistical significance* gives information about the likelihood the outcome would occur again, given the same conditions. *Clinical significance* tells how big the effect was that the trial demonstrated—this one time. Hence, a treatment found somewhat better than another with a *P*-value of .001 causes clinicians to take notice regardless of the magnitude of response; rarely does information appear that offers such confidence. On further examination the analyst may decide that, although it is statistically significant, it does not cause "enough" clinical difference to be worth adding to the therapeutic armamentarium. In addition, a study finding that shows a major difference in effect (i.e., it suggests a 90% improvement in rate of return to normal function or performance), with a *P*-value of .18 (i.e., there is an 18% likelihood that the measured improvement in survival rates was simply due to random chance), also causes the analyst to take notice regardless of the probabilities. Clinicians rarely have access to something that can make such an impact. Analysts may not depend on this outcome, however, so other, secondary modes of treatment may be added, given the nearly 1 in 5 chance that the evaluated treatment will not change things. It is reasonable, then, for clinicians to weigh *both* indicators of outcome "quality," clinical significance and statistical significance, in determining whether to enact the new process or activity, contingent on the circumstances around the specific question at hand (Matthews, 1996).

Measures and Measuring Clinical Significance

Converting numerical statements of significance into terms that can be used directly by clinical decision makers is not that difficult. It requires a few new perspectives and techniques, but none are conceptually challenging. The new terms introduced are *absolute risk reduction (ARR),* a means of establishing total levels of effect, *relative risk reduction (RRR),* a means of standardizing effect, and *number needed to treat,* a quick summary calculation that brings statistical results into the realm of intuitive sense and makes them readily available for economic or epidemiological analysis.

For instance, consider the clinical trial results shown in Table 2-9, testing an all-in-all-out (AIAO) management strategy for grower pigs against a continuous flow (CF) management strategy (Ice et al, 1999). In this study the authors placed barrows of a similar background into either AIAO or CF houses, where various biological parameters were measured. In addition, half of each group was fed chlortetracycline. The authors report health and growth performance data for animals within each system and feeding treatment. In Ice's study, over all age groups, there was a significant difference in the severity of lung lesions between the two groups (AIAO < CF, $P < .02$), a trend to a lower prevalence of lung lesions in the AIAO group ($P = .06$), a difference in days on feed to reach market weight (AIAO < CF, $P < .02$), and a demonstrable negative correlation between total daily gain and severity of lung lesion ($r = -0.212$, $P < .001$). No significant effect of chlortetracycline feeding on growth and health parameters was found in this study. This example was chosen to demonstrate how a practitioner can use information from a study that was not directly presented in the study because the practitioner's point of interest was not a stated goal of the study.

Table 2-9 is arranged to show the derived results from the study and to calculate the measures of risk and return that indicate clinical significance. The data used here were derived using summary data from two figures in the report and are meant to compare outcomes of the 6-month-old barrow subgroups within this study (Ice et al, 1999). From inspection of Figures 3 and 4 in the manuscript, the study found that approximately 95% of the AIAO 6-month-old barrows displayed ≤10% lung involvement from pneumonic lesions (75/79). For the CF cohort, the same value is approximately 61% (47/77). For this exercise the treatment failure rates, listed in Table 2-9 as "adverse effects rate," are the points of interest. Hence, the failure rate for 6-month old barrows in the AIAO and CF groups is 5% and 39%, respectively. That difference in outcome failures should be enough to catch the practitioner's attention. But how does a practitioner translate such values into more intuitive information for decision making? By generating risk reduction and return indices.

ARR is the first and simplest means of adjusting experimental outcomes into results that have clinical meaning; it is merely the numerical difference in rates. By itself, it does not do much for analysts, but it is fundamental to the two other indices to be created. ARR shows the degree of disease reduction expected by using the new management practice (NMP), which in this example is AIAO, compared with the reference management practice (RMP),

*For an experiment comparing continuous flow house management for grower pigs (RMP) against an all-in, all-out house management for grower pigs. The outcome being measured is the proportion of 6-month-old pigs that show >10% lung involvement with lesions compatible with pneumonia.

†Values derived from Ice AD, Grant AL, Clark LK, et al: *Am J Vet Res* 60:603-608, 1999, Figures 3 and 4.

which in this example is CF, based on the underlying population. In the case of the 6-month-old barrows, the ARR is found by subtracting the failure rate of the NMP from that of the RMP (CF − AIAO = 0.39 − 0.05 = 0.34). What does an ARR of 0.34 mean to the veterinarian or producer? It can be interpreted as the observed total magnitude of effect difference; from this study, AIAO-managed grower houses enjoyed a 34% decrease in the prevalence of animals with high levels of lung lesions. The reader should not feel bad if that does not appear as an intuitively amazing finding. Most clinically oriented persons share a lack of enthusiasm for ARR measures. They are not easily transferable to other situations, since other situations might show different base-failure rates. For instance, if a producer uses CF but has a 15% prevalence of slaughter pigs with 10% or higher lung lesion involvement, claiming that they will get a 34% reduction by going to AIAO makes no sense. However, as previously mentioned, it is not so much that ARR itself is enlightening, but what practitioners can do with it. They can calculate two other indices that are both of clinical interest.

RRR is one means of adjusting numerical or probabilistic outcomes into results with clinical meaning, by setting the magnitude of effect of a "new" or experimental treatment *relative* to the control-standard treatment. It is calculated by dividing the ARR by the adverse rate from the RMP. In other terms, it is the difference between failure rates of AIAO and CF, divided by the CF failure rate. For the current example this is ARR/CF = 0.34/0.39 = 87%.

The interpretation of RRR could be that, given the results of this study, we can expect an AIAO management system to achieve an 87% reduction in "adverse effects" (the prevalence of slaughter pigs displaying greater than 10% lung lesion involvement). In human medicine, RRRs of ≥50% are taken almost always as clinically significant. Those of ≥25% may or may not be taken as clinically significant (Sackett et al, 1991). Of course, the efficacy and cost of the NMP versus the RMP come into play here, as does the level of statistical significance. Hence, going back to the client with a CF management system and 15% "failure rate," the practitioner can expect that a switch to AIAO will decrease the client's failure rate to approximately 2% ([1 − 0.87] × 0.15 = 0.02). Both parties now can place this result in terms of economics, animal welfare, return on investment, or whatever decision criteria were chosen. But there is one more step that can really help.

Number needed to treat (NNT) is a simple transformation of ARR that yields a value that can be used intuitively by practitioners in deciding whether to use a new treatment or program. It generates, relative to each tested treatment and risk factor, the number of animals or groups (depending on how the data come to the clinician) that will need to be treated to prevent at least one instance of the adverse effect in question. It is simply calculated as the reciprocal of ARR.

The NNT value from Table 2-9 suggests that three houses need to be treated with the NMP (AIAO) to prevent at least one adverse event. Hence, NNT suggests the effort needed to reach a clinical target by giving a basis for examining costs and success rates. In the example from Table 2-9, if the cost difference between an AIAO management system for three houses was less than the cost incurred from having one house suffer the level and severity of lung lesions displayed by the CF management system, it makes economical sense to use AIAO. However, if the costs incurred through operating an AIAO strategy in three houses are greater than those incurred from having a house suffer the higher disease levels, then it does not make economical sense to switch to AIAO.

Example of Using the Risk Reduction Approach

Using the Risk Reduction Methods to Choose Between Therapeutic Options in Working with Papillomatous Digital Dermatitis

In a clinical trial (Guterbock, 1995) 147 Holstein cows with active papillomatous digital dermatitis (hairy heel wart) were selected from three California dairies and randomly assigned to five treatment groups. Two of the treatments are considered here: (1) ceftiofur, given 1 g IM q24 hr for 3 days versus (2) oxytetracycline, applied topically as 100 mg/ml

Downloaded from Vet-eBooks.com

TABLE 2-10

*Analysis of Choice Between Two Therapeutic Options**

Treatment Protocols	Estimated Cost per Cycle†	Treatment Failure Rate at 28 Days after Treatment‡	Absolute Risk Reduction§	Relative Risk Reduction‖	Number Needed to Treat¶
Ceftiofur *1 g IM q24 hr, for 3 days*	22.40	0.26	–	–	–
Oxytetracycline *100 mg/ml, cotton topically applied and bandaged 7 days*	32.00	0.06	0.20	0.77	5
SIMPLE COST ACCOUNTING					
If a treatment failure average cost is (midpoint of several estimates):			$65	Estimate	
If it takes five oxytetracycline treatments to prevent at least one treatment failure, added cost is:			$48	5 × (32.0 − 22.4)	
Therefore using oxytetracycline protocol saves approximately:			$17	65 − 48	

*Options are for bovine papillomatous digital dermatitis using risk reduction indices and estimated costs. The number needed to treat indicates that for every five cows treated with oxytetracycline bandages, a client prevents occurrence of one treatment failure compared with the ceftiofur management program. The simple cost accounting procedure suggests the cost of 5 oxytetracycline bandage treatments is $17 less than the cost of the treatment failure they prevented. Therefore the rational choice is to enact the oxytetracycline bandage treatment program.
†Data on costs from North Carolina State University, College of Veterinary Medicine, Veterinary Teaching Hospital Pharmacy, and a milk value of $26.45/L ($12/cwt).
‡Data on treatment efficacies from Guterbock WM, Borelli CL, Read DH: *Evaluation of four therapies of papillomatous digital dermatitis in dairy cattle.* Proceedings of the twenty-eighth annual meeting for the American Association of Bovine Practitioners, San Antonio, Tex., September 1995.
§Absolute risk reduction (ARR) = 0.26 − 0.06 = 0.20.
‖Relative risk reduction = ARR/0.26 = 0.20/0.26 = 0.77.
¶Number needed to treat = 1.0/ARR = 1.0/0.20 = 5.

on cotton balls under a duct tape bandage and left on for 7 days. All animals were evaluated at day 28 for clinical response (no pain, no lameness, and healed or healing lesions on inspection). The data in Table 2-10 indicate my estimates of treatment costs (medications, disposables, labor, and a conservative milk withdrawal for oxytetracycline), the published, statistically significant failure rates through 28 days, and the derived risk reduction values and NNT. The table also shows a short calculation to determine if it is worth recommending one protocol or the other.

The oxytetracycline bandage protocol, although almost costing half again more than the ceftiofur treatment ($32/$22 = 1.4) because of its higher success rate (94% [1.0 − 0.06] versus 74% [1.0 − 0.26]), more than recoups its added costs by preventing a case failure in at least one of five treated cows. In other words, according to this study and these cost estimates, by establishing an oxytetracycline bandage protocol for treatment of papillomatous digital dermatitis, the producer invests $48 to avoid spending $65. Here is yet another way to say it: every time the dairy treats five cows with the oxytetracycline bandage protocol, overall, the farm realizes a $17 savings over the ceftiofur protocol.

The risk reduction techniques allow an analyst to evaluate different timeframes of studies, to look at individual animal and herd-level choices, and to place the results into economically important terms. Readers wishing to further their knowledge in these techniques are encouraged to refer to Sackett et al (1991) for advanced uses of these methods.

Accounting for Uncertainty in Clinical Decisions: Decision Analysis

In a changing world choices are made without the full knowledge of their effects. Each choice opens some future options while closing off others. Control can be exercised over some events, such as in ordering a culture or prescribing a treatment. However, many events are beyond control: culture results are not known until they are run, and a herd's response to a treatment program is unknown until therapy is under way. Lastly, as mentioned in the "Likelihood Ratios and Figuring Out the 'Grey' Zones in Clinical Tests" section on clinical tests, the information that becomes available always must be evaluated for validity. Hence, uncertainty is a constant and undeniable part of practice.

Decisions must be made, in spite of the uncertainties. For the majority of choices in life, decisions can be made without much introspection. The decision may not be so important as to warrant analysis, or the outcomes may be so easy to rank that the choice is obvious. Occasionally, however, situations arise in which the consequences of a choice are not obviously apparent. At these times systematic methods are needed to estimate future events, consequences of actions, likelihoods of occurrences, and the end values of the many scenarios facing analysts. This is where a discussion of the tenets and methods of *decision analysis* proves of value. Clemen (1995), Sackett et al (1991), and Weinstein and Fineberg (1980) offer more in-depth explanations and explorations of the powerful techniques in this discipline.

Function of Decision Analysis

Decision analysis techniques (DAT) help practitioners through the quagmire of uncertainty by formalizing the approach to a problem. In doing so, three characteristics of the process become apparent. First, DAT force analysts to be explicit in formulating a problem by its component parts—allowing the temporal quality of a diagnostic or therapeutic workup to be considered in detail, for instance—and by encouraging them to recognize the areas about which they are unsure. Second, DAT integrate quantitative knowledge into the process. The quantitative aspects come to the fore once the analyst has identified the uncertainties of the choices ahead. The algorithms used in DAT force analysts to make statements about probabilistic events, even if the estimates' precision is only with regards to how little is known about an event; it may be sufficient to simply get beyond terms such as "more likely" or "less apt to happen" and get evaluations of "50:50 chance" or "85% of the time." Practitioners are also prodded to seriously examine what kind of outcomes they will be experiencing, and how they (and the client) will value differing outcomes. Third, and this is why DAT can be of such value, the end result is a system-level view that allows decisions of known strength; it allows analysts to prescribe a course of action from among the many available choices. It accomplishes this because the explicitness and quantitative nature of the process allow the analyst to work with the entire problem without losing sight of the details within that system; it forces a look at the entire picture, yet not to the exclusion of its component parts. Decision analysis also promotes consideration and evaluation of the relationship between the information-gathering process and decisions that will need to be made based on that information, so it is helpful in setting up timelines for larger projects.

Decision Analysis Step 1: Identify and Bound the Decision Problem. At times the most difficult part of the process is defining the problem at hand. What, truly, is the problem being faced? Is a respiratory disease outbreak in feedlot steers a problem with nutrition, shipping, processing, purchasing choices, handling, or some combination of all these factors? In an outbreak situation this requires practitioners to carefully identify what a "case" truly is so that findings are not confounded with inappropriate data. In a herd production problem this means establishing thresholds for production indices that differentiate between normal and abnormal. In some situations a clinical state definition may be complete with "sick" and "normal." However, other situations may call for more refined categories such as "full recovery," "partial recovery," "recovered but relapsed," "no recovery," and "death." Other considerations, such as any prognostic value of tests for herd-level decisions, animal welfare, and regulatory limits, can play a role in determining the final choices made.

Decision Analysis Step 2: Structure the Decision Problem (Decision Trees or Decision Diagrams). In structuring a decision problem, analysts aim to keep the different types and timing of events in proper sequence. In the process of evaluating complex decisions, each contingent on information available at that specific time, a "road-map" of decision flows can be formed, often in the form of a *decision tree*. The illustration of the decision tree in Fig. 2-26 displays the three basic parts of any decision diagram, by using an example adapted from a study evaluating the financial and legal outcomes of antimicrobial testing strategies in dairies (Slenning and Gardner, 1997). By convention, decision flow diagrams are read from left to right. The first point to note is that they branch at each alternate action or chance event, making a winding trail of the sequential events that compose one potential *path*. Second, the tree explicitly lists each event in the process, forcing the analyst to consider the uncertainty (i.e., to establish probabilities for uncertain events) inherent in the choices. Third, it quantifiably describes the outcome values the analyst placed on the endpoints of the different branches, again, forcing an evaluation of the outcomes and the best means of achieving, or prescription for attaining, a given desired outcome.

The decision tree in Fig. 2-26 could be "read" as follows. The decision point being addressed is the question inside the *decision node:* whether to test cows following a set withdrawal period for milk residues of penicillin G (the "square"). If the producer decides to test, the path followed is the one leading up from the decision node (with the "yes" description) to the first *chance node* (chance nodes are signified by "ovals"). This node states there is some probability the cow in question will test positive for antimicrobics. Note this is not claiming that the cow actually is violative, only that the on-farm test has called her positive. This node has two paths emanating from it: one for the chance result that the cow tests positive, and the other for the chance result she does not. Given this test result, the producer will not ship the milk. However, there is some chance that the test is a false-positive test, given the testing technology's ability to identify drug concentrations well below the legal thresholds (Gardner et al, 1996). This possibility is illustrated by the next chance node in the path (the path continuing up and to the right), where the cow is assigned to either a true-positive or a false-positive categorization (the "yes" and "no" descriptors following the "≥10 ppb" chance node at the tree's upper right). Note no decision is made here; the test result of "positive" has determined that all such milk, whether classified correctly or not, will not be shipped for human consumption.

Should the producer decide not to test the cow for antimicrobic residues (the path leading down from the decision node with the "no" description), the first chance event is whether the cow actually has violative levels of penicillin. From there is a set of potentially two more chance events, each describing a testing point performed by the milk processor at the level of the milk truck ("Tanker pos") and the dairy's own bulk tank ("BulkT pos"). If the tests are not positive, the milk goes into the human consumption chain. If the test is positive, however, the dairy is traced back and suffers financial, legal, and regulatory consequences of shipping violative milk. Note that the path in which the cow tests negative at the farm level is a stepwise replica of the do-not-test path just described. However, the probabilities for violations are different between the two paths.

Decision Analysis Step 3: Select Decision Criteria. Different analysts choose different criteria for selecting one alternative versus another. It may be fairly clear: one option may offer higher incomes than another (i.e., the decision is to take the maximum incomes) or a certain path might offer less variability (i.e., the decision is to minimize risk) in outcomes. In situations in which an outcome's value is difficult to assess, the decision could be made on the basis of time to conclusion or efficiency of resource utilization (as shown in the previous discussion of screening and diagnostic testing strategies). Or, as in the B:C analysis example, there is no reason why an analyst cannot select a portfolio of several decision criteria and make the decision based on the package results from the portfolio. The important point is to make the choice of decision criteria *before* running the actual analysis. Otherwise it becomes difficult to avoid choosing the criterion that best fits the analyst's or producer's preconceived "favored option."

Decision Analysis Step 4: Choose the Best Course of Action. For most decision analysis problems, this step is the easiest. The analyst merely regularly applies the decision

Downloaded from Vet-eBooks.com

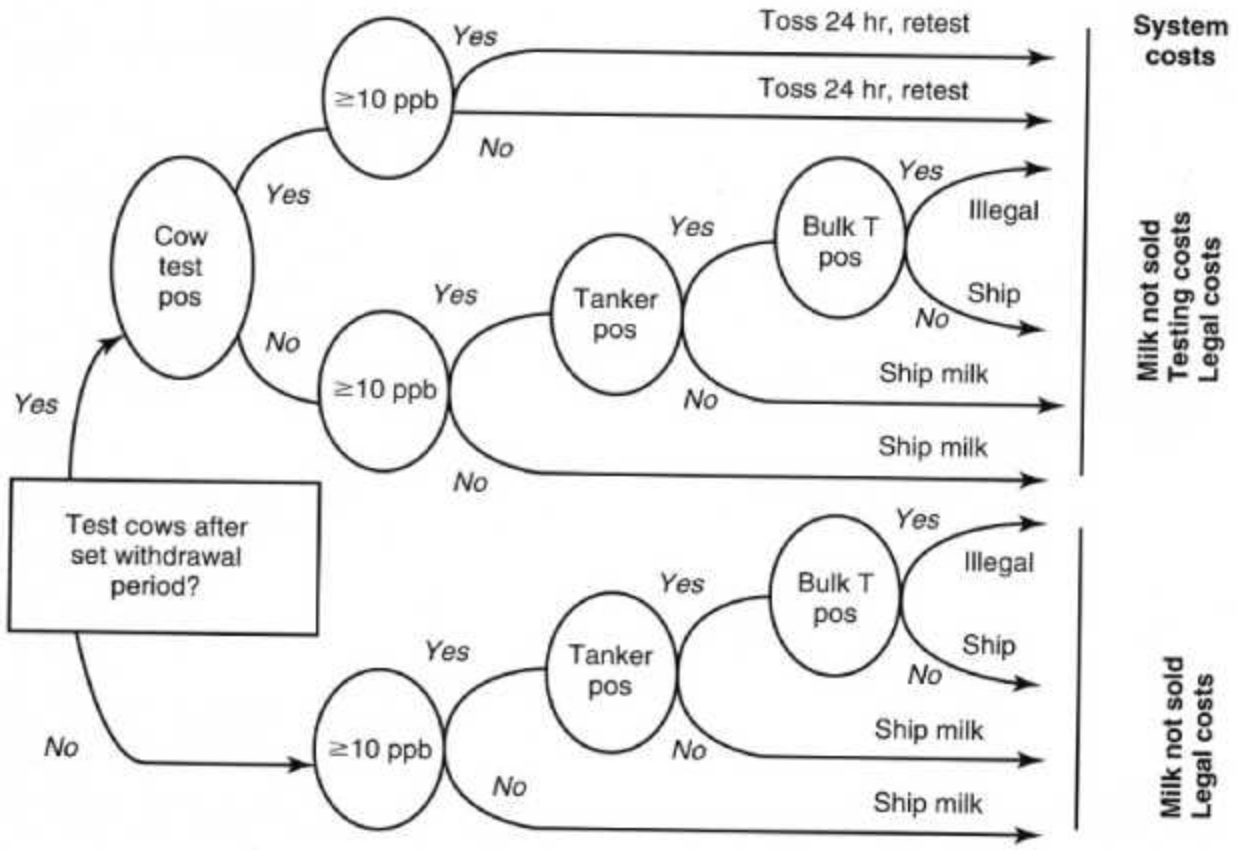

FIG. 2-26 Outline of decision tree investigating the decision to test dairy cows for beta-lactam antimicrobic (penicillin G) residues following a given withdrawal period. The "Test cows after set withdrawal period?" box is the actual decision being addressed. Ovals represent chance nodes–events over which practitioners have no control–for which probability statements must be devised for each path leading from there. Rectangles represent decision nodes. *≥10 ppb,* Antimicrobic concentration is greater than or equal to 10 parts per billion (U.S. tolerance level for penicillin G residues); *pos,* test result is positive for antimicrobic; *Tanker,* milk tanker truck; *BulkT,* on-farm milk bulk tank; *Illegal,* milk shipment is stopped and legal proceedings are enacted; *Ship,* milk is shipped without being detected as violative. (From Slenning BD, Gardner EA: *J Am Vet Med Assoc* 211:419-427, 1997.)

criteria chosen for the problem to each step in the problem, working in reverse chronological order. For decision tree analysis, two algorithms are applied to different paths, depending on the nature of the node immediately giving rise to the path.

For example, in the decision tree illustrated in Fig. 2-26, the solution could begin with the analyst evaluating the endpoint at the upper right where the producer has decided to not ship milk from test-positive cows. Tracing backwards from that endpoint, the analyst can find the first node is a chance node ("≥10 ppb") which has another path emanating from it. The two paths represent the cow being withheld when her milk is truly violative, and the other possibility that she is incorrectly withheld because of a false-positive test result. When a chance node gives rise to a set of paths, the algorithm used is called *averaging out* and requires the analyst to take the probability of each outcome and multiply it by the endpoint's value. The analyst does the same for each path leaving the chance node and finally sums the products of each path's multiplication. This sum is termed the *expected monetary value (EMV)* of the node. In this way the chance node is assigned a weighted value; it is weighted for both the likelihood of each endpoint's occurrence (the probabilities) and its magnitude (the actual endpoint values).

Should the reverse chronology process bring the analyst to a decision node, a different algorithm is used. Remember, at a decision node the practitioner actually controls which path will be followed. Unlike a chance node, in which the outcomes cannot be controlled (and therefore an averaged result is created by "averaging out"), with decision nodes the analyst chooses the path that best meets the decision criteria and disregards the suboptimal paths. This process is called *folding back* or "pruning" the tree.

Once the decision-maker backs up to the original decision and makes the final "fold back," the resulting set of paths left describes the optimal course of action, according to the established decision criteria and values entered into the tree.

Decision Analysis Step 5: Perform Sensitivity Analysis on "Soft" Values. As in the example of the partial budget exercise on intensive grazing of a cow-calf herd (Figs. 2-23 and 2-24), the final step is to review the inputs to the decision and perform a sensitivity analysis of the decision on those values and probabilities that are least certain. This is done by changing one or more inputs over a reasonable range of values and solving the tree for each combination. The set of solutions that is generated this way will be able to establish the range of inputs over which the decision is stable (that is, over which the decision will still be the correct decision).

Walking Through a Practical Example of Decision Tree Analysis

Introduction to the Adjunct Use of Oral Calcium Gels Following Successful Treatment of Hypocalcemia

In 1997 Oetzel et al produced a clinical trial in which they evaluated the feasibility of using oral calcium gels as adjunct therapy for cows who had been down previously and successfully treated with intravenous calcium solutions. In short, the trial used 70 cows with clinical hypocalcemia that had been successfully treated with intravenous calcium. This

Downloaded from Vet-eBooks.com

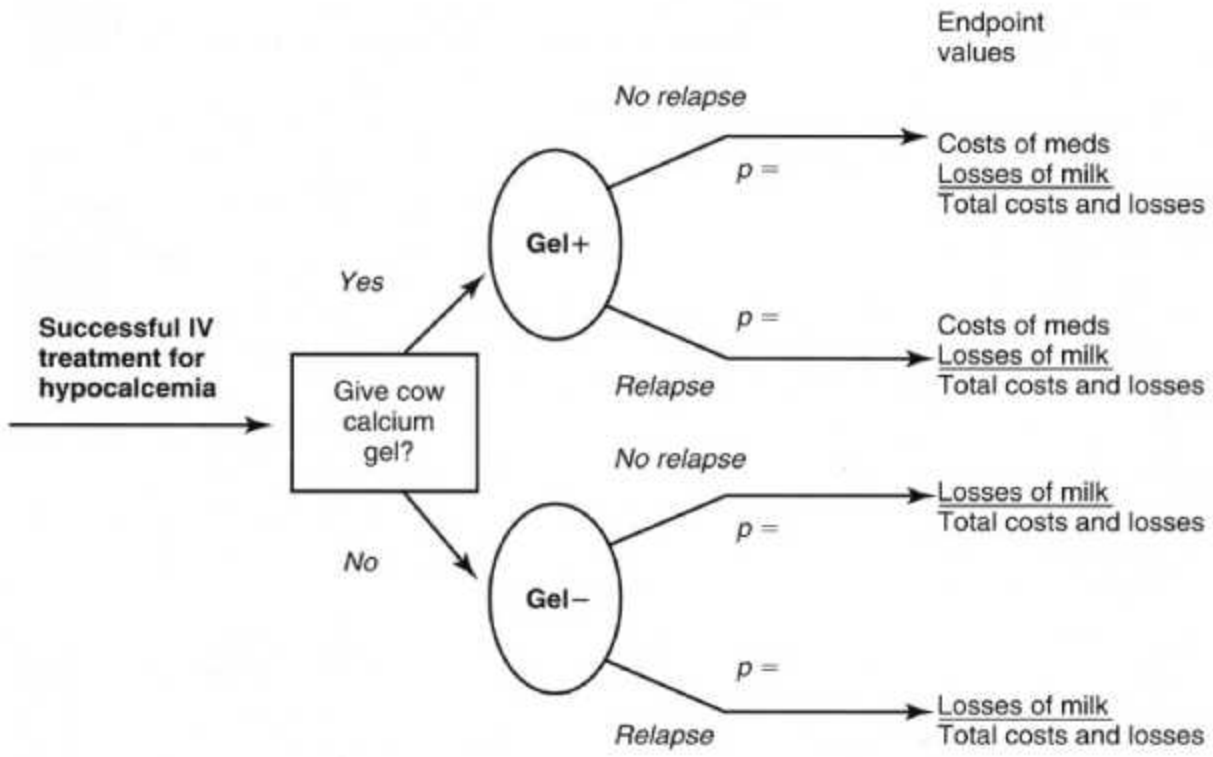

FIG. 2-27 Decision tree to evaluate the choice of using oral calcium gel as adjunct therapy following successful treatment for the initial hypocalcemic event. Values for endpoints and probabilities have not been entered.

population was randomly allocated to two groups: the treated group (n = 31), in which the cows were given two doses of a commercially available calcium chloride gel upon rising, and the control group (n = 39), in which the cows were given two doses of a placebo gel upon rising. The cows were followed for relapse, which was defined as a clinical inability to rise. The basic results were that 4 of the 31 treated animals (13%) relapsed, whereas 14 of the 39 control animals (36%) relapsed. This difference was significant at the 5% level. Hence, it appeared that use of calcium gels following intravenous calcium treatment for hypocalcemia was clinically useful. But was it useful enough to warrant incorporating its use in a dairy's protocol for treating milk fever cases? This is a good exercise to pull together topics from the economics section of this chapter as well as to close off this decision analysis section.

Decision Analysis Step 1: Identify and Bound the Problem. In the current instance, this step is fairly straightforward. The analyst is asking whether oral calcium gels should be instituted in the protocol for working with initially successful hypocalcemia cases, with the aim to reduce relapses. Hence the problem deals only with successfully treated animals and only looks to outcomes of either relapsing or not. It will have, therefore, one decision node (use the calcium gel) with two paths leading from it ("yes," use the gels; "no," do not use the gels) and chance nodes for both parts of that choice ("does the cow relapse after using the gel?"; "does the cow relapse after not using the gel?"). It does not address issues of nutrition (important to affect overall hypocalcemia rates) or other peripartum diseases and management.

Decision Analysis Step 2: Structure the Decision Problem. Fig. 2-27 illustrates the complete decision tree for this problem, except it has no values or probabilities in place. They are listed, but the values themselves have not been identified or defined. It follows the description just given: one decision node, two paths from that node, a chance node at each of those paths, and a yes-no set of paths leading from each chance node. It indicates that the endpoint values for each unique pathway will combine the medical costs to get the animals to that point and the estimate of the milk losses incurred by the animals continuing to be in suboptimal health. Note also that the probabilities, because each chance node has only two possible outcomes (relapses or not), require the analyst to specify only the probability of relapse following treatment or relapse without treatment. The other outcome must be the difference formed by subtracting the first probability from 1.0; the probabilities from any chance node must sum to 1.0 because otherwise not everything that could occur is described.

The probabilities come from the research trial itself. The trial found a 13% relapse rate in the treated group and a 36% relapse rate in the control group. Hence, those are the relapse rates to place in the decision tree. The opposing rates (no relapse) will, as mentioned above, be 1 − (relevant relapse rate), or 87% for the treated group and 64% for the control group.

Calculating the endpoint values is more complicated. The reader probably already realizes that each endpoint entails its own unique partial budget that compares changes in revenues and costs. Since minimizing costs following a disease event is being examined here, all the entries in the partial budget can be described in terms of costs (i.e., no revenue enhancement is involved). Fig. 2-28 lists the entries and shows the simple cost accounting that meets the current needs. The assumption has been made that having gone through a hypocalcemic event will lower later lactation milk production. The choices made here were for a 14% loss in total lactation milk production (expressed in terms of 305-day fat corrected milk) for cows that relapse; half that loss for cows who do not relapse but are not given the calcium gel and, therefore, still undergo subclinical losses; and a 3% loss for those who do get the gel and who also do not relapse.

Decision Analysis Step 3: Select the Decision Criteria. As the analyst is looking at costs, the rational choice is to select the course of action with the lowest costs, as demonstrated by comparing the EMVs of the two chance nodes ("Gel+" versus "Gel−"). Were the analyst looking at revenues, the rational choice would be to select the chance node with the highest EMV.

Decision Analysis Step 4: Choose the Best Course of Action. The analyst first starts at the endpoint designated by the path that ends with the "Gel+" chance node's "No re-

FIG. 2-28 Spreadsheet-based depiction of estimated costs for the calcium gel decision tree (Fig. 2-27). Cost estimates in section A are from local market prices at the time of writing. The problem assumes some subclinical effect of hypocalcemia, hence the losses suffered for all groups. However, the treated/no relapse group has the least loss (3.5%) over a lactation, the cow that relapses has the greatest loss (14%), and the control/no relapse cow has a midlevel loss (7%). Section B calculates the costs for each of the four unique endpoints, according to the information in section A. Negative values are shown in parentheses. *FCM,* Fat corrected milk. (Data adapted from Olson JD: Health and reproductive aspects of the peripartum cow. National Dairy Database website. Available at: http://www.inform.umd.edu/EdRes/Topic/AgrEnv/ndd/health/HEALTH_AND_REPRODUCTIVE_ASPECTS_OF_THE_PERIPARTUM_COW.html. Accessed August 30, 2000.)

lapse" potential, the path ending at the upper right of Fig. 2-27. Fig. 2-28 shows that this node has an endpoint value of ($110); note that parentheses are a commonly used means of indicating negative financial values. Based on the original data, there is an 87% ([31 − 4]/31) probability of this occurring. If this path is traced backward in time to its node, the analyst finds that it has one accompanying path (the "Relapse" path). From Fig. 2-28 this path has a probability of occurring of 13% (1 − 0.87 = 0.13) and an endpoint value of ($444). Since the paths are connected by a chance node, the "averaging out" algorithm is followed. Hence, the EMV of the "Gel+" chance node is generated by multiplying each path's probability against its endpoint value and summing them. This is accomplished as follows:

$$EMV_{GEL+} = [\text{Endpoint Value}_{\text{PATH ONE}} \times \text{Probability}_{\text{PATH ONE}}] + [\text{Endpoint Value}_{\text{PATH TWO}} \times \text{Probability}_{\text{PATH TWO}}]$$

$$EMV_{GEL+} = [(\$110) \times 0.87] + [(\$444) \times 0.13]$$

$$EMV_{GEL+} = (\$153)$$

Had three or more paths been emanating from the chance node, the same process would have been followed: multiply each endpoint value times its probability and sum them all. The exercise for generating the EMV of the "Gel−" chance node is accomplished by combining data from Fig. 2-28 in a similar manner:

$$EMV_{GEL-} = [\text{Endpoint Value}_{\text{PATH ONE}} \times \text{Probability}_{\text{PATH ONE}}] + [\text{Endpoint Value}_{\text{PATH TWO}} \times \text{Probability}_{\text{PATH TWO}}]$$

$$EMV_{GEL-} = [(\$196) \times 0.64] + [(\$432) \times 0.36]$$

$$EMV_{GEL-} = (\$281)$$

The final decision tree, with solution, is shown in Fig. 2-29. The EMVs have been calculated as just described. Since the decision criterion chosen in the "Decision analysis step 3" section is to select the course of action with the lowest costs, as demonstrated by comparing the EMVs of the two chance nodes ("Gel+" versus "Gel−"), the analyst chooses to go with the option of the "Gel+" node. The "fold back" algorithm is performed, and the "Gel−" path is dispensed with as being suboptimal. This is signified by using standard DAT symbols, the double line crossing the path leading from the decision node to the "Gel−" chance node.

Decision Analysis Step 5: Perform Sensitivity Analysis on "Soft" Values. Several values may be in question regarding this problem. One such issue deals with the failure rates found in the Oetzel study. What if they were different? How different could the experience be and still have the treatment be optimal? To do this the probability for relapse is simply changed and the EMVs recalculated. This is shown in Fig. 2-30, in which the EMV for each group has been calculated over the range of potential failure rates (i.e., relapse rates), from no failure to 100% failure.

One way to interpret Fig. 2-30 is to determine equivalent EMVs at differing failure rates. For instance, suppose the analyst felt the relapse rate found in the study for the control (e.g., Gel−) group (36%) was reasonable but doubted the claimed relapse rate for the treated animals (13%). Perhaps the analyst's experience with the calcium gel was not as good. How high could the treated group's relapse rate be and still remain the right choice of action? To do this the analyst merely identifies the point on the control EMV line that signifies the 36% relapse rate and draws a horizontal line

Downloaded from Vet-eBooks.com

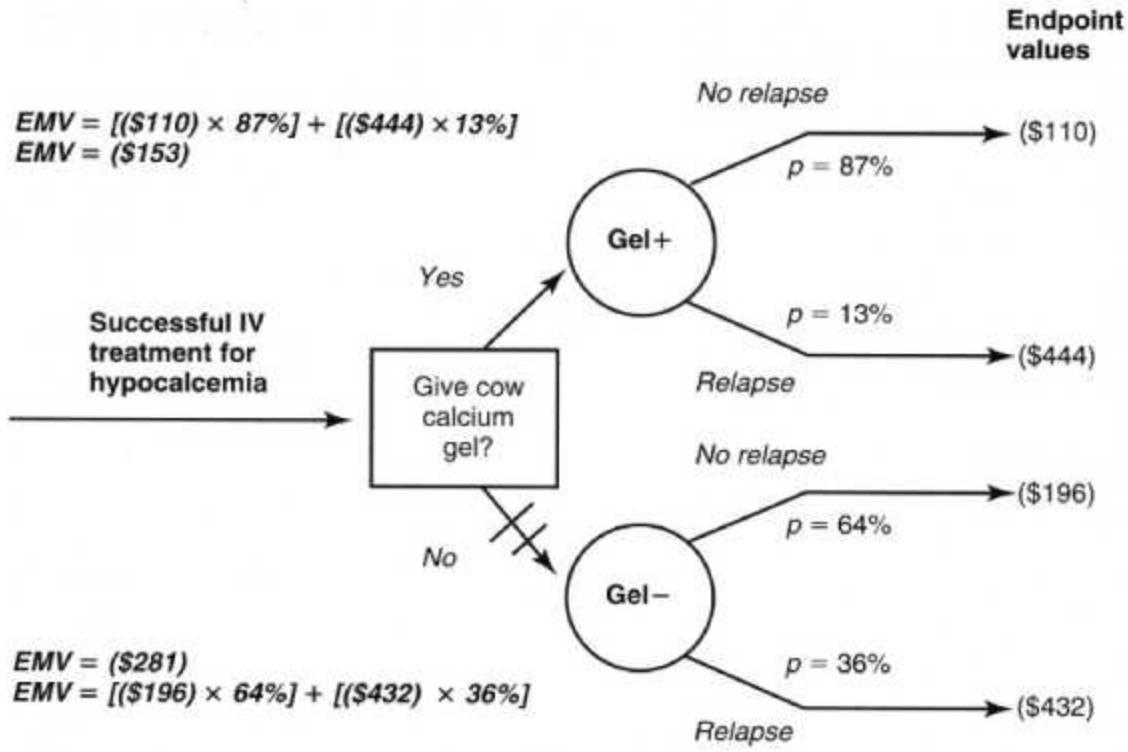

FIG. 2-29 Completion of the decision tree evaluating the choice of using oral calcium gel as adjunct therapy following successful treatment for the initial hypocalcemic event. The endpoint values and probabilities were taken from Fig. 2-28. The expected monetary value *(EMV)* for the two chance nodes were generated by following the "average out" algorithm. The rational choice is to select the option with the lowest EMV. This is the "Gel+" path at ($153). The analyst dispenses with the other option by drawing a double line across that path. The optimal path, when faced with a cow successfully treated with IV calcium, from this decision tree, is to treat the cow with calcium gel.

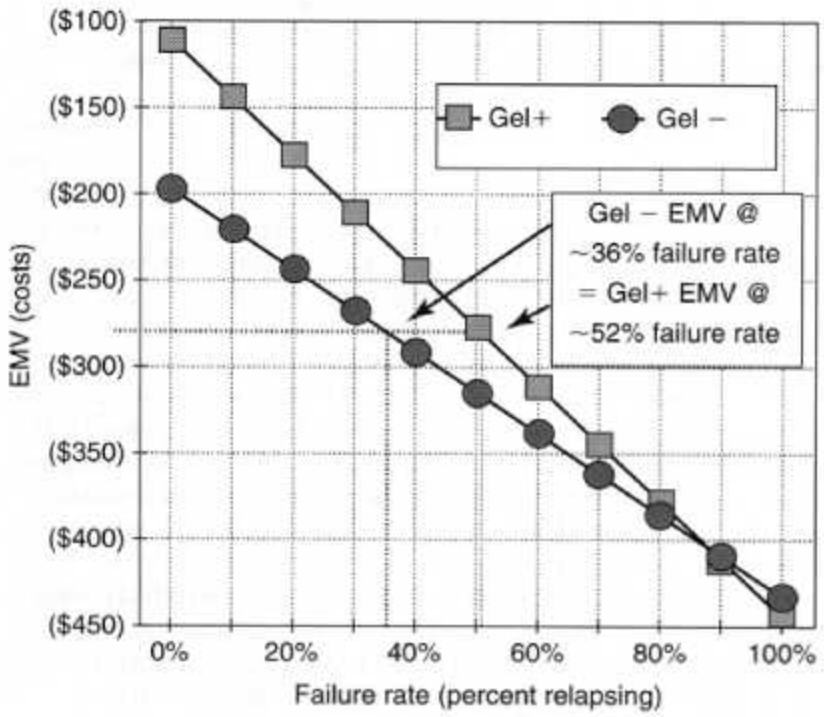

FIG. 2-30 Sensitivity analysis of the calcium gel decision to failure rate for both the treated and the control groups. The graph indicates that at the foundation study's control failure rate of 36%, the treatment group could have a failure rate of over 50% and display an equivalent expected monetary value *(EMV)*. It also suggests that even if the control group had a 0% failure rate, the treated group could suffer up to approximately a 25% failure rate and still be the optimal choice (i.e., the EMV of control at 0% failure rate is approximately equal to the EMV of treatment at between 25% and 30% failure rate).

from the y-axis across that point and continues the line to the treated EMV line. Then the analyst drops a vertical line from the intersection of the horizontal line and the treated group EMV line and reads where it intersects the x-axis. Doing this, with the relations shown in Fig. 2-30, suggests that the treated group could suffer a relapse rate of nearly 52% before its EMV drops below that of the control group. Another way of saying this would be to identify a treatment relapse rate of approximately 52% as being the "indifference" relapse rate, since at that point the analyst would be indifferent to either treating or not treating with the calcium gel. Since the study's relapse rate was approximately one fourth the magnitude of the indifference level, the analyst can claim that this decision is stable with regard to failure rates.

The most glaring assumptions in this model surround the relationship of long-term milk production losses relative to relapses, to nonrelapsed animals treated with calcium gel, and to nonrelapsed animals not treated with calcium gel (Fig. 2-28). A sensitivity analysis is certainly called for to evaluate the effect of changes in that set of assumptions. One question might address the costs of treating relapses. The relative magnitudes of loss (i.e., that the loss for a full relapse is approximately twice the loss of a nontreated, nonrelapsing cow, which itself is about twice the loss for a treated, nonrelapsing cow) could be another point of contention. One way to look at this issue is to keep the relative magnitudes the same but to alter the relapse losses down to no loss. With no loss, then, none of the animals would show long-term effects of hypocalcemia. Both issues—the cost of treatment and long-term losses—are illustrated in Fig. 2-31.

In Fig. 2-31 the analyst is looking at a two-way sensitivity analysis and evaluating the effects of changes in relapse rates and the effects of changing the cost of treating a relapsed case. The measure being used is the difference between the two groups' EMVs, such that a positive difference indicates that, for the given combination of relapse rate and relapse treatment costs, the EMV of the treated group was greater than that for the control group—and the gel treatment is the best choice. If the EMV difference is negative, not treating with the calcium gel is optimal. The first thing to note is that if the medical costs incurred in treating a relapsed case exceed approximately $50, the calcium gel therapy is optimal,

Downloaded From Vet-eBooks.com

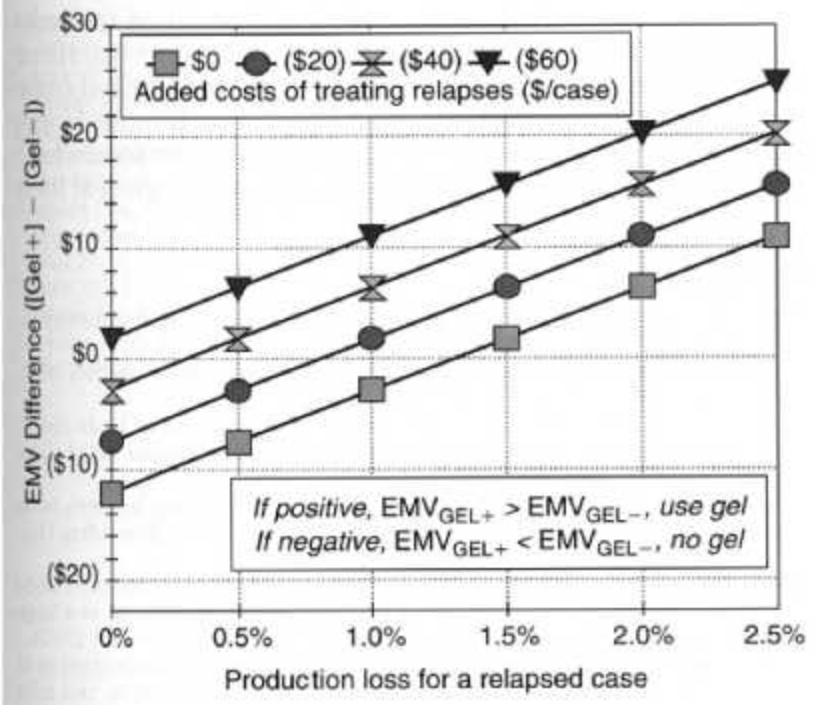

FIG. 2-31 Illustration of a two-way sensitivity analysis for the calcium gel decision problem. Estimated monetary value (EMV) difference changes ($EMV_{GEL+} - EMV_{GEL-}$) are being evaluated with regards to the actual medical costs of treating a relapsed cow (range from $0 to $60) over expected production losses for a relapsed case (range from 0% to 2.5%). If relapsed cows showed no decrease in production, medical costs of treating a relapsed case would need to exceed $40 to make the calcium gel preventive therapy cost effective (between a treatment cost of $40 and $60, the 0% production loss situation switches to a positive EMV difference). However, if a relapsed animal suffers a production loss equal to or above 1.5%, even if no extra costs were incurred in treating a relapsed animal, the calcium gel treatment is optimal (the $0 medical cost line crosses the $0 EMV difference threshold between 1.0% and 1.5% production loss). Hence the choice to use the calcium gel appears stable relative to changes in treatment costs and long-term losses.

regardless of whether any production loss results from the relapse. Note also that if a relapsed cow suffers more than approximately a 1.25% production loss, the gel therapy is again optimal, regardless of the cost of treating a relapsed animal. Since it is difficult to support a claim that relapsed cases will have little or no long-term effects, the analyst can also declare the decision to use the calcium gel as being fairly robust against estimates of long-term effects.

With the use of the basic decision tree, along with a one-way and a two-way sensitivity analysis, a general statement can be made:

Assuming the study's relapse rates approximate reality for a given client, treating all posttherapy hypocalcemic cows with oral calcium gel appears to be the economically rational choice within reasonable levels of failure rates (i.e., any treatment relapse rate of less than 50%), treatment costs (i.e., if treating a relapsed cow incurs approximately $60 in extra costs, and no long-term effect can be claimed), and long-term loss estimates (i.e., if long-term losses are at least 1.5% over a lactation).

The value of being able to make such a general statement is that it frees the analyst from having to prove costs or success rates or other inputs to a narrow range. For instance, if a client feels that the calcium gel therapy will not keep relapse rates at 13%, as found in the study, the calcium gel therapy is still optimal as long as the client's experience is that untreated animals relapse in about one third of cases and that the treated animals relapse at less than a 1 in 2 rate. It will not have as great a monetary advantage over not treating at a 40% failure rate, but it will still have the advantage.

READING THE LITERATURE ON ECONOMICS OF ANIMAL DISEASES AND CONTROL PROGRAMS

Literature abounds with reports on the costs of disease and disease control programs. Some are quite good, offering useful information and comparisons for decision-makers. Others are incomplete, only hinting at total costs. Still others are covertly misleading, having been built on preconceived notions.

Some hints at evaluating such literature follow. When reading a paper relating to the economic evaluation of a disease, there are several questions to keep in mind:

1. Is the study (or the several studies) on which the economic analysis is based *valid, both scientifically and clinically*? If the paper addresses the B:C of a new treatment versus an older treatment, are the differences described statistically significant? Do the results make sense in biological, medical, or epidemiological terms? If the underlying science is inappropriate, no amount of economic expertise will salvage the results.

2. What *kind of analysis* is being portrayed? Is it a partial budget, marginal analysis, decision analysis, capital budget, simulation, or some combination thereof? Is it based on a clinical trial, a model, or a retrospective study? The type of analysis used brings with it certain advantages and disadvantages, as discussed previously. None are perfect, but the reader still needs to know what to consider.

3. Recognizing that no analysis is ever complete, does the study *include areas of major importance, or at least acknowledge important areas omitted*? This can be looked at in two ways:

- *Does the study account for important items* for the particular area, industry, and time it considers? If so, does it also account for important items for the particular area, industry, and time about which *the analyst* and the client(s) are concerned?
- *From whose viewpoint does the study address costs and benefits?* Some studies evaluate a system from the social or governmental point of view. In such cases, benefits accruing to the public are considered true benefits, whereas costs assumed by producers may not be considered program costs (Hanson and Hanson, 1983). Farmers might disagree with this.

4. Does the analysis conclude with *some recommendation for action or behavior change?* Does it shed light on how to solve a problem? This should not be misinterpreted; a simple "this is what happened" type of report is often useful, in and of itself. However, without also proposing solutions it is difficult to see which problems the authors thought to be amenable, and hence, where the options for addressing those problems lay.

A recommendation may be the least important of the criteria, for what an author sees as an option may or may not be applicable to the reader's situation. However, if proposed solutions are included, they give the reader another means of understanding the system being evaluated.

5. What *assumptions* have been made? This can be tricky. The baseline from which the analysis starts must be carefully identified: is the comparison or foundation disease model or herd setting assumed to be perfect (i.e., no diseases of any kind), optimal (i.e., as good as it can get), or average (i.e., about what to expect for most producers). The "perfect" baseline inflates the relative costs of any disease and hence exaggerates the value of controlling that disease. For the "average" comparison, the analyst will underestimate the value of controlling the problem under study if the client is better than average.

Many assumptions are not stated; they are *implicit*, not *explicit*. For example, when the practitioner assumes a constant herd size, he or she is also assuming that this is a reasonable,

Downloaded from Vet-eBooks.com

or maybe even optimal, situation. In a way, it is assuming the industry cannot take the decreases in income resulting from shrinking herd sizes, or that increases in herd size are equally unacceptable. This assumption may limit the number of options available, because it removes any management strategy from the decision that might alter herd size.

6. How sensitive will the recommendation be to the assumptions made? *Sensitivity analysis* for the "softer" numbers and assumptions always should be addressed. If not, the reader should be careful with how widely the results are referred. Just because something made it into a publication and therefore got wide distribution does not mean the results are applicable across a wide audience.

7. Have long-term financial flows been *standardized using present value concepts?* If so, what kinds of discount rates are used? Are they appropriate? Are they overly low or high and therefore inordinately favoring of certain types of cash flows? If they are not used, do the data allow the outcomes to be converted using time value of money techniques? In a similar vein, if the study evaluates results over years, the study should use *"constant" costs and returns*. Often an author will say something to the effect of the following: "...Financial information was converted into constant 1997 values...." This allows the research to dampen the effects of inflation, currency exchange rates, recessions, and other macroeconomic effects, upon the outcomes.

8. If the report describes gains and losses, does it present the *biological effects separately from the economic effects?* The economic effects may change as markets change. In the United States during the late 1980s, day-old Holstein bull calves were selling for $5 to $10. Within 5 years they were selling for $125 to $150, a reflection of the interest in dairy beef and of a general upswing in the cattle market. Certainly a project to protect such calves from neonatal diarrheas would look much more favorable economically when bull calf values were high, just from the differences in the market. The biological effects should form the basis for modifying the analysis for future market conditions. Without biological data, a study's findings cannot be adjusted to changes in markets and finance.

Interested readers are encouraged to refer to Greenhalgh (1997) for a more in-depth discussion on critical review of the medical economic literature.

CONCLUSION

This chapter touches on just some of the most powerful analytical tools available to the production medicine practitioner. From reading the chapter and working through its examples, the reader should be able to perform the following:

- Evaluate data with regards to its type and distribution
- Understand and develop basic epidemiological rates, proportions, and ratios from personal clinical experiences
- Differentiate between those differences and associations that are important and those that are spurious
- Interpret diagnostic tests, whether on an individual or group basis
- Design diagnostic and treatment programs using clinical test efficiencies
- Work with financiers and producers on economic issues of markets, production, and time value of money
- Establish and analyze partial budgets, B:C analyses, and decision analysis systems

Additionally, if the reader turns back to the start of this chapter and the hypothetical questions a client might ask a modern production veterinarian, the contents just completed should allow the practitioner to know what type of information and what kind of analysis are needed to address those concerns.

Will a conscientious reader be good at all of the techniques mentioned just from reading the chapter? No. He or she will be just starting. Some readers may never need some of these techniques, and others will need much more. Hopefully both types of reader, and the many who fit somewhere in between, have been given the guidance to progress at their own speed.

APPENDIX A

STATISTICAL TEST VALUES FOR Z-TESTS AND CHI-SQUARE TESTS

CONFIDENCE	50%	60%	70%	80%	90%	95%	99%
Z-test*	0.68	0.84	1.04	1.28	1.64	1.96	2.57
Chi-square†	0.45	0.71	1.07	1.64	2.71	3.84	6.63

*Listed Z scores are for a two-tailed test; the analyst is testing whether the value in question are different, not whether one is bigger, better, higher, etc. than the other.
†Chi-square statistic values are exclusive for a 2 × 2 table (i.e., a test with 1 degree of freedom; no. of degrees of freedom = [no. of rows − 1] × [no. of columns − 1]). Larger tables (i.e., 2 × 3, 3 × 4) require a different set of chi-square statistic values.

EXAMPLES:

A *Z-test* value of 1.17 is calculated. This yields a statistical confidence between 70% and 80% (i.e., *P* is between .20 and .30) that the observed difference is real.

A *chi-square test* value of 4.46 yields a statistical confidence level between 95% and 99% (i.e., *P* is between .01 and .05) that the observed difference is real.

Downloaded From Vet-eBooks.com

APPENDIX B: H.O.T. STATS WORKSHEET 1

Z-TEST CONFIDENCE INTERVAL FOR THE DIFFERENCE BETWEEN TWO MEANS

I. **DATA.** A practitioner is looking as heifer weights, both pregnant and open, to see if a difference exists between the two groups. The following counts, mean weights, and standard deviations are found by using a calculator:

	Open	Pregnant
Count	15	22
Mean weight	667	676
SD weight	18	22

II. **INTERVAL STATISTIC.**

$(\text{mean1} - \text{mean2}) \pm Z_{score} \times \text{SQRT}\,[(\text{SD1})^2/\text{count1} + (\text{SD2})^2/\text{count2}]$

Where: meanX = Average of group X
Z_{score} = Z score value from a statistics table
SQRT = Square root function
SDX = Standard deviation of group X
countX = Number of animals in group X

Which, for this example, would be:

$(667 - 676) \pm Z_{score} \times \text{SQRT}\,[(18)^2/15 + (22)^2/22]$

III. **Z SCORES.** Z scores for the following levels of confidence (from any statistics text, or see Chapter Appendix A):

80%: 1.28 **90%:** 1.64 **95%:** 1.96

IV. **DO THE MATH.** Calculate the confidence intervals for the difference between means:

80%: −17.5 to −0.5 **90%:** −19.8 to 1.8 **95%:** −21.9 to 3.9

V. **DECISION RULE.** A confidence interval shows the likely range of the true difference in mean values between the two groups; if all the herd's open and pregnant heifers are captured (or were sampled numerous times), this is where their average weight differences would lie.

The *decision rule* is to reject the conclusion that a difference exists if 0.0 is captured in the range. There is 80% confidence that the nonpregnant group weighs somewhere between 17.5 lb to 0.5 lb less than the pregnant heifers. Note that to be 90% confident that the true mean difference was captured, the practitioner would need to admit that, given this sample size and the variability in the data, the pregnant group could actually be *lighter* that the open group by 1.8 lb—which does not fit the initial hypothesis. Hence, the practitioner cannot be 90% certain that the nonpregnant group is lighter than the open group. The same is true, of course, for the 95% confidence interval: It contains zero, so the practitioner cannot be 95% certain an actual difference is present.

Therefore the practitioner can be at least 80% confident that the apparent weight difference is real. Given that the range for the 80% confidence interval almost hits zero, the practitioner cannot be much more confident than 80%. Statistical theory does not tell whether 80% confidence is sufficiently certain to warrant action. That is the job of nonstatistical processes. But now we know just how certain we are.

Caveats

The Z-test confidence interval assumes a fairly normally distributed set of data. It is important to realize that this is usually true for differences between means of skewed data. It also assumes the samples being compared were selected at random from the overall population. If these do not apply, it means that you must be more careful in interpreting the results.

Downloaded From Vet-eBooks.com

APPENDIX C: H.O.T. STATS WORKSHEET 2

CHI-SQUARE TEST FOR CONTINGENCY TABLES

I. DATA. A practitioner has finished doing fertility work on a dairy and has the impression that fresh heifers do not "clean up" as well as fresh cows. The following 2 × 2 table shows the results of the examination. The italicized letters identify dells used in the next step.

	Clean	Metritis	Total
Heifers	15 *(a)*	12 *(b)*	27
Cows	42 *(c)*	16 *(d)*	58
Total	57	28	85

II. TEST STATISTIC. The equation for calculating the chi-square test statistic, using the letter identification with the table above:

$$\frac{[(a \times d) - (c \times b)]^2 \times \text{TOTAL}}{(a + b) \times (c + d) \times (b + d) \times (a + c)}$$

III. CHI-SQUARE VALUES. Chi-square values for different levels of confidence (from any statistics text [chi-square, 1 degree of freedom], or from Chapter Appendix A)

80%: 1.64 **90%:** 2.70 **95%:** 3.84

IV. DO THE MATH. Plug in the cell values and solve.

$$\frac{[(15 \times 16) - (42 \times 12)]^2 \times 85}{27 \times 58 \times 28 \times 57} = 2.37$$

V. DECISION RULE. If the test statistic exceeds the value of the chi-square at a given confidence level, the *decision rule* is to accept the idea that an association between the row and column factors exists at that level of confidence. Since the test chi-square at 2.37 is greater than an 80% confidence level chi-square value (1.64), but is below the 90% confidence level chi-square value (2.70), the practitioner is between 80% and 90% certain that an association exists between metritis and being a heifer. Heifers performed worse than the cows.

Caveats

As long as no cell in a 2 × 2 table has a value less than 5, and as long as the groups are independent and mutually exclusive, the chi-square for contingency tables is a very robust and easy method of determining statistical significance in data sets. In other words, this cannot be used for "before-after" comparisons on the same animals (not independent) or in situations in which the classification is not clear (not mutually exclusive).

APPENDIX D: H.O.T. STATS WORKSHEET 3

THE SIGN TEST FOR PROPORTIONS WITH REPEAT MEASURES

I. **DATA.** The practitioner changes a dairy's ration and wonders how production changed. Since milk production is affected by days in milk, an index based on an entire lactation would remove the confounding in milk production from the pre-ration change measurement to the post-ration change measurement because of time. Therefore Mature Equivalent Milk Production (MEMP) was chosen. The number of animals whose measure went up and the number that went down is counted. In this example, suppose after changing the ration the practitioner gets these results for a 67-cow string: increased MEMP = 41, decreased MEMP = 26.

II. **TEST STATISTIC.** The calculation is the absolute value (i.e., ignore final negatives) of the following:
(Total − [2 × lesser of the two] − 1)/(Total$^{0.5}$)
where taking a number to the 0.5 power equals taking its square root.

III. **Z SCORES.** This fits a Z-test distribution, so the appropriate values are (from any statistics text, or see Chapter Appendix A)

80%: 1.28 **90%:** 1.64 **95%:** 1.96

IV. **DO THE MATH.** Plug in the numbers to the test statistic equation and compare to the published "Z" scores:

$$(67 - [2 \times 26] - 1)/(67^{0.5}) = (67 - 52 - 1)/8.19 = 1.71$$

V. **DECISION CRITERIA.** The *decision rule* is similar to before: Since the test value is between the "Z" scores for 90% and 95% confidence, the results show between 90% and 95% confidence that more cows increased MEMP than decreased MEMP after the ration change.

Caveats

To work well, at least 25 pairs of measures (i.e., 25 animals, evaluated twice) are needed. The observations also must be taken at random.

APPENDIX E: SPREADSHEET STATS WORKSHEET 1

STUDENT'S t-TEST FOR THE DIFFERENCE BETWEEN TWO MEANS

I. DATA. A practitioner is looking at heifer weights, both pregnant and open, to see if a difference exists between the two groups. The values are entered into a commercial spreadsheet to get the following counts, mean weights, and standard deviations:

	Open	Pregnant
Count	15	22
Mean weight	667	676
SD weight	18	22

	Body Weight			Body Weight			Body Weight			Body Weight	
	Open	Pregnant		Open	Pregnant		Open	Pregnant		Open	Pregnant
1.	661	659	7.	691	713	13.	655	690	19.	–	665
2.	650	669	8.	652	678	14.	663	698	20.	–	687
3.	651	709	9.	670	658	15.	701	679	21.	–	679
4.	672	655	10.	690	688	16.	–	700	22.	–	669
5.	671	701	11.	631	669	17.	–	630			
6.	662	640	12.	680	645	18.	–	688			

II. THE STUDENT'S t-TEST (using Quattro Pro 8, Windows)

A. The test is run through a set of menu choices:
Tools / Numeric tools ⇒ / Analysis

B. This starts an automated analysis process. Choose, in order:
1. t-Test <*Next* ⇒>
2. Enter cell range for the 15 nonpregnant animals into *Variable 1 Input*
3. Enter cell range for the 22 pregnant animals into *Variable 2 Input*
4. Select a blank cell with at least 13 blank rows under it for the *Output Cells*, then hit <*Next* ⇒>
5. Click on the button for *Two Sample with Equal Variances*, then hit <*Finish*>. (Don't worry about selecting <*Alpha*> *or* <*Difference*> values.)

C. Starting in the *Output Cells* from step 4, the following is displayed:

t-Test: Two Sample Assuming Equal Variance

	Variable 1	Variable 2
Mean	667	676
Variance	340	498
Observations	15	22
Pooled variance	435	
Hypothesized mean difference	0	
df	35	
t	−1.3	
P (T <= t) one-tail	0.10	
t Critical one-tail	1.69	
P (T <= t) two-tail	0.20	
t Critical two-tail	2.03	

III. DECISION RULE. The *decision rule* is executed by examining the value for the line "P(T <= t) two-tail," which in this case is 0.20. This is the P value suggesting that there is a 20% chance that the difference seen is simply due to random events, and that the true difference could be zero. In other words, the practitioner can be 80% confident that the difference observed is not due to random events. This is just what was found when the Z-test confidence interval for the difference between two means was run in H.O.T. Stats Worksheet 1.

Caveats

This test assumes samples are independently drawn from two normally distributed groups. It cannot, therefore, operate on before and after or paired selection samples.

Downloaded From Vet-eBooks.com

APPENDIX F: SPREADSHEET STATS WORKSHEET 2

CHI-SQUARE TEST FOR CONTINGENCY TABLES

I. **DATA.** A practitioner doing fertility work on a dairy has the impression that fresh heifers do not "clean up" as well as fresh cows. The following 2 × 2 table shows the results of the examination:

	Clean	Metritis	Total
Heifers	15	12	27
Cows	42	16	58
Total	57	28	85

II. **THE CHI-SQUARE TEST—GENERAL** (using Microsoft Excel 97, Windows)

A. The first step is to create the table of expected values, following the same process described in H.O.T. Stats Worksheet 2. To reiterate, the analyst calculates the cell sizes, assuming there is no effect of the row factors (i.e., the cells in each column assume the same proportion as the overall proportion for that factor). In this case, it is the following:

Proportion heifers overall = 27/85 = 0.32
Proportion cows overall = 58/85 = 0.68

B. Multiply the above proportions by the sum of "clean" and "metritis" cases to develop the proportion of heifers and cows in each class:

	Clean	Metritis	Total
Heifers	57 × 0.32 = 18.1	28 × 0.32 = 8.9	27.0
Cows	57 × 0.68 = 38.9	28 × 0.68 = 19.1	58.0
	57.0	28.0	85.0

C. A reasonable way the spreadsheet might look, following these two steps, would be as follows:

	A	B	C	D	E	F
1	***DATA***		**CLEAN**	**METRITIS**		
2		**Heifers**	15	12	27	32%
3		**Cows**	42	16	58	68%
4			57	28	85	
5			67%	33%		
6						
7	***EXPECTEDS***		**CLEAN**	**METRITIS**		
8		**Heifers**	18.1	8.9	27.0	
9		**Cows**	38.9	19.1	58.0	
10			57.0	28.0	85.0	

Microsoft® Excel 97, Microsoft Corporation. 1997.

D. Statistical "=" functions can be used here instead of invoking a set of menu commands as in Spreadsheet Stats Worksheet 1. These are functions that perform certain procedures, saving the analyst from doing it all. The functions to be used are as follows:

=CHIINV Computes the inverse of the cumulative one-tailed chi-square distribution and develops the critical value for a test involving a chi-square variable.

Syntax = =CHIINV (Prob, Deg_of_Freedom), where Probability = Cumulative probability value (must be between 0 and 1), and Deg_of_Freedom = Integer number of degrees of freedom (must be ≥1). Calculated as (no. of rows – 1) × (no. of columns – 1)

=CHITEST Computes the probability that the actual and expected frequencies are similar by chance. =CHITEST returns the probability for a chi-square test distribution with (r – 1) × (c –1) degrees of freedom, where r = number of rows and c = number of columns. Actual and Expected must have the same number of values and must contain multiple rows or columns of data.

Syntax = =CHITEST (Actual, Expected), where Actual = Cells containing actual values and Expected = Cells containing expected values.

Downloaded from Vet-eBooks.com

These two "=" functions are included in this spreadsheet as shown below:

	A	B	C	D	E	F	G	H	I	J	K
1	***DATA***		**CLEAN**	**METRITIS**							
2		**Heifers**	15	12	27	32%					
3		**Cows**	42	16	58	68%					
4			57	28	85						
5			67%	33%				***CHI STATISTIC*** [a]		2.37	
6								***P-VALUE (2-TAIL)*** [b]		0.12	
7	***EXPECTEDS***		**CLEAN**	**METRITIS**							
8		**Heifers**	18.1	8.9	27.0			a = CHIINV (J6,1)			
9		**Cows**	38.9	19.1	58.0			b = CHITEST (C2:D3,C8:D9)			
10			57.0	28.0	85.0						

Microsoft® Excel 97, Microsoft Corporation, 1997.

III. DECISION RULE: The *decision rule* is executed by examining the value for the cell identified as *P*-value (Cell J6 in the table just shown), which in this case is 0.12. This suggests there is a 12% chance the difference seen is simply due to random events and that the true difference could be zero. In other words, the practitioner can be nearly 88% confident that the difference observed in the metritis rates between heifers and cows is not due to random events. The chi-square test run in H.O.T. Stats Worksheet 2 claimed an 80% to 90% confidence that a significant association was present.

Caveats

As long as no cell has a value less than 5, and as long as the groups are independent and mutually exclusive, the chi-square for contingency tables is a robust and easy method of determining statistical significance in data sets. In other words, this cannot be used for "before-after" comparisons on the same animals (not independent) or in situations in which the classification is not clear (not mutually exclusive).

APPENDIX G: SPREADSHEET STATS WORKSHEET 3

PAIRED t-TEST FOR THE DIFFERENCE BETWEEN TWO MEANS

I. **DATA.** A practitioner changes a dairy's ration and wonders how production changed. Since milk production is affected by days in milk, an index based on an entire lactation would remove the confounding, therefore the mature equivalent milk production (MEMP) is chosen.

In this example, suppose after changing the ration the practitioner gets these results for a 67-cow string: increased MEMP = 41; decreased MEMP = 26. This is shown below along with other descriptive statistics. Also included is the actual data set itself.

	Average	Standard Deviation	Minimum	Maximum	No. Increased	No. Decreased
MEMP before	22,559	1236	19,783	25,789	–	–
MEMP after	22,621	1327	19,782	25,998	41	26

Cow	Before	After	Diff	Cow	Before	After	Diff
1.	22842	22702	−140	35.	21155	21354	199
2.	22719	22521	−198	36.	22427	22135	−292
3.	23700	23854	154	37.	20461	20409	−52
4.	23995	24271	276	38.	22434	22534	100
5.	23432	23583	151	39.	23647	23812	165
6.	24009	24182	173	40.	19783	19782	−1
7.	23922	24073	151	41.	25789	25998	209
8.	23138	23371	233	42.	24097	24319	222

30.	22670	22874	204	64.	21178	21001	−177
31.	23117	22842	−275	65.	21903	22298	395
32.	22840	22938	98	66.	21922	21989	67
33.	24648	25895	1247	67.	21969	21689	−280
34.	20798	21004	206				

II. **THE STUDENT'S t-TEST** (using Quattro Pro 8, Windows)

A. The test is run through a set of menu choices:
Tools / Numeric tools ⇒ / Analysis

B. This starts an automated analysis process. Choose, in order:
1. t-Test <*Next* ⇒>
2. Enter cell range for the 67 "before" animals into *Variable 1 Input*
3. Enter cell range for the 67 "after" animals into *Variable 2 Input*
4. Select a blank cell with at least 13 blank rows under it for the *Output Cells*, then hit <*Next* ⇒>
5. Click on the button for *Paired Two Sample for Means*, then hit <*Finish*>. (Don't worry about selecting <*Alpha*> or <*Difference*> values.)

C. Starting in the cell selected for the *Output Cells* from step 4, the following is displayed:

Downloaded from Vet-eBooks.com

t-Test: Paired Two Sample for Means

		Variable 1	Variable 2
Mean		22,559	22,621
Variance		1,551,915	1,787,997
Observations		67	67
Pearson correlation		0.98	
Pooled variance		1,668,956	
Hypothesized mean difference		0.00	
	df	66	
	t	−2.02	
P (T <= t) one-tail		0.02	
T Critical one-tail		1.67	
P (T <= t) two-tail		0.05	
t Critical two-tail		2.00	

III. **DECISION RULE.** The *decision rule* is executed by examining the value for the line "*P*(T<=t) two-tail," which in this case is 0.05. This is the *P* value suggesting that there is a 5% chance that the difference seen is simply due to random events, and that the true difference could be zero. In other words, the practitioner can be 95% confident that the difference observed is not due to random events. The sign test run earlier claimed a 90% to 95% confidence that more cows went up in MEMP than down. Given how different the data going into the analyses were, this is plenty close for decision making.

Caveats

This test assumes samples are from two normally distributed groups.

Downloaded From Vet-eBooks.com

APPENDIX H: SPREADSHEET STATS WORKSHEET 4

SIMPLE LINEAR REGRESSION OF TWO VARIABLES

I. **DATA.** A practitioner suspects that a recent long-term drop in a grass-fed dairy client's milk production, as measured by the herd's changes in rolling herd average (RHA) milk production, could be due to a concomitant increase in somatic cell count (SCC). The practitioner wants to determine, in regression vernacular, whether SCC (the independent variable) plays a major role in describing the variability in rolling herd average (the dependent variable, or outcome). The herd's Dairy Herd Improvement Association (DHIA) records are reexamined, and the last 24 months' data on RHA and SCC are extracted, as shown below. (Note: To run the test, the data should be in single columns for SCC and RHA; they are split here to save space.)

DHIA test date	Estimated avg SCC score	KG rolling herd milk	DHIA test date	Estimated avg SCC score	KG rolling herd milk
Feb-00	3.4	6256	Feb-01	3.8	6141
Mar-00	3.4	6253	Mar-01	3.6	6030
Apr-00	3.5	6156	Apr-01	3.8	6038
May-00	3.7	6161	May-01	3.9	6016
Jun-00	3.6	6148	Jun-01	4.2	5896
Jul-00	3.5	6129	Jul-01	3.8	5900
Aug-00	3.6	6208	Aug-01	4.1	5904
Sep-00	3.4	6191	Sep-01	3.7	6079
Oct-00	3.7	6205	Oct-01	4.0	6011
Nov-00	3.6	6118	Nov-01	3.8	5983
Dec-00	3.7	6196	Dec-01	4.0	5892
Jan-01	3.5	6192	Jan-02	3.9	5867

II. **LINEAR REGRESSION.** (using Quattro Pro 8, Windows)

A. The test is run through a set of menu choices:
Tools / Numeric tools ⇒ /Regression

B. This starts an automated analysis process. Choose, in order:
1. Enter cell range for the 24 SCC observations into *Independent*
2. Enter cell range for the 24 RHA recordings into *Dependent*
3. Select a cell at the top left corner of a blank range of at least 9 rows and 5 columns, for *Output*
4. Click on the button for *Y Intercept/Compute*
5. Click the <OK> button to run the test.

C. Starting in the cell selected for *Output Cells* from step 3, the following is displayed (the "Notes" section is my inclusion and not part of the output):

Regression output		Notes
Constant	7804.87	Theoretical RHA at 0 SCC score
Std Err of Y Est	71.55	Error in estimate
R Squared	0.68	Proportion of variation in RHA explained by SCC
No. of Observations	24	Number of months evaluated
Degrees of Freedom	22	df = n − 2; used in statistical significance tests
X Coefficient(s)	-463.53	RHA change per 1 unit increase in SCC
Std Err of Coef.	67.21	Error in estimate

D. The equation for the regression is built according to the following format (variables underlined are from the above regression output table):

"Y" = Constant + X Coefficient × "X" (R^2 = R Squared)

For the RHA by SCC example, this would be as follows:

RHA = 7804.87 + -463.53 × SCC (R^2 = 0.68)

This can be interpreted as meaning that, with a theoretical RHA production at zero SCC (it does not matter than an SCC of zero is physiologically impossible; this is mathematics and the math can find numerous uses for impossible events!) of approximately 7805 kg, for every unit increase in SCC (i.e., if hard average SCC score moves from a 3.4 to a 4.4), the RHA is expected to change by approximately –464 kg (i.e., to drop 464 kg). This relationship explained approximately two thirds of RHA's variability over the 2-year period observed (R^2 = 0.68 ~ 2/3); something else is needed to explain any more of the variability (perhaps season or demographic changes?).

III. **STATISTICAL ANALYSIS OF THE REGRESSION.** The two main components of a linear regression evaluation for statistical significance is whether (a) the slope of the line created by the regression is different form zero (Hamburg, 1983), and (b) the constant (also known as the y-intercept) is zero (Kilpatrick, 1987). If the regression's slope (e.g., the x-coefficient) is statistically indistinguishable from zero, then the independent variable is not of value in predicting the dependent variable. If the constant equals zero, then the regression must be forced through zero. In this example it makes no sense for the constant to be zero, but the test is run here just for the sake of completeness.

For both tests, if the sample size is less than 30 observations, a t-test distribution for reference should be used. If the sample size is 30 or greater, a Z-test distribution for reference should be used. The test statistic is calculated the same either way. Since the number of observations in this example is 24, the t-test is used.

Downloaded from Vet-eBooks.com

A. Test for slope equals zero = x-coefficient / standard error of coefficient
= −463.53/67.21
= −6.90

Using the @TDIST function (Quattro Pro's function to find the probability associated with a t-statistic [syntax = @TDIST (X, Degrees_of_Freedom,2)], or by looking up the t-statistic for 22 degrees of freedom in a statistics book (the negative sign should be ignored if this is done), the test t-value is found to have a related probability of approximately 0.000001. This suggests there is less than a 1 in one million likelihood this correlation is due to chance. Of course, with only 24 observations it is not rational to claim resolution to within seven decimal places—but by any measure this passes the common limits of statistical significance.

In some textbooks (Hamburg, 1983; Snedecor and Cochran, 1989) the authors speak of a test of R2 as the way to determine if the correlation is statistically significant. It is more complicated, requires values not printed out in standard spreadsheet regressions, and gives the same result as noted previously.

B. Test for constant equals zero = constant / (standard error of coefficient^2 × [sum of x^2])$^{0.5}$

This needs a bit of explaining. The "standard error of coefficient^2" means to square the standard error of coefficient. The "sum of x^{2n} means to square each of the x-values and then add them up. Luckily, the spreadsheet has an "@" function that does the job: @SUMSQ (column of numbers holding the x-values)

The last step, taking it to the "0.5" power, is the same as taking the square root of everything. So here is the test for constant equals zero in spreadsheet terms:

= 7804.87/(67.21^2 × SUMSQ *[SCC Scores]*)$^{0.5}$
= 7804.87/(4517 × 333)$^{0.5}$
= 7804.87/1226
= 6.37

Using the @TDIST function (Quattro Pro's function to find the probability associated with a t-statistic [syntax = @TDIST(X, Degrees_of_Freedom,2)]), or by looking up the t-statistic for 22 degrees of freedom in a statistics book (any negative sign should be ignored if this is done), the Test t-value is found to have a related probability of approximately 0.000002. This suggests there is less than a two in one million likelihood this correlation is due to chance. The previous argument, that it is not logical to claim that degree of resolution with only 24 observations, holds. At any rate, this is a significant finding.

Caveats

Linear regression techniques assume, by definition, that two variables are related in a linear fashion. Many associations with which practitioners deal are not linear; therefore they are missed in simple regressions. They also assume that the variation in the dependent variable is the same across the observed values of the independent variable. Again, this is not always the case in biology; often variablility in performance is greater at the extremes than at the middle of a range of normal values. A big assumption of linear regression is that the values of "Y" are independent of each other. If clinic costs are being examined, and costs are low one month, they may be low the next month. The costs, then, are not independent of each other. If clinic costs are regressed over time, however, the regression assumes they are independent of each other. Finally, in regression analysis, the outcome or dependent variable is assumed to carry all the measurement error; the independent variable is assumed to be known exactly. In other words, using the previous example, it is assumed we know SCC exactly (doubtful) so that all the system variation is ascribed to RHA.

Rarely are linear regression's assumptions met in the real world. However, the technique is called, in statistical jargon, "robust." This means that the technique can take fairly major violations of the assumptions and still yield useful data. However, the analyst always should think about these assumptions before embarking on an analysis. The references at the end of Chapter 2 list numerous sources for more in-depth regression analysis, and the "Beyond Spreadsheets: Stand-Alone Statistics Packages" section demonstrates a few of these.

CHAPTER 3

Record Systems and Herd Monitoring in Production-Oriented Health Management Programs in Food-Producing Animals

JEFFERY K. RENEAU and MARK L. KINSEL

The management information system (MIS), which includes production, health, and financial records, is the foundation of all food animal production–oriented health management programs. These herd records must be of high quality and used skillfully to ensure productive and profitable food animal businesses.

Current management inefficiencies are considered in the same light as clinical or subclinical disease, since they all result in suboptimal performance (Blood et al, 1978; Rollin, 1983; Stein, 1986a,b,c; Lessard et al, 1988; Ruegg, 1996). Identifying the cause(s) of suboptimal performance is often difficult, requiring systematic study of herd records and the application of epidemiological techniques.

Veterinary herd health programs in the past have been focused narrowly and integrated poorly into the farm's total management scheme (Wise, 1988). According to a national survey of producers by the American Veterinary Medical Association, veterinarians are still perceived somewhat narrowly as sources of technical services and information only regarding reproductive management and control of clinical disease. However, beef, dairy, sheep, and swine producers report a high degree of satisfaction with their veterinarian. Veterinarians are highly regarded for their teaching ability and the quality of their advice (Gehrke, 1994; Brown and Silverman, 1999). Large herd owners in particular are looking for a more integrated production-oriented approach (Goodger et al, 1982; Goodger and Kushman, 1983; Fetrow et al, 1987; Fetrow et al, 1988a,b; Guterbock, 1994). It has been suggested that a lack of integrated whole farm "systems thinking" has hampered the success of previous veterinary administered herd health programs (Goodger et al, 1996).

Systems thinking is a discipline for seeing wholes. Today, systems' thinking is needed more than ever because we are becoming overwhelmed by complexity. Perhaps for the first time in history, humankind has the capacity to create more information than anyone can absorb, to foster greater interdependency than anyone can imagine, and accelerate change far faster than anyone's ability to keep pace. Certainly the scale of complexity is without precedent. (Senge, 1990)

Cooperation among the entire farm management team is crucial. The size and technical complexity of livestock operations today make it impossible for any single individual to "know it all." However, each advisor or farm staff member, in spite of his or her area of expertise, must have sufficient knowledge of the entire production system to understand how his contribution fits as an integrated part of the whole. The MIS ties the production system together. It provides a common ground and objectively communicates the successes and failures of the production system. It provides a format fostering productive discussion and timely development of action plans. A systems orientation keeps input from becoming a fragmented insertion of the latest fads and gimmicks. A systems approach among sincere participants enhances cooperation, reminding everyone that the whole is truly greater than the sum of the parts (Nelson, 1999).

Epidemiology is the "core" of preventive veterinary medicine (Schwabe et al, 1977; Schwabe, 1982). It is also the central problem solving discipline in a livestock system. Epidemiological principles, classically applied to the understanding of disease processes, are equally effective in understanding suboptimal productivity. Training in epidemiology is critical for successful implementation of a production-oriented health management program; it is what makes the veterinarian's input unique among all other consultants visiting the farm. Veterinary training in the practical application of epidemiology needs to be emphasized more. This training places the veterinarian in the ideal position to provide guidance in helping the livestock producer successfully integrate all of the disciplines of the production system.

Cognizant that herd health management services offer the greatest long-term potential for revenue growth (Wise, 1987), veterinary professionals have worked to remedy the perception of being too narrow in their perspective. Veterinary colleges have changed curriculum to increase food-animal student exposure to epidemiology, computer literacy and record analysis, herd management, housing, and environment. Veterinary professional organizations, such as the American Association of Bovine Practitioners, American Association of Swine Practitioners, and American Veterinary Medical Association (AVMA), have sponsored countless continuing education workshops and seminars in a concerted effort to build and expand food-animal veterinary expertise. Food-animal practitioners and students who have taken advantage of these opportunities are ready to tackle the challenges of a production-oriented health management practice.

To the new eager veterinary graduate or the experienced practitioner who is wondering how to escape the jaws of traditional food-animal veterinary practice, the authors offer for reflection the following anecdote. *The new infantryman asked his commanding officer: "Sir, where is my foxhole?" To which the officer's reply was quick: "You are standing on it; just dig the dirt out."* The objectives of this chapter are the following:

- To provide a background and greater understanding of the basic principles involved in livestock record use
- To provide guidance in the practical application of herd records for herd monitoring and problem solving

Downloaded From Vet-eBooks.com

The chapter is divided into two parts. Part I is a discussion of the basic principles and issues involved in livestock record keeping. Part II is focused on the practical application of livestock records in monitoring and problem solving. Although emphasis is given to dairy record examples, the principles apply in other food-animal species.

Part I: Basic Principles

HERD RECORDS ARE THE KEY

Livestock operations that do not use herd records cannot be taken seriously in today's competitive livestock industry. Conversely, food-animal veterinarians who plan to become involved in production-oriented health management programs must be skilled in herd monitoring and problem solving using the herd records.

Computerized Herd Records Are Preferable

Although manual herd records still may be adequate for small livestock operations, they are not practical for larger commercial enterprises today. Computerized herd records (i.e., Dairy Herd Improvement Association [DHIA] or on-farm computer-based records) are preferred. This fact was recognized over 20 years ago. "In our view, it is necessary for such a system to be computer-based in order to avoid overloading both the farmer and the veterinarian with repetitive tasks of data preparation and analysis." (Blood et al, 1978) Certainly this statement is even more legitimate in today's fast moving and competitive livestock businesses. If manual record systems are going to be used, a daybook approach is preferable (Morrow, 1963; Morrow, 1966a,b; Reneau, 1993). Daily barn sheets or individual cow worksheets that are formatted to make for easy data entry and retrieval are superior to a plain spiral notebook or other ad hoc recording systems.

Computerized Herd Records Improve Herd Management Skill

Computerized on-farm record systems offer many advantages, which not only make them very practical but also have been shown to be profitable investments of time and money. The hypothesis offered is that having accurate, up-to-date records will enhance the quality and timeliness of management decisions. A descriptive study of New York dairy farm managers found that those farms that used on-farm computerized management information systems (Jofre-Giraudo et al, 1990) had the following properties:

- Had more timely up to date records
- Had more detailed and accurate records
- Were less reliant on "rules of thumb" or product-biased information, preferring instead herd-specific data to guide their decisions
- Carried out control decisions more frequently
- Spent more time in management activity and more delegating of routine labor activities
- Were more skilled managers

Certainly these are attributes that would enhance the formation of strong production-oriented health management programs.

Computerized Herd Records Are Economically Sound

It has been difficult to determine the economic value of the adoption and use of a computerized herd record system. Recent attempts have been made to quantify the effects attributable to computerized management information systems (Table 3-1). It seems evident that adoption and use of a computerized MIS is not only practical—it is an economically sound herd management strategy and should be encouraged on all commercial livestock farms.

RECORDS TAKE TIME

Maintenance of a herd record system takes time. Obviously the time it takes depends on the keyboard skill of the computer operator and the amount of data being entered. Different software also varies in the amount of data accepted and the ease of the data entry interface. Computer MISs do not save herd managers time; instead they shift time toward strategic management decisions. Computer tasks take time away from the routine labor tasks that had been previously done by the herd manager. Producers often give time constraints as a reason for not keeping good records. However, studies to date indicate that the time allocation needed to

TABLE 3-1

*Improvements in Herd Performance as a Result of Using On-Farm Computerized Record Systems**

Study	Country	No. of Herds	Species	Performance Change
Lazarus et al, 1990	U.S.	196	Dairy	$85 higher income/cow first year of study
Verstegen et al, 1995	Holland	71 over 10 years	Swine	0.56 more piglets/sow/yr and an increased return over investment of 220% to 348%
Lorsing et al, 1996	U.S.	846	Dairy	207 kg/cow higher RHA
Hayes et al, 1998	New Zealand	438	Dairy	1.2 kg/cow/day more milk and improved reproductive performance
Guilhermino et al, 1997	U.K.	450	Dairy	334 kg more milk/cow/yr and 52 kg more/cow/yr
Tomaszewski, 1997	U.S.	66	Dairy	421 kg/cow/yr increased production
Van Asseldonk et al, 1999	Holland	714	Dairy	62 kg/cow/yr and improved calving interval 5 days

Downloaded from Vet-eBooks.com

maintain and use computerized record systems is relatively small and that shifting more of the herd manager's time toward being a decision-maker is beneficial to herd performance (Jofre-Giraudo et al, 1990; Lazarus et al, 1990).

It took dairy producers an average of 37 sec/cow/week to record observations in herd diaries that were then transcribed into a bureau service computer (Lissemore et al, 1992a,b). This was considerably more time than the 16 seconds/cow/week reported earlier in a similar study (Menzies et al, 1988). Expressed in terms of time/100 cows/day, the estimated amount of time required to record data onto a data entry worksheet or into a manual record system would range from 4 to 9 min/100 cows/day.

A 3-year study in 13 dairies with on-farm computers reported the average data entry time of 5.4 min/100 cows/day, and that report generation time added another 1.7 min/100 cows/day (Lissemore et al, 1992a,b). Using a value of $10/hr the computer time cost for data entry and report generation was estimated to be $4.40 per cow per year. A study comparing data entry time of four dairy management software programs found a range in data entry time of 2.5 to 6 min/100 cows/day (Gabler, 1998). This time is dependent on the keyboard skill of the operator, the degree of data entry automation, the amount of data, and the data detail each program would accommodate. Based on these studies it is expected that dairy producers with computerized herd records spend a total time (manual recording on work sheets, keyboard data entry, generating reports) of 6 to 12 min/100 cows/day.

The efficiency of data recording is greatly enhanced by the use of handheld data recorders. Handheld data recorders are being used successfully in a few swine and dairy operations, totally eliminating the transcribing of data from hand-written barn worksheets.

RECORD SYSTEMS SUPPORT DECISION MAKING

As shown previously, record-keeping takes time and costs money. The type of information needed should drive the system for recording data and extracting information. *The information derived should be useful—that is, it should be needed to support some decision or course of action. In addition the information should be used to improve the quality of the management decision.* In general, information needed to support decisions in food animal production can be divided into six categories: single animal decisions, group decisions, monitoring, herd investigation, food safety and quality, and research.

Single Animal Decisions

Is this animal ready to breed? Should she be treated or culled? These types of decisions affect only the individual animal, and the information is needed *now.* They generally require fairly detailed, *up-to-date,* individual animal data.

Group Decisions

The information needed for group decisions is typically for "action lists." Typically these are routine daily or weekly management activities. Which cows need to be dried off? What sows are due to farrow? Which animals are expected in estrus? Which animals are due for vaccination? Which cows should be cultured for mastitis? Which ewes had twins last year? These questions require that the whole population be sifted to select only those individuals with some common characteristics. There are many useful record systems that can produce these lists. But as the population of animals in a herd becomes larger, computerized records are essential to make efficient and timely selection of animals for the appropriate action lists.

Monitoring

Monitoring is the routine, systematic collection and evaluation of information from the farm. Monitors should be strategically selected measures of key processes in the production system. The best monitors are those known to have economic as well as biological outcomes. For example, the bulk tank somatic cell count (SCC) is an excellent indicator of milk quality (economic outcome) and subclinical mastitis (biological outcome) and is an indirect indicator of the management of cow sanitation or the adequacy of the milking routine. The body condition score is an excellent measure of herd nutrition.

A task-responsive monitor that is as directly reflective of changes in management protocol is desirable. For example, in a herd in which the age at first calving is too high, age at first breeding (or conception) is a more responsive measure than age at first calving. In this example measuring age at first calving will require several months before the results of the management change is evident. When lagging reproductive performance is caused by poor heat detection, neither calving interval nor days open may be task sensitive enough to stimulate improved performance. Perhaps weekly measurement of "service rate" would be more effective, with the service rate being the proportion of animals eligible for breeding and expected to be in heat that are actually detected in heat and bred.

Some monitors may be used to help maintain compliance with standard operating protocols. For example, display in the sock filter on the milking parlor bulletin board after each milking provides the milkers with a self-evaluation of whether adequate premilking cow prep is being accomplished. Although these may not be data to record in the herd records, it is a good example of a protocol-sensitive monitor. Monitoring disappearance of supplies and comparing actual usage with expected usage based on compliance with standard procedure are ways of using inventory control as a means of monitoring standard operating procedures.

Routine tracking of these herd monitors is intended to identify emerging problems and to follow performance over time. To act appropriately, herd managers and advisors must monitor the farm's status, noting changes or trends that indicate new conditions that need to be addressed. Livestock producers in general recognize the value of monitoring performance. Dairy farmers in Michigan and the Netherlands indicated a desire for more timely and precise monitoring of animal status and cost control (Huirne et al, 1997).

Herd Investigation

On any farm, unusual, unexpected problems can arise. It is in this area that a veterinarian's epidemiological training becomes invaluable. Answering the questions of who, what, where, and when to characterize the problem is a routine part of every diagnostic investigation. Solving these problems almost always requires the use of records. The storage capacity and process speed of today's microcomputer theoretically make possible the storage and retrieval of all information pertinent to a detailed comprehensive herd investigation. Typically livestock producers get stacks of diagnostic information that clutter shelves and desktops. For lack of a constructive thing to do with them, producers often may just let them gather dust. *Any data that have predictive value for the future are worthy of keeping for future diagnostic use.* The real question of what data to collect and store in the MIS depends

Downloaded From Vet-eBooks.com

on the following questions: Will the software being used store and retrieve the data in an informative format? Is the herd manager motivated to enter the data? Is it practical to enter and store data that may never be used? Ideally, a record system should allow the users the flexibility to enter the level of detail that they deem useful based on a balance of their attitude toward risk aversion and the economy of spending time entering "just in case" data. For problems that occur frequently, there is no question that all data that relate to the problem should be kept and, if possible, stored in the MIS for quick retrieval and analysis. For example, milk culture data on clinical mastitis should always be kept so that a periodic analysis of what types of mastitis pathogens predominate can be accomplished. This information will be extremely useful in noting shifts in pathology (environmental versus contagious pathogens) and in designing future mastitis control programs.

Food Safety and Quality

Food safety and quality are of great concern to today's consumer. There is an increased worldwide vigilance to prevent tainted and unwholesome food animal products from reaching the marketplace. In the United States, it has been mandated that all meat and dairy product processing plants have hazard analysis critical control point (HACCP) plans in operation. Since the first critical control point in the food chain for livestock products is the farm, it is logical that HACCP-like programs will trickle down to the farm level. There are already recommendations being made for the tracking and documentation of food safety and quality of food animal products from the farm to the market (Griffin et al, 1998). Obviously this means a need for more records. Some producers and veterinarians may see this as an intrusion. However, in reality it offers food-animal veterinary medicine another great opportunity. The 1994 AVMA study on producer attitudes toward food-animal veterinarians indicated that 50% of beef producers, 33% of dairy producers, 39% of swine producers, and 64% of sheep producers did not think the local veterinarian was very important to the milk and meat quality assurance programs (Gehrke, 1995). The 1998 AVMA market study found that these attitudes still persisted, although 65% of food-animal practitioners feel that veterinarians have an important role in food safety (Brown and Silverman, 1999). It seems obvious that producers need veterinary advice on this topic more than ever. The development of sound, effective treatment protocols for clinical disease is another herd health management opportunity (Rapnicki, 1999). Producers need direction in the design of more appropriate diagnostic (Markusfeld, 1990) and treatment protocols as well as encouragement to properly record clinical treatment data, not only for food safety and regulatory purposes but also to facilitate analysis of the cost effectiveness of treatment protocols.

Research

Record systems are needed to conduct research. Research may be conducted within and across herds. Some of the major improvements in animal agriculture have come from the analysis of pooled records from many farms. The remarkable genetic advances in the dairy industry spring directly from the analysis of breeding records available through the DHIA. Epidemiological studies of the patterns and risk factors of disease depend on record analysis. Research is not limited to those in academia. Practitioners need to use records in their own practice to keep track of local conditions, to test the effectiveness of their efforts, and to demonstrate the usefulness of new services.

FUTURE RECORD DEVELOPMENT NEEDS

At present there are no comprehensive herd health management record systems that can optimally support all the farm decision-making needs. It has long been recognized that a need exists for such an integrated system. This will require standardized data definitions as well as standardized production and health and financial information calculations (Priester, 1975; Rowlands, 1983; Bartlett et al, 1986; Dohoo, 1988; Fetrow et al, 1990; Kelton et al, 1998). Integration between health and production records is commonplace today, but more needs to be done to make this process easier so that a greater impact can be realized (Lazarus, 1990). Integration with financial data is rare. It is notable that the swine industry under the direction of the National Pork Producers Council (NPPC) has developed production and financial standards (Marsh, 1999). The goals of the NPPC for this project were the following:

- "To promote uniformity in production and financial standards for the pork industry by presenting methods for financial and production reporting, which are theoretically correct and technically sound"
- "To present standardized definitions and methods for calculating financial and production measures"
- "To develop a national pork database of standardized production and financial information to allow accurate benchmarking"

Another example of futuristic thinking is the work being done by the National Cattlemen's Beef Association. As a part of the Integrated Resource Management program, the Standardized Performance Analysis (SPA) has been developed. SPA is a systematic method of tracking beef-cow-calf performance. It uses a standard set of guidelines for the calculation of production and financial measures (Collett, 1998; Miller et al, 1998; Collett, 1999). A similar effort to standardize disease definitions in dairy cattle has been suggested (Kelton et al, 1998). These efforts are commendable and should be taken seriously. Much more work in these areas is needed to bring to fruition the idea of the early founders of health management record systems (Cannon et al, 1978; Sundgren et al, 1980; Eddy et al, 1981; Willeberg et al, 1984; Bartlett et al, 1986; Dohoo, 1988) of integrating production, health, and financial information.

DESIRABLE FEATURES OF COMPUTERIZED RECORD SYSTEMS

There are many opinions and preferences regarding basic features of a computerized herd health management record system. Considerable time and thought were devoted to this subject beginning in the late 1960s through the early 1980s (Preister et al, 1975; Cannon et al, 1978; Sundgren et al, 1980; Rowlands et al, 1983; Russell et al, 1983; Willeberg et al, 1984; Bartlett et al, 1986; Dohoo, 1988) These workers outlined data collection, storage, and retrieval standards for development of computerized livestock record systems. Since early microcomputers lacked data storage capacity and processing speed, the first programs were written for use on mainframe machines as a bureau service. The classic example of such a bureau system is the DHIA record system. The DHIA has had a major impact on dairy cattle improvement and genetics (Voelker, 1981). In the basic DHIA program the milk production of each cow in an enrolled herd is weighed once a month by an official supervisor at two consecutive milkings. Milk samples are taken for composition analyses of butterfat and protein content. In many herds the sample is also examined for somatic cell count as an indication of subclinical mastitis. In addition, considerable data on individual cow and herd production, such as feeding information, reproductive events, and cows leaving the herd, are col-

Downloaded from Vet-e-Books.com

lected. All these data are processed through DHIA centers, and reports are mailed back to the farmer. If requested by the farmer, copies of the reports can also be mailed to the veterinarian. In some dairy records processing centers (DRPCs), immediate processing and access to the farm's data can be performed over the telephone using a microcomputer. Other processing centers mail diskettes with the herd's data. All DRPCs provide electronic transfer of most DHIA data into on-farm herd management software. These programs are available in Canada, the United States, and other countries. They are usually financed by participating dairy farmers and are often subsidized by provincial or state governments.

The advantages and disadvantages of the bureau approach to records have been reviewed (Etherington et al, 1993). Advantages of the bureau service approach are as follows:

- Data entry conventions are consistent across herds; hence there are more uniform data for multiple herd comparisons
- Producers who do not wish to purchase a computer or learn to use one still benefit from the technology
- Reports are consistent and provided at regular intervals
- Comparison among herds within a practice can be accomplished easily
- Reports are generated and evaluated by someone with experience from a number of herds

Disadvantages noted by the bureau approach authors are as follows:

- Less use can be made of the day-to-day herd management aspects of the programs because of time delay between retrieval of data and delivery of reports
- Increased likelihood of errors in transfer of data from farm to bureau, since data entry person is not as familiar with the situation at the individual farm
- Restriction of the ability of dairy personnel to learn about and improve dairy management through hands-on use of software
- User-defined (custom) reporting capabilities may not be used to full advantage
- Reports and analysis reflect the bureau personnel's interests and goals, not necessarily those of the farm

During the 1980s, microcomputers had advanced to the stage at which the on-farm approach to record-keeping was feasible. For the on-farm approach, all data entry is done on the farm and farm personnel are encouraged to record pertinent events observed during their daily working routines. The advantages of on-farm approach are as follows:

- Computer is on-farm so that data are more current and reports are available at any time
- A person familiar with the animals and events happening on the farm performs data entry
- Dairy personnel have the opportunity to increase their knowledge of the software and dairy management
- The farm computer can be used for multiple farm software applications, including accounting systems, sire summary and selection programs, spreadsheets, and nutritional evaluation programs
- Modem communications allow consultants online instruction to the herd manager should problems arise

These are disadvantages of the on-farm approach as follows:

- Lack of uniformity of data entry across herds (can be overcome with prospective standardization of data entry conventions)
- Greater startup costs to the producer
- Excessive cost because of travel time for consultant unless modem access is available
- Lack of peer-to-peer comparisons for benchmarking
- Lack of standardization of reporting methods and data summary

With today's high-performance microcomputers it seems reasonable to expect future herd management software to be based on the farm. However, hybrid systems have been developed enabling on-farm systems to send and receive data to centralized (bureau) systems. DHI-PLUS and PC-Dart are excellent examples of such integrated systems. Another example of this hybrid system is the use of DairyCOMP 305 record keeping on farms in Minnesota coupled with centralized data processing at the Dairy Regional Processing Center in Tulare, California. If data are standardized for the on-farm system, this hybrid approach offers the benefits of both approaches while minimizing the disadvantages of each.

In view of today's high-performance microcomputers it seems reasonable to expect future herd management software to efficiently accomplish all of the six decision-making categories previously listed. Based on a review of the literature, the ideal on-farm microcomputer system would contain the following characteristics.

Data File Structure

There are many technical and philosophical issues regarding data file structure. Most are beyond the scope of this chapter. Hidden in the "bowels" of software, the data file structure is not obvious to the user. However, suffice it to say the choice of the data file structure may be the single most important design issue in developing an MIS. Every spring during the mud season, workers at a New England farm would post a sign at the end of the long driveway that read, "Choose your rut carefully, you'll be in it for the next ½ mile." The choice of data file structure when developing software is analogous to this quaint anecdote. Knowing something about the file structure of a MIS is helpful in anticipating its analytical capability.

Once the data file structure is set, all analysis and report generation will be at its mercy (Dill, 1992). Ideally the data file structure should accommodate complete animal histories of current and removed animals. In addition, the file structure should not restrict the number of events recorded for animals. Incomplete animal histories result in an erroneous and distorted analysis (current and retrospective) that may mislead the problem-solving process.

Unique Animal Identification

Readable, unique animal identification is critical to most livestock record systems, particularly when dealing with breeding females. Electronic ID systems are now becoming practical options, and it is expected that such systems will be in common commercial use in the future. Record systems simply do not work if all ewes are just ewes, if two sows are numbered 326, or if the cows' ear-tags are too faded to see which ones are in estrus. A surprising number of recording schemes fail at this stage. Until corrected, no effort should be made to implement any higher level records. Even in the case of animals destined for slaughter (feeder pigs, feedlot steers, market lambs), individual identification may become necessary. Current interest in tracking animals from farm to market is gaining acceptance. However, in most cases the pen is the unit of interest and records should reflect the pen's performance. Even here, however, some degree of individual identification is needed to identify sick animals for treatment or drug withdrawal.

Downloaded From Vet-e-Books.com

Minimum Data Required

Rowlands (1983) succinctly recommended that an animal record contain two parts: biographical data (ID, birth date, sex, breed, dam, sire, place of birth, herd of residence) and a chronological listing of events that occur during its life. For maximal use all events should be recorded in the simple and consistent format linking ID-date-event.

Data Accuracy

Data accuracy is important to the acceptance and utility of any record system. Errors create mistrust in the information. They weaken the resolve of management decisions and cause hesitance in implementation of an action plan. Several sources of potential error exist in farm record data that may result in biased estimates of disease and risk factor status. Errors result from human failings in data entry or from software shortcomings. Therefore knowledge of both the personnel involved in record processing and the software system being used is required to identify these errors. Errors may be grouped into classes including the following:

- Data entry error
- Logical consistency error
- Duplication error
- Misclassification error
- Computational error
- Selection error
- Software restriction error

Data entry error is the simplest type of error. This occurs when data are incorrectly transferred into the computer. This type of error may be in any one of a number of fields ranging from animal identification to event date or event comments. As a result the effects of this type of error are extremely diverse such that their influence on the outcome of epidemiological studies cannot be predicted. One consequence is logical consistency errors.

Logical consistency errors occur when the data entered do not make biological sense, and such errors are most often associated with incorrectly entered event dates. Examples of these types of errors are estrus lengths of less than 18 days or gestation lengths less than normal length without an abortion occurring. Some software have error-checking capabilities that reduce the rate of these errors. As a means of determining the degree of data entry error, routine screening of data for minimum and maximum values of a field is helpful.

Duplication errors arise in two basic forms: duplicate animal identification and duplicate event data. Duplicate animal identification is a common problem and is the more serious of the two basic forms. This error occurs in herds in which identification numbers are reused, either by recycling ear tags from animals that have been removed from the herd or by using the same number series for mature animals and young stock. In situations in which this type of error has occurred, the data may be useless because the computer cannot recognize the difference in the animals and will combine records. In situations in which hard copies of the original data are available, errors of this type can be corrected by modifying identifications so that all animal names are unique. Fortunately, in most software, the potential for duplicate identification is reduced by alerting data-entry personnel that the identification being entered already exists. Duplicate-event data pose less of a problem and occur when a given event is entered more than one time. Many of the newer software have routines that automatically prompt users if they are entering a duplicate event. The effect of this error in epidemiological analyses is to overestimate the incidence of an event, either disease cases or risk factors. This effect will reduce the risk estimate if the event represents a discordant pair (case without a risk factor, control with risk factor) while enhancing the risk estimate if the event represents a concordant pair (case with risk factor, control without risk factor). This error is most commonly a problem in computer analysis involving "counts" of the occurrence of events and can be avoided easily by listing the event date and event names for count data and screening for duplication.

The *misclassification error* is an unavoidable form of farm-record error and one of the most significant sources of concern. Misclassification error can be defined as the incorrect assignment of an animal's status and is most important in relationship to disease events and potential risk factors. It is produced by three related factors:

1. The lack of standardized definitions for disease or exposure status
2. The inaccuracy of diagnostic procedures
3. The reliance on farm personnel or other nonprofessionals to correctly classify events

A special case of misclassification is recording failure. This may happen if the data are lost, if the disease is not detected ("detection failure"), or if there are differences in case definition. Recording failure results in an underestimation of relative risk. This is of some comfort to the researcher, since risk factors with significant association with disease actually would have a stronger association if recording failure did not exist. On the other hand, the effects of recording failure make interpretation of "negative" associations more difficult.

Computational errors most often occur in situations in which records are hand calculated; however, they may occur within the computer software when the equations used for performance parameters are not standardized or are incorrect.

Selection errors are similar in that they occur because of differences in records used to calculate the numerators and denominators of rates. These errors are also due to a lack of standardization of formulas used to calculate performance parameters. A good example of selection error is the calving to conception interval (also known as "average days open"). As many as five different rates may be calculated depending on the criteria used for the denominator of the equation; all animals in the herd, animals assumed to pregnant, animals confirmed to be pregnant, etc. Effects of these errors are most severe when trying to compare rates across herds; however, as long as the methods used are consistent, the influence of these errors will be minimal.

Software restriction error is specific to the software itself. These errors occur because of coding conventions that are built into the software. An example of this is the situation in one computer program in which a late abortion event is coded as a calving, and calving events can be coded only when the cow has been previously dried off. Thus the dilemma arises of which is worse: adding a dry-off event that does not exist or omitting a known abortion event. The effect of this error is either a recording failure or addition of an event that does not exist. The choice of coding depends on which outcome will have the most deleterious effect. In the example, adding a dry-off event may lead to problems in the milk production data (because of logical consistency error checking), since a cow cannot have milk production if she is dry. It is important to be aware of these errors and always to be consistent in the way they are handled.

Eddy (1982) reported 10 years of experience dealing with data errors in the Melbread (bureau service) and Daisy (on-farm) computerized record systems. The error rate averaged 8% per month in the bureau service system compared with 1% per month with the on-farm data entry. In this case, the

Downloaded From Vet-e-Books.com

Melbread system did not have an internal error check system and the DAISY program did. Most systems today do have an internal error system, with DHI being the best example of a bureau system that has an extensive error check system. Embedding an error-checking system into the software is the most effective means of ensuring data-entry accuracy because the prompt identification of an error and immediate request for correction at the farm computer keyboard are the best means to ensure that data accuracy is maintained. Eddy found over 200 different data-entry errors. The most common errors encountered were errors of omission, or events not recorded by the herdsman (dry-off dates, cull dates and reasons for culling, calving dates, and insemination dates). The degree to which errors of omission occur should be considered and factored into the data interpretation. The origin of errors in recorded data occurs at the level of the farm and at the computer.

- Farm level
  - -Lack of or poor (unreadable) identification
  - -Incorrect number recorded (e.g., 369 instead of 396)
  - -Transcription of data to the permanent record system from the herdsman's notebook or memory
- At the computer
  - -Data misread by the computer operator, or operator cannot read the writing
  - -Incorrect keys punched

Pick lists help to improve the accuracy of keyboard data entry, thus reducing the problems of typographical errors. Care must be taken in entering remark-based data to be sure that descriptive information is typed exactly the same.

Data Standardization

There is unanimous recognition of the need for common standards for data definition (production, management, disease, and financial) (Dohoo et al, 1984; Willeberg et al, 1984; Bartlett et al, 1986; Dohoo, 1988; Kelton et al, 1998; Marsh, 1999). Priester perhaps said it best in his comments at the 1975 International Symposium for Animal Disease Monitoring in Guelph, Ontario: *"There are computer specialists who will insist that coding is unduly restrictive, and that most information can be put into the system free form. For those who are tempted to accept such advice, be prepared to pay in programming effort and computer time to get that easily entered data back as usable information"* (Priestler, 1975). Standardization of data definition as well as import and export formats will greatly improve the flow and exchange of data at all levels of the livestock industry.

Attempts to compute the economic cost of disease and the cost benefit of control procedures have been studied for years. Although efforts have been made, the lack of an integrated production, health, and accrual-based financial record system has hampered progress in this area. Fruitful study in these areas will require large standardized databases. All veterinarians need to take seriously the recommendations for standardization of disease definitions. Tables 3-2 through 3-4 are examples of suggested disease definitions of the eight economically important diseases in the lactating dairy cow.

Multiple Herd Comparisons

The ability to easily pool farm-level data into larger multiherd data sets is potentially one of the most powerful benefits of standardizing definitions for data as well as for production, health, and financial calculations. The genetic progress made by studying national DHI databases is strong evidence of this. Identification of genetic markers for study of disease resistance would be greatly enhanced by availability of such a database. Pooling farm data within a practice for herd performance comparison is a powerful benchmarking tool to help identify management weaknesses and motivate clients into taking action (Bartlett et al, 1986; Smith, 1996). Combining herd level data at the veterinary practice, regional, state, or national level increases the scope and accuracy of epidemiological study (Dohoo et al, 1983; Morris, 1983a,b; Bartlett et al, 1986). Veterinarians becoming involved with field research would find such a tool invaluable. The capacity for multiple herd analysis should be encouraged as a standard feature of future livestock MIS.

Many current record systems have already begun to use data dictionaries and pick lists for consistent coding within their database. However, remark-based record systems (systems that provide fields with no restriction on what is entered) that focus on flexibility over consistency provide a significant challenge when conducting retrospective analyses and when pooling data from several herds. This problem can be avoided by those using such systems if they are careful to set up standardized terminology and coding systems for all personnel involved in data entry.

TABLE 3-2

Lactational Incidence Risk (LIR) and Estimated Loss per Case for Eight Common Dairy Cattle Diseases

Disease	Median LIR (%)	Range LIR (%)	No. of References	U.S. Loss/Case ($)
Hypocalcemia	6.5	3-22	33	335
Retained fetal membranes	8.6	1.3-39.2	50	285
Metritis	10.1	2-37	43	
Ketosis	4.8	1.3-18.3	36	145
Left displaced abomasum	1.7	0.3-6.3	22	340
Cystic ovarian disease	8.0	1-16	44	39
Lameness	7.0	1.9-30	39	302
Clinical mastitis	14.2	1.7-54.6	62

Downloaded From Vet-eBooks.com

TABLE 3-3

Recommended Case Definitions for Eight Common Dairy Cattle Diseases

Hypocalcemia	Clinical signs consistent with stages 1, 2, and 3 of the disease within 72 hours after calving
Retained fetal membranes	Fetal membranes visible at the vulva or were identified in the uterus or vagina by vaginal examination more than 24 hours after calving
Metritis	Abnormal cervical and/or vaginal discharge or uterine contents (not including lochia or clear estral mucus)
Ketosis	Decreased appetite and if there was evidence of elevated urine, milk, or breath ketone levels in the absence of another concurrent disease
Left displaced abomasum	Decreased appetite accompanied by high-pitched tympanic ping in the left abdominal wall between the ninth and twelfth rib
Cystic ovarian disease	A smooth rounded structure greater than 25 mm on one or both ovaries
Lameness	An episode of abnormal gait attributed to either foot or leg regardless of etiology or duration
Clinical mastitis	Visibly abnormal milk (clots, flakes, or watery) in one or more quarters

From Kelton DF, Lissemore KD, Martin RE: *J Dairy Sci* 81:2502-2509, 1998.

TABLE 3-4

Recommended Definition of a New Case for Eight Common Dairy Cattle Diseases

Term	Definition
Hypocalcemia	Only one case per lactation
Retained fetal membranes	Only one case per lactation
Metritis	New case if no observed clinical signs occurred within the last 30 days
Ketosis	New case if no observed clinical signs occurred within the last 30 days
Left displaced abomasum	Rarely more than one case per lactation
Cystic ovarian disease	New case cow had been noncystic for the past 30 days or cyst is present on the other ovary
Lameness	New case if not clinically lame in previous 30 days
Clinical mastitis	New case if there is no abnormal milk from a previously infected quarter for the previous 8 days or there was no abnormal milk in "new" quarter

From Kelton DF, Lissemore KD, Martin RE: *J Dairy Sci* 81:2502-2509, 1998.

Part II. Practical Application

GETTING STARTED

"Great ideas need landing gear as well as wings"

C.D. Jackson, publisher

Yes, even airplanes need wheels. Lofty ideas are no different. Unless they can be brought down to earth and transformed into practical application, they are of little value to anyone. This leads to the following question: what are the requirements of getting a production-oriented health and management program started?

Early proponents listed the following basic farm requirements (Blood et al, 1978):

- Skilled herd manager motivated to improve animal health and productivity
- Skilled veterinarian or advisor who will take interest in the producer's goals and objectives and is willing to apply his or her expertise toward meeting the objectives of the farm
- Animal handling facilities
- All animals uniquely identified
- Herd records and monitoring system

Implicit in these recommendations is that the farm will have a sense of mission and clearly defined goals. Experience has shown that this has been a mistaken assumption and, as a result, many well-intended programs have dwindled by failing to produce anticipated results. In the absence of clear expectations, farm evaluation can even become an adversarial process, whereas mutually agreed-on goals release power and mobilize resources, thus bringing about a more proactive working relationship that tends to shift the focus from "who is to blame" to "what is the best plan for the future based on what we see now." When there is a shared vision of what needs to be done along with clearly understood responsibilities, herd evaluation and monitoring become a tool rather than a threat.

The herd owner's or manager's responsibilities (Drucker, 1974) are as follows:

- Set farm goals and objectives
- Organize assets to accomplish goals and objectives
- Train, communicate, and motivate
- Maintain records and monitor performance

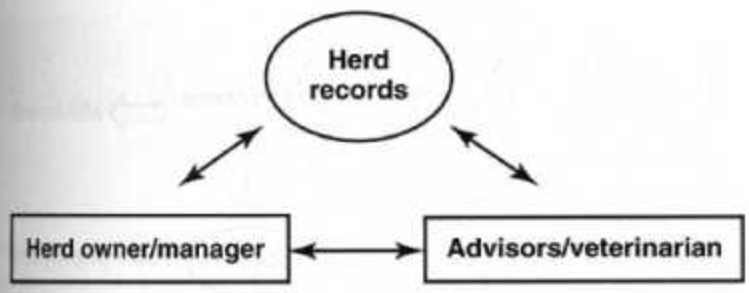
The herd advisor's or veterinarian's responsibilities are to support the herd owner or manager with the following:

- Assisting in herd monitoring
- Providing up-to-date information
- Providing technical and biological expertise
- Providing unbiased professional perspective
- Participating in training or motivating employees

Both the herd manager and the veterinarian must be committed to the philosophy of continuous improvement. Deming has shown that consistent application of this concept results in improvements of both quality and productivity (Wheeler and Chambers, 1992).

Fig. 3-1 is an outline of record use in a production-oriented health management program. The principles of continuous improvement must be the foundation on which

Downloaded from Vet-eBooks.com



STEP 1: **Farm/animal observations, record evaluation,** and strengths, weaknesses, opportunities, and threats (SWOT) analysis. Select mutually agreed-on goals by using "goal form" or benchmarking tools. } Build knowledge; create a shared vision.

STEP 2: **Select area(s)** (i.e., nutrition) and focus on the process(es).

STEP 3: **Select monitor** and measure actual performance, which in process-control language is called "voice of the process."

STEP 4: **Select target** of performance based on goals, which of process-control language is called "voice of the customer."

STEP 5: **Deming cycle:** Continue follow-up monitoring, evaluating, planning adjustments in protocols, and tasks within the process and supervise implementation of the plan. This is a continuous process to close the gap between the desired target and the actual performance.

FIG. 3-1 Outline for record use in production-oriented health management program.

such a program is designed. A production-oriented health management program is a continual quest for improvement of herd productivity and profitability. Viable programs require maintaining a focus on identifying emerging problems and a commitment to their solution. While monitoring herd performance may be interesting, it is pointless if there is not a continuous commitment to recognizing and solving herd problems.

Step 1: Record Use in Goal Setting

The first step is setting goals. Benchmarking is an excellent tool to use in a goal-setting discussion. Identification of the herd's strengths, weakness, opportunities, and threats (SWOT analysis) is a productive starting point. An example of another effective approach is the "goal form" (Chapter Appendix 1), which Nordlund (1993) developed to identify dairy herd problems and establish production goals. It is very useful as a tool for the initial farm visit and for periodic reevaluation of herd performance as a means of avoiding program stagnation. Wassell and Chamberlain (1994), using a similar approach in the United Kingdom, reported a high level of acceptance by both farmers and veterinarians. Completion of the "goal form" with the dairy manager can increase commitment to solving herd problems and monitoring herd performance.

The "goal form" is designed to:

1. Be *completed in a discussion with a client*
2. Use the *client's records and estimates of costs* whenever possible
3. Provide a *limited economic assessment* of different production problems
4. Provide a format to *mutually agree on production goals* for the herd
5. Set the stage to *develop a plan* to accomplish these goals

TABLE 3-5

Considerations for Appropriate Goal Selection

	Should the plan be implemented?	
Consideration	**No**	**Yes**
Potential return	Low	High
Cost to implement	High	Low
Interval to effect	Years	Weeks
Odds of success	Questionable	Certain
Impact of failure	Bankruptcy	Minimal

From Kelton DF, Lissemore KD, Martin RE: *J Dairy Sci* 81: 2502-2509, 1998.

Completion of the form requires several pieces of information (records): the number of heifers on the farm that have not calved, the girth and height of recently calved heifers, current milk-plant pricing policy, and the on-farm computer or DHI herd summary sheet. In addition, records or estimates of heifer deaths, clinical mastitis case rates, and a variety of prices will be needed. Experience indicates that it takes approximately 2 to 3 hours to complete the form and the resulting discussions.

The form is divided into sections: replacements, culling, udder health, reproduction, genetics, and nutrition. References used as a basis for the calculations suggested are given in the text of the form. A caution should by noted with regard to the genetics section. Predicted transmitting ability (PTA) values should be updated annually. Most DHI processing centers routinely update these values and are willing to share the information.

Step 2: Selection of Goals

The intent and limitations of the "goal form" need to be made clear. The goal form is designed to bring attention to the big opportunities for a dairy and assist in the goal-selection process. The exercise also provides valuable insight into the status of the herd's records. The equations in the form produce gross economic estimates of the losses the dairy incurs annually in failing to meet the specified targets of performance. The costs of achieving the goals are not estimated. Thus the form is simplistic as an analytical tool. However, attempts to estimate net benefit of achieving a goal usually make the process too unwieldy and extensive to accomplish in 2 to 3 hours. The rationale is that a less-than-precise tool that can be completed may be more effective than a precise analysis that is rarely done. The "goal form" was designed to depend on data that were readily available on most dairy farms, and the process had to take less than 3 hours to complete. Some effort has been made to make the process more realistic by avoiding counting the same problem twice.

Goals and plans are usually selected simultaneously. Users of the form tend to rank problems in order of highest dollar amount and create a goal based on the biggest item. This may be correct sometimes, but the area selected for change should be based upon several considerations, which are listed in Table 3-5. Two examples may be useful in demonstrating this idea. There may be indications of large losses in the mastitis section of the goal form for one client.

Downloaded From Vet-eBooks.com

After some investigation, the problem appears to be due to environmental organisms and the plan would involve increasing the vacuum level to reduce liner slips and the initiation of a predip program. Should the plan be implemented? The potential return is high, the cost to implement the program is minimal, the interval to effect would be weeks or days, the odds of success are good, and the impact of failure would be that things remain as they are now. All considerations say YES, the program should be implemented.

The mastitis section may indicate the largest dollar losses on a neighboring farm. However, after further investigation, it may be discovered that this second dairy has a high level of *Staphylococcus aureus* infections and an inadequate milking system. Modernization of the milking system will cost $25,000, and perhaps 25% of the herd should be culled. A review of the "considerations" (Table 3-5) shows that the potential return also may be high as in the earlier example. However, the interval to effect may be months and the odds of success uncertain because of inconsistent milking practices, which suggests a "maybe." Notwithstanding, the cost to implement is high, and the added debt might make the farm vulnerable to bankruptcy if they experienced a poor crop year in addition to their current precarious debt situation. These considerations would make this plan less attractive. In this situation the client should be advised to consider the decision further, perhaps to develop partial budgets to study the issue further and to obtain professional financial advice regarding farm debt management. Perhaps the client should find other areas of the goal form that could yield income more quickly and with lower risk to the operation. Regardless of what goals are selected, they should be SMART (specific, measurable, attainable, rewarding, and timed) goals. The selected goals in this case become the "target of performance" or, in the language of process control, "the voice of the customer"(Fig. 3-2). In this case the customer is usually the herd owner or manager; however, it also could be the milk plant or packing house.

Step 3: Selecting the Monitors

The monitor is the measurement of the actual performance of the process, which in the language of the process control is called the "voice of the process" (Fig. 3-2). Since it is impractical to measure everything, it is important to select the most critical measurements, which are the best reflections of the process behavior. Monitors should have a correlation with the goals (e.g., profit). They must be easy to measure precisely and accurately, and they should have as little "lag" or "momentum" as possible. Carefully selected task-sensitive monitors are best. For example, if heifer management were identified as the problem area because the average age at calving was too old, then average age at calving would not be the best monitor to use. This monitor has too much lag. The average age at conception would be more appropriate, since it is a more timely reflection of those tasks within the heifer reproduction process that result in pregnancy.

Step 4: Selecting a "Target"

A target of performance should always be selected based on the mutually agreed upon goals generated from the goal form or benchmarking exercise.

Step 5: Deming Cycle

Follow-up is an essential component of successful programs. The Deming cycle with a focus on continuous improvement represents a subtle but powerful change in management attitude. The "target of performance" is now not just an arbitrary number from a page of published guidelines or benchmarking data; it is an attainable, mutually agreed upon goal tied into a continuous plan of action designed to improve the process(es) involved until the goal is reached. Once the goal is reached and the process is stable, monitoring is continued as a means of verifying that the system remains "in control." In this case "in control" means that the process is stable and predictable. If the herd owner decides further improvement is needed, the "target of performance" is reset, the process is redesigned, and adjustments are made until the new goal is reached and the process is once again stable. This same procedure can be performed for every process within the entire production system. Thus a program organized in this manner is a continual quest for process improvement.

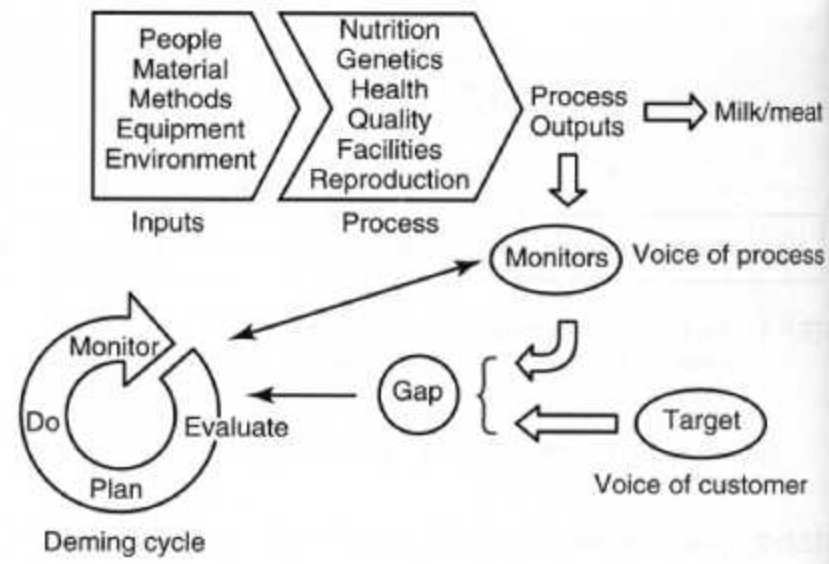


FIG. 3-2 Livestock production system process control diagram.

Deming points out that all processes fall into one of four states (Fig. 3-3):

- Ideal state
  - –The process is in control
  - –The performance target is being met 100%
- Threshold state
  - –The process is in control
  - –The performance target is not met 100% of the time
- Brink of chaos
  - –The process is out of control
  - –The performance target is being met 100%
- State of chaos
  - –The process is out of control
  - –The performance target is not being met

It would be rare and probably impossible to find a livestock operation with all of its processes in the "ideal state." It is obvious from study of herd records that the best farms have proportionately more of the production system processes in the "ideal state" and fewer in the "state of chaos" than poorly managed farms. The objective of a production-oriented health management program is to move each production system process toward the "ideal state."

There is a universal force acting on every process that over time causes deterioration, decay, wear and tear, breakdown, and failure. This is called "entropy." Morris et al (1978a) recognized that the difficulty of maintaining mastitis control measures is almost inevitable. Turnover in employees, taking short cuts on established protocols, wearing out of equipment and facilities, and running out of critical supplies are all examples of process entropy. Without attention all processes eventually migrate to a "state of chaos." The only way to overcome this natural process is to continually repair the effects of process entropy. Routine repair and mainte-

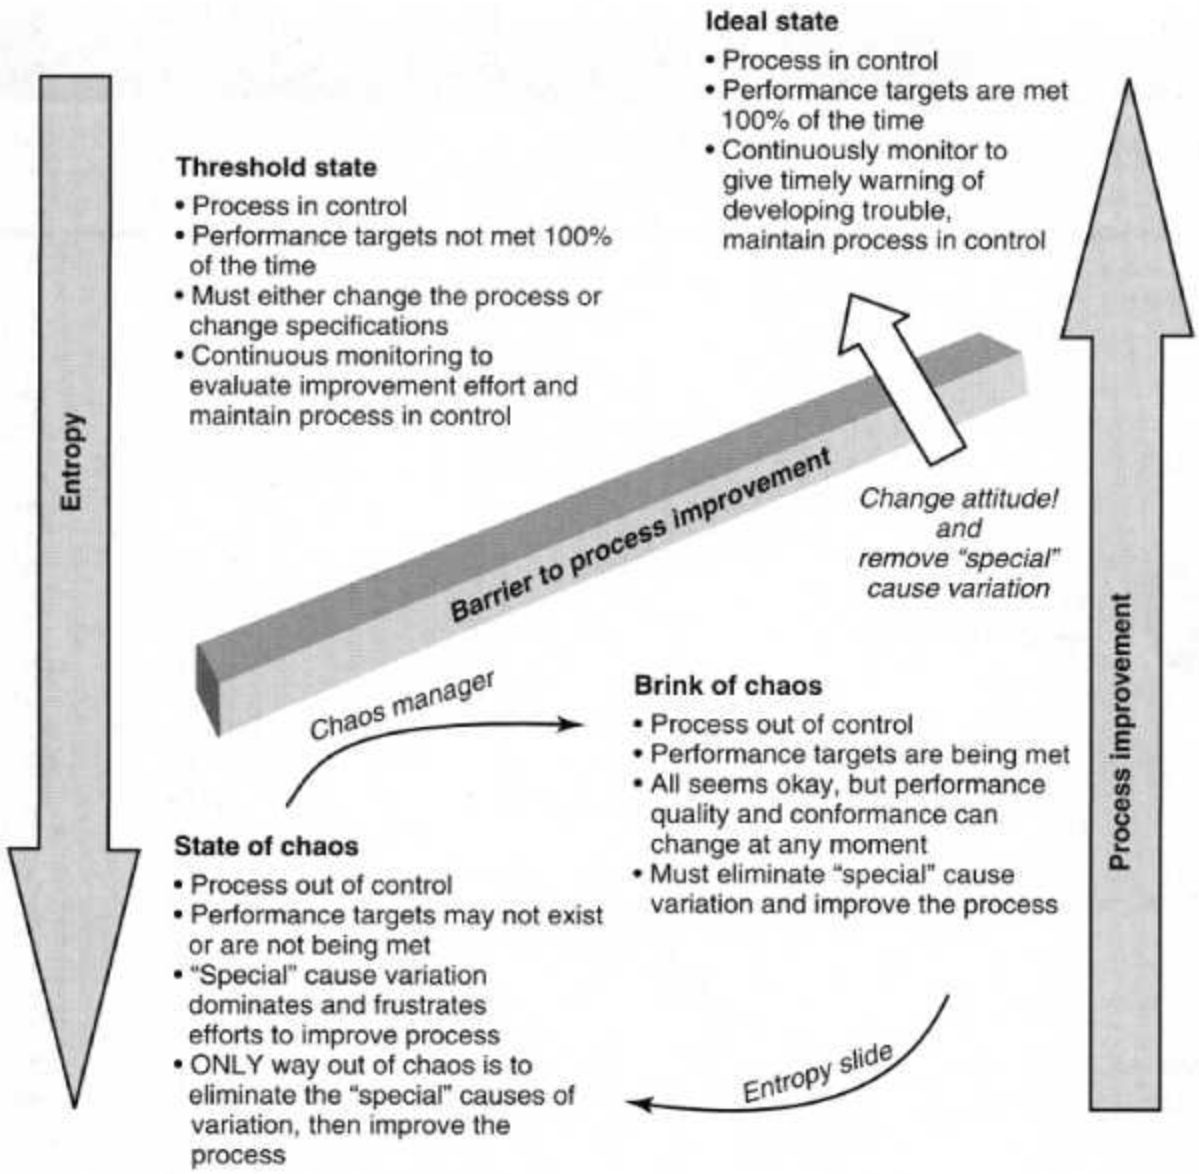

FIG. 3-3 Process status in a livestock production system. (Adapted from Wheeler DJ, Chambers DS: *Understanding statistical process control*, Knoxville, Tenn, 1992, SPC Press.)

nance of equipment and facilities and training of employees are examples of process entropy repair. The more proactive and consistent the farm is in maintaining optimal function of each process, the more likely that they will succeed in reaching and maintaining the "ideal state."

Veterinarians frequently are called to a farm to respond to a process in a "state of chaos." The farm personnel have a situation in which they know they are in trouble. For example, the bulk tank SCC has just exceeded the legal limit, and the farm has been issued an ultimatum to lower the bulk tank SCC or face the consequences of losing their market. The farmer is asking for the veterinarian to be a chaos manager. The farmer's expectation is to get the SCC down to legal limits as soon as possible. Using diagnostic skill the veterinarian identifies the chronically high-SCC cows and may recommend culling some of those cows and the use of a quarter milker on a few other high-SCC quarters. The goal has been achieved. With the veterinarian's assistance, the farm is now able to sell their milk again; the farmer is happy and feels temporarily out of trouble. However, even though the milk now conforms to the legal standards, in reality the processes that govern milk quality have not changed and are still likely "out of control." The veterinarian's intervention as a chaos manager has moved the situation from a "state of chaos" to the "brink of chaos." However, without further intervention to change the processes, this herd is doomed to slip back into a "state of chaos" and the cycle of despair continues.

The greatest barrier to achieving the quality of management depicted by the process in the "ideal state" is attitude. The only way to sufficiently overcome process entropy and reach the more desirable "threshold" and "ideal" states is by commitment to the concept of continuous process improvement and a continuous monitoring system that alerts the herd manager to the effects of process entropy. The causes of abnormal ("special cause") variation must be found and eliminated, and then emphasis must be placed on process improvement. This is why it is critically important that herd manager and the veterinarian have a shared vision of what the goals are and a firm commitment to the long-term process of continuous improvement.

Guidelines and Benchmarking

Guidelines

Table 3-6 is an example of dairy performance guidelines. These values are useful in gauging herd performance and setting goals. However, guidelines must be kept in perspective. They are often a collection of independent values, some of which are based on research and some based on the experience of industry experts. They are usually out of context of any real production system and may be even out of date. Therefore the guidelines may not directly apply to a specific livestock operation. They should be taken as "ballpark" values and not as "gospel."

Calf death loss (day 1 to weaning) (%)	<3	>5	
Calf death loss (weaning to 1 year) (%)	<2	>3	

SCC, Somatic cell count.

Benchmarking

The 1998 PigCHAMP database (Table 3-7) (PigCHAMP Inc, Apple Valley, Minn.) is a good example of benchmarking data. The only real reason to use benchmarking is to improve on existing performance in an objective way. Benchmarking is a performance measurement tool used in conjunction with improvement initiatives to measure comparative operating performance of similar livestock businesses. Benchmarking is way to discover impending problems and assist in pointing out opportunities for improvement. It fosters the questions of *"Are we doing the right things?"* (effectiveness) and *"Are we doing things right?"* (efficiency) (Smith, 1996). Benchmarking is superior to the use of guidelines since the values are "real" and "in the context" of similar commercial

production systems. Benchmarking databases are periodically updated and often published by state or region. Therefore they may reflect more accurately performance under current conditions. These values offer a convincing comparison and a powerful means to identify your client herd's strengths and weaknesses. However, benchmarking does have shortcomings. Benchmarking tells where the practitioner is in relation to other similar operations but it does not tell how he or she got there or how to get out of the current mess. Therefore benchmarking is not a stand-alone analytical procedure and must be teamed with other more diagnostic techniques to resolve the cause(s) of suboptimal performance and derive appropriate action plans.

Table 3-8 is another example of a benchmarking database in which the management variables have been arranged in columns based on level of herd productivity. DHIA organizations are excellent sources of benchmarking databases for dairy herds. Table 3-9 is a beef-cow-calf database. The CHAPS software provides, via the Internet, a benchmarking database for cow-calf herds. This particular database represents data from over 200 cow-calf herds and more than 100,000 cows. All are good examples of the application of benchmarking as a performance measurement tool.

Standardization of data definitions and the calculations of performance measures facilitate the pooling of individual herd data into benchmarking databases. It is for this reason alone

that the livestock industry should follow the lead of the NPPC in creating industry-wide standardization of production and financial standards. Likewise, standardization of disease definition (Kelton et al, 1998) would permit similar benchmarking benefits regarding subclinical and clinical disease.

The use of both guidelines and benchmarking is a means by which veterinarians can motivate livestock producers to achieve higher levels of performance by fostering increased expectations that are economically realistic. Benchmarking, in particular, is a tool, that if used wisely can prevent program stagnation by promoting the attitude of continuous improvement.

DATA, INFORMATION, AND KNOWLEDGE

The only reason for record use is simply to *know* what is happening. Knowledge is defined as an understanding and clear perception of reality. Knowledge is power. On the other hand, lack of knowledge leads to powerlessness. It is clear that the foundation on which timely and accurate herd management decisions are made is based on knowledge. Ideally this *knowledge* is gleaned from thoughtful consideration of *information* generated from usefully summarized *data* that have been recorded into a herd *MIS*. The best type of data summary and the usefulness of the information are situation specific; they depend on the question being asked.

As an example, the data in Table 3-10 are from a farm that experienced a dramatic increase in their average SCC in July. This sudden increase in SCC was a result of cows becoming infected with mastitis. The list in Table 3-10 includes only those cows in the herd with high SCCs. Imagine the same list if it included all cows in the herd, both milking and dry (about 200 animals). The expanded list would include much more data but would be cumbersome and, in effect, have less informational value. The question at hand (why did the SCC increase?) is more easily addressed by looking only at the cows with high counts. Table 3-11 includes the same data, but here the cows have been sorted by lactation number and days in milk and new infections are indicated. Cows are presumed newly infected if their SCC was low in

Downloaded from Vet-eBooks.com

the previous month (linear score less than 4) and high in the current month (linear score greater than or equal to 4). In Table 3-11 it is even easier to see that most of the new cases of high counts are first-lactation heifers in early lactation. However, the practitioner must be careful not to jump to conclusions too quickly until herd demographics are taken into account fully. If, for example, this was a newly started dairy in which mostly first-calf heifers had been purchased, a conclusion that the problem was new infections in early lactation heifers might be incorrect. In fact it could be that the proportion of second and third lactation cows with new infections in early lactation might be equal to or greater than

that in first lactation heifers. The point is that when considering disease rates within a population, practitioners must consider denominators before drawing accurate conclusions. Once this is done, the summarized data in Tables 3-10 and 3-11 become valuable information. The herd's veterinarian can now investigate why first-calf heifers in early lactation seem to be at unusually high risk of new cases of mastitis.

Converting Data to Information

Information is the result of the conversion of raw numbers (data) into an organized or summarized form. The goal of converting data to information is to present all essential pieces of knowledge from a collection of raw numbers in the simplest way possible. The question is how the best or most information can be gleaned from the production systems. For livestock record systems, information can be divided into three general types of output: lists, numerical reports, and graphical reports. Lists are raw data summarized into columns, numerical reports include counts (tallies) and statistics, whereas graphical reports include scatter-plots, histograms, survival curves, and time series plots. Each type of report has strengths and weaknesses that are important to consider when interpreting results.

Lists are the simplest form of information but are the most difficult to interpret, since they do little to process data into a succinct form. Tables 3-10 and 3-11 are good examples of how strategic sorting enhances the use of tabular data. A *numerical report* is a text-based summary based on mathematical calculations. Numerical methods remove extraneous detail by expressing, in numerical form, specific characteristics of the data (Wheeler and Chambers, 1992). Information may be counts of values meeting a set of criteria (frequency distributions or cross-tabulations) or summary measures such as averages (statistics) (Fig. 3-4). A general disadvantage of numerical reports is that they are nonintuitive. In other words, it is difficult to visualize patterns in data just by looking at "the numbers."

Graphical reports are reports that summarize information into visual patterns. In general graphical reports are much more powerful then numerical reports, since inferences may be "seen" in the image; hence the axiom "A picture is worth a thousand words." However, two general disadvantages exist for using graphical reports:

1. Graphical reports can, at most, represent three dimensions
2. The dangers associated with using different scales for axes

The fact that graphs can represent only three dimensions becomes a problem when analysis of complex systems is conducted. Being able to "see" only part of the relationships may lead to inappropriate conclusions, as the whole may be more than the sum of the parts. A larger danger is the inappropriate use of scale. Fig. 3-5 shows a comparison of milk production for several cows in a dairy herd. At a quick glance, we might conclude that cow no. 232 produced less than half that of cow no. 583. When this figure is adjusted to the appropriate scale (by starting milk production at zero) as shown in Fig. 3-6, a much different picture of the relative levels of milk production appears. As a general rule, numerical scales should start at zero and each interval should be of equal size.

Placing data into categories and reporting the frequency of items for each category derives counts. *Frequency distributions* (also termed *tallies*) are the simplest form of a count as they represent the relative occurrence of values within given intervals for a variable. Fig. 3-7 shows a frequency distribution of lactation numbers within a dairy herd. *Cross-tabulations* are frequency distributions in more than one dimension. The simplest form of a cross-tabulation is a 2 × 2 table as shown in Fig. 3-8. In this figure, animals are classified into four groups: diseased and vaccinated, diseased and not vaccinated, healthy and vaccinated, and healthy and not vaccinated. A danger inherent in using count-based summaries occurs when quantitative data are "collapsed" into categories by selecting "cut-point" values.

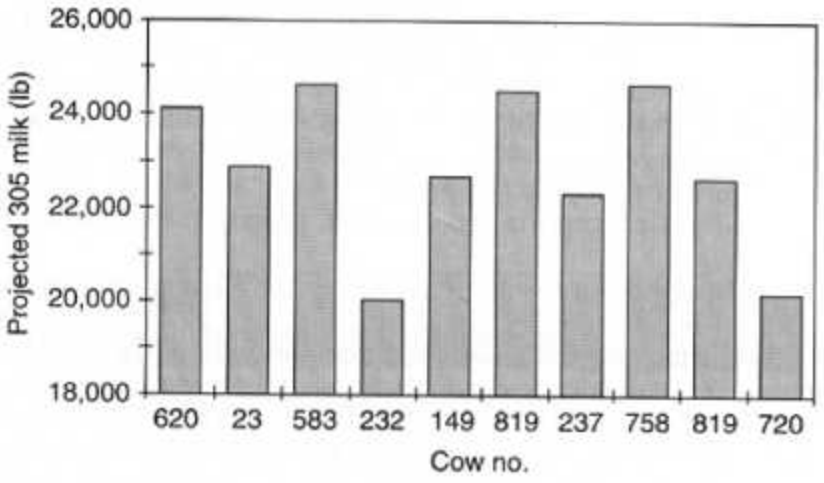

FIG. 3-5 Example graphical report with inappropriate scale.

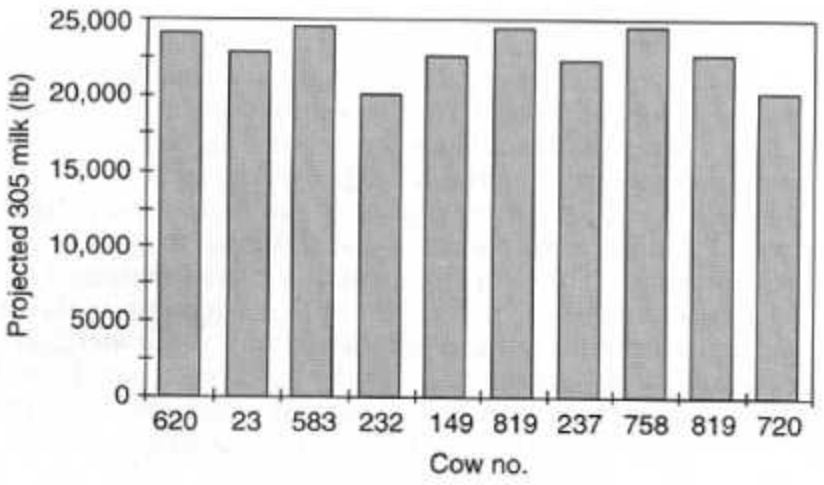

FIG. 3-6 Graph presented in Fig. 3-5 redrawn with appropriate scale.

Care must be taken when doing this, since this approach leads to a loss of power (the ability to detect an effect given that one exists). For example, the veterinarian could convert the ages of cows in a herd from the actual age to the categories young (less than or equal to 3 years old) and old (greater than 3 years old) for use in a 2 × 2 table. However, there is now no longer a difference between a cow that is 10 years old and a cow that is 4 years old. If an important effect occurred for animals more than 6 years old, the veterinarian would be less likely to detect it. For this reason, it is imperative to choose cut-points with biological significance, such as first-lactation heifers versus second lactation or higher.

A second potential problem with count summaries occurs when absolute numbers are compared instead of proportions (termed "dangling numerators"). For example, suppose a veterinarian tallied the number of mastitis cases for each lactation number in a herd and found that heifers had more mastitis. He or she may or may not be able to conclude that heifers were at higher risk depending on what proportion of the herd (both healthy and having mastitis) was heifers. Thus any comparison of characteristics of an animal must be expressed in terms of the appropriate denominator (e.g., expressed as a rate).

Numerous statistical measures exist and may be used in record analysis. The strength and weakness of statistical analysis are its narrow and specific interpretation (Wheeler and Chambers, 1992). Although the assumptions specific to each statistic give more power in "sifting through the chaff," if these assumptions are not appropriate, they may hide important features of the data. It is the inappropriate use of statistics that has led to the quote, "There are lies, damned lies, and statistics" (Huff, 1954).

A *scatter-plot* is a graphical summary of the relationship between two variables with one variable on the vertical axis and the second on the horizontal axis. Scatter-plots commonly consist of two continuous variables (variables that may take on any value within a range). A common adaptation of scatter-plots used in record systems is to define cut-points for one or both variables to divide the graph into quadrants as shown in Fig. 3-9. A scatter-plot with cut-points is analogous to a numerical cross-tabulation report and has the same problems associated with collapsed data and dangling numerators.

Downloaded from Vet-eBooks.com

A *histogram* is a graphical summary of data with possible values divided into categories (intervals) on one axis (normally the horizontal axis) and the frequency of values in these categories on the other (Wheeler and Chambers, 1992); it is analogous to the frequency distribution (Fig. 3-7). General guidelines for histograms are using equal-sized intervals, choosing endpoints where there is no uncertainty about where borderline values belong, and using 10 to 15 intervals, more or less, as appropriate (Wheeler and Chambers, 1992). A feature of the histogram is that it obscures sequential information such that care should be taken in using histograms with time-related data.

Time series plots, also known as running records, are plots in which values are shown on one axis (the vertical axis) and the time-order sequence is shown on the other. Hence the running record is a representation of a process over a period of time. The running record and the histogram can be thought of as complementary figures; the histogram collapses all the data to show the overall shape, whereas the running record stretches out the data to show the sequential information that is not apparent in the histogram (see Fig. 3-15). Special adaptation of the running record is the statistical process control chart and the *Kaplan-Meier survival curve* described in later sections.

Record Use in Herd Investigation

Herd investigation is a fundamental component of production medicine programs. Despite all best efforts, problems do occur in livestock operations. Many practitioners feel uneasy with the prospect of delving into a formal record/problem investigation, but the diagnostic skills are the same as those used in individual animal cases. The key to any successful diagnostic effort is to have a standardized, stepwise approach. A standard procedure makes practitioners less likely to miss something, generates as much information as possible to analyze, and makes it easier to check for any mistakes that may have occurred.

The goal of herd investigation is to identify management changes that will resolve the problem, not just to identify the problem. Two concepts are important to understand the rationale for this approach. First is the concept that all disease or suboptimal performance is multifactorial and that there are multiple ways that a given problem may occur. The second is the concept of a sufficient cause. A sufficient cause is the combination of risk factors (also called component causes) that produce the problem each and every time. A sufficient cause can be thought of as a pie with multiple pieces (component causes), and that multiple sufficient causes may exist for a given problem. Fig. 3-10 shows a hypothetical example from a diarrhea problem in calves with five component causes.

The goal of the investigation, in the context of the "pie" analogy, is to try to identify and eliminate at least one piece of the pie to prevent the completion of a sufficient cause. The "slices" of the pie are identified in two general ways: (1) by identifying management changes associated with the initiation of the problem and (2) by comparing affected animals with unaffected, at-risk animals.

Currently, there are no record programs that have all of the required features to conduct a comprehensive problem investigation, so some hand calculation is needed. The five steps that should be followed in a herd investigation are shown in Box 3-1. Remember, the goal of this protocol is to identify key determinants (risk factors that are under management control) as potential points of intervention. In addition, the herd investigation protocol should be used as a supplement, not replacement, for standard diagnostic methods.

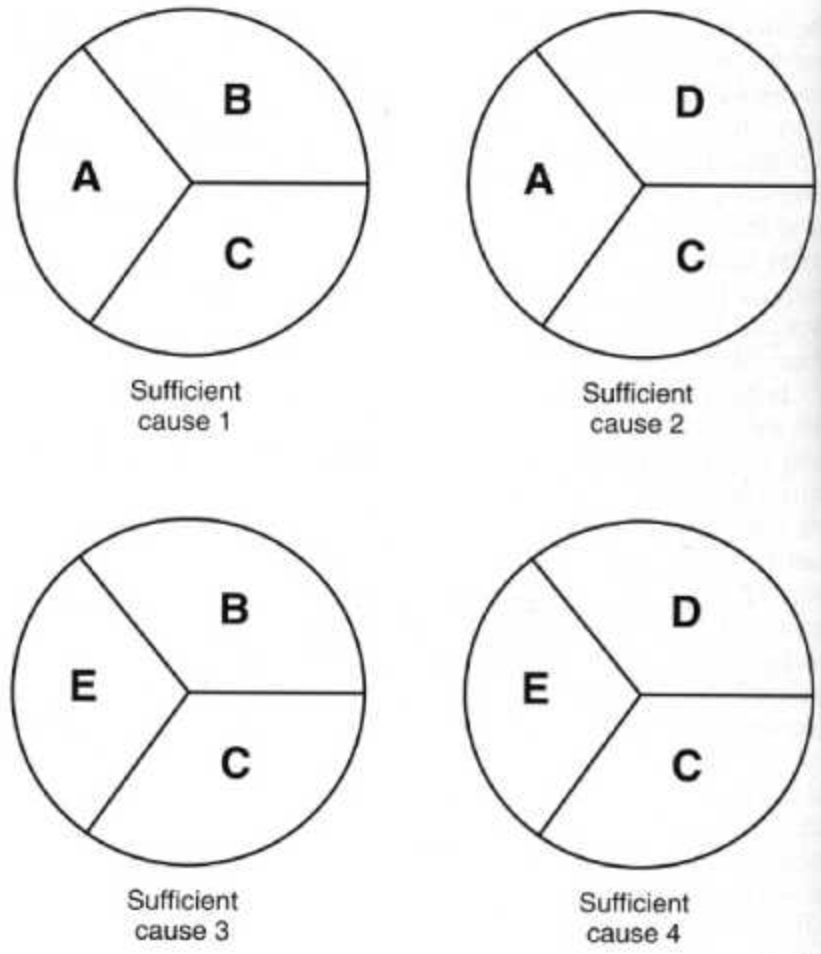

FIG. 3-10 Hypothetical sufficient causes for *Escherichia coli* diarrhea. *A,* Lack of passive transfer; *B,* stress from the environment; *C,* presence of *E. coli* 0157:H7; *D,* presence of second pathogen; *E,* malnutrition. (Adapted from Martin SW, Meek AH, Williberg P: *Veterinary epidemiology,* Ames, 1987, Iowa State University Press.)

Confirming the Problem

The first step in investigating a herd problem is to confirm that a problem exists and to what degree. Determining that a problem exists requires deciding on a case definition, deciding on the population at risk, and deciding the time frame of interest. The requirement of a case definition is necessary because in herd level problems, there are multiple animals involved with differing severity of the problem. Thus it is imperative to establish, *a priori,* some method to classify animals as cases, controls, or not at risk. For example, a dairy client asks a veterinarian to investigate a respiratory disease problem in his heifers. What constitutes a diseased heifer? Is a heifer that has a rectal temperature of 39.1° C (102.5° F), slightly increased lung sounds, but no nasal discharge, a case? Having a clear case definition is important.

Once the criteria have been established for classifying an animal as a case, the next step is to determine what the population at risk is and the timeframe of interest. This is necessary to define the unaffected, at-risk control for the case-control analysis. For the respiratory disease example, the population at risk would be heifers in the dairy during the period of interest. Determining the extent of the problem is then a matter of summarizing the number of animals at risk that became cases during the timeframe of interest.

Collecting Herd Data and Animal Information

Collect Animal History for Case-Control Analysis. Once the extent of the problem has been determined, a basic set of information is gathered concerning each case for later use in the case-control analysis. This data set should include information regarding all potential risk factors. Common risk factor categories include animal age, location,

Create production history (e.g., bulk tank) temporal plot
Perform case-control risk factor analyis

COLLECT RISK GROUP–BASED SAMPLES

MAKE MANAGEMENT RECOMMENDATIONS

level of production, reproductive status, vaccination history, treatment history, and feed groups.

Management Questionnaire. The second set of information that needs to be collected is data concerning the management policies of the dairy. This can best be accomplished by administration of a management questionnaire. The questionnaire serves three functions: it allows comparison of management influences between farms, it structures questioning such that specific topics are not forgotten, and it serves as a measure of policy compliance. Topics that should be included in the survey include general information (farm ID, location, etc.), information concerning new animal arrivals, vaccination history, housing management and facilities, reproductive management, grouping of animals, nutritional management, and waste management and sanitation.

Farm Event Listing. The next step of the investigation should focus on creating a farm event listing. This document is a written record of farm-wide events listed by date of occurrence (Table 3-12). Events that should be recorded are the date of entry of animals from outside the farm, the date of feed changes, the dates of whole herd vaccination, previous episodes of illness, and any herd-wide management changes. Farm events are things that affect the entire herd regardless of herd size. Therefore information collected for this farm event listing should go back at least 6 months before the start of the problem, if possible.

Record of Product and Performance Output (i.e., Bulk Tank Shipments and Milk Quality Reports). The last set of data to collect on a dairy farm is a record of the bulk tank shipments and milk quality reports. Evaluation of this information may provide evidence of a date of exposure to the inciting event. It is important to remember that shipping weights alone must be carefully interpreted in light of the number of cows contributing to the tank and that the average production per cow is a much better measure of milk production. Daily variation in milk production may be smoothed using a 10-day moving average. Data should be collected for at least 6 months before the first case of disease.

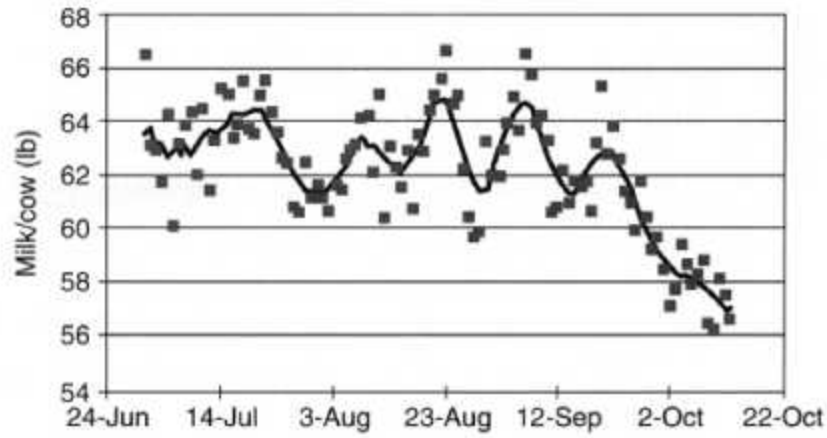

FIG. 3-11 Example of bulk tank shipment temporal plot.

05/06/99	Started feeding alfalfa stack #1
05/12/99	Hired new feeder
05/15/99	Bought load of 17 springers from auction
05/27/99	Started feeding corn silage
06/01/99	First abortion of cluster
06/17/99	Vaccinated whole herd for leptospirosis

Fig. 3-11 shows a graph of the bulk tank shipments for a dairy with a significant drop in production starting in late September. Further investigation found that the dairymen had started feeding a low-quality haylage in August. The dairy also initiated the use of bovine somatotropin (bST) in August, causing the impending drop in production to be delayed. Following "disappointing" performance of the bST, the product was discontinued and the production drop occurred.

Summarizing Herd Data into a Standard Format

Create Farm Event Temporal Plot. The first data processing step is to create temporal plots of the farm event listing and bulk tank data. These graphical depictions of events allow juxtaposition of the problem history with farm level events or changes in production that can provide valuable insight into events that may be associated with the onset of the problem. Plotting of farm events is most easily performed using a horizontal bar graph with each type of farm event listed on the y-axis and time plotted on the x-axis. Events that occur on a single day are best represented by a symbol such as an "X." Abortion cases are best plotted as the first row above the x-axis. Using this arrangement, the investigator can scan for vertical associations of farm events with the start of the abortion problem. A hypothetical farm event temporal plot is shown in Fig. 3-12. This dairy used three different forages before the outbreak, vaccinated the whole herd 36 days before the outbreak and 16 days after, purchased 10 new springers 17 days before the outbreak, and hired a new feeder 20 days before the outbreak. Possible

Downloaded From Vet-eBooks.com

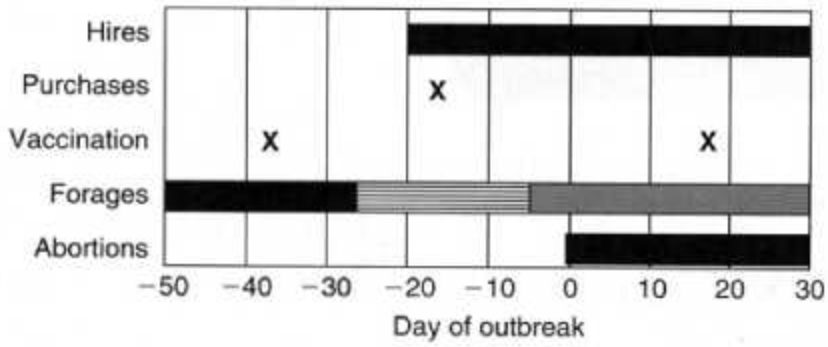

FIG. 3-12 Example of farm event temporal plot.

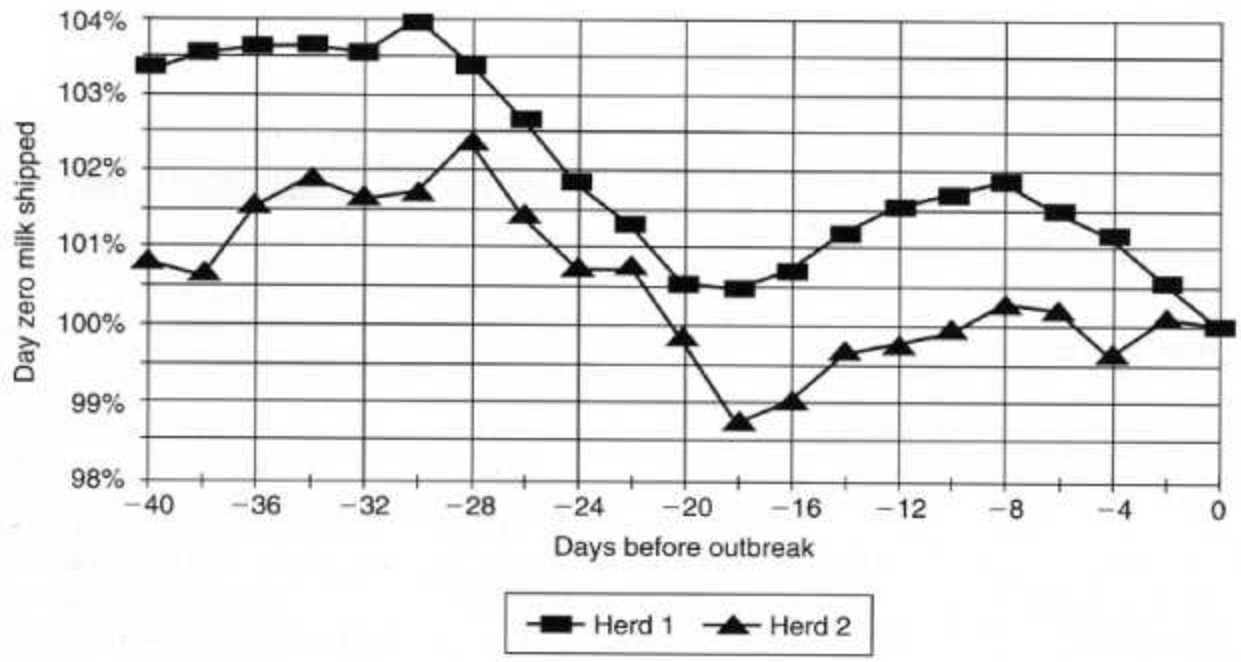

FIG. 3-13 Bulk tank milk shipments for two dairies before *Neospora* abortion outbreak.

sources of the problem are the new feed, the new feeder, and the purchased springers.

A temporal plot of bulk tank data can be constructed in a similar manner with moving average milk production, fat, protein, and SCCs plotted against time. Fig. 3-13 shows a bulk tank milk shipment temporal plot from two *Neospora* abortion outbreaks. Milk production has been standardized to a percentage of day 0 production to allow comparison across herds. Notice how there is a biphasic pattern with the initial drop approximately 30 days before the outbreak and a second decline the week before the outbreak. Further questioning of the herd managers on these dairies identified a change to a wet feed associated with the initial drop, suggesting the possibility of these *Neospora* outbreaks being initiated by a cofactor.

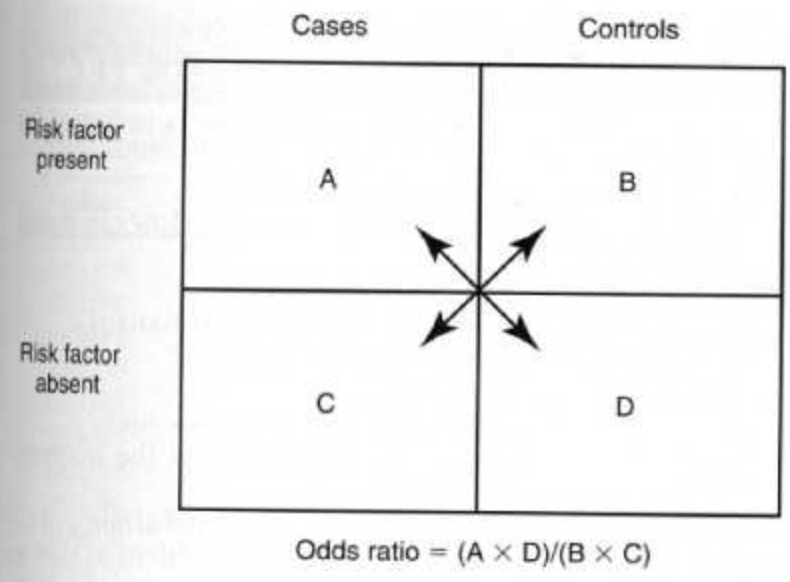
Case-control comparison. After construction of temporal plots, a matched case-control analysis is performed. The concept of a case-control analysis is to identify what is different about animals that developed the problem compared with animals that did not but could have. Thus the idea in selecting controls is to choose animals that would have developed the disease given they had all the risk factors. Selection of controls is a three-step process. *Step one* is to make a table of all cases by month of the variable of interest. For example, in abortion investigation, cases are listed by month of conception. For postpartum cow problems, cases are listed by month of calving. This cohort approach enables removal of any effects relative to changes in the environment (i.e., weather differences, feed changes). *Step two* consists of making a similar table of all cows that were at risk but did not have the problem using the same monthly cohort (e.g., month of calving). In *step three* each case cow is paired with a randomly selected control cow from the same monthly cohort. Thus there should be one control for each case and the same number of controls from each month as there are cases.

After the controls have been selected, the core information recorded earlier for each case should be recorded for each control (for more information on the proper selection of controls, see Rothman, 1986, or Martin, 1987). Data from cases and controls are then used to create 2×2 tables similar to Fig. 3-14 for analysis of the proportion of cases (and controls) found in each risk group. From this 2×2 table, an odds ratio may be calculated (as shown in Fig. 3-14).

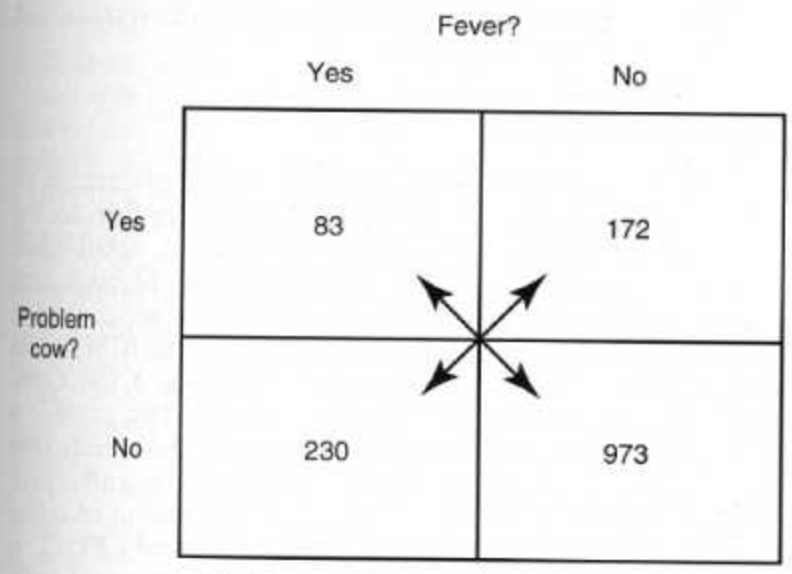
The odds ratio represents the odds of disease for animals in the top row of the table (defined as animals with the risk factor) relative to the odds of disease for animals in the bottom row (defined as animals without the risk factor). For example, if the top row refers to animals more than 3 years old and the bottom row refers to animals 3 years old or younger, an odds ratio of 2.0 means that the older animals are 2.0 times more likely to get the disease than the younger animals. Fig. 3-14 shows example data from a field trial investigating the relationship between problem cows (cow with postpartum problems) and the subsequent development of fever. In this example cows with problems are 2.04 times more likely to develop a fever later in lactation.

Notice that the odds ratio by itself does not provide any indication of the actual disease frequency; it would be the same if 50% of the old and 25% of the young were diseased,

Downloaded from Vet-eBooks.com



Odds ratio = (A × D)/(B × C)



Odds ratio = (83 × 973)/(172 × 230) = 2.04

FIG. 3-14 Two-by-two setup with odds ratio calculation. The example field trial data show an odds ratio calculation. Cows with a postpartum problem are 2.04 times more likely to develop fever later in lactation.

or if 5% of the old and 2.5% of the young were diseased. It just indicates the *relative* frequency.

So what does it mean if the odds ratio is less than one? Many times as practitioners set up a table, they may not know if the factor they put on the top row is related to an increase in disease risk or not. In the case in which the odds ratio is less than one, the risk factor chosen for the top row is actually protective (i.e., animals with this characteristic are at less risk). In this case, the practitioner could invert the odds ratio and list the bottom row as the risk factor. For example, suppose the practitioner constructs a table with old cows as the top row and young cows as the bottom and the calculated odds ratio is 0.5. This finding can be interpreted as old cows being 0.5 times as likely to develop this disease, or as young cows being 2.0 (1 divided by 0.5) times more likely to develop the disease.

As a general rule of thumb, odds ratios greater than 2.0 (or less than 0.5) are considered fairly large. It is important to note that statistical testing is not being used in this approach—just the strongest relationships. For example, suppose a veterinarian is investigating a disease outbreak in cattle, and the odds ratio for old versus young cattle was 1.9, the odds ratio for fat versus thin cattle was 2.3, and the odds ratio for pasture 1 versus pasture 2 was 14.0. The veterinarian really should be curious about how pasture 1 differs from pasture 2. When using this approach, always be cognizant of the biological plausibility of these relationships. Just because a "large" odds ratio is found does not necessarily mean that this relationship is important in the disease progression. At times a mathematical relationship will be found (statistical significance) by chance that does not represent a true relationship for the progression of the disease (biological significance). Whether a large odds ratio is biologically significant should be determined by current circumstances and sound medical principles.

Risk group–based sampling. The last step in investigating problems in livestock operations is to collect laboratory samples based on risk groups. This risk group–based sampling has two benefits. First, it allows comparison of case animals to animals in other risk groups for changes in laboratory values. Second, it will increase the total number of samples submitted, which increases the likelihood of identifying the source of the problem. An example risk group sampling protocol for a dairy herd abortion investigation would be to bleed animals for serology in the following groups: cows that have aborted (at risk, affected), cows that are pregnant but did not abort (at risk, unaffected), and cows that are not pregnant (not at risk). It is important to remember that at least 10 samples should be collected from each risk group if possible to ensure adequate sample size for comparison across risk groups.

Management recommendations. It is important that no management changes be made on the farm at the time of the problem investigation. It is best to first combine the results of the investigation protocol with the results of the laboratory testing to obtain a clearer understanding of the total picture before making final recommendations. It is wise to implement only a few of the management changes at any one time so that both positive and negative effects can be more easily determined. Finally, it is absolutely essential to designate an appropriate monitor for each recommended change so that success or failure of the recommendations can be measured.

Advanced Record Analysis Techniques

Statistical Process Control

"SPC (statistical process control) is a way of thinking with charts acting as a catalyst for this thought process" (Wheeler and Chambers, 1992). SPC is one of the most powerful tools for process improvement. However, unless SPC is used as a part of a production system in which the idea of continuous improvement is embraced, it is just another way of representing data in a graph (Polson et al, 1999). It is important at the onset of this discussion to emphasize this point. Experience has shown that application of SPC without commitment to the continuous improvement concept will not be a very productive or satisfying experience. SPC is not new, having been used successfully in manufacturing businesses for over 70 years. SPC has not been extensively used in animal agriculture. SPC was first tried in swine production over 20 years ago (Wrathall, 1977). However, the principles of SPC are proven, and use in animal agriculture is merely a shift of application to a biological production system. Although the biological system is more variable and thus presents a greater challenge, there is great optimism that SPC techniques will become another valuable tool for livestock monitoring (DeVries et al, 1997; Polson, 1998; Polson et al, 1999).

How great a deviation from "normal" constitutes real change? Is this change sufficient to merit the expense and effort of the recommended intervention? Sometimes the decision is a "no brainer," but too often neither the practitioner nor the client is really sure. It is this lack of confidence that

Downloaded from Vet-eBooks.com

may weaken the practitioner's resolve to insist that action be taken as well as erode his or her client's commitment to take seriously the recommendations and initiate timely corrective action.

Each time practitioners face this sort of dilemma, they are in danger of making errors in interpretation. When random variation (common cause variation) is mistaken for a real change in cow productivity or health, veterinarians may diagnose a nonexisting change (Type I error or false positive). Application of unnecessary corrective action truly would be a waste of labor, time, and money. Such action detracts from productive management. It adds complexity and creates management chaos. On the other hand, failure to identify an emerging problem quickly enough to initiate timely corrections (Type II error or false negative) is also a great concern. The indecisive strategy of "let's wait to see what it looks like next month" may squander the opportunity to nip the problem in the bud. Furthermore, subtle changes could go undetected for months, creating a deep-seated herd problem.

SPC is a set of several analytical tools of which the control chart is an important one. This discussion focuses only on control charts. Control charts are helpful in signaling that a true change has occurred. The fundamental concept of control charts is to distinguish between inherent random variation and real changes in output, quality, or measured performance. Properly applied control charts can prevent the misinterpretation of inherent random variation because of "common causes" of variation. More important, they provide a timely signaling of real change because of "special cause" variation. Common causes affect all data and are chronic, stable, and predictable within limits. Special causes affect some data and are sporadic, unstable, and unpredictable. SPC methods can be used to signal emerging problems and evaluate the positive or negative impact of a change in a management practice or the implementation of a new product.

Typical livestock management reports provide a plethora of data, usually in tabular form. The inevitable result of having such a large volume of data presented in such a small area is that it requires much study and effort to interpret. The human mind does not do very well absorbing large amounts of data. In addition, most veterinarians tend to be numerically illiterate (Wheeler, 1993). It is not that they do not understand the mechanics of arithmetic. Rather they do not intuitively know how to extract knowledge from data. The most common use of livestock management data is to compare this month's average with last month's average. Are they doing better or worse? The problem with such limited comparisons is that they are out of context. Context here means that the data should be interpreted in context of the time order in which they were generated. Context also means that the natural variation in the data and its relationship with similar data generated by the process must be taken into consideration.

Data divorced from their context can be misleading. Although several months of tabular data would provide ample context, most people find it difficult to assimilate and provide accurate interpretation. For example, consider the relatively simple table of daily bulk tank somatic cell count (BTSCC) data for a Minnesota dairy (Table 3-13). Looking at the table, readers might ask a few simple questions to aid in interpretation:

- How were the data collected and calculated? By whom?
- What is the highest value? The lowest? The average? The median?
- What is the normal, day-to-day level of variation?
- What causes the normal variation?
- When is variation abnormal?
- When should veterinarians be worried?
- How does this herd compare to other herds?
- Is there potential for improvement? How much?
- Is intervention worth the cost?
- Does this herd currently have a problem as indicated by the BTSCCs?
- Have there been problems in the past?
- Is mastitis management "under control"? How can someone tell?
- If mastitis were to go "out of control":
  - –How soon would these data tell the veterinarian?
  - –How quickly would the veterinarian react?
  - –What would the veterinarian do?
  - –How would the veterinarian measure response?
  - –Would the veterinarian be confident that the intervention had made a difference?

Obviously study of tabular data is overwhelming, time consuming, and often unproductive. The problem of how to analyze tabular data is depicted in the statement of a busy veterinarian: "I don't have time to study all the records, just give me the abridged version."

Time Series Charts

Since people are visually oriented and tables of data are visually boring, graphs make data more accessible to the human mind. Graphs can remove extraneous detail while providing context for visual interpretation. Management data usually have a time order. Therefore a time series chart of data improves interpretation. Consider again the BTSCC data for a Minnesota dairy in a time series chart (Fig. 3-15). Compared with the tabular format, the plotted data provide a much clearer idea of the BTSCC changes and trends over time. Practitioners can use their prior knowledge and experience of BTSCC data to form a general impression of udder health of this herd. They can see that this herd's BTSCC is generally too high with possibly a slightly upward shift. However, a simple time series chart does not have sufficient resolution for more meaningful interpretation. It is still difficult to identify subtle changes or to know if the BTSCC in this herd is "in control" or "out of control." This is because the inherent random variation (noise) masks real changes. Noise, like static on a car radio, makes listening annoying and difficult to understand. The Shewhart control chart is the simplest method to separate potential signals from probable noise.

Control Charts

In the 1920s Dr. Walter Shewhart at Bell Laboratories invented control charts to help interpret data that are generated over time. Control charts provide further insight into data by displaying the level of normal, random variation in the data and by revealing the observations that indicate real change. This approach affords the practical application of statistical theory in a visual, easy to interpret context. The steps to develop a Shewhart control chart are as follows:

1. Start with a time series chart.
2. Add a centerline (mean) for central reference.
3. Add control limits, computed from the data and based on the common cause variation only, equidistant on either side of the centerline.
4. Apply tests to distinguish between data points resulting from special causes and data points resulting from common causes only.

Control limits are calculated by two methods. One method uses standard deviation (SD), which is a common measure of variation. Experience has shown that 3 SDs away from the center line is a good balance between the number of false-positive signals (type 1 error) and false-negative sig-

11/13/98	255	12/26/98	275	2/8/99	349

nals (type 2 error). The other method (mean range method) uses the mean of the values plus or minus the average range between values times a constant. The constant depends on the number of values within each subgroup and is looked up in a table. The mean range method gained acceptance historically because in the early years of SPC, calculation of SDs was difficult. Both methods are designed to give the same approximate answer. Today even relatively inexpensive hand calculators compute SDs. It should be noted, however, that the SD method is more prone to error when there is more than one subgroup of data being considered (Wheeler and Chambers, 1992). However, if calculation of control limits are done correctly, both methods result in nearly identical control limits as well as the same interpretation.

The resulting zone between the center line and 1 SD is called Zone C, between 1 and 2 SDs is Zone B, and between 2 and 3 SDs (the control limit) is Zone A (Fig. 3-16). These zones are important for applying the interpretive tests discussed later.

Control limits are calculated based on the data collected in a timeframe called the "control period." Experience has show that 20 data points are needed to calculate credible control limits (Wheeler and Chambers, 1992). When a practitioner initiates a control chart, it is appropriate to use the first 20 data points collected as the control period. Once control charting is established, the control period can be set depending on the question being asked. If the intent is to monitor a process for the purpose of maintaining a stable process, then using data from an apparently stable period makes sense. If the intent is to use the control chart to evaluate the introduction of a new product or a change in process procedure, for instance, then the control period should be

Downloaded from Vet-e-Books.com

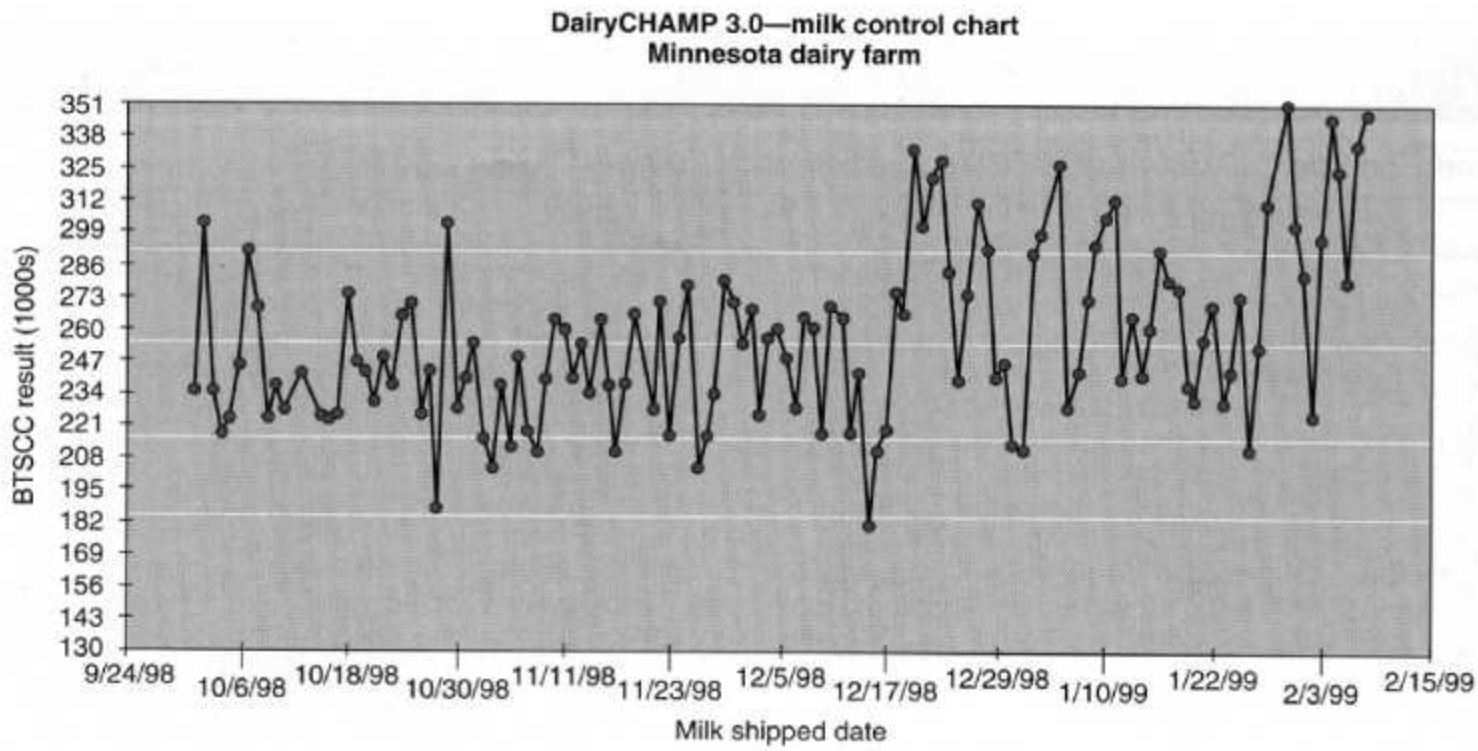

FIG. 3-15 Time series plot of the daily bulk tank somatic cell count (*BTSCC*) for a 200-cow Minnesota dairy. The upward trend is more apparent than the tabular data, but how certain could the practitioner be on December 18 that the processes contributing to BTSCC were "out of control"?

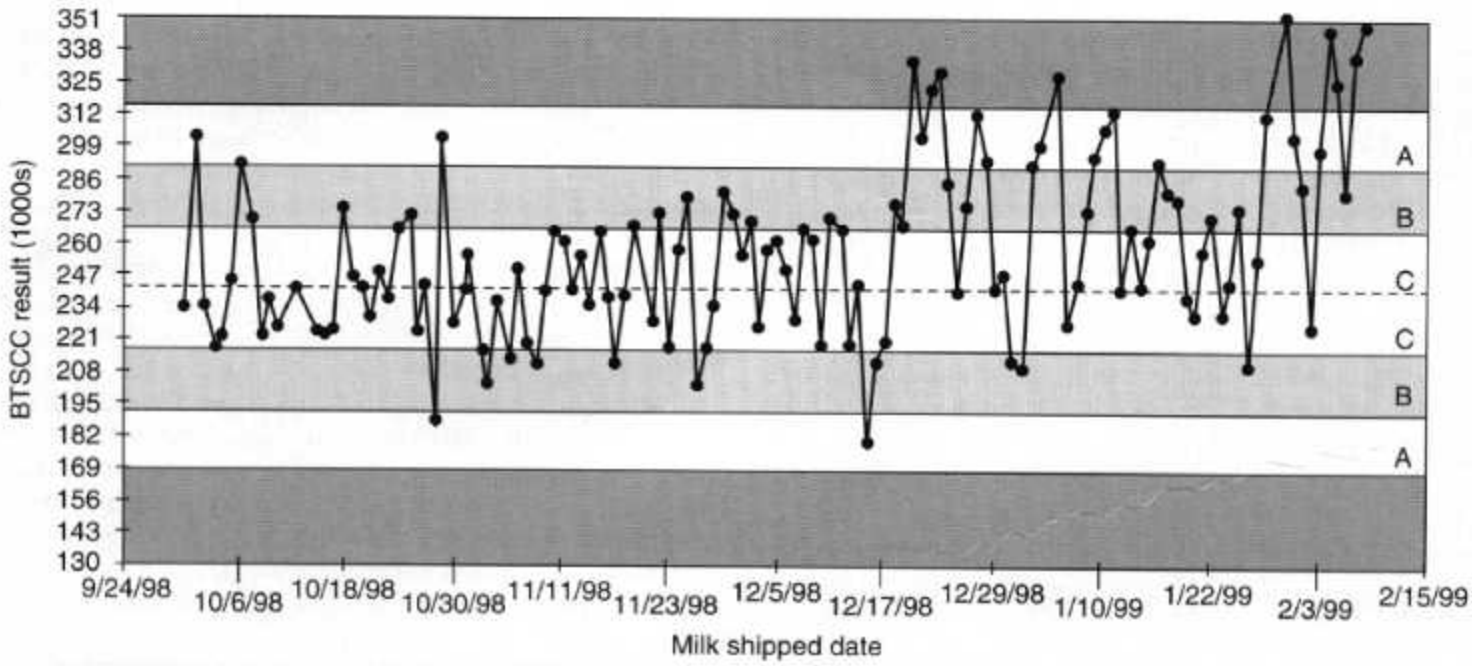

FIG. 3-16 Bulk tank somatic cell count (BTSCC) for a Minnesota dairy plotted in a Shewhart control chart. The mean and 3 standard deviations (zones A, B, and C) were calculated using the daily BTSCC data for the period from October 1, 1998, to December 1, 1998.

calculated from data collected just before the introduction of the product or change in procedure. The control limits for the example using the BTSCCs were calculated using the October 1998 to December 1998 BTSCC data, since there was no indication of special variation in that period; thus the process appeared to be "in control." Mean BTSCC for the designated control period was 243,000 and the SD was 24,300. Thus the limits for Zone C were 243,000 ± 24,300 (between 218,700 and 267,300). The limits for Zone B were 243,000 ± (2 × 24,300) (between 194,400 and 218,700 and again between 267,300 and 291,600). Finally, the control limits were calculated as 243,000 ± (3 × 24,300). Zone A, therefore, is between 170,100 and 194,400 and again between 291,600 and 315,900 (Fig. 3-16). Calculation of control limits using the mean range method gave the same results.

Note that the picture becomes more clear than a time series plot, but it remains difficult to interpret the data without a formal and standardized approach to distinguish between "normal" (common cause) variation and variation that deserves more attention.

Interpreting Control Charts Using Tests

Several tests exist that can help in the correct interpretation of control charts. When a single data point is observed out-

Downloaded From Vet-eBooks.com

side one of the control limits, the probability is that this point is not a real change (false positive) but is only 3 out of 1000. Seven additional tests use multiple data points to indicate, with a high probability, that a real change has occurred (Nelson, 1984). Using several tests simultaneously for signaling special causes increases the sensitivity of a control chart but also increases the possibility of a false positive. The combined probability that any of the eight tests indicate a "real change" when there is none is about 20 out of 1000, or 2%. Thus it is generally safe to assume that the process is "out of control" when any one of these tests indicates a change. The eight tests are as follows:

- Test 1: A single point outside one of the control limits
- Test 2: Nine points in a row on one side of the centerline
- Test 3: Six points in a row either all increasing or all decreasing
- Test 4: Fourteen points in a row alternating up and down
- Test 5: Two out of three points in a row in or beyond Zone A on either side of the centerline
- Test 6: Four out of five points in or beyond Zone B on either side of the centerline
- Test 7: Fifteen points in a row in Zone C on either side of the centerline
- Test 8: Eight points in a row on either side of the center line with none in Zone C

A simplified version of the eight tests has been used extensively in industry and is known as the Western Electric Zone Test (Wheeler and Chambers, 1992):

- Detection rule one: A lack of control is indicated whenever a single point falls outside the (three-sigma) control limits (Zone A).
- Detection rule two: A lack of control is indicated whenever at least two out of three successive points fall on the same side of, and more than two sigma units away from, the central line (within Zone A).
- Detection rule three: A lack of control is indicated whenever at least four out of the five successive values fall on the same side of, and more than one sigma unit away from, the central line (within Zone B).
- Detection rule four: A lack of control is indicated whenever at least eight successive values fall on the same side of the central line.

Wheeler (1993) summarized the aforementioned eight tests into three simple tests that he felt are adequate for most management situations. They are as follows:

- Test 1: A single point outside control limits
- Test 2: Three out of four consecutive points closer to the control limit than to the centerline
- Test 3: Eight or more successive points on one side of the centerline

Anytime the conditions of any one of these three tests are met, the veterinarian can be certain the process has changed and is by definition "out of control." Considering these tests as new data become available ensures timely signaling of real changes. Using Wheeler's three tests to detect special cause variation, the reader should reconsider the control chart of BTSCC data (Fig. 3-16).

Wheeler's second test indicates that starting on December 18, there is clear and significant upward shift in the level of BTSCC. The process is "out of control." There is no need to vacillate, since the practitioner can be 95% certain that the shift is "real" and it is not just normal variation. Since data should be interpreted in their context, these observations may or may not be a surprise to the dairy manager. For example, in this case the distractions of the Christmas holiday may have disrupted normal herd management. If this were the case, this may well explain the shift in BTSCC level. The control chart then confirms the expectation about the BTSCC level. However, if no explanation can be given readily, investigating the probable causes of the shift in BTSCC is well worth the effort and cost. There are two basic questions regarding a breakdown in the process:

- Is this a personnel management issue? (e.g., protocols not being followed)
- Is there some flaw in the process itself? (e.g., breakdown in equipment or an inadequate protocol)

For example, maybe the new employee does not do a good job scraping the stalls, or the replacement bedding material is contaminated. Control charts provide a means for early detection of "real" changes, providing the opportunity to nip the problem in the bud. In this particular case there was no action taken. As can be seen, the consequences resulted in further process entropy and obvious deterioration of those processes contributing to BTSCC level.

Control charts also offer a means to evaluate efforts toward continuous process improvement. Fig. 3-17 is a control chart of a large Wisconsin dairy that has kept its herd bulk tank count less than 200,000 for 20 years. During the period between January 1, 1999, through mid-February, the BTSCC was averaging 140,000 and was "in control." However, the herd manager felt that the herd BTSCC should be 100,000 or less, as had been the case during previous years. During the March 21, 1999, meeting with the milking parlor staff, a consensus was reached:

- That more attention be placed on premilking teat end sanitation
- That cows with extremely high SCC quarters be identified with a leg band so that the high SCC quarters could be milked into a quarter bucket

The plan was implemented immediately. Did the program work? Study of Fig. 3-17 clearly indicates a dramatic and significant decline in herd BTSCC. Wheeler's second test indicated that by March 26 the herd manager knew with 95% certainty that the plan was working and could use the chart as positive feedback to the parlor crew to reinforce their dedicated effort.

Control charts are not intended for retrospective use. The whole philosophy of SPC is geared toward proactive, continuous improvement. However, Fig. 3-18 is a control chart plot showing severe butterfat depression, which was plotted retrospectively. A similar plot of the milk protein over the same period as well as study of individual cow DHI test day data indicated a profound fat-protein inversion. University extension specialists had been asked to help this herd recover from an episode of severe butterfat depression and rumen acidosis. The control chart was used to help pinpoint the time when the problem began and validate the triggering cause. Had this herd manager or the herd nutritionist been more vigilant, and had they been using a control chart to monitor bulk tank milk components, the whole unfortunate episode might have been avoided. New corn silage was introduced to the herd on September 13, 1998, without appropriate adjustments in the diet. Note that by September 17, 1998, the cows were sending a clear signal that something significant in the diet had changed. A timely correction could have avoided the serious harm and economic losses caused by this unfortunate incident.

Control charts are commonplace in the manufacturing and service industries. They have great potential for improved decision making in livestock management. Monitoring BTSCC with a Shewhart control chart is a good example of a valid application. Plotting of frequently collected individual data in a control chart (i.e., daily feed intakes, daily milk weights, milk components including milk-urea nitrogen) is the simplest of SPC techniques. Pigs weaned per breeding female, percent mortality, piglets born dead, and average daily gain are examples of data from production groups (cohorts), which in large operations are started on a

Downloaded From Vet-e-Books.com

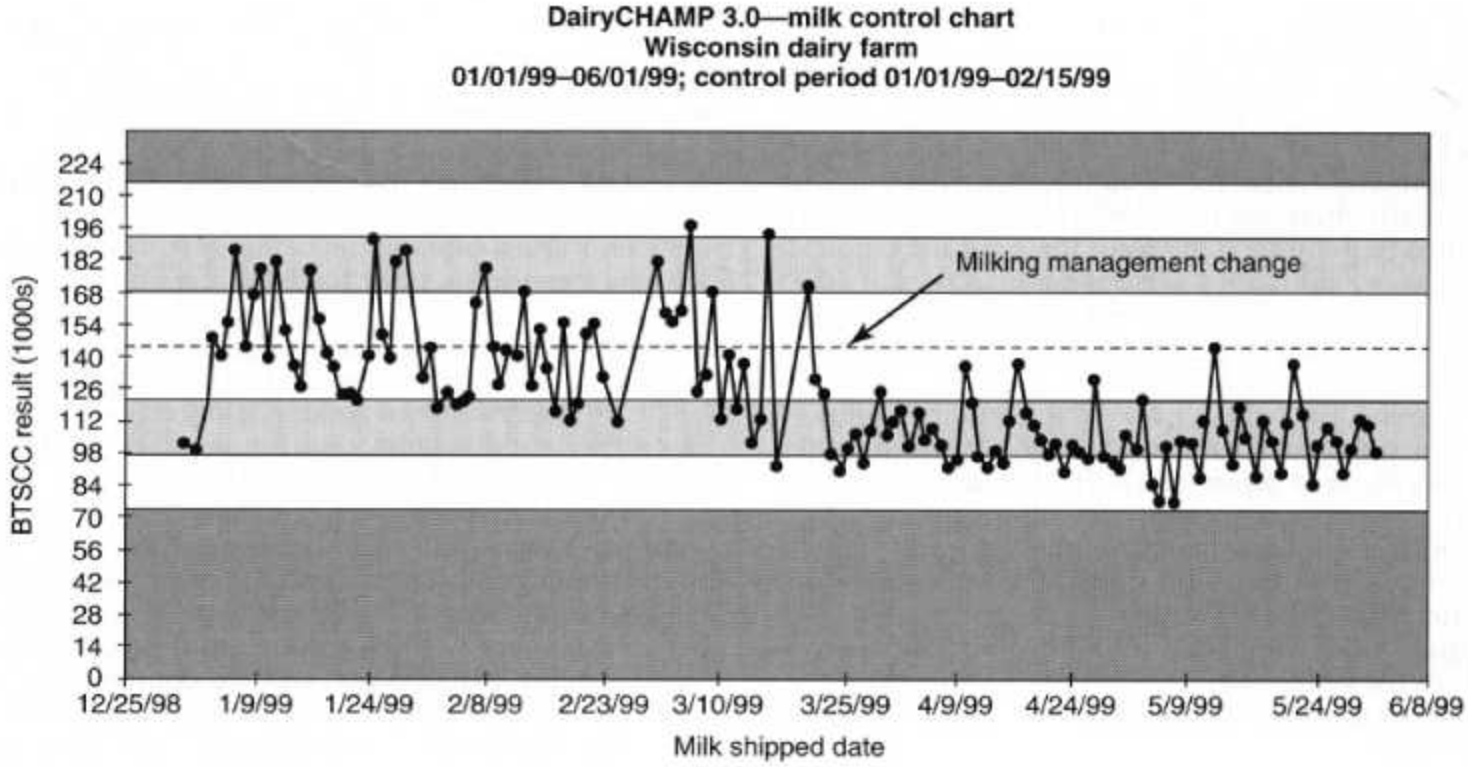

FIG. 3-17 Shewhart control chart of daily bulk tank somatic cell count (BTSCC) on a Wisconsin 700-cow dairy. Control chart use allowed the herd manager to know with certainty on March 26, 1999, that the changes in parlor management implemented March 22, 1999, were working.

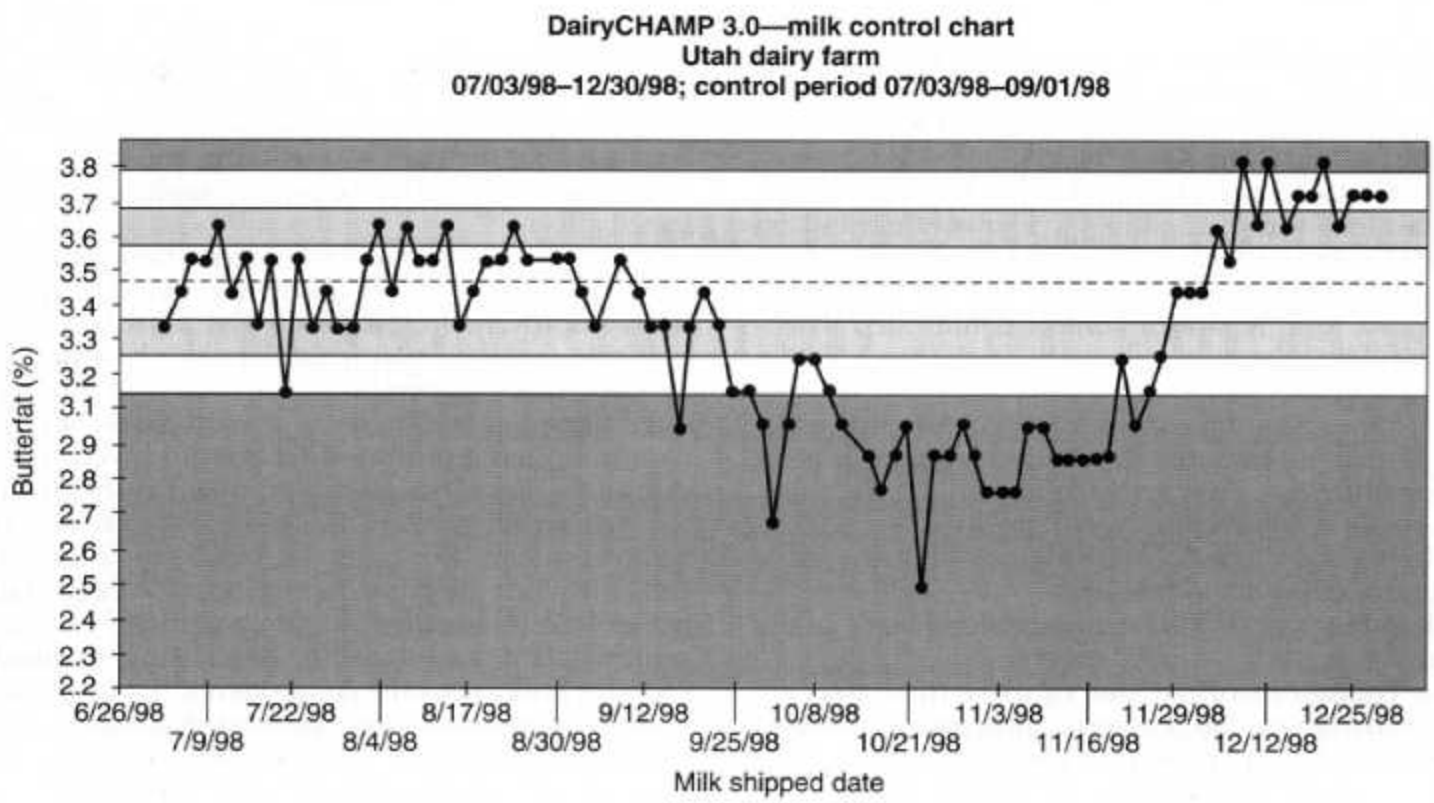

FIG. 3-18 Shewhart control chart of daily bulk tank butterfat percent in a herd with severe butterfat depression. The earliest signal that things were "out of control" appeared within a few days after the ration change, which precipitated the rumen acidosis.

frequent enough basis for possible use of SPC techniques. There is still much research work to be done in confirming which variables are appropriate for SPC applications. Generally data suitable for SPC application are the following:

- Data that are easy and practical to collect
- Data collected on a frequent basis (daily, weekly) are preferable
- Data of economic significance
- Data that, as directly as possible, reflect process behavior

Besides monitoring the mean of a process, the range of the data points can also be monitored. When individual raw data are averaged into subgroups of data (e.g., weekly BTSCC averages, piglets born dead, pigs weaned per cohort of breeding females), it would be necessary to monitor both

Downloaded from Vet-eBooks.com

the mean and the range to adequately detect "signals" caused by special cause variation. These methods can be extended and refined to a greater degree; for example, the sensitive CUSUM can be used to detect small shifts in the process mean. A CUSUM is a cumulative sum of deviations from a prediction or target. At present more study is needed to determine the appropriateness of applying all of the SPC techniques in monitoring livestock production systems.

Although SPC and the use of control charts are useful monitoring tools, there are pitfalls. The greatest pitfall is initiating SPC techniques without the right mindset. If these techniques are attempted where management is not willing to embrace the philosophy of continuous improvement, they will inevitably fail to produce anticipated results. Another pitfall is improper calculations of control limits, which as was previously mentioned results in too many false signals. However, these techniques are robust and when used appropriately are effective herd monitors. It is expected that SPC will play a major role in livestock monitoring in the future.

Cohort-Based Analysis

The term "cohort" comes from the Roman word for "group"; cohort-based analysis is record analysis based on common groups. These cohorts may be groups based on location, production, or, most commonly, stage of lactation. The advantage of cohort-based analysis is that animals are already managed in groups such that deficiencies identified for any specific group represent a common problem at a common time; this problem may be directly addressed through a management change. A good place to show the differences between conventional and cohort-based analysis is to consider reproductive performance. A conventional method of evaluating reproductive performance is to consider the whole herd at a given point in time. For example, on a monthly interval, a DHIA herd summary may be generated that provides the herd's average days open, conception rate, heat detection rate, days to first service, etc. The difficulty with this approach is that these parameters represent different groups of animals in different stages of production. Average days open and conception rate are calculated for animals that are assumed to be pregnant, while heat detection rate and days to first service are calculated for animals that are eligible to be bred. Thus veterinarians are evaluating reproductive performance for two groups of different timeframes. In cohort-based analysis, we would evaluate these reproductive parameters for each cohort. For example, average days open, conception rate, and so on would be calculated for cows that had calved in the month of May. Any deficiencies identified would correspond to a specific timeframe and would be much more likely to indicate a potential management problem.

Survival Analysis

Survival analysis is a family of recently developed statistical techniques used to investigate the occurrence of events over time. Originally developed to look at mortality patterns in humans (hence the name "survival analysis"), all survival analysis techniques are based on the concept that the analyst is more interested in the length of time until an event occurs rather than the fact that the event occurs. For example, we know that eventually we will die; what is important is knowing when. Thus survival analysis can be used in any situation in which an initial status (e.g., alive) and a change in status (e.g., death) can be identified at some point later.

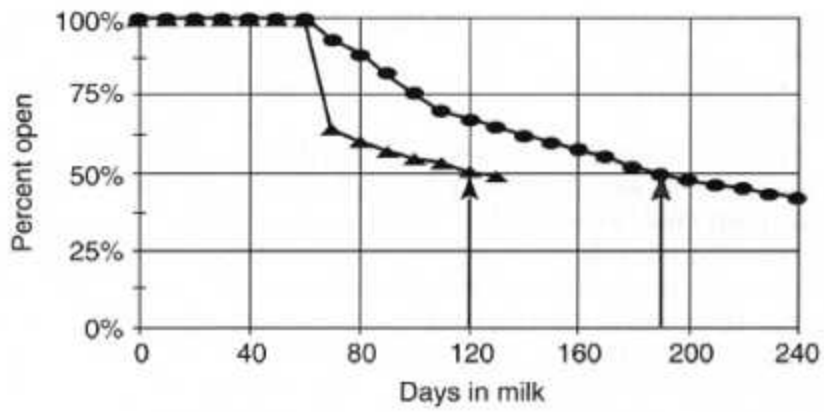

FIG. 3-19 Kaplan-Meier survival curve for days open for two reproductive management programs.

The ability to evaluate the length of time until an event occurs is well suited to livestock evaluation. There are numerous discrete events that may serve as initiating points in time, such as parturition, entry into a herd, diagnosis of a disease, and treatment with a product, to allow practitioners to evaluate the time interval until they change status by having a second event. Examples of intervals of interest are the intervals from parturition to conception, from disease diagnosis until removal, or from herd entry until disease diagnosis.

The main advantage of survival analysis over traditional methods of evaluation is the ability to evaluate data from animals that are "lost to follow-up." Loss of follow-up occurs when information regarding the timing of the second event in the interval of interest is not available. For example, if the veterinarian is interested in the length of time between calving and conception ("days open"), what value should he or she assign for a cow that is culled before being declared pregnant or for cows that have not been pregnancy examined yet? Conventional solutions to this problem are to exclude these cows from the average "days open" calculation or to assign some common value for cows leaving the herd. The approach used in survival analysis is to reason that even though the practitioner does not know when the second event occurred, he or she at least knows it did not occur before the point of the cow's being lost to follow-up. For example, the practitioner knows that the cow that was culled before being declared pregnant was open at least up to the point of the last breeding. Thus every cow eligible to be bred is included in the calculation, giving a more accurate (unbiased) and precise representation of what is happening in the herd.

The simplest type of survival analysis is the Kaplan-Meier survival curve. Fig. 3-19 shows actual Kaplan-Meier survival curves of calving to conception interval for a dairy herd before and after a new reproductive management program is adopted. Data required to generate this figure were calving date and conception date (if they existed) for each animal. Data then were summarized into calving to conception intervals, and the proportion remaining open at each 10-day interval was plotted.

Several advantages of survival analysis can be noted from Fig. 3-19. First, notice that the graph may be ended at any stage in time (e.g., 240 days in milk). For the period of time before the management change, 41.9% of animals had not been declared pregnant by 240 days in milk. This fact leads to the second advantage of survival analysis over calculating a simple average: it is not important whether animals open more than 240 days are lost to follow-up or had a long calving to conception interval (were an outlier). The survival curve is the same. When the average is calculated, especially

Downloaded From Vet-e-Books.com

in operations with small herd size, these animals pose a significant problem because an outlier may greatly influence the calculated average leading to a biased estimate of performance.

The arrows in Fig. 3-19 indicate the median days open (the point at which 50% of animals evaluated have become pregnant) for before and after the management change. This demonstrates a third advantage of survival analysis: the ability to calculate median values (or other proportions) directly from the figure. In this example, median days open has changed from approximately 190 days to approximately 120 days. Based on published (U.S.) costs associated with additional days open of $3.50 cow/day (Plaizier et al, 1997), the management change can be estimated as leading to a savings of $245/cow/lactation.

A fourth benefit of survival analysis, as shown by the current example, is that veterinarians can evaluate improvements in performance almost immediately. Notice that for the "after management change" group, data were only available up to 130 days in milk. With conventional methods, the veterinarian could not compare the "before" and "after" group until the "after" group had completed the lactation. However, with survival analysis, the veterinarian can see already that reproductive performance has improved, since the proportion of cows that are pregnant is higher (the proportion of cows open is lower) at any given day in milk. This leads to an important reproductive management concept that although reproductive performance is essentially equal (same slope) after 110 days in milk, improvements early in lactation have the largest effect on reproductive performance, since they reduce the pool of animals requiring additional breedings.

Use of Kaplan-Meier survival curves is a powerful tool that is being incorporated currently into livestock record systems. This technique has the advantages of the following:

- Using data from all animals so that more accurate and precise assessment of performance can be made
- Allowing calculation of various proportions, including median values, that can be made directly from the curve
- Allowing before-and-after comparisons to be made easily within a short timeframe
- Avoiding biased results, since the survival curves are less sensitive to outliers or lost to follow-up

Other more sophisticated analytic methods based on survival analysis concepts, such as Cox regression, exist; however, these methods are beyond the scope of this textbook.

Computer Models in Livestock Management

Why Develop Models? The use of computer models in livestock management is an extension of the record system. Models provide a means of asking the "what if" questions regarding contemplated management choices in the context of current herd performance. Therefore the principal reason for developing models is to assist in making decisions. Although there are many different potential applications for modeling, most models are used for one of three purposes. The first and most common purpose is to predict or compare the effects of manipulating system components. In this situation, veterinarians may want to predict the impact of a change on future performance of the system (termed "simulation") or may try to decide the best option from a list of possible changes (termed "optimization"). Simulation models can also be extended to allow comparison of the relative merit of a number of choices. The second purpose of models is to allow investigation of the interrelationship of complex systems, such as studying the economics of different reproductive management strategies for dairy herds using growth hormone. The latter purpose of models may not be clear at first. During the model building process, the modeler must define the system and how system components are believed to be related. Often in being forced to consider the model framework, the investigator identifies a piece of information that is poorly understood and has dramatic impact on the predicted outcome of the model. This is extremely useful in determining factors that need to be researched further and information that is vital to making an accurate decision.

Although models share many functions with experimental methods, there are several situations in which experiments cannot be performed and models are indicated. First, many systems, especially those that are biological, are extremely complex, and the interaction of the system components can influence greatly the behavior of the overall system (i.e., the outcome is greater than the sum of the parts). In this situation, experimental methods are not valid. Models that allow simultaneous consideration of all inputs must be used. Second, the enormity of manually evaluating all the possible combinations of factors is not feasible or economical in an experimental setting, so that modeling becomes the most practical option. Third, if the amount of time required to complete an experimental study exceeds the decision timeframe, models, which by nature compress the passage of time, are required. Finally, models allow the investigation of the effects of alternatives or situations that only potentially exist. This is extremely useful for evaluating the potential benefits of proposed interventions or the amount of money that would be logical to invest in developing a technology with a given effect.

Overview of Modeling Process. Fig. 3-20 shows the steps that are common to all types of models. This cyclical nature of modeling leads to an important concept: modeling is a dynamic process in that models are almost always refined with time.

Even though the model building process is basically the same for all models, several different model types exist based on function and approaches to handling variation. The first major classification scheme is based on the desired

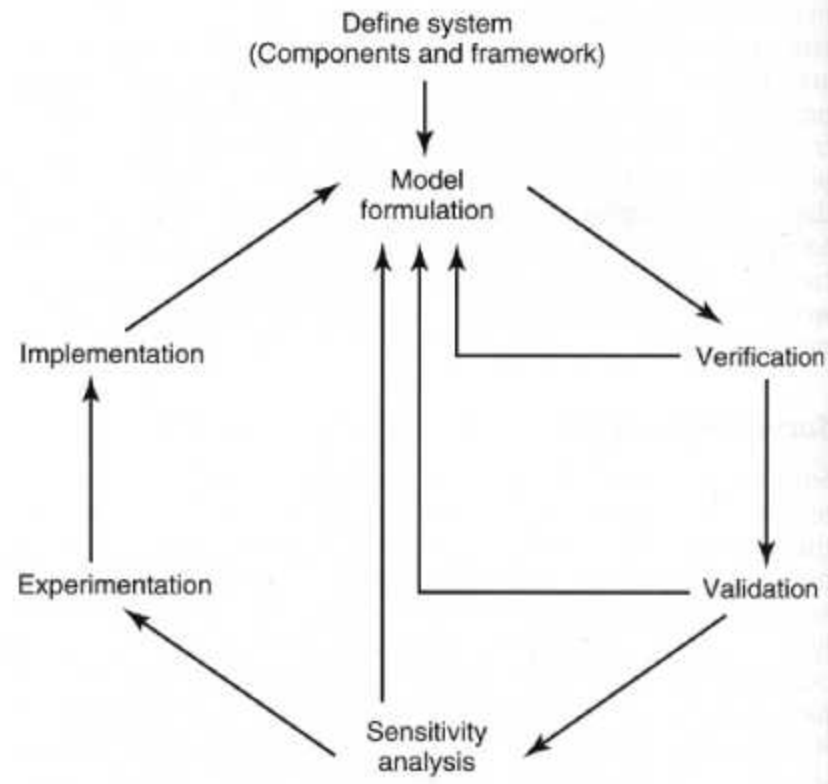

FIG. 3-20 Steps in model development. (Adapted from Martin SW, Meek AH, Willberg P: *Veterinary epidemiology*, Ames, Iowa, 1987, Iowa State University Press.)

Downloaded from Vet-eBooks.com

outcome of the model and is divided into optimization models and simulation models. As mentioned earlier, optimization models are models that determine the optimal or "best choice" solution for a given set of conditions. Examples of this kind of model would be linear programming used for ration balancing. Simulation models are sometimes called "what-if" models and determine the future effects of a given alternative. These models are most commonly run multiple times with different options to allow the comparison of several different strategies.

The second major classification scheme is the model's approach to handling biological variation. Basically two types of approaches may be used: a deterministic approach or a stochastic approach. Deterministic models are models in which no element of chance exists in the model calculations such that the results of the model are the same each time it is run. The outcomes in these models represent the "typical" or average response of the system and give no indication of the range of possible outcomes. Stochastic models contain elements of chance (usually the outcome is determined from a range of probabilities) in their calculations such that the result of the model given the same set of conditions are not the same each time it is run. Thus multiple runs are required to generate the range of responses. The major advantage of stochastic models is that the results provide both an estimate of the typical response and a distribution of possible responses compared with just an average response provided in deterministic models. The major disadvantage of stochastic models is the added complexity and requirement of multiple runs.

The final classification system relates to the way the model handles variations in model parameters and relationships over time. Models in which the values stay constant over the entire timeframe of the model are said to be "static," whereas models in which values are allowed to change over time are said to be "dynamic."

Difficulties of modeling. The greatest difficulty in modeling is dealing with the uncertainty inherent in the inputs (that is, the values used to describe the relationships of model components). There are three important concepts associated with uncertainty in every model: model assumptions, bias, and precision. The concept of model assumptions is relatively intuitive and represents the fact that in order for a model to be useful, it has to be simple. Bias is a measure of how accurate an estimate is compared with the truth. Precision is how reliable the estimate is. An analogy that may be useful for understanding the concepts of precision and accuracy is shown in Fig. 3-21. As indicated by this figure, the goal is to construct a model that hits the center of the target as often as possible (highly accurate and highly precise). If the model is inaccurate but precise, a consistent but wrong result occurs. If the model is imprecise but accurate, the right answer may appear most of the time but not be consistent. The worst-case scenario is the inaccurate, imprecise model that is both inconsistent and off-target.

The effects of assumptions, precision, and bias are best described by a description of the modeler's trade-off: as models become more complex, they become more accurate, but they also require more expensive data and become more difficult to interpret. In other words, the simplicity of a model decreases as the accuracy increases. Therefore the goal of model building can be described as creating the simplest model for a given amount of accuracy. How much accuracy is required is based on the relative costs of making an inaccurate decision.

The most common method to increase precision is to increase the sample size by collecting more data. By having more information, practitioners can become more confident that the model estimates are representative of the truth. Methods to decrease bias (or increase accuracy or validity) are more complex, since there are numerous potential sources of bias, each requiring different control measures. Sources of bias for statistical analysis and model building are generally classified into five categories: confounding bias, information bias, selection bias, follow-up bias, and specification bias. The most significant source of bias in model construction is specification bias. This class of bias occurs because when an analytic technique is chosen to determine the relationship between two model components, the assumptions inherent with that type of analysis are automatically acquired. These assumptions often make the difference between finding a significant effect or not.

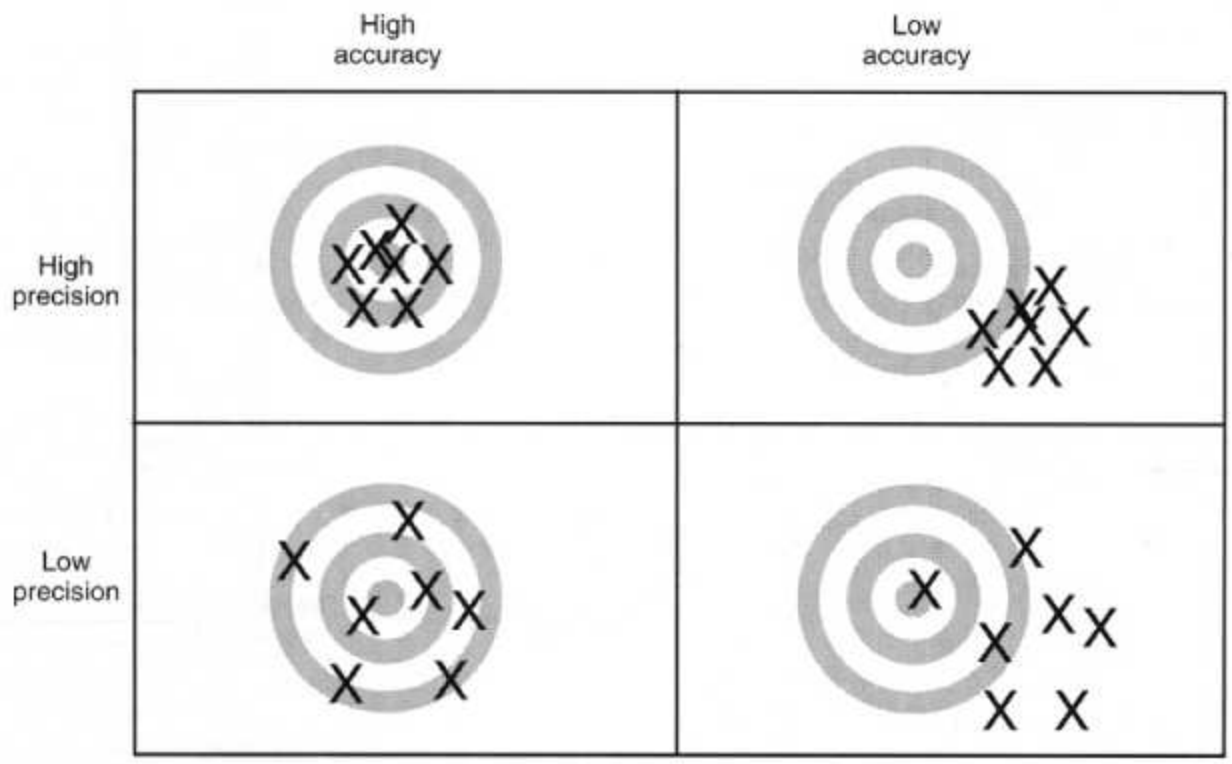

FIG. 3-21 Targets contrasting accuracy and precision.

Downloaded From Vet-eBooks.com

One of the most common questions regarding models is why model results differ, especially when the same data set is used as input in the analysis. These differences usually occur for three reasons: (1) models have different structural components or frameworks, (2) models may consider different input values or make different assumptions about inputs, and (3) models make different assumptions about the relationships of components.

Fig. 3-22 shows the schematic diagram for the DairyORACLE model developed at the University of Minnesota. DairyORACLE is a stochastic computer simulation model based on Monte Carlo methods designed for studying the impact of management interventions on dairy farms (Marsh, 1986; Kinsel, 1998). The Monte Carlo process is initiated by providing the model with a starting population of dairy cows of known characteristics. It is best to use the current performance measures of the herd in question. Users are then able to specify herd level performance, such as that shown in Fig. 3-23, and the occurrence and timing of subsequent events are determined by taking random observations from suitably defined probability distributions (Marsh, 1986). For example, a decision on whether a given animal becomes pregnant to a particular mating can be determined by taking random observations from the uniform distribution ranging from 0 to 1. If the user-defined conception rate is 40%, and the random number generated by the computer is greater than 0.40, the animal fails to conceive. If the random number is less than or equal to 0.40, the animal is deemed pregnant. The determination of the *timing* of a simulated event is more complex. The appropriate probability distribution selected for the timing of each event depends on the biological process being simulated (Marsh, 1986; Kinsel, 1998).

Fig. 3-24 shows a portion of the DairyORACLE projected herd performance summary from a 6-year run for a 176-cow dairy. User-defined inputs for this scenario were 60-day voluntary waiting period, 50% heat detection rate, 45% conception rate, 15% involuntary cull rate, 5% calf mortality rate, and a target milking herd size between 141 and 185 cows. Values listed in Fig. 3-24 indicate that for this scenario, excess heifer calves will be available to sell year 2 through 6 in the future, cull rates will range between 34.5% and 48.2%, and between 52 and 82 cows can be expected to be culled each year. Another example of a livestock decision model is DECI, developed for beef cattle by the Meat Animal Research Center in Clay Center, Nebraska.

Simulation models are decision aids that attempt to forecast future performance based on current performance and underlying conditions. They have different uses depending on the individual's perspective for using them. For the researcher, quality (complete and accurate) field data are difficult and expensive to obtain. Simulation models allow estimation of multiple effects and interactions of interventions from one data set that can be validated with field data. Therefore more research information can be obtained from a single data set. Research with financial models provides

Input Options

Accounting | Income Tax | Ration Makeup | Disease Incidence

Heifer Management | Herd Management | Culling Rules | Market Prices

Reproduction

Probability of a cow having a difficult calving (%)	5.0%
Proportion of calves born alive (%)	95.0%
DIM to begin serving all cows	50
DIM to cease serving a low to average producing cow	200
DIM to cease serving an above average producing cow	200
Probability of detecting a cow in heat (%)	50.0%
First service conception rate (%)	45.0%
Second or higher service conception rate (%)	45.0%
Probability of a cow aborting (%)	5.0%

Milk Production

Average 305 day M.E. milk yield for herd (1000 lbs)	18.0
Critical milk production for dry-off (lbs/cow/day)	35
Minimum desired length for the dry period (days)	56
Average body weight of cows in herd (lbs)	1400
Labor required per cow and replacement per year (hrs)	60.0

clues to what information and interventions are associated with financial success and suggests what information is necessary for successful decision making.

From the producer's and consultant's standpoint, simulation models allow rapid comparison of alternative interventions within the context of herd dynamics based on the herd's own records. This comparison does more than just suggest a best course of action; it also provides two very important pieces of information. First, these models provide an estimate of the response (or range of responses for stochastic models) for a given intervention. For example, adding a total mixed ration might be estimated to boost milk production 4%. Thus a herd that currently produces 20,000 lb RHA will now produce 20,800 lb, and this increased production can be weighed against the cost of implementing the program. Second, simulation models provide a framework for planning for changes in feed requirements, facility requirements, labor needs, and so on that will be necessary to implement the intervention. Sophisticated models project cow flows, feed requirements, labor requirements, and cash flows over the timeframe of implementation.

CHAPTER APPENDIX A

REPRODUCTION (Average days in milk [lactating cows ONLY])

Reproduction problems result in cows having extended lactations. The herd average days in milk is reflective of long-term reproductive status of the herd.

Because average days in milk is highly variable in seasonally calving herds, the average days in milk should itself be averaged over the previous 12-month period.

CHAPTER 4

Control of Infectious Diseases of Food-Producing Animals

OTTO M. RADOSTITS

"Most human beings, indeed probably all living things, carry throughout life, a variety of microbial agents potentially pathogenic for them. Under most conditions, these pathogens do not manifest their presence by either symptoms or lesions; only when something happens which upsets the equilibrium between host and parasite does infection evolve into disease. In other words, infection in many cases is the normal state; it is only disease which is abnormal."

Rene Dubos: *Biochemical determinants of microbial diseases,* Cambridge, Mass, 1954, Harvard University Press.

This chapter describes the principles of the control of infectious diseases in herds or flocks of food-producing animals. Examples to illustrate the principles employed in the control and eradication of infectious disease in herds are used, where appropriate. The details necessary for the control of the specific infectious diseases of cattle, swine, sheep, and goats are available from other sources (Radostits et al, 2000).

INFECTIOUS DISEASES OF FOOD-PRODUCING ANIMALS

There are many infectious diseases of food-producing animals, caused by bacteria, viruses, protozoa, rickettsia, helminth parasites, and arthropod parasites (Box 4-1). The list provides the reader with an appreciation of the many different diseases that affect cattle, sheep, goats, and swine. Some of these diseases are important zoonoses.

MAGNITUDE OF THE PROBLEM

The control of the infectious diseases of food-producing animals must be considered in any health management program. These diseases are important for several different but related reasons, as follows.

Loss of Productivity and Economic Losses

Infectious diseases commonly cause loss of productivity, may cause considerable pain, and can result in major economic losses. Obvious examples include pinkeye in cattle, footrot in sheep, pneumonia in feedlot cattle, and foot-and-mouth disease in cattle. Parasitic gastroenteritis in sheep flocks, respiratory disease in beef feedlots, and mastitis in dairy cattle are examples of diseases that cause major economic loss in those individual animal industries.

Some diseases have been effectively controlled by vaccination or eliminated by eradication schemes. The clostridial diseases, for example, can be effectively controlled using vaccines. Brucellosis and tuberculosis have been eradicated from some countries, and progress toward their eradication in other countries is being made. However, control of tuberculosis in New Zealand has been hampered over the past two decades by the presence of an important wildlife reservoir, the Australian brushtail possum *(Trichosurus vulpelca)* (O'Neil and Pharo, 1995). In the United Kingdom the control of bovine tuberculosis is a major problem because of the reservoir of *Mycobacterium bovis* in badgers (White et al, 1993). Many infectious diseases, such as transmissible gastroenteritis of pigs, porcine respiratory and reproductive syndrome, and *Actinobacillus* pleuropneumonia of pigs, are still common, are difficult to control, and cause large economic losses. The bovine virus diarrhea virus (BVDV) causes acute clinical disease, but subclinical infections in dairy herds may be a major cause of economic loss because of decreased milk production and more severe respiratory disease in calves (Moerman et al, 1994). Following the development of improved diagnostic and research techniques, BVDV has now been shown to be associated with significant reproductive loss in cattle (McGowan and Kirkland, 1995). Surveys in Sweden have found that dairy herds with an increasing prevalence of bovine virus diarrhea virus antibody–positive cows (cows not vaccinated for BVDV) had higher frequencies of mastitis and retained placenta. Calving intervals were longer and the use of estrus-stimulating treatments was higher in herds with an increasing or high prevalence of BVDV antibody–positive cows (Niskanen et al, 1995).

In general, infectious diseases of the respiratory and digestive tracts and the mammary system, the body systems lined by mucous membranes and exposed to the environment, are endemic on most livestock farms and account for a large portion of the veterinary activity involved in disease control.

The direct costs associated with 30 different endemic diseases of farm animals in Great Britain were estimated (Bennett et al, 1999). The diseases included 13 diseases affecting cattle: bovine viral diarrhea/mucosal disease, enteric disease in calves, fascioliasis, infectious bovine rhinotracheitis, infectious bovine keratoconjunctivitis, lameness, leptospirosis, mastitis, lungworm, Johne's disease, pasteurellosis, salmonellosis, and summer mastitis in dry cows. Five diseases affected pigs: atrophic rhinitis, enteric disease in piglets, *Streptococcus suis* type II meningitis, swine dysentery, and swine influenza. Seven diseases affected sheep: acute enzootic pneumonia, blowfly strike, enzootic abortion, maedi visna, contagious pustular dermatitis (orf), sheep pulmonary adenomatosis, and toxoplasmosis.

BOX 4-1

Infectious Diseases of Food-Producing Animals

DISEASES CAUSED BY BACTERIA
Mastitis
Neonatal streptococcal infection
Streptococcus suis infection of young pigs
Contagious bovine pyelonephritis
Cystitis and pyelonephritis of sows
Enzootic posthitis of ruminants
Caseous lymphadenitis of sheep and goats
Listeriosis
Erysipelas
Anthrax
Clostridial diseases
Colibacillosis of calves, piglets, lambs and kids
Escherichia coli infections in weaned pigs
Coliform gastroenteritis
Salmonellosis
Pasteurellosis
Brucellosis
Actinobacillus and *Haemophilus* pleuropneumonia of pigs
Tuberculosis
Johne's disease
Dermatophilosis
Necrobacillosis of the liver
Footrot of cattle
Digital dermatitis
Infectious foot rot of sheep
Footrot in pigs
Oral and laryngeal necrobacillosis
Porcine proliferative enteritis complex
Leptospirosis
Swine dysentery
Mycoplasmosis

DISEASES CAUSED BY VIRUSES, PROTOZOA, RICKETTSIAE, HELMINTHS, AND ARTHROPODS
Hog cholera
African swine fever
Postweaning multisystemic wasting syndrome of pigs
Enzootic bovine leukosis
Foot-and-mouth disease
Swine vesicular disease
Vesicular stomatitis
Vesicular exanthema of swine
Rinderpest
Malignant catarrhal fever
Bovine virus diarrhea
Transmissible gastroenteritis of swine
Viral diarrhea of calves, lambs, kids, piglets
Winter dysentery of cattle
Bluetongue
Porcine reproductive and respiratory syndrome
Swine influenza
Enzootic pneumonia of calves
Bovine respiratory syncytial virus pneumonia of cattle
Infectious bovine rhinotracheitis
Chronic enzootic pneumonia of sheep
Maedi of sheep
Jaagsiekte of sheep
Rabies
Pseudorabies
Caprine arthritis encephalitis of goats
Scrapie
Bovine spongiform encephalopathy
Border disease of sheep
Contagious ecthyma
Papillomatosis
Lumpy skin disease
Cowpox
Pseudocowpox
Bovine ulcerative mammillitis
Sheep-pox
Swinepox
Chlamydial abortion of ewes and cattle
Anaplasmosis
Eperythrozoonosis
Tick-borne fever
Heartwater or cowdriosis
"Q fever" of ruminants
Ringworm
Babesiosis
Coccidiosis
Sarcocystosis
Neosporosis
Cryptosporidiosis
Toxoplasmosis
East Coast fever
Tropical theileriosis
Trypanosomiasis
Diseases caused by helminth parasites
Diseases caused by arthropod parasites

The direct costs associated with a disease (C) are defined as the sum of the losses in expected output or resource wastage, or both, due to disease (L), the treatment costs incurred (T), and the costs associated with specific disease prevention (P) (that is, C = L + T + P). Details of the formula are available (Bennett et al, 1999). Simple spreadsheet models of each disease can be constructed, which can be used to estimate L, T, and P for the livestock population in Great Britain. These models can be used to estimate the direct costs associated with 30 different diseases in the country using a standardized approach and common valuation base that allows comparative assessments. The spreadsheet models and supporting documentation can be accessed from the following website: http://www.rdg.ac.uk/AcaDepts/ae/AEM/livestockdisea/.

Epidemics of Disease

Epidemics of infectious diseases in food-producing animals now represent a significant activity of veterinary practitioners and diagnostic laboratories. These epidemics may be associated with the intensification of livestock production, increased population density within herds, and a greater opportunity for the spread of infectious agents from infected to susceptible animals. Epidemics also may be due to the emergence of new strains of pathogens and to inadequate vaccination of cattle (e.g., the highly fatal form of bovine viral diarrhea that occurred in Ontario in 1993 to 1995 [Carman et al, 1998]). Epidemics of certain diseases may be difficult and expensive to diagnose, treat, and control and are a source of anxiety to the producer and the vet-

Downloaded From Vet-eBooks.com

erinarian. Even when a diagnosis can be made relatively easily, the clinical management of some diseases can be frustrating when affected animals do not respond to therapy and the mortality rate is high. Notable examples include outbreaks of peracute coliform mastitis in dairy cattle, *A. pleuropneumoniae* in swine, acute undifferentiated diarrhea of newborn calves, undifferentiated respiratory disease in feedlot cattle, and the porcine reproductive and respiratory syndrome. The difficulty of predicting the occurrence of disease also makes control uncertain.

Outbreaks of contagious animal diseases pose a major threat to livestock production. Outbreaks of diseases that are on List A of the Food and Agriculture Organization/Office International des Epizooties/World Health Organization (FAO/OIE/WHO) Animal Health Yearbook are especially feared because they are communicable diseases that have the potential for very serious and rapid spread, irrespective of national borders. (Diseases on List A include classic swine fever, African swine fever, foot-and-mouth disease, and swine vesicular disease.) These diseases are of serious socioeconomic or public health consequences and are of major importance in the international trade in livestock and livestock products (Horst et al, 1996).

In 1994 Belgium and Germany experienced serious outbreaks of classical swine fever (hog cholera). More than 7.4 million pigs were killed and destroyed, the total costs of which were estimated at almost 7.4 million ECU. However, these were only the direct costs (operational costs, market support, sanitary actions). Indirect costs, resulting from market disruption because of export restrictions, are often much higher and account for the major part of the total economic losses because of outbreaks of hog cholera and other List A diseases. Because of the great economic impact of outbreaks, adequate disease prevention and eradication are of major importance. Extensive research has been done on contagious animal diseases, but an integrated model that combines the various aspects of outbreaks and risks with economic consequences is still missing. An outline for an integrated modelling approach concerning risks and economic consequences has been proposed (Horst et al, 1996).

The recognition of bovine spongiform encephalopathy in England in 1985 and the subsequent public health concerns is an example of the enormous economic loss associated with a disease of cattle (Taylor, 1996). The disease is not of major economic significance to individual herds because of the low within-herd incidence. However, the national cost associated with detection and control procedures and the cost of compensation and disposal of affected animals and the loss of export markets was very high (Wells and Wilesmith, 1995). The occurrence of this disease has also resulted in a public questioning of the safety of cattle products as human food and a shift in the dietary habits of concerned people. This has caused a significant fall in beef consumption and beef prices. In response to market forces, Great Britain instituted a compulsory slaughter of at-risk but healthy cattle, with significant economic and social costs. The disease generated an extraordinarily, probably unprecedented, large number of field investigations of clinical cases, extensive diagnostic laboratory work, neuropathological research activities in human and veterinary medicine, drafting and implementation of legislation to control the disease, destruction of large numbers of cattle as part of the control procedures, and banning of beef exports from the United Kingdom. The eradication program combined with the decline in beef consumption had serious economic effects on both the dairy and beef cattle industries. The economic costs for eradication, including the destruction of animals over 30 months of age, and compensation to the farmers were estimated to be between $2 and $3 billion.

Diagnosis

The specific etiological diagnosis of subclinical infection is a major problem for the control and clinical management of some diseases such as Johne's disease, leptospirosis, enzootic pneumonia of swine, scrapie, and animals persistently infected with the bovine virus diarrhea virus. The routine laboratory diagnostic tests are time consuming, laborious, and often expensive. Being able to identify infected animals that are carriers and shedders is a prerequisite to the elimination and eradication of infection from a herd. Sampling the necessary proportion of animals in a herd for laboratory diagnostic testing and interpreting the results correctly are important related aspects of making an accurate diagnosis (Hancock et al, 1988). (See Chapter 5.)

Biotechnology is being used to develop new veterinary diagnostic tests that are based on such techniques as hybridization with nucleic acid probes, polymerase chain reaction (PCR), restriction fragment length polymorphism , and nucleic acid sequencing (Jackwood, 1994). The development of PCR has revolutionized the field of molecular biology (Rodriguez, 1997). The acid-based technique enables the rapid and sensitive detection of specific microorganisms. The technique consists of the enzymatic synthesis of millions of copies of target DNA sequence. Using a thermostable DNA polymerase, and a succession of cycles that includes denaturation of the template DNA and hybridization of specific DNA primers to the template and extension of the primers, practitioners can generate multiple copies of the target region enzymatically. Thus PCR provides a method for obtaining large quantities of specific DNA sequences from small amounts of DNA. The technique is widely used in veterinary research but has not yet found applications in routine microbiological analysis of veterinary clinical samples. PCR will most likely become the standard diagnostic test in situations in which the concentration of the suspected pathogen in the tissues is low, differentiation between morphologically identical organisms is required, or the immune response to the infection is uninformative. Diagnosis of viral diseases should be a major target for PCR application because laboratory tests for identification of viruses are slow, expensive, or insensitive. Among animal viral diseases, the following are good candidates for early development: foot-and-mouth disease, rinderpest, bluetongue, bovine herpesvirus-1, porcine reproductive and respiratory syndrome, swine influenza, pseudorabies, bovine leukemia, and BVDV. PCR can be used for the detection of those pathogens when in vitro cultivation is difficult, time consuming, or unavailable. The bacterial species for which PCR tests have been developed include *Staphylococcus aureus* strains that cause mastitis, *Listeria monocytogenes, Bacillus anthracis, Clostridium botulinum, Clostridium perfringens,* enterotoxigenic *Escherichia coli, Salmonella* spp., *Yersinia enterocolitica, Helicobacter pylori, Brucella* spp., *M. bovis, Mycobacterium paratuberculosis, Dichelobacter nodosus, Leptospira* spp., *Borrelia burgdorferi, Mycoplasma mycoides* spp. *mycoides, Mycoplasma hyopneumoniae, Chlamydia psittaci,* and *Coxiella burnetii* (Rodriguez, 1997).

Principles of Control

Educating livestock producers about the importance of the various risk factors associated with infectious diseases and the strategies for control is a challenging responsibility for the veterinarian (Williamson et al, 1988). Many infectious diseases could be controlled effectively and economically if livestock producers adopted the management procedures that are effective and readily available. Producers adopt certain control procedures more readily if they understand

Downloaded From Vet-e-Books.com

the reasons for the procedure. For example, many dairy producers do not fully understand the principles of mastitis control. Thus the *elimination of existing infections* and the *prevention of new infections* do not occur because dry cow therapy and postmilking teat dipping are not implemented to apply those principles. When dairy producers do appreciate those principles, the adoption rate of the control procedures increases significantly.

The control of some infectious diseases of food-producing animals can be unreliable because of the questionable efficacy of the vaccines available. Most vaccines are evaluated in animals that are vaccinated and then challenged with the infectious agent(s) under experimental conditions. Until recently, most vaccines were not evaluated in well-designed field trials against naturally occurring disease under commercial farm conditions with emphasis on cost effectiveness. This is discussed in general terms later in this chapter and more specifically in other chapters that discuss particular vaccines.

Use of Antimicrobials in Food Producing Animal Production

In modern food-producing animal production, animals are kept in groups of varying sizes so that the individuals share a common air and ground space, in close contact with one another and exposed to feces and urine, allowing the spread of microbial agents to occur easily. Antimicrobial agents are used in food animals for therapy and prophylaxis of bacterial infections and in feed to promote growth. The use of antimicrobials in food animals may cause problems in the therapy of infections by selecting in resistance among bacterial pathogens in animals that then may be transferred to humans (Aarestrup, 1999). Because of the public health concerns regarding the use of antimicrobials in food animals, the following is a brief summary of the salient features of the subject.

Under intensive systems of food animal production, it is rational to provide medication when necessary to the entire group whether the size is 20 or 20,000 because the source and occurrence of infection would be the same. In fact, the use of subtherapeutic levels of antimicrobials is one of the methods of health and production management that has allowed confinement housing and large numbers of animals to be maintained in production facilities of a given size. This has contributed significantly to the lower costs of production and ultimately to the lower cost to the consumer for meat, milk, and eggs.

About 40% of the antimicrobials produced in the United States are used in animal feed, but exact figures are unavailable. This represents 55% to 60% of the total production of penicillin G and tetracyclines, with 50% of the total animal feed medication being tetracyclines. In the United States this may represent up to 8500 tons, a large amount in terms of the microgram antibacterial potency of these chemicals (Table 4-1). However, on an individual animal basis, the amounts are small. Moreover, contrary to popular misconception, agricultural use of antimicrobials is extensively regulated. Under the food and drug legislation in both Canada and the United States, there are three uses of antimicrobials in agriculture: as *feed antimicrobials*, as *over-the-counter (OTC) drugs*, and as *veterinary prescription drugs* (Prescott, 1997).

The amounts of antibiotics used in livestock production in the United States are summarized in Table 4-1, and the amounts of antimicrobial agents prescribed to people in Canada in 1996 are shown in Table 4-2 (Prescott, 1997).

Antimicrobials Used in Beef Cattle Health Management and Production

Antimicrobials are used in beef cattle health management and production in North America for the treatment of clinical disease in cattle of any age, for prophylaxis of certain diseases, and for growth promotion of young growing animals, usually feedlot animals. The successive stages of the production life cycle in cattle include the nursing calf from birth to weaning at 6 to 8 months of age, the weaned beef calf, the growing yearling on pasture, the feedlot animal fed high-energy rations for 6 to 12 months, breeding females, and bulls of various ages.

Treatment. The therapeutic use of antimicrobials occurs after a diagnosis of a disease is made and treatment is governed by label instruction.

Cattle of all ages from the young calf to the mature cow may require treatment with antimicrobials for clinical disease caused by bacteria. The most common diseases are caused by bacterial infections of the respiratory and alimentary tracts, the mammary gland, and the reproductive tract.

Oxytetracycline, florfenicol, tilmicosin, and trimethoprim-sulfonamides are used parenterally for the treatment of acute undifferentiated respiratory tract disease of feedlot cattle (Harland et al, 1991; Guichon et al, 1993; Hoar et al, 1998). It is noteworthy that, in spite of the intensive use of the com-

TABLE 4-1

mon antimicrobials for more than 30 years, *Mannheimia haemolytica (Pasteurella haemolytica)*, a primary cause of fibrinous pneumonia in cattle, has not developed significant antimicrobial resistance.

Medication of High Risk Groups of Individual Animals (Metaphylaxis) for Respiratory Disease. Feedlot animals at high risk of acute undifferentiated bovine respiratory disease, most of which is bacterial pneumonia, are administered antimicrobials at therapeutic doses on arrival at the feedlot to reduce morbidity and mortality (Harland et al, 1991). Long-acting oxytetracycline (20 mg/kg BW) and tilmicosin (10 mg/kg BW) are the parenteral antimicrobials currently used (Morck et al, 1993). It is estimated that 10% to 20% of feedlot animals receive prophylactic-metaphylactic tilmicosin and 20% to 40% of feedlot animals receive prophylactic-metaphylactic long-acting oxytetracycline. When oxytetracycline is used, it is sometimes used with a "follow-up" injection 3 days later.

Florfenicol is also used for the treatment of acute bovine respiratory disease and is considered superior to tilmicosin when feedlot calves have previously received tilmicosin prophylaxis on arrival (Jim et al, 1999).

Subtherapeutic Medication of Feed. The subtherapeutic dose of an antimicrobial is defined in the United States as the use of the drug at less than 200 g per ton of feed. Antimicrobials used at these levels are intended to control certain infectious diseases and are provided most commonly in the feed and occasionally in the water supply. Some of the common disease complexes controlled with subtherapeutic medication of the feed of feedlot cattle are outlined here.

Respiratory Disease (shipping fever pneumonia). It is common practice to feed chlortetracycline (350 mg/head/day) and sulfamethazine (350 mg/head/day) (Aureo S-700 G) to high-risk feedlot animals during the first part of the feeding period (typically 50 to 60 days) because of significant reductions in the *Haemophilus somnus* disease complex–associated mortality under commercial field trial conditions. Aureo S-700 G is licensed for the first 4 weeks of the feeding period "as an aid in the maintenance of weight gains and feed efficiency in cattle during periods of stress, due to weaning, shipping or handling" (Gallo and Berg, 1995). It is estimated that 20% to 30% of feedlot animals receive this type of program.

The inclusion of a feed additive containing 350 mg chlortetracyline and 350 mg sulfamethazine each per head per day in the feed of feedlot cattle from arrival in the feedlot to day 56 of the feeding period significantly improved average daily gain and reduced the incidence rate of respiratory disease, the rate of relapses, and the rate of chronic respiratory disease (Gallo and Berg, 1995). Performance and health improvements from using the feed additive were cost effective.

Coccidiosis. Decoquinate in the feed is occasionally used to prevent coccidiosis in feedlot cattle.

Foot Rot. Oxytetracycline or chlortetracycline in the feed is occasionally used to provide mass medication to control outbreaks of footrot (1 g/head/day).

Liver Abscesses. Liver abscesses in beef cattle are the result of high-level grain-feeding programs (Nagaraja and Chengappa, 1998). The incidence, averaging from 12% to 32% in most feedlots, is influenced by several dietary and management factors. Liver abscesses represent a major economic liability to producers, packers, and ultimately consumers. Economic losses are due to reduced feed intake, reduced weight gain, decreased feed efficiency, and decreased carcass yield. *Fusobacterium necrophorum*, a member of the ruminal anaerobic bacterial flora, is the primary etiological agent. Ruminal lesions resulting from acidosis are generally accepted as the predisposing lesions for liver abscesses. Certain virulence factors of the organism permit its penetration and colonization of the ruminal wall and subsequent entry and establishment of infection in the liver. Control of liver abscesses in feedlot cattle on high-level grain feeding has depended on the use of antimicrobials. Five antimicrobials—bacitracin methylene disalicylate, chlortetracycline, oxytetracycline, tylosin, and virginiamycin—are approved for prevention of liver abscesses in feedlot cattle. Tylosin is the most effective and the most commonly used feed additive and reduces liver abscesses by 40% to 70%.

Virtually all feedlot animals receive antimicrobials to reduce the incidence of liver abscesses. In most situations they are fed for the entire feeding period. However, if they are used to control bovine respiratory disease or undifferentiated fever or the *H. somnus* disease complex for a portion of the feeding period, then the antimicrobial for liver abscess reduction is often excluded from the ration. It should be noted that although a reduction in the incidence of liver abscesses is the licensed claim for these products, the inclusion of these products results in significant improvements in average daily gain or feed efficiency. It is currently not known whether or not the observed improvements in average daily gain or feed efficiency are a direct result of antimicrobial usage, an indirect result of the reduced incidence of liver abscesses, or a combination of both. The antimicrobials used include tylosin, oxytetracycline, and chlortetracycline. Of these antimicrobials, tylosin is the only compound licensed to reduce the incidence of liver abscesses. However, a series of commercial feedlot studies have demonstrated that both oxytetracycline and chlortetracycline are effective at reducing the incidence of liver abscesses, and both are licensed in the United States for this claim. Oxytetracycline and chlortetracycline are also licensed to improve average daily gain and feed efficiency in the United States. In Canada, tylosin (11 ppm) is the most commonly used antimicrobial to reduce the incidence of liver abscesses (estimate is 40% to 60% of feedlot animals) and tylosin is cocleared with monensin at 33 ppm. Oxytetracycline (11 ppm) is the next most commonly used antimicrobial to reduce the incidence of liver abscesses (estimate is 30% to 50% of feedlot animals). Chlortetracycline (11 ppm or 350 mg/head/day) is used occasionally to reduce the incidence of liver abscesses (our estimate is less than 5% of feedlot animals). Both oxytetracycline and chlortetracycline require veterinary prescription in Canada for this use and the combination with monensin.

Growth Promotant Antimicrobials in the Feed. Various antimicrobials used as feed additives and hormonal implants are approved in North America for use throughout the feeding period of feedlot cattle to enhance growth rate and feed efficiency. Antimicrobial feed supplements for growth promotion have been used extensively in almost every major livestock-producing country for the past 40 years. It is generally accepted that their use has contributed to lower animal production costs and ultimately to lower costs to the consumer for meat, milk, and eggs.

The antimicrobials used as growth promoters are grouped broadly into *ionophores* and *nonionophores*. Ionophores are compounds that beneficially modify ruminal fermentation activity. Monensin, lasalocid, laidlomycin, and salinomycin are the most commonly used. Monensin was the first ionophore approved in 1976 for increasing feed efficiency in feedlot cattle and in 1978 was approved for increasing rate of gain of pasture cattle. It was also shown later that monensin is effective in preventing coccidiosis. Generally, in grain-fed animals, ionophores depress feed intake, but body weight gain is increased or

Downloaded from Vet-eBooks.com

unaffected and feed efficiency (feed-gain) is improved. In pasture-fed cattle, ionophores do not reduce feed intake but body weight gain is increased, thus resulting in improved feed efficiency.

The effectiveness of ionophores in achieving increased efficiency of feed conversion and, under some conditions, in improving the rate of gain is attributed to alterations in ruminal fermentation. Ionophores are not used in human medicine and do not pose a risk to human health from the development of antimicrobial resistance in animal pathogens that may be transferred to humans.

All feedlot animals receive ionophores for the entire feeding period to control coccidiosis and to improve feed efficiency. The Canadian options include monensin, lasalocid, and salinomycin; however, the overwhelming majority (an estimate is 95% plus [Radostits, 1999]) of feedlot animals receive monensin. Monensin is generally fed at levels from 22 ppm to 33 ppm, with several postlicensing studies conducted under commercial feedlot conditions demonstrating that 25 ppm is significantly more cost effective than 33 ppm. However, including monensin at 25 ppm requires a veterinary prescription, since the product is licensed at 33 ppm for the entire feeding period or 11 ppm for 28 days followed by 33 ppm for the remainder of the feeding period to improve feed efficiency and at 22 ppm for the prevention of coccidiosis.

Nonionophore antimicrobials are the conventional antimicrobials used as feed supplements and include avoparcin, bacitracins, chlortetracycline, sulfonamides, flavomycin (bambermycin), neomycin, oxytetracycline, spiramycin, tylosin, and virginiamycin. These antimicrobials are a diverse group that differ in chemistry, primary antibacterial spectrum, mode of action of bacterial inhibition, molecular weight, and ability to be absorbed from the intestine. Those that are not absorbed from the intestine or poorly absorbed at the low dosage used are more acceptable as feed additives because of the absence of residues in milk and meat and because there is no need for a withdrawal period before slaughter.

Antimicrobials used in the feed decrease the amount of feed needed, increase the rate of weight gain, and improve feed efficiency. The growth promotion response in cattle is much more varied than in swine or poultry depending on the level of subclinical infection, level of management and nutrition, and environmental and managemental stressors such as recent shipping and mixing feedlot animals from many sources. Antimicrobials are used as feed additives for growth promotion in growing cattle at continuous low levels (2 to 50 g/ton of feed). Most studies indicate that chlortetracycline, oxytetracycline, and zinc bacitracin are the most effective nonionophore antimicrobials for improving the performance of beef cattle.

Chlortetracycline is used at 11 mg/kg of complete feed as an aid in stimulating growth rate and improving feed efficiency in calves. Oxytetracycline hydrochloride is used at 11 mg/kg of complete feed for growth promotion in calves.

The mechanism of action of antimicrobials in improving growth and enhancing feed efficiency is not fully understood. The most commonly accepted explanation is that the growth response is primarily due to actions on the microbial flora of the intestine. This is supported by the observation of a lack of improved growth under germ-free conditions. At least four general modes of action have been postulated to account for growth promotion by antimicrobials:

- Metabolic effect by directly influencing the rate or pattern of metabolic processes
- Nutrient sparing effect by altering the bacterial populations and conservation of nutrients
- Control of subclinical disease by suppressing bacteria causing clinical or subclinical infections
- Modification of ruminal fermentation by altering rumen population to improve fermentation efficiency

Most feed additive antimicrobials have their antibacterial activity against Gram-positive bacteria, but some Gram-negative bacteria are also susceptible. The tetracyclines are inhibitory to both Gram-positive and Gram-negative bacteria. It is important to note that antimicrobials have a beneficial effect on growth rate other than through their effect on enteric microflora.

Antimicrobial Use in Swine Herds

Antimicrobials are used extensively in newly weaned pigs, a critical time for infections in young animals, and to a lesser extent in growing and finishing pigs where their use may not be effective (Prescott, 1997). Raising pigs under intensified conditions has similarities to beef feedlots where large numbers of animals are fed under intensified conditions.

A 1991 mail survey of swine herds in Ontario, Canada, found that 86% of herds added antimicrobials to starter (weanling pig) rations, and only 29% added these drugs to finishing pig rations (Dunlop et al, 1998a). The most commonly used antimicrobials were tylosin, carbadox, and furazolidone in weanling pigs and tylosin, lincomycin, and tetracycline in finishing pig rations. Water medication of grower-finisher pigs was practiced on 25% of farms; 80% of farms had injected at least some grower-finisher pigs with antimicrobials in the 12 months preceding the survey. Approximately 20% of the producers added antimicrobials to finisher rations for growth promotion purposes only, while others used them for the treatment of disease, prevention, control, or a combination of both. Among those not using antimicrobials in finisher rations, 83% did not consider them necessary, and 37% were concerned about the potential for residues in marketed pigs.

Feed additive antimicrobials are those that livestock producers can order without a veterinary prescription through licensed feed mills for growth promotion (2 to 50 g/ton), for subtherapeutic use (200 g or less/ton of feed), or for disease treatment (over 200 g/ton of feed). Subtherapeutic use, the most contentious and the largest of the uses, encompasses prevention of specified diseases but includes growth promotion in the face of certain diseases. Most feed antimicrobials are used for this purpose, particularly in swine. Many of the feed antimicrobials are unique to agriculture (carbadox, flavomycin, monensin, salinomycin, virginiamycin). Other feed antimicrobials in common use in animals (bacitracin, lincomycin, sulfonamides, tetracyclines, tylosin) are not commonly used in human medicine. Only penicillin G, which is often used in swine feed in combination with sulfonamides and tetracyclines, is commonly used in human medicine.

Potential Drug Residues in Meat and Milk

In food-producing animal health management and production, antimicrobials are used for the treatment and prevention of infectious diseases and to enhance growth promotion. These uses of antimicrobials represent one of several important health management strategies that contribute to animal health and well being and to the economical production of wholesome meat and milk products. The control of animal disease also means control of certain infectious diseases that may be transmitted to humans. However, there are some potential human health hazards associated with antimicrobials used in food animals. Residues of drugs may occur in meat and milk and could enter the human food

Downloaded From Vet-eBooks.com

chain and increase the risk of ill health in persons who consume products from treated animals. Of greater current importance is the potential for the emergence of antimicrobial resistant enteric bacteria that could be transferred to humans, resulting in clinical disease that may be difficult to treat.

The use of antimicrobials for the treatment of infectious diseases in food-producing animals may result in drug residues in meat and milk if the withdrawal periods following use of the drugs are not observed. There is now much public health concern about residues in meat and milk. The human consumption of meat containing more than the tolerable levels of residues of antimicrobials could cause hypersensitivity reactions if the person is already sensitive to that particular antimicrobial because of previous exposure, usually through medication. Remarkably, however, since the introduction of antimicrobials some 40 years ago, on a worldwide basis there have been only a few reports of suspected cases of hypersensitivity reactions because of residues in meat. Direct human toxicity caused by the ingestion of meat containing more than the tolerable levels is unlikely because the levels are so low.

Quality assurance through residue screening has become an important health management activity for producers and veterinarians. Using the highly sensitive laboratory techniques now available, smaller and smaller amounts of residues can be detected. Consideration now must be given to tolerance levels that do not constitute a human health hazard. However, satisfying the consumer of the safety of tolerance levels is a major educational exercise. Residues are being found in cull dairy cows, veal calves, and market pigs, and the most frequently cited cause is failure to observe the withholding time for the drug. Several different antimicrobial agents, including neomycin, streptomycin, sulfamethazine, tetracycline, and gentamicin, were found in the tissues of bob veal calf tissues surveyed by the U.S. Department of Agriculture (USDA) Food Safety Inspection Service during the fiscal year 1988 (Wilson et al, 1991a,b,c).

The livestock producer is considered to be the person responsible in over 80% of the cases for which responsibility was determined. Poor production practices, associated primarily with inadequate medication records, contribute to the incidence of drug residues. The Milk and Dairy Beef Quality Assurance Program (MDBQAP), a 10-point Hazard Analysis Critical Control Points (HACCP) program, was intended to promote rational protocols directed at managing and reducing the use of antibiotics on the farm (Sischo et al, 1997). Certification in the program is not associated significantly with a reduced risk of having violative antibiotic residues in milk (Gibbons-Burgener et al, 1999). An on-farm risk assessment was done using the cooperation of dairy field representatives and 250 dairy producers to determine the risk for antibiotic residue violation. A lack of adequate treatment records was the highest risk factor for antibiotic residues, followed by deficiencies in understanding how to use antibiotics, and poor relationships between veterinarians and their clients (Sischo et al, 1997). When field representatives jointly used an interactive risk assessment tool with their producers, most producers responded by decreasing risk by approximately 19%. More farms kept written records or kept more complete records than previously. Thus field representatives were effective in their role as educators and as agents of change, promoting a reduction in the risk for antibiotic residues.

Although harmful residues are extremely rare, the problem is perceived by the public as a potential human health hazard. One newspaper report indicated that antimicrobial residues were found in 38% of milk samples tested from milk purchased off the shelf in Washington, DC. No documented, published evidence has been found of any adverse reaction in humans directly attributable to the presence of antimicrobial residues in meat.

Whether the drug to which the animals are exposed reaches the consumer depends on a number of factors, including the specific drug involved, its absorbability and pharmacokinetics, the interval from administration of the last dose of the drug until slaughtering, the tissue to be eaten, and the degree of cooking of the meat.

Antimicrobial residues in meat above the maximal tolerable levels occur extremely rarely and are usually the result of the slaughter of cattle that were treated therapeutically and not retained on the farm until expiry of the withdrawal period for the drug in question. The percentage of drug residue violations in beef in North America is extremely low and continues to decrease as producers become more knowledgeable about the judicious use of antimicrobials and their withdrawal period. *Feedlot owners want to produce wholesome meat free of harmful residues of any kind.* Statistically valid random sampling and testing of beef carcasses are done routinely in federally inspected abattoirs across Canada. In addition, carcasses with evidence of drug injection sites are tested as suspect and condemned if positive for antimicrobials. A follow-up investigation is conducted, and future shipments from the farm are examined specifically for violations.

There is no evidence that the subtherapeutic or prophylactic use of antimicrobials in the feed of beef cattle has resulted in residues in the tissues of treated animals. In large part this is due to the low levels of drug that are achieved in the tissues compared with the higher levels following therapeutic use of the drug. Adherence to the stated withdrawal periods allows for the elimination of the drug, and there is no public health hazard (National Research Council, 1999). In a 1991 to 1993 study performed by the Food Safety Inspection Service Residue Violation Information System of violative chemical residues in U.S. beef, most of the animals found to have violative residues were bob calves and culled cows. In bob calves neomycin was the most frequently identified violative chemical, followed by tetracycline, gentamicin, oxytetracycline, and penicillin. In culled cows penicillin was the most frequently identified violative chemical and was most frequently found in combination with other chemicals in cows with multiple violative residues (Gibbons et al, 1996). In a 1-year survey of beef cow-calf herds in Tennessee, the drugs most commonly used were anthelmintics and insecticides for the control of external and intestinal parasites (Kelch and New, 1993). Antimicrobials were seldom used for prophylaxis.

In summary, there is no evidence that the judicious therapeutic, prophylactic, or subtherapeutic use of antimicrobials in beef feedlot animals, the use of which includes strict adherence to the withdrawal times, constitutes a human health hazard associated with drug residues in tissues.

Antimicrobial Resistance

There is concern that the use of subtherapeutic levels of antimicrobials in the feed of farm animals can result in the development of antimicrobial-resistant enteric bacteria that are then transferred to humans, where they may cause disease that is consequently difficult to treat. The genetic material coding for antibiotic resistance is known as the R factor; this is usually carried on plasmids and can be transferred among strains of the same species of bacteria and also among different species. The major means whereby humans can be infected with organisms harboring these R factors is through meat and meat products, which are often contaminated with antibiotic-resistant enteric bacteria. R factors can be transferred to humans by direct transmission to their intestine,

Downloaded From Vet-eBooks.com

where it may colonize. However, most animal strains colonize only for short periods. The organism may also transfer the R factor to resident strains in the human intestine but not colonize. A third mechanism is indirect; the organism, after leaving the host animal, may transfer R factors to other organisms, such as another strain of *E. coli* 0157:H7 or *Salmonella* sp., which subsequently may colonize the human intestine. The possibility that this could occur on the surface of meat was examined, but it did not occur. However, the results of large-scale surveys in Europe and North America have indicated that the use of antibiotics in livestock farming during the past 20 years has not compromised public health.

When the prevalence of resistance in specific bacteria increased, the increase was usually associated with the introduction of a new antimicrobial drug in human or veterinary practice. A literature review indicated that there is no evidence that the subtherapeutic use of antimicrobials in livestock feeds is a human health hazard (Institute of Medicine, 1989). Although the biological possibility exists, neither drug residues nor the presence of bacteria resistant to antimicrobials has been documented as a problem.

Since 1993 a multiple antibiotic resistant strain of *Salmonella typhimurium* DT 104 has accounted for most cases of salmonellosis in cattle in the United Kingdom (Evans and Davies, 1996; Threlfall et al, 1998; Wall et al, 1995), the United States, (Besser et al, 1997), Australia (Mackie et al, 1996), and Canada (Poppe et al, 1998). Originally isolated in England in 1984 from a human specimen, *S. typhimurium* DT 104 remained rare until about 1990 when there was a rapid increase in isolation rates in humans and the first isolation in livestock. Cattle are thought to be the main reservoir of infection (Calvert et al, 1998). The herd-associated risk factors for disease caused by multiple-resistant *S. typhimurium* DT 104 in cattle herds in Great Britain have been examined (Evans, 1996). The epidemic strain is classified as R-type ACSSuT through being resistant to ampicillin, chloramphenicol, streptomycin, sulfonamides, and tetracycline. Some strains of *S. typhimurium* DT 104 have chromosomally integrated multiple drug resistance (Threlfall et al, 1994). Since 1994, the percentage of DT 104 with additional resistance to trimethoprim and reduced sensitivity to ciprofloxacin has increased. The emergence and dissemination of multiresistant DT 104 with reduced sensitivity to ciprofloxacin (a fluoroquinolone) have occurred since the licensing for veterinary use in the United Kingdom in 1993 of the related fluoroquinolone, enrofloxacin, which has subsequently been used for treatment and prophylaxis in both cattle and poultry in the United Kingdom (Frost et al, 1996; Threlfall et al, 1998). In contrast to the United Kingdom, while multiresistant strains of DT 104 have been isolated in the United States, none of the human or veterinary isolates of DT 104 have been resistant to fluoroquinolones (Besser et al, 1997; Glynn et al, 1998). Since chromosomal integration has been cited as a method whereby bacterial cells can retain antimicrobial resistance genes in the absence of selective pressure, it is unlikely that withdrawal of antimicrobials would have any significant effect on the current epidemic of DT 104 ACSSuT in cattle in Britain (Threlfall et al, 1994).

Nalidixic acid is a first generation quinolone antimicrobial now used to detect changes in susceptibility to other more modern fluoroquinolones such as enrofloxacin. In Great Britain nalidixic acid resistance in salmonellae was rare and sporadic until 1994, when increasing resistance in DT 104 isolates was noted in most of the livestock species except ducks and sheep. By 1995 there had been a rapid increase in the proportion of resistant *S. typhimurium* isolates from turkeys and a more gradual increase, largely as a result of increasing resistance in DT 104, in isolates from other species (Davies et al, 1999). In 1997, 72.7% of other *S. typhimurium* DT 104 isolates from turkeys were resistant to nalidixic acid compared with zero and 16.1% from chickens.

In the United States multidrug-resistant *S. typhimurium* DT 104 has been isolated from cattle, sheep, goats, pigs, wild birds, dogs, cats, mice, and horses. Serotyping, phage typing, and antibiograms must be performed to identify isolates as DT 104.

Compared with most other countries, antimicrobial resistance among *Salmonella enterica* isolated from Danish pig herds is uncommon (Baggesen and Aarestrup, 1998) and the number of multiresistant isolates is still small. The prevalence of multiple-resistant *S. typhimurium* DT in Danish pig herds is still low.

In Denmark the frequency of antimicrobial resistance and epidemiological relatedness among 473 isolates of *S. enterica* spp. *Enterica* serovar typhimurium from humans and veterinary sources has been examined (Seyfarth et al, 1997). The human strains were isolated from patients with diarrhea and the animal strains from clinical and subclinical infections in cattle, pigs, or poultry. All strains were tested against 22 antimicrobials used in both human and veterinary medicine with the tablet diffusion method. Strains were phaged typed and the plasmid content determined in all resistant strains. Ribotyping was performed on selected strains. Of 228 human isolates tested, 19.3% of the strains were resistant to one or more antimicrobials compared with 10.4% of strains from cattle, 11.1% of strains from pigs, and 9.2% of strains from poultry. Multiple resistance to at least four antimicrobials was found in 9.2% of the human strains, but in only two of the cattle isolates. The majority of the multiresistant strains in humans were from infections contracted outside Denmark, most often in southern Europe or southeast Asia. Resistance in human strains was most common against tetracycline (13%), ampicillin (12%), sulfonamide (12%), streptomycin (10%), and chloramphenicol (8%). The resistance pattern differed somewhat in animal isolates. Poultry strains usually were resistant only to ampicillin, whereas pig and cattle isolates were most often resistant to sulphonamides, tetracycline, and streptomycin. Typing of the strains found some animal strains and human strains were indistinguishable.

Antimicrobial use in swine production is associated with increased resistance to those antimicrobials among fecal *E. coli* 0157:H7of finisher pigs (Dunlop et al, 1998b). Antimicrobial treatment of groups of pigs was more important than individual medication in increasing the risk of resistance among *E. coli* 0157:H7, but there was little evidence that group treatment practices increased the risk of resistance to gentamicin, which was used only for individual animal therapy. Antimicrobial use in starter rations was associated with resistance to ampicillin, carbadox, nitrofurantoin, sulfisoxazole, and tetracycline. Antimicrobial use in grower-finisher rations was significantly associated with resistance to ampicillin, spectinomycin, sulfasoxole, and tetracycline. The results suggest that antimicrobial medication of rations of postweaning pigs selects for and maintains antimicrobial resistance among *E. coli* 0157:H7 of finisher pigs. Antimicrobial resistance was also common on farms that did not medicate rations of postweaning pigs; the results indicate that antimicrobial use does increase the risk of resistance to antimicrobials studied. It was concluded that reducing group medication with broad-spectrum antimicrobials of weanling and grower-finisher pigs might reduce the prevalence of resistant *E. coli* 0157:H7 in market pigs. Thus antimicrobials should be used only when necessary, and the swine industry should continue to invest in the maintenance of a healthy population of pigs in which the need to treat with antimicrobials is reduced.

Downloaded from Vet-e-Books.com

Information on the use of feed additives in swine herds was collected from 710 farms (Dewey et al, 1997). Of all the feeds, about 79% contained feed additives used in the labeled manner. For all classes of pigs, the prevalence of labeled feed additive use was greater than 75%. Penicillin was used according to its label most often, followed by apramycin, bacitracin, tetracyclines, lincomycin, and tylosin. Carbadox had the highest prevalence of off-label use. Of the 699 feeds that included feed additives in an off-label manner, about 57% included additives at greater than the recommended concentrations or were fed to an incorrect class of pig. About 56% of the feeds had off-label combinations of additives. Small farms were more likely to use rations with no feed additives than were intermediate or large farms. Of those farms using feed additives, the odds of a small farm using all feed additives in the labeled manner was 7.7 times that of an intermediate or large farm. After controlling for herd size, producers who used a veterinary consultant were 2.1 times more likely to use feeds with feed additives.

Zoonoses

Some infectious diseases of food-producing animals are zoonoses, and the veterinarian has a vital role in ensuring that these diseases are controlled in animal herds so that spread to the human population does not occur. Rabies is one of the world's most important zoonotic disease, killing an estimated 35,000 people annually mostly in China and India (Frost and Hamir, 1998). It is an economically significant disease in livestock in areas where vampire bats are common, such as in South and Central America and the Caribbean. Raccoons are known to be a long-standing reservior for the virus in the southeastern United States, and the more recent outbreaks, in the 1990s, in the mid-Atlantic and northeastern states are the result of the translocation of infected animals from the southeast (Smith, 1996).

Examples of zoonotic diseases from food producing animals include tuberculosis, Q fever, listeriosis, chlamydiosis, brucellosis, and cryptosporidiosis. In recent years, tuberculosis in red deer caused by *M. bovis* has become a disease of economical as well as public health importance to the deer farming industries of several countries, especially in Denmark, Sweden (Wahlström et al, 1998), New Zealand, and the United Kingdom (Clifton-Hadley and Wilesmith, 1991). Orf, or contagious pustular dermatitis, is a zoonotic skin disease of sheep and goats caused by a parapox virus. In a survey in England, 27% of those employed or living on a sheep farm reported having had orf, and the antibody serological profiles indicated a prevalence of 4% and an annual incidence of 2.8% (Paiba et al, 1999). The main risk factors associated with the infection were contact with sheep, the size of the flock, and contact with dogs. Ringworm is still a common occurrence in family members exposed to cattle with the disease. Protection of the consumer from zoonoses transmitted through animal products depends on the efforts of veterinarians to provide advice for the control of disease on the farm and to increase the emphasis on meat inspection in abattoirs. In some cases eradication of the disease from the herd is necessary to prevent spread to humans. Veterinarians are often the first to identify diseases in farm livestock and have a unique opportunity to offer advice on the prevention of human disease through the emphasis of personal hygiene and the avoidance of raw milk consumption.

Foodborne Illness

Foodborne illness is a major public health concern in many countries. The largest potential sources of harm in foods are microbiological contamination and nutritional imbalance, in that order. In the United States, estimates of the incidence of human foodborne illness range from 6.5 to 33 million cases annually, with about 9000 fatalities (Petersen and James, 1998). Meat and eggs are commonly implicated vehicles, and *Salmonella* spp. and *E. coli* 0157:H7 account for about 50% of agents reportedly isolated (Petersen and James, 1998). The cost of diarrheal foodborne illness alone has been estimated as $3.5 to $17 billion annually (McCapes et al, 1991). In Ontario, salmonellosis, *Campylobacter* enteritis, and yersiniosis are the most commonly reported zoonoses that occur in people living on family farms. Infection can occur after the consumption of raw milk or contaminated well water or after contact with livestock.

The most important pathogens that occur daily are *Salmonella* spp., *E. coli* 0157:H7, and *Campylobacter jejuni.*

Salmonella spp.

The *Salmonella* species are one of the most common foodborne pathogens. Economic costs associated with human salmonellosis are nearly $1 billion annually in the United States.

Humans can become infected by most serotypes of *Salmonella.* In the United States, the most common serotypes among isolates recovered from humans annually are *S. typhimurium, S. enteritidis, S. heidelberg, S. hada,* and *S. newport.* Poultry are the food animal reservoir for *S. enteritidis,* and eggs provide a source of the organism for humans. Cattle are the reservoir for *S. newport* and *S. dublin. Salmonella* is also an important pathogen to cattle, and the organism can be found in the feces of about 5% of feedlot cattle (Losinger et al, 1997).

S. typhimurium is not host specific and is equally infectious to both animals and man. Infection with salmonella does not always cause clinical disease. A localized gastroenteritis is most common, and spontaneous recovery without treatment is common. The very young and elderly, immunocompromised patients, and those already taking oral antimicrobial medication are most at risk of developing systemic illness with septicemia.

Escherichia coli

Several different virotypes of *E. coli* 0157:H7 can cause disease in humans and animals (Su and Brandt, 1995). The most important one causing disease in humans is the enterohemorrhagic type (EHEC) known as *E. coli* 0157:H7, a verocytotoxigenic type (VTEC), which causes hemorrhagic colitis (HC) and the hemolytic uremic syndrome (HUS) (Whipp et al, 1994).

Serotype *E. coli* 0157:H7 is classified as an enterohemorrhagic *E. coli* because it causes hemorrhagic colitis, produces a verotoxin Shiga-like toxin, does not produce either heat-stable or heat-labile toxin that is characteristic of enterotoxigenic *E. coli,* and it is not invasive. *E. coli* 0157:H7 is considered the epidemic strain because it has been responsible for major outbreaks reported in the United States, Canada, and the United Kingdom (Whipp et al, 1994; Dorn, 1995).

Cattle are a source of *E. coli* 0157:H7, which causes foodborne disease in humans in North America, Europe, and the United Kingdom. Transmission of the organism occurs through the ingestion of *uncooked* ground beef and consumption of raw milk, although outbreaks have been associated with fresh-pressed apple cider, unchlorinated drinking water, and person-to-person transmission. Investigations of outbreaks of disease in man have linked most of the cases to consumption of hamburgers from fast-food restaurant chains. *E. coli* 0157:H7 was isolated from ground hamburger

Downloaded From Vet-e-Books.com

supplied to restaurants by meat suppliers. This was followed by recall of the incriminated meat (Dorn, 1993).

While the herd prevalence of infection may vary from 50% to 75% depending on geographical location, the prevalence of *E. coli* 0157:H7 in the cattle population is low. In a survey in the United States, the prevalence in dairy heifers and in all cattle was 0.37% and 1.85%, respectively. Person-to-person spread also occurs. Overall, *E. coli* 0157:H7 was recovered at higher rates from pens of cattle that had been on feed for the shortest period of time (3.01%). Samples from pens of cattle that had been on feed the longest time and were closer to slaughter were less likely to give positive results for *E. coli* 0157:H7 (1.08%) (U.S. Department of Agriculture, 1995). Other studies found that 0.33% of the fecal samples and 10% of feedlot pens sampled gave positive results for *E. coli* 0157:H7 (Hancock et al, 1994).

Contamination of carcasses during slaughter and processing may explain how beef and beef products become contaminated and thereby transmit the organism to man. The organism can survive in bovine feces for long periods and still retain its ability to produce verotoxins (Wang et al, 1996). In vitro studies of the growth of the organism in rumen contents indicate that the organism does not grow well in rumen fluid collected from fasted cattle, suggesting that well-fed animals appear less likely to become reservoirs for pathogenic *E. coli* 0157:H7. The organism has been isolated from dairy calves less than 8 weeks of age, and calves were 3 times more likely to shed the organism after weaning than before weaning (Garber et al, 1995).

The persistence of *E. coli* O157:H7 in dairy cattle is transient, and persistence of the organism cannot be demonstrated from farm environment sites tested. The duration of detected *E. coli* O157:H7 by individual cattle is usually less than 1 month. In Washington State, the organism was found in 0.28% of fecal samples from dairy cattle in 8.3% of herds. Fecal samples, bulk milk samples, and milk filters were negative for the organism. The strain was also isolated from 0.71% of fecal samples from pastured cattle of 16% of herds sampled. The organism has also been isolated from the feces of cattle and deer on a ranch in Texas, which suggests that wild ruminants may shed verocytotoxic *E. coli* O157:H7. In beef feedlots the prevalence was 0.33%. Drinking water on dairy farms in Wisconsin has also been identified as one source.

E. coli 0157:H7 is not resistant to antimicrobials and is not used for the treatment of patients clinically affected with the disease.

Epidemics of HC and the HUS in humans infected with *E. coli* 0157:H7 have been attributed to the consumption of ground beef, which potentially could have originated from cattle infected with the strain of the organism. Verotoxin-producing strains of *E. coli* 0157:H7 known to be pathogenic for humans have been isolated from the feces of healthy cattle.

Campylobacter jejuni

Campylobacter jejuni is a common foodborne pathogen and a leading cause of foodborne disease in humans in the United States and other industrialized countries (Altekruse et al, 1998). Most outbreaks are associated with raw milk or surface water, whereas most sporadic cases are often associated with mishandling and consumption of undercooked poultry or cross-contamination of foods by raw poultry. Most retail chicken for human consumption contains *C. jejuni*. The organism may be present in bulk milk samples, tissue specimens of beef cattle, and raw ground beef. Other foods associated with campylobacteriosis include barbecued sausage and shellfish. The organism can be found in poultry, cattle, pigs, sheep, and other food animal species. Several species of birds and rodents may also carry the organism.

Bovine Spongiform Encephalopathy and New Variant Creutzfeldt-Jakob Disease in Humans

Bovine spongiform encephalopathy (BSE) was recognized in cattle in the United Kingdom in 1986, causing major economic costs and international controversy about the safety of beef as a human food (Bruce et al, 1997). The Phillips Inquiry into the emergence and identification of BSE and variant Creutzfeldt-Jakob disease (vCJD) and the action taken in response to it up to March 20, 1996 was handed to the government on October 2, 2000 (BSE Inquiry, 2000). As a result of over 2 years of inquiry, the report comprises 16 volumes containing findings and conclusions. It is now accepted that the new vCJD in humans in the United Kingdom is directly linked to the epidemic of BSE first described in 1986. It is probable that humans affected with vCJD became infected from eating beef products containing the prions that cause the disease. In recognition of this, beef products with risk for infectivity were banned for human consumption early in the outbreak, and the list was enlarged as further information on infectivity of by-products became known. The occurrence of this disease has also resulted in a public questioning of the safety of cattle products as human food and a shift in the dietary habits of concerned people. The threat of the human disease resulted in a significant fall in beef consumption and prices. In response to market forces, the United Kingdom instituted a compulsory slaughter of at-risk, but healthy, cattle, with significant economic and social costs.

Livestock Production in Developing Countries

Infectious diseases of livestock are a major impediment to livestock production and economic development in Africa (Jawara, 1990). The tropical climate is extremely conducive to the growth and propagation of pathogens, and consequently the environment is rife with diseases and their vectors. The major diseases affecting livestock are rinderpest, foot-and-mouth disease, contagious bovine pleuropneumonia, theileriosis, and trypanosomiasis. Helminth infections are significant and are a cause of high mortality in young animals. Ticks are also a major cause of disease in Africa. Tick infestations directly depress the productivity of livestock, but, more importantly, they are vectors of diseases such as East Coast fever or theileriosis, babesiosis, anaplasmosis, heartwater, and streptotrichosis. Streptotrichosis is a primary production-limiting disease of cattle in humid areas. Trypanosomiasis is one of the most important diseases in the subhumid and humid tropics of Africa (Jawara, 1990). It is obvious that animal diseases are a major constraint on the economic development of Africa, and effective control depends on well-trained and educated personnel, availability of resources, and a much-needed interdisciplinary approach. Considerable research efforts are being carried out by many different agencies in regard to the economic control of these infectious diseases (Jawara, 1990).

Problems with Exportation and Importation

Certain diseases, such as brucellosis, enzootic bovine leukosis, pseudorabies, and bluetongue, interfere with the exportation of breeding livestock to countries requiring that imported animals be certified free of pathogens that cause certain diseases. In some cases, as with enzootic leukosis, there is evidence that the disease may have been introduced into England from unknown infected cattle imported from Canada. Scrapie in sheep certainly has been spread internationally by the movement of infected sheep.

Previously unrecognized infectious diseases may emerge unexpectedly in a region or country and can create considerable and expensive veterinary diagnostic laboratory activity and public health concern. The recognition of BSE in Eng-

Downloaded From Vet-e-Books.com

land in 1986 and the potential risk that the beef could be the source of the agent causing vCJD in humans was one of the most important zoonotic concerns in the last decade (Bruce et al, 1997). There is evidence that the biological and molecular transmission characteristics of vCJD are consistent with it being the human counterpart of BSE (Hill et al, 1997). The disease was declared a notifiable disease, affected cows were slaughtered, and compensation was paid to the owners. These actions by regulatory authorities are often made into sensational news stories, which can have a marked adverse effect on the sales of meat and milk.

The fact that some diseases have been brought under control or eradicated in some countries may create a false sense of security, and this could result in less emphasis on surveillance, the introduction of infected animals into the country, and the spread of the disease before it is detected. Examples include brucellosis, tuberculosis, and enzootic bovine leukosis. The potential for new infections requires a reliable surveillance system that prevents the entry of infected animals. The state of Texas achieved class "A" brucellosis status in 1994 and is approaching eradication status. Brucellosis is recognized as one of the most important zoonotic diseases in Mexico because of the economic and public health implications. Since Texas is the primary export market for cattle from Mexico, the importation of sexually intact cattle originating from breeding herds in Mexico could provide a source of infection (Brown and Hernández de Anda, 1998a). This necessitates a strict import sanitary requirement to mitigate the potential risk of transmission of brucellosis from sexually intact cattle of Mexican origin to Texas cattle. Tuberculosis in steers imported from Mexico into the United States is an important animal health issue for the livestock industry (Brown and Hernández de Anda, 1998b). In some years, about 70% of all tuberculosis cases in cattle in the United States were in cattle originating from Mexico. The overall prevalence of tuberculosis at slaughter in adult beef cattle that originated in Mexico was approximately 0.5/1000.

Carcass Condemnations

Infections such as arthritis and pneumonia are a major reason for the condemnations of cattle and swine in abattoirs in the United States. The treatment and control of infectious diseases in food animals may involve the intramuscular injection of antimicrobials and vaccines, which can result in a significant prevalence of *injection site lesions*. When these lesions occur in valuable cuts of meat, they must be trimmed at processing, the cuts are devalued, and there may be consumer dissatisfaction from eating tough beef. These defects in quality constitute a significant economical loss to the cattle industry (Van Donkersgoed et al, 1997; Van Donkersgoed et al, 1998a; Van Donkersgoed et al, 1998b; Van Donkersgoed et al, 1999a). Pharmaceutical companies have been developing animal health products that can be administered subcutaneously, orally, or topically, rather than intramuscularly.

CAUSES OF INFECTIOUS DISEASES

Specific Infectious Diseases of Food-Producing Animals

Some examples of infectious diseases of food-producing animals that may cause herd problems include the following.

Cattle

The common diseases of cattle are contagious and environmental mastitis, acute undifferentiated diarrhea of newborn calves, pneumonic pasteurellosis, infectious abortions, viral interstitial pneumonias, salmonellosis, winter dysentery, footrot, pinkeye, leptospirosis, coccidiosis, intestinal helminthiasis, ectoparasitism, and ringworm. The less common diseases include anthrax, brucellosis, hemophilus septicemia, infectious bovine rhinotracheitis, bovine virus diarrhea, rabies, anaplasmosis, cowpox, and pseudocowpox. Uncommon diseases include tuberculosis, paratuberculosis, pseudorabies, bluetongue, bovine malignant catarrh, enzootic bovine leukosis, BSE, and clostridial diseases. In Africa, rinderpest, foot-and-mouth disease, trypanosomiasis, contagious bovine pleuropneumonia, theileriosis, and helminthiasis are major diseases of cattle.

Swine

The common diseases of swine are acute diarrhea of piglets caused by *E. coli* 0157:H7 and transmissible gastroenteritis virus, postweaning diarrhea, *Streptococcus suis* infection, mastitis, enzootic pneumonia, porcine reproductive and respiratory syndrome, hemophilus pleuropneumonia, atrophic rhinitis, swine dysentery, leptospirosis, and intestinal helminthiasis. Less common diseases include pseudorabies, exudative epidermitis, swine influenza, and ectoparasitism. Exotic diseases of swine include hog cholera, African swine fever, swine vesicular disease, and vesicular exanthema.

Sheep

The common diseases in sheep are footrot, intestinal helminthiasis, ectoparasitism, pasteurellosis, enzootic abortion, caseous lymphadenitis, and maedi-visna. Less common diseases include bluetongue, scrapie, border disease, contagious ecthyma, clostridial diseases, and leptospirosis.

The successful control of any infectious disease depends on a knowledge of the causes of the disease; this includes the specific pathogen or combinations of different pathogens that are considered to be the cause of the lesions of the disease. The epidemiological determinants or predisposing risk factors related to the host or the environment, such as age, stress, lack of immunity, and breed susceptibility, that contribute to the development of the disease are also considered as causative factors.

Etiological Agents

The infectious diseases of major concern in food-producing animals are those caused by bacteria viruses, protozoa, helminths, and ectoparasites. Diseases caused by mycoplasma are of lesser importance. The diseases that appear to cause the greatest economic loss, particularly under conditions of intensive production, are those that affect the mucosal surfaces of the body, such as the gastrointestinal tract, respiratory tract, mammary gland, reproductive tract, skin, conjunctiva, and eyes. Some diseases, such as clostridial infections, occur uncommonly because of the use of effective vaccines; some, such as mucosal disease, occur sporadically. Others, such as subclinical mastitis in dairy herds, are endemic. Pneumonia in feedlot cattle is a common occurrence in recently arrived cattle. A disease such as acute undifferentiated diarrhea of newborn calves occurs in most herds of cattle as sporadic epidemics, resulting in high morbidity and mortality.

Some diseases, such as rabies, are *causally defined* and are caused by a single pathogen, the rabies virus. However, many common infectious diseases of the respiratory and digestive tracts of food-producing animals are not causally defined but are *multifactorial* disease complexes caused by two or more pathogens, with or without predisposing causes or risk factors. Diarrhea and pneumonia can be caused by any one of or a combination of several pathogens, but the mere presence of the pathogens in those body systems does not necessarily cause disease. A *necessary cause* of disease is one

Downloaded from Vet-e-Books.com

without which the disease cannot occur. The rabies virus is a necessary cause of rabies. However, although *M. haemolytica (P. haemolytica)* is a necessary cause of pneumonic pasteurellosis, it is not a necessary cause of pneumonia. Enterotoxigenic *E. coli* 0157:H7 is a necessary cause of enterotoxigenic colibacillosis but not of diarrhea. In contrast to a necessary cause, a *sufficient cause* is one that always produces the disease. Single factors are infrequently sufficient causes. Almost all sufficient causes are composed of a grouping of factors, each called a component cause; thus many diseases can have a multifactorial cause (Martin et al, 1987). By definition, necessary causes are a component of every sufficient cause. Generally speaking, *M. haemolytica (P. haemolytica)* is the cause of pasteurellosis in cattle. However, a sufficient cause of pasteurellosis requires the presence of other factors, such as stress, a preceding viral infection, or lack of immunity, as well as the presence of the organisms in the lung, before the disease can occur. It must be emphasized that the mere presence of the organisms in the respiratory tract is not sufficient cause for the disease to occur. It has been suggested that acute undifferentiated bovine respiratory disease occurs in feedlot cattle that have been stressed (Ribble et al, 1995a; 1995c). It may be more effective to attempt control by identifying and minimizing the stress factors rather than by relying on specific control measures, such as vaccination or mass medication, which are aimed principally at the pathogens thought to be important (Martin et al, 1988).

Can a necessary cause also be a sufficient cause of disease? The rabies virus is the necessary cause of rabies. Is it also a sufficient cause? Not all animals that are bitten by a rabid animal develop rabies, but rabies probably occurs more commonly in exposed, unvaccinated animals than in vaccinated animals.

A *multifactorial* disease can be defined as one that requires the interaction of more than one infectious agent or of one or more infectious agents with other factors to produce disease. In many infectious diseases of the respiratory and digestive tracts of food-producing animals, mixed infections occur in which two or more pathogens act cooperatively or synergistically. In those cases, host or environmental risk factors increase the susceptibility to clinical disease. For example, *M. haemolytica (P. haemolytica)* may be the ultimate cause of most cases of acute respiratory disease in feedlot cattle. However, it has been hypothesized that respiratory viruses such as parainfluenza-3 (PI-3), infectious bovine rhinotracheitis (IBR), bovine respiratory syncytial virus (BRSV), or other viruses or environmental stressors may decrease the resistance of the animal, which allows the *Pasteurella* organisms to colonize the lung and produce the lesion. Experimentally, a viral infection of the lung can inhibit lung clearance mechanisms and interfere with alveolar macrophage function, which allows the *Pasteurella* organisms to colonize, produce leukotoxin, and initiate the inflammation. It can be difficult to reproduce pneumonic pasteurellosis experimentally solely with the bacteria unless the lower respiratory tract is swamped with the bacteria, but experimental aerosol respiratory viral infection preceding an aerosol bacterial challenge is usually more successful.

Herd outbreaks of disease occur commonly in which the etiology is uncertain but evidence of seroconversion to certain infectious agents in association with clinical disease may indicate a causal relationship. For example, outbreaks of bovine respiratory disease in western Europe have been associated with seroconversion of lactating dairy cattle to influenza A virus in association with respiratory disease and reduced milk yield (Brown et al, 1998). Similarly, a syndrome of milk drop, body condition loss, and respiratory signs, often accompanied by abortion in dairy herds, was associated with significant seroconversion to *Chlamydia* spp. (Dannatt et al, 1998). These are examples of herd epidemics of disease of unknown etiology, but the seroconversion of affected animals to certain infectious agents may provide evidence of a causal relationship and the need to investigate the cause-and-effect relationship.

In acute undifferentiated diarrhea of newborn calves, mixed infections with enterotoxigenic *E. coli* 0157:H7, rotavirus, coronavirus, and *Cryptosporidium parvum* may occur in up to 30% of affected calves and in some normal calves in the same population. The pathogenetic mechanisms that result in clinical disease in some calves and not in others in the same population are not well understood. Inadequate colostral immunity, however, is an important risk factor.

The diagnosis, clinical management, and control of multifactorial disease complexes can be difficult because of the uncertainty of the role of each pathogen or risk factor. For example, the interpretation of the presence of a mixture of pathogens in the lungs of cattle that have died from pneumonia and have been treated with antimicrobial drugs can be difficult. The reliability of making causal inferences about the isolation of a pathogen from clinically affected animals can be improved by the submission of samples from normal animals kept in the same environment as the affected ones (Martin et al, 1987). Without knowing which pathogen is most important, it is difficult to formulate an effective vaccination program. Furthermore, it is usually difficult to determine which of the many host and environmental risk factors are most important so that they can be minimized or removed if they are sufficient causes. The control of many infectious diseases of food-producing animals has been difficult because the evidence that certain risk factors are important has been empiric and based on crude field observations. Qualitative and quantitative epidemiological techniques are now available to help plan and carry out meaningful observational studies, which can identify and quantify risk factors according to their relative importance. The most important risk factors then can be minimized or removed and can result in a decrease in the incidence of disease. The successful control of a multifactorial disease also requires the simultaneous manipulation of several management practices. For example, the control of bovine mastitis caused by contagious pathogens depends on good milking technique, postmilking teat dipping, dry cow therapy, and culling of chronically infected cows. Constant surveillance of the somatic cell count (SCC) and culturing milk samples to detect infected cows are important, as are good sanitation and hygiene practices in the dairy barn.

A number of methods can be used to study the causal relationships of disease and to evaluate risk. They include simple, descriptive epidemiological methods and study designs, such as case control studies, prospective and retrospective cohort studies, and cross-sectional studies. Statistical techniques include 2×2 tables, regression analysis, path analysis, discriminant analysis, and analysis of variance. The difficulty of obtaining a definitive, causative diagnosis for a problem such as bovine abortion in dairy herds has prompted the development of an innovative epidemiological approach. A computer-based, on-farm surveillance system of dairy cow abortion has been developed, which may help in the diagnosis and provide more information about abortion (Thurmond and Picanso, 1990). The frequency of occurrence of abortions is calculated as the number of abortions observed during a specified period divided by the sum of cow-days at risk for that period. The abortion density could be used to determine the risk of abortion during each month of the year. Etiological agents are isolated in only about 33% of aborted fetuses, and lesions are detectable in only about 12% (Agerholm et al, 1997).

Downloaded from Vet-eBooks.com

In summary, infectious diseases of food-producing animals are caused by many different infectious agents that act singly or as a mixed infection, with or without predisposing factors, which render the animals susceptible to infection and clinical disease. The identification and elimination or minimization of the risk factors are important in the control of disease.

EPIDEMIOLOGY OF INFECTIOUS DISEASES

Epidemiology may be defined as the study of the patterns of disease that exist under field conditions (Martin et al, 1987). Martin et al (1987) said, "More specifically, epidemiology is the study of the *frequency, distribution,* and *determinants* of health and disease in populations." In other words, epidemiology is the study of how frequently the disease occurs, where and when it occurs, which animals it affects, and the determinants or causes of diseases in populations of animals. A comprehensive understanding of the epidemiological characteristics of a specific infectious disease, including its natural history, is a prerequisite to the formulation of control procedures. Qualitative epidemiology deals with the details of the transmission, maintenance, and ecology of infections and infestations. Quantitative epidemiology requires an understanding of basic observational techniques, such as sampling and measurement of association. This enables practitioners to separate random variation in levels of production from decreases in productivity caused by disease in intensive livestock enterprises. An understanding of economic theory and statistics is also necessary for the formulation of economical disease control programs and to set priorities. This requires a major reorientation of the traditional veterinary curriculum, away from the exclusively individual animal approach to one that is both individual animal and population based. New approaches to animal health problems include more science than art and more of a mathematical or observational approach than an experimental one. The application of clinical epidemiology to veterinary practice is an imposing challenge. However, once veterinarians become familiar with the application of epidemiological parameters, such as sensitivity, specificity, prevalence, positive and negative predictive values, and odds ratios, the diagnostic accuracy and clinical management of disease will be enhanced.

The *natural history* of an infectious disease includes the method of transmission from infected to susceptible animals, the portals of entry into the body, the incubation period, the distribution of the infectious agent within the body, the immune response of the animal to the infectious agent, its persistency or latency in body tissues, and the frequency and persistency of shedding of the pathogen. These are all important in the spread and persistence of infection in a population. Persistent infections of individuals, even when shedding occurs only sporadically, can form important reservoirs of infection. Typical examples include young cattle persistently infected with the bovine viral diarrhea virus, long-term shedders in cattle and pigs affected with leptospirosis, and the persistent infection that is possible with footrot in sheep. Horizontal transmission can occur by direct or indirect contact through inanimate fomites, mechanical or biological vectors, or other species acting as a reservoir. Ticks are important vectors for several major infectious diseases of livestock. Infections can also be transmitted vertically from dam or sire to offspring either congenitally or, for some retroviruses, genetically. A knowledge of the life cycles of internal and external parasites is also important for the formulation of effective parasite control programs.

Risk Factors

Although there are many different pathogens that are ultimately the cause of subclinical or clinical disease, the risk factors that contribute to its cause and distribution are often more important as a foundation for the formulation and application of control measures. The *host, environmental and managemental,* and *pathogen* risk factors of a disease are the characteristics that interact to contribute to the development of the disease. Some of the examples used here illustrate the interdependence among many risk factors, and often it is controversial whether a particular risk factor belongs in one or more of the three categories.

Host Risk Factors

Factors that influence or control a host's susceptibility to infection, or if it is infected, that determine the development of disease, are called host risk factors. These factors include *age* at infection, *size of herd, nutritional status, immunity status, preexisting disease in the herd, stage of pregnancy and production,* and *breed.*

Age of Animals. The level of colostral immunity in newborn farm animals is a major determinant of resistance against neonatal disease in addition to survival from clinical disease, such as neonatal diarrhea. Many factors influence the amount of colostral immunoglobulins absorbed by the calf, including how much colostrum it ingests, how soon after birth the colostrum is ingested, the concentration of immunoglobulins in the colostrum, the maternal behavior of the dam, and the vigor of the calf. Postnatal respiratory acidosis in newborn dairy calves can adversely affect colostral immunoglobulin absorption, despite colostrum intake early in the postabsorptive period (Besser et al, 1990). Several infectious diseases of the intestinal tract are more common in newborns because of their high susceptibility, whereas with other diseases, such as enzootic pneumonia of pigs, the incidence increases with the age of the pig. This is probably a reflection of prolonged exposure (Gardner and Hird, 1990). Most severe respiratory disease from primary infections of BRSV occurs in calves under 5 months of age (Van der Poel et al, 1993). Calves can become reinfected but seldom develop disease after reinfection, which is more common in adults.

Size of Herd. The size of the herd may be a risk factor. Large herd size (at least 500 sows) significantly increases the odds of positive transmissible gastroenteritis serostatus compared with herds of 100 to 199 sows (Yanga et al, 1995). In large herds there are frequently more contacts with potential sources of infection, such as feed and pig transport trucks entering the premises. In large breeding herds some susceptible females may not be exposed to infection during a primary outbreak of disease, and these females fail to transfer adequate colostral antibodies to nursing piglets that are at greatest risk of infection. In large herds that are expanding, there may be greater odds of infected animals because the absolute number of replacement females increases as herd size increases. Theoretically, a larger pool of susceptible females facilitates circulation of the virus and hence the persistence of infection in the herd. However, transmission of a virus infection in a herd may be independent of the size of the population, providing that groups of animals are housed at equal density (Bouma et al, 1995).

Nutritional Status. Although the subject is somewhat controversial, some workers have claimed that the presence of a *nutritional deficiency* of copper or selenium may increase susceptibility to infection. There is some evidence that copper deficiency associated with increases in molybdenum on pasture may increase the susceptibility of certain genetic lines of lambs to microbial infections. There is much interest

Downloaded from Vet-eBooks.com

in the observations that supplementation of the diet of dairy cows with selenium can reduce the incidence of mastitis and lower the SCC. Selenium deficiencies have been reported to suppress the immune response in various species, and the selenium status can affect IgM concentrations following stress. However, many of these observations on the effect of deficiencies on the immune system of animals are based on experimental work. Whether these deficiencies constitute a risk factor in naturally occurring infectious diseases has yet to be determined.

Immunity. In general, nonimmune animals are more susceptible to infectious clinical disease than animals that are immune as a result of adequate vaccination or natural infection. For example, the percentage of beef cow-calf herds in the United States that are naive to BVDV is small (Paisley et al, 1996). More than 90% of herds and more than 65% of animals have been exposed to BVDV either through vaccination or natural exposure. Thus it is unlikely that large epidemics would occur. The risk of morbidity and mortality or reproductive loss in individual nonimmune animals and herds could be large if the virus was introduced, but the number of these herds appears to be small. The vaccination of breeding and finishing swine herds aids in the eradication of pseudorabies infection (Lehman et al, 1993). Outbreaks of infectious disease, such as those due to BRSV, may occur in cattle herds in which the herd immunity has waned over time and certain unidentified factors precipitate increased replication, or a change in virulence, and shedding of the pathogen, resulting in clinical disease (Ellis et al, 1996b). In dairy herds affected with winter dysentery, cow-level risk factors for the development of the disease have been evaluated. Cows with the clinical disease were more likely to shed detectable amounts of bovine corona virus antigen in their feces, and pregnancy appeared to protect cattle from the disease (Smith et al, 1998b). The likelihood of developing disease in individual cows increased as the enzyme-linked immunosorbent assay (ELISA) value for bovine coronavirus antigen detectable in feces increased. Cows with high acute bovine coronavirus antibody titers that seroresponded had greater odds of developing disease, compared with seroresponding cows with low acute titers. The immune factors that appeared to increase a herd's risk of winter dysentery included an increase in the herd prevalence of adult cows that had a fourfold or more increase in bovine coronavirus serum IgG antibody titer and an increase in herd prevalence of adult cows that had a fourfold or more increase in BVDV.

Varying degrees of *immunosuppression* can be measured experimentally in animals affected with infectious agents, including bacteria, viruses, parasites, and fungi, and by noninfectious factors, such as malnutrition, stress, and weaning. However, whether a preexisting immunosuppression is a significant factor in most cases of common, naturally occurring infectious diseases is unknown.

Preexisting Disease in the Herd. Host risk factors for certain diseases may be related to the presence of disease and other host variables existent in the herd. An examination of the risk factors for clinical mastitis in dairy heifers found that a relationship between the risk of mastitis for heifers and the total incidence rate for clinical mastitis in the corresponding herd, a decrease in the bulk milk SCC, an increase in the mean milk yield, and an increase in age at first calving (Waage et al, 1998). A high overall herd incidence rate for clinical mastitis may reflect the presence of a prevalent reservoir of contagious udder pathogens in the herd and, thus, increased risk of exposure of the heifers to such pathogens. Milk leakage was also associated with an increased risk for mastitis.

Stage of Pregnancy or Production. There is a close relationship between foul-in-the-foot (interdigital dermatitis) and calving in Danish dairy cows (Alban et al, 1995). This relationship may be associated with the abrupt metabolic and environmental changes that are associated with calving. The cow's incidence risk of the disease was 0.6% during the first month postpartum, which was 6 times higher than in the last month prepartum and in any other month postpartum. Almost half of the first treatments for the disease were in the first 30 days postpartum.

Breed. Certain *breeds* of animals may be more susceptible to some specific infections than others, but this is not well documented.

Environmental and Management Risk Factors

Environmental and management risk factors include wind, rain, snow, adequacy of ventilation and air quality (including concentrations of dust, noxious gases, and relative humidity), population density, comfort of housing, level of contamination of bedding with pathogens, level of animal management and care given to animals, handling methods used to treat animals, and other management strategies that can contribute to an increased susceptibility to infectious disease or can make the occurrence of disease possible. These risk factors, alone or in combination, can play an important role in predisposing to infectious disease. The veterinarian should attempt to identify these risk factors and make producers aware of them so that disease can be prevented or minimized. Some examples are outlined here.

Housing Conditions. Respiratory diseases are common in swine raised under intensive housing conditions and represent one of the most prevalent and costly health problems in pig production worldwide. For each 1% of lung affected by enzootic pneumonia, there can be a significant reduction of average daily gain and an increase in the number of days to market. Surveys of lung lesions and risk factors for respiratory diseases in swine herds have found a relationship between environmental factors related to housing and management of the farm (Stark et al, 1998). In particular, factors related to stocking density and air quality such as manure management and general hygiene are highly influential. Among the various control measures, the development of specific pathogen free herds has been most effective. However, these herds also have difficulties in maintaining their disease-free status in regions with high pig densities, short farm-to-farm distances and complex trade structures (Stark et al, 1992).

Factor analysis of swine farm management practices can be used to examine the role of risk factors in respiratory disease (Hurnik et al, 1994a,b). Management factors can include farm size, growth rate, feeding styles and feedstuffs, manure handling and bedding, ventilation, pen space and flooring, moving and mixing pigs, sources of pigs, people contact in the barn, labor source, and experience. First the factors are identified and then analyzed to determine which factors contribute to disease. The prevalence of disease on farms is then correlated with the presence of the factors and odds ratios calculated. In one example, family farms using floor feeding methods had an odds ratio of 3.31, suggesting that this combination of management styles may be a risk factor in enzootic pneumonia. Integrated farms had an odds ratio of 2.3 for having the disease, suggesting that larger farms that mill their own feed and are closer in proximity to other pig farms have a greater chance of having enzootic pneumonia. A linear regression of the prevalence estimates of enzootic pneumonia on positive farms revealed that only farms with multiple-source feeder barns and floor-fed family farms were associated with a higher prevalence of enzootic

Downloaded from Vet-eBooks.com

pneumonia. Farms with extensive pig housing were associated with a lower prevalence, suggesting that farms with ample pen space and air volume had fewer pigs with enzootic pneumonia. Thus many commonly accepted risk factors, in combination, increased the likelihood of enzootic pneumonia (Hurnik et al, 1994a).

Winter dysentery in dairy cattle herds was associated with housing cattle in tie-stall or stanchion barns rather than free-stall facilities as well as use of equipment to handle manure and subsequently handle feed (Smith et al, 1998a).

Hygienic Conditions. An unsatisfactory level of hygiene and sanitation in any animal holding facility can be directly associated with an increase in certain infectious diseases. This principle applies in many situations, such as beef cow-calf herd calving corrals, farrowing crates in swine herds, lambing sheds in sheep flocks, pens in beef feedlots, and dairy calf barns and calf hutches. Clean and dry environmental conditions in dairy herds may be associated with lower bulk-tank SCCs and a lower incidence of clinical environmental mastitis (Bartlett et al, 1992). Dairy herds with designated maternity pens that are isolated and clean have a lower incidence of clinical mastitis. Case-control studies of papillomatous digital dermatitis in dairy farms found that the odds of a higher proportion (>5%) of cows affected were 20 times greater in dairy farms with muddier corrals than in drier dairy farms (Rodriguez-Lainz et al, 1996).

Importation of Animals into a Herd. The importation of replacement breeding animals into a herd is common practice but is often associated with the subsequent occurrence of an infectious disease. Case control studies of papillomatous digital dermatitis in southern California dairy farms found that buying replacement heifers was associated with a 4.7-fold increase in the odds of a higher prevalence of digital dermatitis, compared with dairy farms that did not buy heifers (Rodriguez-Lainz et al, 1996). There was also a positive association between risk and number of heifers purchased.

Geographical Distribution and Density of Herds. The geographical distribution and density of herds can influence the spread of infections. The spread of pseudorabies infection from herd to herd increases with geographical proximity to infected herds (Norman et al, 1996). A decreased density of pseudorabies-quarantined herds in a region was associated with reduced risk of a herd becoming quarantined, whereas increased density of nonquarantined, uninfected herds was associated with decreased probability of a herd becoming quarantined. Decreased density of vaccinated herds was associated with increased probability of a herd becoming quarantined. Using a computerized database linked to a *geographical information system (GIS)*, researchers found that location of a herd within 1 km of a river or lake decreased the risk of pseudorabies infection, and closeness to farrow-to-finish operations, complete confinement, and increasing density of swine herds within a 5-km radius increased the risk of infection (Marsh et al, 1991).

Marketing and Transportation Stress. There is considerable controversy about the effects of marketing and transporting animals, such as feeder calves destined for the feedlot. (Martin et al, 1988). Recent critical studies have shown that when the incidence of fatal fibrinous pneumonia in feedlot calves was high, the disease clustered within truckload groups of calves, within pens, or within both (Ribble et al, 1994). Most of the calves that died of fibrinous pneumonia were sick within 2 weeks of arrival (Ribble et al, 1995b). Transportation itself was not found to be a risk factor, since the risk of fatal fibrinous pneumonia was just as high for calves arriving from nearby markets as that for calves transported much greater distances (Ribble et al, 1995d). Calves entering the feedlot in November had a risk of fatal fibrinous pneumonia 2 to 8 times greater than calves entering in September or December, which was a pattern over a period of 4 years (Ribble et al, 1995a). Several factors could have contributed to this pattern, including changes in transport truck availability, changes in density of calves at markets, changes in population dynamics at the feedlot that affected the feedlot crew efficiency, and weather. There was a positive linear relationship between mixing of calves in truckloads supplied by different buyers and a risk of subsequent fatal fibrinous pneumonia (Ribble et al, 1995c). This suggests that increased mixing of calves from different farms at the auction mart increases the risk of fatal fibrinous pneumonia in calves after their arrival at the feedlot. The incidence of fecal shedding of *Salmonella* sp. in feeder calves can increase, from the time they leave the farm of origin and are moved through auction marts and into the feedlot.

Climatic Changes. Rapid changes in climate, such as a sudden increase or decrease in ambient temperature, increase in relative humidity, snowstorm during calving season in beef herds, or prolonged rainfall causing excessively wet ground surfaces in feedlots, are environmental risk factors. *Inclement weather* and inadequate housing and ventilation often contribute to the onset of epidemics of infectious diseases in farm animals. Several common respiratory diseases of cattle are associated with certain seasons of the year, air temperature, wind, rain and humidity, and air quality. A computerized information retrieval system of slaughter lesions recorded in the abattoir, linked with meteorological data, has been used to investigate the effect of weather conditions on the occurrence of pleurisy and pneumonia in the sheep population of Northern Ireland. Highly significant correlation coefficients were found between the percentage of lung condemnations in sheep and the rain-wind-chill factor prevailing during the same month and 1 or 2 months previously (McIlroy et al, 1990).

Ventilation. Failure of ventilation systems in swine barns during warm seasons can precipitate outbreaks of pneumonia in growing and finishing pigs. The term "environmental medicine" has been suggested to describe the study of the environmental factors that contribute to disease. It is well known that extremely high or low temperatures, extremely high humidity, overcrowding, and other unfavorable rearing conditions lower the production of livestock.

Population Density. Population density is probably the most important factor in intensive animal husbandry influencing the onset of infectious disease in the individual animal and in promoting spread within a group of animals. The mixing of feedlot cattle from different sources on arrival is an important risk-related factor in increasing the morbidity because of lower respiratory tract disease. Persistent problems with environmental mastitis in dairy cattle are associated with inadequate hygiene and sanitation. Growth of organisms in the bedding and on ground and floor surfaces results in contamination of the teats and udders by environmental pathogens.

Overcrowding. The stress of overcrowding can cause changes in the intestinal flora. The high population densities used in intensive livestock production allow the rapid spread and replication of infectious agents. For example, if not properly managed, integrated livestock enterprises with large holdings associated with the adoption of intensive livestock production are conducive to the spread of infectious disease. These large holdings have resulted in major problems with manure disposal and storage, which poses a threat to health.

Air Quality of Buildings. The aerial environment of buildings is considered a major risk factor in the epidemiology of diseases of the respiratory tract of farm animals.

Downloaded from Vet-e-Books.com

Atmospheric ammonia, aerial dust, and microbial concentrations in the farrowing house and dust in the weaning house of swine herds can contribute to the incidence and severity of atrophic rhinitis in swine (Robertson et al, 1990).

Floor Quality. Flooring materials in farrowing pens may abrade the hooves of newborn pigs and provide a route for entry of pathogens into the foot, resulting in foot abscesses. The factors associated with foot abscesses in newborn pigs include pigs born in large litters (>10 pigs at birth) and born to sows with postpartum illnesses (Gardner and Hird, 1994). It is suggested that sows that were are ill at farrowing produce less milk. The reduced availability of milk probably increased fighting among the piglets and the time spent attempting to suck, and thus this resulted in more traumatic foot injury. This effect would be more pronounced in large litters in which competition for milk is already substantial. The increased frequency of lesions in the newborn of sick sows is consistent with the hypothesis that much of the injury to the claws results from the downward and outward movement of hindlimbs during sucking.

Bedding Quality. The number and type of bacteria in bedding are related to the microbial load on teat ends and rates of clinical mastitis in lactating dairy cows. Organic materials such as straw, corn fodder, and sawdust often contain $>10^6$ cfu/g of coliform bacteria when used as bedding. Bacteria counts also differ within organic beddings; wood products often contain the greatest number of coliform bacteria. Wood products, such as sawdust and shavings, have been found to be heavily contaminated with *Klebsiella* spp. In dairy herds using wood chips or sawdust as bedding, higher rates of clinical mastitis may occur than in herds in which other bedding materials are used (Bartlett et al, 1992). To control bacterial populations, a common practice on many farms that use wood products for bedding is to add hydrated lime to the stalls to control bacterial populations, because lime elevates the pH and reduces the moisture content of the bedding to inhibit bacterial growth. The addition of lime to sawdust before use as bedding reduced Gram-negative bacteria, coliforms, *Klebsiella* spp., and streptococci (Hogan and Smith, 1997).

Topography and Climatic Conditions. A number of environmental factors affect the spread of disease, including climate and topography. Temperature and relative humidity can permit the survival of pathogens outside the body and the activity of biological vectors. Tropical climates are conducive to the development of pathogens. For example, streptothrichosis is common in tropical climates because the high relative humidity promotes the development and maintenance of the causative organism. Interrelated with temperature and humidity is wind, which can disperse infectious agents either directly or through the dispersal of biological vectors, such as arthropods. The spread of insect-borne animal virus diseases can be influenced by several factors. Hosts may migrate, move, or be conveyed over long distances. Vectors can be carried on the wind for varying distances in search of hosts and breeding sites. For example, outbreaks of vesicular stomatitis have indicated that wind could have been responsible for carrying infection from northern Mexico to Arizona and New Mexico, and from there to Colorado and Utah and on to Wyoming, Idaho, and Montana (Sellers and Maarouf, 1990). The virus was isolated in sufficient amounts from *Simulium* sp. during the outbreak to suggest that it was possible that the fly infected with the virus could have been carried downwind to introduce disease elsewhere. The topographical features of a farm or an area can also influence the spread of airborne disease by affecting wind and air movements and the movement of infected animals. Deserts, mountains, and forests restrict the movement of domesticated animals. Water is even more restrictive, allowing islands a privileged position with respect to disease control.

Insect Vectors. The key determinants of the occurrence and epidemiology of theileriosis in parts of Africa are the distribution and abundance of the tick *Rhipicephalus appendiculatus*, which can be influenced by the climate (Lessard et al, 1990). Geographical information systems are now being developed to help improve the methods for defining the environmental parameters that influence the distribution and prevalence of tick-borne disease in Africa. The moisture index and the vegetation index are two parameters that have been shown to be important in determining the areas of suitability for the survival and development of the tick.

Commingling with Other Species. The presence of other species of animals on a farm may be a risk factor for infection. For example, the presence of deer on cattle farms may increase the risk of Johne's disease if the deer serve as a reservoir of the organism and graze on the same pasture (Cetinkaya et al, 1997). Natural infection of red deer with *M. bovis* from tuberculous possums occurs in New Zealand (Lugton et al, 1997). Observations suggest that the deer probably became infected through close inspection and investigation of the tuberculous possum. This deer-possum contact, and thus exposure to *M. bovis*, was related to the curiosity and social ranking of the red deer hinds.

Trade of Animals. Trade can also be responsible for disease spread by the movement of animals and their products. The pressure to improve the gene pool of a species of food-producing animal has increased the potential of spreading infectious agents internationally. Many diseases have been introduced into one country from another by the importation of unknown infected animals. At least 12 diseases of farm livestock were introduced into the United Kingdom between 1968 and 1979 following relaxation of importation regulations. Some of these diseases have been eradicated, but others such as enzootic leukosis, maedi-visna, and *Leptospira hardjo* infection are still present. It has been suggested that *L. hardjo* was introduced by the importation of leptospira-infected cattle that were obtained as a source of brucella-free stock. It is particularly difficult to prevent the entry and control the spread of those diseases with long incubation periods because infected animals may be imported and be present for several years before clinical disease or the infection is recognized. Enzootic bovine leukosis has a long incubation period, and the infection was present in Great Britain for about 5 to 6 years before it was recognized. Similarly, maedi-visna of sheep is caused by a slow virus, and the incubation period is several years. Scrapie in sheep is another example of the difficulty of preventing the entry of infected animals because of the long incubation period and the lack of a diagnostic test in the live animal. The introduction and expansion of free trade in livestock in Europe are of concern because of the risks of importing infected animals.

Treatment Techniques. An investigation of the risk factors for nocardial mastitis in dairy herds revealed that the use of dry cow therapy with intramammary products containing neomycin and the use of multidose vials of dry cow medications are the only predisposing factors identified as being significantly associated with nocardial mastitis (Ollis et al, 1991).

Pathogen Risk Factors

The risk factors of the pathogen or causative agent include its virulent characteristics and its reservoir of infection. In general, each causative agent causes a characteristic disease. However, virulence may vary among strains of an agent. For example, different genotypes of BVDV have been identified,

Downloaded From Vet-e-Books.com

which have antigenic and pathological differences that have practical significance (Ridpath et al, 1995). In the early 1980s mucosal disease in young cattle was invariably associated with persistent infection with a noncytopathogenic biotype of the virus, which the animal had since birth, followed by clinical disease later in postnatal life associated with a superinfection with a cytopathogenic strain of the virus. Newly identified isolates of the noncytopathogenic biotypes of BVDV in the 1990s were found to cause highly fatal disease (Deregt and Loewen, 1995).

Clinical disease caused by *H. somnus* was initially characterized by meningoencephalitis. Within the last decade clinical disease caused by the same organism is characterized by pleuropneumonia and myocarditis, which in some feedlots accounts for one of the most important causes of mortality in fall placed weaned beef calves in North America (Janzen, 1997). The change in the clinical manifestations is probably due to the changes in virulence of the organism. Some pathogens exist in more than one serotype, which is important if recovery from one infection with one serotype does not provide protective immunity against another. Mutations occur in infectious agents; these include changes in antigenic determinants, virulence, and the ability to spread in a susceptible population. Subgroups of BRSV have been identified based on antigenic differences (Schrijver et al, 1996). Certain subgroups are associated with severe respiratory disease, and these strains may circulate concurrently in the cattle population. It is important to monitor the strains that circulate in order to determine infection patterns and cross-protection of the subgroups over time. This provides vital information on the protection that can be provided after repeated infections with BRSV strains belonging to the same or different phenotypes, which might help design of vaccines. Infections in the absence of clinical disease are common in calves with rotavirus infections (Hall et al, 1993). Differences in virulence among bovine rotaviruses have been detected and have important implications for diagnosis and vaccines. Restriction endonuclease analysis of Australian bovine herpesvirus-1 isolates recovered between 1989 and 1993 revealed the emergence of a new genotype of the virus associated with severe respiratory disease (Smith et al, 1995). The ability of pathogens to spread from animal to animal may also vary from strain to strain. Also, vaccination with one serotype may not provide protection if the animal becomes infected with a different serotype of the same pathogen.

In recent years *Actinobacillus suis, Haemophilus parasuis,* and *S. suis* have emerged as important pathogens of swine, especially in high health status herds. These organisms are early colonizers and, for that reason, are difficult to control by management procedures such as segregated early weanings (MacInnes and Desrosiers, 1999). Vaccination, serodiagnostic testing, and even serotyping are complicated by the presence of multiple serotypes, cross-reactive antigens, and the absence of clear markers for virulence. To date, 35 different capsular types of *S. suis* have been described. Although it appears that some serotypes are typically more virulent than others, virulence varies not only between serotypes but also between strains of the same serotype. Clonal analysis is being used to assess the relationship between genetic groups of *S. suis* type 2 (Mwanki et al, 1994). *S. suis* type isolated from healthy and diseased pigs originated from diverse genetic backgrounds, which confirms that serotyping cannot be relied on for strain identification of the organism. Highly virulent and completely avirulent *S. suis* capsular type 2 strains do exist. Most Canadian field isolates of *S. suis* capsular type 2 tested do not produce the virulence-related proteins described for this bacterium (Gottschalk et al, 1998). The *S. suis* strains from Europe are genotypically different from those of North America. In a U.S. retrospective study, the various serotypes could not be readily separated based on antibiograms, epidemiological factors, or geographical region (Reams et al, 1993). Such information emphasizes the importance of improving the understanding of the pathogenesis and virulence factors of many pathogens so that effective management strategies including vaccination can be developed.

The factors that affect the viability of the organism in the environment may affect the prevalence of disease in herds in certain geographical regions. The prevalence of paratuberculosis-positive dairy herds in Michigan was greater (54%) than expected and was associated positively with acidic soil and increased soil iron content (Johnson-Ifearulundu and Kaneene, 1999). The addition of lime to pasture areas was associated with a herd being only 10% as likely to be paratuberculosis positive and with a 72% reduction in the number of test-positive cattle. Soil iron availability also may be an important risk factor for paratuberculosis because of its essential role as a bacterial micronutrient. *Mycobacterium paratuberculosis* may be particularly sensitive to environmental iron content because of its poor capacity for iron uptake. As an inefficient iron chelator, the organism competes less effectively with other bacterial species for sequestration of available iron when it exists in limited quantities. Thus higher soil iron content may favor survival of the organism in the environment, increasing the risk of transmission to a susceptible host.

Concurrent infections with two pathogens may result in more severe clinical disease than that caused by one pathogen alone. Cattle are susceptible to infection and disease caused by multiple pathogens, such as BRSV, BVDV, bovine herpesvirus-1, and *M. haemolytica (P. haemolytica),* and it is likely that concurrent infection exacerbates clinical respiratory tract disease. Concurrent infection with BRSV and BVDV resulted in more severe respiratory tract disease than did infection with either virus alone, which suggests a synergistic effect (Brodersen and Kelling, 1998).

Knowing the reservoir of infection or the source of the pathogen of an infectious disease can assist in formulating control procedures. One of the best examples is bovine mastitis caused by *Staphylococcus aureus,* in which the source of the organism is the infected cow. By milking infected cows last and using postmilking teat disinfectant and dry cow therapy, practitioners can help decrease existing infections and minimize the spread of the organism. In acute undifferentiated diarrhea of newborn calves, the causative pathogens originate from the dams and older calves, which spread the infection directly or indirectly to newborn calves. In some cases, semen is the reservoir of viruses, such as bovine herpes 1 (IBR-IPV), bovine leukosis virus, bluetongue, bovine virus diarrhea, and foot-and-mouth disease (Afshar and Eaglesome, 1990). The ability of viruses to withstand long-term freezing in semen with the potential for spreading disease among cattle populations internationally is a major pathogen risk factor. Semen from a bull persistently infected with the pestivirus can be a potential source of pestivirus infection for clean herds using the semen (Kirkland et al, 1994).

Molecular diagnostic and typing methods can be used to investigate the source of an organism. For example, in listeriosis of ruminants the identification of the source of the organism is often complicated because *Listeria monocytogenes* is ubiquitous. Use of advanced molecular techniques can help to identify the sources and restrict the scope of an epidemiological investigation (Wiedmann et al, 1997).

The antimicrobial susceptibility of bacterial pathogens can affect the clinical management of a disease such as bovine respiratory disease. A substantial decrease in efficacy

Downloaded From Vet-e-Books.com

of treatment, as indicated by increased mortality or numbers of animals requiring retreatment, requires the submission of laboratory samples for bacteriological culturing and antimicrobial susceptibility testing. Thus monitoring of the antimicrobial susceptibility trends of bacterial pathogens associated with many common diseases is an important aid to the veterinarian in selecting the most efficacious and cost-effective therapeutic agents. A 4-year survey of antimicrobial susceptibility trends for isolates from cattle with bovine respiratory disease in North America found some resistance to several common antimicrobials and high susceptibility to some newer antimicrobials such as ceftiofur and tilmicosin (Watts et al, 1994). Wide fluctuations in susceptibility also occur from year to year.

Risk Factor Assessment

The systematic identification and assessment of the interaction of all risk factors in a herd could be used to predict the health status of herds. Such protocols have been developed and are being validated (Buddle et al, 1997). The relative risk of a herd developing a syndrome (risk status) is calculated from the measurements of all the risk factors for that syndrome and then plotted on a risk status map. In the risk status map each risk factor is positioned according to the closeness of its relationship with other risk factors. Strongly associated risk factors are close together in the diagram; weakly associated ones are further apart. One position on the map represents the overall "risk" for that syndrome occurring in that herd. The position of the herd on the map indicates whether the herd has a low, intermediate, or high risk of developing that disease syndrome. Examination of French protocols for risk factor assessment to predict the health status of Australian pig herds found that risk factors were most accurate in predicting health status in postweaning problems (Skirrow et al, 1997). For example, a weaning weight of at least 7.9 kg and weaning age of 30 days optimized weaner pig performance (Buddle et al, 1997). Stocking densities and shed designs providing at least 3 m^3 air volume and 0.6 m^2 floor space per pig throughout the growing phase should be considered for an improved respiratory health status.

Methods of Transmission of Infectious Disease

Infectious disease is the result of the invasion of a susceptible host by a pathogen. Depending on the characteristics of the pathogen and the host, infection of a susceptible host may or may not result in clinical disease. Following infection, the pathogen may be destroyed and essentially eliminated by the immune response of the host. The pathogen may be excreted in various discharges for varying periods of time and serve as a source of new infection for other susceptible hosts. In some infectious diseases, the pathogen persists in the tissues of the host, even in the presence of antibody, for prolonged periods. It may be shed in various discharges continuously or intermittently. The spread of the pathogen from an infected host to another host, thereby causing infection in the new host, constitutes the complete life cycle or life history of the pathogen. A knowledge of the life history of an infectious agent, including the modes of transmission, is essential when formulating the most effective control procedures. The important aspects of the life history of an infection are the methods of transmission of infectious agents and the factors that influence the maintenance and transmission of the pathogen.

Transmission of infections may occur *horizontally* or *vertically*. Horizontal transmission is from one animal or group of animals to another. Vertical transmission is from one generation to another, usually from the dam to the newborn through embryonic or fetal infection (congenital) or through the milk after birth.

Horizontal transmission can occur by direct or indirect means. Direct transmission occurs when a susceptible host comes into contact with an infected host or its discharges, which provide a source of the pathogen. Examples of diseases that are spread by direct transmission include tuberculosis, Johne's disease, pneumonic pasteurellosis, rinderpest, infectious diarrheas of calves and piglets, and several of the helminth diseases. Cattle herds usually become infected with *M. paratuberculosis* through purchase of *unknown infected* animals. Severe outbreaks of respiratory disease in dairy cattle herds can occur following infection with BRSV after the introduction of purchased animals into the herd (Elvander, 1996). The existence of bovine herpesvirus-1 infection in Dutch dairy farms that had never vaccinated for the disease was directly related to purchase of cattle and to participation in cattle shows (van Schaik et al, 1998b). Indirect transmission of disease involves an intermediate vehicle, living or inanimate, which transmits the pathogen between infected and susceptible hosts. Living or animate vehicles of transmission are commonly known as vectors. Typical examples are arthropod and insect vectors, such as ticks and mosquitoes, that transmit infectious agents from infected to susceptible animals. Mechanical vectors are those that simply carry the pathogen from the infected or primary host to the noninfected or secondary host. The infectious agent does not multiply in a mechanical vector. For example, it is thought that *Moraxella bovis*, the causative agent of pinkeye, is spread between animals by the face fly. In a biological vector, the pathogen multiplies or undergoes part of its life cycle before transmission to the secondary host occurs. Inanimate vehicles of transmission, such as contaminated feed and water supplies, equipment, clothing, and sacks, are known as fomites. The bovine leukemia virus may be spread from an infected animal to an uninfected animal by rectal palpation without a change of sleeves between animals (Divers et al, 1995). The bacteria causing contagious mastitis in dairy cattle are commonly spread by milkers' hands, milking machines, and common udder washing towels. Anthrax may be spread through the contamination of feed and water supplies, including bone meal, forage grown on contaminated soil, and fertilizer. There are several examples of infectious agents being transmitted by airborne transmission. This may explain the recent introduction of porcine respiratory coronavirus into Denmark (Flori et al, 1996).

In England, tuberculosis is endemic in the badger population, and the badger is considered to be an ideal maintenance host for *Mycobacterium bovis* (Cheesman et al, 1989). Outbreaks of tuberculosis due to *M. bovis* continue to occur in cattle and primary infections in man are presumed to be from cattle or infectious cases in the country (Hardie and Watson, 1992). Direct contact between badgers and cattle is believed to be infrequent, but it is hypothesized that the contamination of pasture by the deposition of infectious material such as urine, feces, or sputum and the badgers' use of cattle facilities or the presence of moribund or dead badgers increase the risk of transmission. Various methods of controlling tuberculosis in badgers are now being explored and evaluated (Smith et al, 1997).

The transmission of infectious diseases is not as simple as described. The transmission of many of the common infectious diseases of food-producing animals is not well understood. A number of assumptions have been made about the modes of transmission. Many diseases are probably transmitted by both direct and indirect means. For example, nursing beef calves at 2 months of age affected with coccidiosis may ingest the oocysts from the fecal-contaminated skin of the dam while sucking or from contaminated ground, which may be wet and muddy in the spring of the year.

Downloaded from Vet-eBooks.com

Sources of pathogens from infected animals include feces, urine, nasal and ocular discharges, saliva, exhaled breath and sputum, milk, semen (Afshar and Eaglesome, 1990), uterine fluids and fetal tissues, blood, and tissues from live and dead animals. These sources provide the pathogens that can contaminate the environment of animals. Feed and water supplies, including pastures and natural water reservoirs, feeding utensils, manure disposal sites, air of animal barns, bedding and ground surfaces, equipment used in the handling and management of animals, and streams and rivers can act as contaminated environments. They also are the source of pathogens for intermediate and amplifier hosts that are involved in the transmission of some infectious diseases. Viruses are shed into the environment from clinically ill or carrier hosts. The viruses do not replicate outside living animals or humans, but they are maintained and transported to susceptible hosts. Population concentrations and movement, both animal and human, have been increasing steadily in the past century, enhancing transmission of respiratory and enteric viruses and compounding the difficulty of preventing environmental transmission. Studies on environmental survival factors of viruses have been most definitive for polioviruses, foot-and-mouth disease viruses, and Aujeszky's disease virus. Heat resistance studies have been reported on adenoviruses, African swine fever virus, and the Norwalk virus. Resistance to disinfectants has been studied for many viruses, including picornaviruses, papovaviruses, reoviruses, and retroviruses. Survival of viruses in and on a variety of fomites has been studied for influenza viruses, paramyxoviruses, poxviruses, and retroviruses. Some agents such as that causing bovine spongiform encephalopathy have incredible stability in the environment (Pirtle and Beran, 1991).

The ability of a pathogen to survive and to be transmitted on farm and veterinary equipment is a major factor in transmission of disease within and between herds. For example, *S. suis* is able to survive under farm conditions and can be transmitted by fomites such as manure-covered work boots and veterinary vehicles (Dee and Corey, 1993).

The means of entry of infection include ingestion, inhalation, conjunctivae, percutaneous, genitourinary, and intramammary routes and the umbilical vessels in newborn animals. All of these occur by natural means. Infection transmitted by medical or surgical techniques, such as the use of contaminated hypodermic needles or contaminated medications, is known as iatrogenic transmission.

To determine whether or not an infection in a herd will spread from a small inoculum, the investigator must compute the number of secondary cases resulting from one infectious animal. The ratio of secondary cases to originally infected animals is called the reproduction ratio and is commonly denoted by R_0. When $R_0 < 1$, the infection will not spread and the animal population is effectively protected from the infection. When the infection is established, but R_0 is reduced to <1, the infection will disappear provided that some additional, commonly satisfied assumptions are met. When $R_0 > 1$, the infection can spread. Therefore a strategy for controlling an infectious agent is effective when, and only when, the ratio for that strategy is <1 (DeJong and Diekmann, 1992). The value of R_0 for a given host population is determined by a number of different factors, including the transmissibility of the infection, the period over which an infected host is infectious, the population density of hosts, and, where appropriate, the density of vectors and the capacity of the vectors to transmit the infection. Some estimates of the reproduction ratio for a few animal pathogens and parasite are available (Woolhouse et al, 1997). (See application of this principle later under "Efficacy of Vaccines.")

Vertical transmission of infectious agents occurs from the parent to the offspring through embryonic or fetal infection (congenital) or through the milk after birth. Infections that are transmitted vertically include *Neospora caninum* in cattle (which may result in abortion, stillbirths, fetal mummification, and live full-term calves with or without clinical evidence of disease [Davidson et al, 1999; Gonzalez et al, 1999]), BVDV causing persistent infection in calves when infection occurs in the nonimmune dam between 42 and 125 days of pregnancy, and *M. paratuberculosis* causing Johne's disease in cattle with infection transmitted from the infected carrier dam to the calf early in life (Goodger et al, 1996). Removal of the calf from the immediate environment of the cow within 1 hour after birth minimizes the exposure of the calf to the organism from the feces-laden calving environment.

Prevalence of Infectious Disease

The food-animal industries and veterinarians are becoming increasingly aware of the need for valid information concerning the occurrence, trends, and economic impact of all diseases of herds of food-producing animals. The availability of such information is essential for improving the health and production management of herds. The National Animal Health Monitoring System (NAHMS) has been established in the United States to measure the incidence, prevalence, trends, and economic costs of diseases in food-producing animals on a national level. (Detailed information is available on the Internet at http://www.aphis.usda.gov.) Data for the monitoring program are collected by federal, state, and university veterinarians through monthly visits to farms, which are selected by a random sampling procedure in seven states. Dairy cattle, beef herds, beef feedlots, sheep flocks and feedlots, swine herds, and poultry flocks have been included. Similar national programs for monitoring diseases of food-producing animals have been established in Canada and in the United Kingdom. The results provide information on the incidence of infectious diseases in the herds selected at random and surveyed for the incidence and costs of all clinical diseases over 1- to 2-year periods. They are discussed in the chapters dealing with the general aspects of dairy and beef herd health management.

Routine health management programs provide the sentinel herds and general data for an ongoing disease and production surveillance system (Dohoo, 1988). As described in Chapter 1, the Animal Productivity and Health Information Network (APHIN) in Prince Edward Island consists of a number of microcomputers on farms, in veterinary and diagnostic laboratories, and in processing industries, which are linked to a central database at Atlantic Veterinary College. Health and production data from these various sources are entered into the system using microcomputers linked to the central database by long-distance telephone. The central database prepares summary reports of animal health and production of all participating herds. In addition, reports are generated for individual farms. The major advantage of this system is that it allows producers and veterinarians to see what animal health and production performance values are being achieved in the population of animals at large and to compare them with those of individual producers. Such comparisons can serve as a powerful motivating force for producers to improve the efficiency of livestock production by health management.

Economics of Infectious Disease

Livestock producers need to know the cost of diseases, especially of subclinical or insidious diseases that affect production and are usually more costly than overt clinical disease. Knowledge of the prevalence and costs of both subclinical and clinical diseases is necessary to examine the

Downloaded From Vet-eBooks.com

cost-effectiveness of changing management or initiating specific eradication or control procedures.

The costs associated with infectious diseases include losses from deaths, decreased production from clinical and subclinical diseases, time and resources necessary to make a clinical and laboratory diagnosis, drugs, time and labor required to treat animals, cost of vaccines and their administration, and cost of depopulation and repopulation if used as a technique to control or eradicate a disease. The cost of continued surveillance to prevent the entry of infected animals is also significant in the management of infectious diseases.

Traditionally, the economics of disease have been considered in two ways (McInerney, 1988). The first has been to measure the losses caused by disease and to assign monetary values to those various losses, such as suboptimal performance, treatment costs, and deaths. The second method for economic application has been assessing disease control programs using cost-benefit analysis. In recent years, much has been written about the cost-benefit approach, which attempts to show the value of different methods of treating or controlling disease. However, these traditional methods of economic analysis, although useful management techniques, are considered to be merely cost accounting and do not represent an economic analysis of disease. They do not provide any guidance in devising, selecting, implementing, and monitoring a management plan, which is required for an economic analysis of livestock disease.

A rigorous economic analysis of disease begins with the principles of economics, which consider all activity in the real world (McInerney, 1988). Economic activity is the process whereby basic resources are physically transformed into other physical goods (or services) by a process called production. The physical goods are then distributed to the people who make up the economy by the process of consumption. Thus there are two central axioms of economics: (1) economic activity is directed entirely toward the benefit of people, and value arises solely from what those people want, and (2) economic activity is governed by the resources available, and the concept of cost derives from the resources that have to be diverted from some other use (McInerney, 1988). These principles provide the basis for introducing disease as an economic concept. Disease can operate on the production system to reduce the amount (or quality) of livestock products gained from the resources and thus reduce the benefits available to the people.

Predicting and Preventing Epidemics of Infectious Disease

An epidemic is the occurrence of disease in a population at a level that is clearly in excess of its expected frequency. The ability to predict that certain circumstances, unless removed or modified, could result in an epidemic of disease in a herd would be a valuable asset in a health management program. A variety of different methods are used to forecast potential problems. During regular herd health or emergency visits, a veterinarian may recognize the presence of certain risk factors known to predispose to disease. If corrective action is recommended, it may be possible to prevent the disease or minimize its incidence. For example, the examination of a beef herd a few months before calving may reveal the presence of risk factors, which if removed or modified could minimize the incidence of acute undifferentiated calf diarrhea. A change in milking technique may result in an increased incidence of subclinical mastitis. However, sometimes the veterinarian does not learn about such changes until the incidence of disease increases. Regular monitoring of the individual SCC is a useful aid in monitoring the prevalence of infection in the herd.

It may be possible to take corrective action before a costly herd problem develops. In large beef feedlots, the use of computers to monitor the occurrence of disease in recently arrived animals can predict the possible occurrence of epidemics. Based on the rate of new cases each day (the *epidemic curve*), within a few days after arrival it is possible to predict that a certain group of animals are of high risk and can develop a high incidence of respiratory disease. Unless efforts are made to minimize the daily rate of new cases, the affected group will develop a high incidence of respiratory disease. The treatment of each animal in such a high-risk group with an antimicrobial before they become clinically affected can reduce the morbidity and case fatality rates (Harland et al, 1991). (See Chapter 5.)

A national computerized system of abattoir condemnation data from cattle, sheep, and pigs has been developed in Northern Ireland (McIlroy et al, 1990). Liver condemnations because of fascioliasis reflect the prevalence of the disease in cattle and sheep populations. When combined with meteorological data, the condemnation rates can be used to forecast the prevalence of fascioliasis for the next year accurately. Such a system would allow the formulation of control strategies based on the expected prevalence of disease in any region of the world where relevant abattoir and meteorological data are available.

For certain infectious diseases, the prevalence of infection can be monitored over time by regular laboratory examination of a small, random sample of the population. A seroepidemiological profile of the presence of several diseases of cattle can be followed indefinitely and changes in prevalence related to the seasons of the year, number of clinical cases and other factors (Rodriguez et al, 1990). Selected enteropathogens from the feces of calves can be monitored over time and the results related to season of the year and age of the calf (Hird et al, 1990). Microbiological surveillance of infection is used to detect persistent infection with BVDV in resident and newly acquired bulls in artificial insemination centers (Howard et al, 1990). The prevalence of some infectious agents that may be associated with abortion in cattle can be estimated by the serological examination of bovine fetuses from pregnant cattle in an abattoir.

The number of animals that must be sampled in a population in order to detect infection or disease depends on the prevalence of infection in the herd (DiGiacomo and Koepsell, 1986). (See Chapter 5.)

INVESTIGATION OF INFECTIOUS DISEASE IN HERDS

Recognition of an Herd Epidemic

Investigation of infectious diseases in herds is becoming a more common activity in farm animal practice. A disease may be endemic in the herd, and the veterinarian may attempt to identify infected animals as part of a control program. In other instances, the diagnosis may be obvious but the causes and risk factors may not be well understood. Epidemics and episodes of endemic disease in herds provide opportunities for the veterinarian, the veterinary researcher, and the diagnostic laboratory to obtain some useful epidemiological information about the disease. Screening tests are also used commonly to monitor the prevalence of disease in herds as is generally done in mastitis control in dairy herds. Surveillance programs to monitor the prevalence of disease are only useful if a good screening test is available and when the characteristics of the test, such as sensitivity, specificity, and predictive values, are well understood.

Veterinarians should provide comprehensive clinical and epidemiological diagnostic services when herd epidemics occur. These include working with veterinarians from the

Downloaded From Vet-e-Books.com

state and provincial diagnostic laboratories and field investigation services so that as much useful information as possible about the nature of the disease can be generated for application to future epidemics and for the control of new cases. Investigation of herd epidemics provides an opportunity for the veterinarian to establish a health management program on the farm for the control of specific diseases. Veterinarians need to become more involved with herd health management; this includes solving herd problems, giving plans of action and recommendations, and conducting subsequent follow-ups to complete the health management cycle.

Clinical Examination of the Herd

Epidemics occur sporadically and may require in-depth clinical, epidemiological, and laboratory investigations to determine the risk factors or specific causative agents. An epidemic is the occurrence of disease in a population of animals at a level clearly in excess of its expected frequency (Lessard, 1988). The term is also used to describe any sudden impairment of the productivity of a herd or group of animals that may indicate the presence of subclinical disease. A sudden, unexpected decrease in milk production or reproductive performance in a dairy herd, a decrease in weight gain in grower pigs, or a reduction in the number of piglets born per sow may indicate an outbreak of subclinical disease despite the absence of clinical signs of disease.

Herd epidemics of infectious disease occur even in well-managed herds. Whenever possible, the veterinarian should visit the herd and conduct a thorough epidemiological investigation of the epidemic, including clinical examination of affected animals. If necessary, appropriate laboratory samples should be collected from both affected and normal animals. It is difficult to determine the important risk factors for outbreaks of infectious disease without visiting the farm and conducting a clinical and epidemiological investigation. The aim is to identify risk factors and attempt to eliminate or modify them. For most of the common types of infectious disease outbreaks that occur in North America, there is little evidence that the differences in disease levels among herds can be attributed to microbiological differences among herds (Hancock and Wikse, 1988). Many of the differences in disease levels among herds can be attributed to differences in the host and environmental factors under the control of management.

The principles and methods used in the investigation of disease outbreaks in herds are presented in Chapters 2 and 5.

Clinical Management of the Epidemic and Future Control

The investigation and clinical management of herd epidemics also involves providing recommendations about appropriate treatment, such as antimicrobial therapy, and advice on the withholding of milk from lactating dairy cattle or the slaughter of animals until the withdrawal period has expired.

The veterinarian has an obligation to use every opportunity to make livestock producers aware of the principles of effective disease control. This is most effectively done on a one-on-one basis. Such information can also be presented on a group basis with regular meetings of producers, at which information on disease control is given and discussed. Livestock producers look to their veterinarian for advice, and veterinarians should respect that trust. The success of infectious disease control on the farm depends heavily on the willingness and ability of the farmer to implement the recommendations of the veterinarian, who in turn must become skilled in explaining the principles so that they are understood and can be implemented. Once the veterinarian has left the farm, control of infectious disease, as with all other diseases, is in the hands of the livestock producer.

Final Report to the Owner

In order to complete a disease outbreak investigation, the veterinarian must record detailed epidemiological and clinical data for the duration of the epidemic. The appropriate analysis and interpretation should be made, followed by a final report to the producer.

DECISION ANALYSIS IN THE CLINICAL MANAGEMENT OF INFECTIOUS DISEASE

Decision analysis can be used to assist the veterinarian in making economic decisions. Concerns about groups or herds of animals with certain infectious diseases, whether to vaccinate as part of a control program or in the face of an outbreak of disease, and whether to depopulate and repopulate when faced with a disease, can be dealt with using decision analysis. Structuring the problem into a decision tree makes the questions clearer and forces the decision maker to think through the problem systematically while considering all alternatives Often, several possible options are available as well as uncertainties or risks associated with the possible outcomes for any given potential alternative. Decision analysis techniques are presented in Chapter 2.

TREATMENT OF INFECTIOUS DISEASES OF FOOD-PRODUCING ANIMALS

Animals affected with infectious diseases caused by bacteria are usually treated with antimicrobial drugs to minimize the effects on production, to prevent deaths, and to prevent further spread of the disease by elimination of the infectious agent, if possible. Animals affected with certain viral infections, particularly of the respiratory tract, may also be treated with antimicrobials in an attempt to prevent secondary complications caused by bacterial infections. In some situations, all animals in a group may be treated prophylactically to reduce the incidence of disease. For example, the parenteral administration of an antimicrobial to all high-risk feedlot cattle on the day of arrival in the feedlot can markedly reduce the incidence of acute respiratory disease, most of which is pneumonic pasteurellosis (Harland et al, 1991).

Culture and sensitivity testing to determine the most appropriate antimicrobial for a particular bacterial infection is commonplace. The relationship among the zone of inhibition of the disk diffusion test, the minimal inhibitory concentration achieved in the animal, and the concentration of the drug at the site of the lesion is critical and makes interpretation of the test results difficult.

The use of antimicrobial drugs in food-producing animals may result in drug residues in meat and milk, which are now a major public health concern. It is the veterinarian's responsibility to educate the producer on the correct use of antimicrobials and to adhere to stated withdrawal times for each drug used. Violations of drug withdrawal requirements in dairy herds that sent culled cows to slaughter before the withdrawal period elapsed have been reported (Marteniuk et al, 1988). The positive identification of each treated animal and the keeping of appropriate records to indicate the date on which the animal was treated and with which drug have become vital components of animal health management programs. A food-animal residue avoidance databank (FARAD)

Downloaded from Vet-e-Books.com

is now available by online computer as a single source of large amounts of information on veterinary pharmaceuticals, pharmacokinetics, and physicochemical properties of drugs and other chemicals used in livestock production (Sundlof et al, 1986). Several tests are available to detect antimicrobial residues in milk; the live animal swab test (LAST) can be used for residues in urine (Korsrud and MacNeil, 1988), and tissue testing can be performed for a wide variety of drugs and chemicals. Sulfamethazine residues were found in swine carcasses because of producers' failing to observe drug withdrawal times, feed mill mixing errors, fecal drug recycling, and unintended exposure of animals to feed contaminated with the drug before marketing (Bane et al, 1989). The tests used for the detection of sulfamethazine residues in swine, however, are not considered adequate for on-farm monitoring. Mass medication of feed and water may be an option for the clinical management of certain infectious diseases affecting herds of food-producing animals. However, the practice is not reliable because of wide variations in the amount of feed and water intake by individual animals within a group affected by varying stages of infection.

The extra-label use of antimicrobials and other drugs for the treatment of infectious diseases of food-producing animals can be a cause of drug residues in meat and milk. Extra-label refers to using drugs at a dose higher than approved, or by a route not approved, for the treatment of diseases other than for those approved, in a species for which the drug is not approved, or when unapproved for any use in any species. In the United States, veterinarians are allowed to prescribe, dispense, and use drugs at extra-label indications provided they follow certain conditions, including the following:

1. A careful medical diagnosis is made by an attending veterinarian within the context of a valid veterinarian-client-patient relationship.
2. A determination is made that there is no marketed drug specifically labeled to treat the condition diagnosed, or that drug therapy at the dosage recommended by the labeling has been found clinically ineffective in the animals to be treated.
3. Procedures are instituted to ensure that the identity of the treated animals is carefully maintained.
4. A significantly extended period is assigned for drug withdrawal before marketing meat, milk, or eggs; steps are taken to ensure that the assignment timeframes are met and no illegal residues occur.

Veterinarians have a responsibility to use drugs at the proper dosage, to justify their use by an extra-label route to provide specific information regarding withholding times associated with extra-label use, and to recognize the privileges and responsibilities.

REGULATORY VETERINARY AUTHORITIES AND DISEASE CONTROL

Most provincial, state, and federal government agencies employ veterinarians whose responsibility it is to ensure that the animal disease regulations for a particular area or for the entire country are followed by livestock producers and veterinary practitioners. A major responsibility of regulatory veterinary medicine is preventing the entry into the country of foreign or exotic diseases, which are a potential threat to the native population of animals. These diseases do not normally exist in the country or, if they have occurred, have been quickly eradicated by a slaughter policy. Preventing the entry of exotic diseases such as foot-and-mouth disease in cattle, bluetongue in sheep and cattle, hog cholera, and African swine fever is a major concern of regulatory authorities in countries that are declared free of those diseases. Regulatory agencies are also responsible for another group of diseases, which may also be reportable or notifiable but are not exotic. These diseases are considered important enough to the health of the national herd or to the human population as possible zoonoses that control procedures are part of the animal disease statutes of the country. Anthrax, brucellosis, tuberculosis, rabies, scrapie, pseudorabies, and bluetongue are examples of reportable diseases in Canada. Private practitioners must report the occurrence of these diseases to the regulatory veterinarians, who investigate the incident, conduct appropriate diagnostic testing, and institute standardized control procedures.

PRINCIPLES OF CONTROL OF INFECTIOUS DISEASES

Prevention, control, and *eradication* are the three terms used most commonly in association with disease control activities. We are unaware of any precise distinguishing definition for each of these terms, and there can be considerable overlap among their meanings. However, under practical conditions, all three methods are used to varying degrees to either eliminate disease or minimize its frequency and effect on production.

Prevention can refer to excluding clinical disease or infection from an unaffected population or protecting a population from clinical disease in an infected area by vaccination or other means. Quarantine and vaccination are examples of primary prevention. Vaccination does not prevent subsequent exposure to the infectious agent but can prevent a sufficient cause from causing clinical disease by rendering the animal immune to the level of challenge by the agent under field conditions. Secondary prevention includes those activities designed to detect disease processes as early as possible and to apply treatment before clinical disease occurs.

Control describes efforts directed toward reducing the frequency of existing disease to biologically or economically justifiable levels. For most of the common infectious diseases of food-producing animals, it does not mean the complete elimination of disease, because there may be a level of disease in the population below which the cost of further expenditure on control would be greater than the benefits derived.

Eradication usually refers to eliminating specific pathogens and hence disease from a herd or a defined area. However, the term is not absolute. Compulsory eradication schemes involving the slaughter of all affected and exposed animals are used to eradicate foot-and-mouth disease when it occurs in countries that are normally free of the disease. The disease usually does not recur unless the pathogen is introduced into the population of animals. Eradication is also used when attempting to eliminate the organism that causes footrot in sheep and *Streptococcus agalactiae* as a cause of mastitis in dairy herds. In both these examples, the possibility always remains that the organisms may not be completely eliminated from a particular herd of animals or they may be reintroduced more easily than are the foreign diseases into a country.

The following sections outline the principles of eradication and control procedures that can be used in herds of food-producing animals at the population level. It must be emphasized that, with the exception of a compulsory eradication program, the control of infectious disease is generally relative rather than absolute.

Principles of Eradication

Some infectious diseases can be eradicated from a herd, geographical area, or country. Eradication means complete elimination of the causative agent from the individual, usually by treatment or by removal or disposal of the infected animal(s) from the herd, so that no additional cases occur unless intro-

Downloaded From Vet-eBooks.com

duced from the outside, and so that specific immunization or treatment procedures are no longer needed. The control of disease by eradication has been a strategy used for many years, even long before the specific causes of diseases were known. Eradication can be achieved in a number of ways.

Compulsory Destruction and Disposal of All Clinically Affected and Exposed Normal Animals in an Affected Herd

Compulsory destruction and disposal is used by regulatory veterinary authorities for the eradication of exotic or foreign diseases, such as foot-and-mouth disease in countries that have a policy of being free of the disease. All clinically affected and in-contact susceptible animals are identified, killed, and disposed of by burning or burying. It may even mean destruction of animals from an adjoining farm that may have had contact with the affected herd through the movement of personnel back and forth between farms. All affected farms are quarantined, and movement of animals in a specified area may also be prohibited. In countries with such an eradication policy, the public at large supports the policy and the public treasury usually provides the owner with financial compensation for the animals that are slaughtered. Following disposal of the herd, standardized clean-up and disinfection procedures and a period of vacancy are mandatory, followed by the use of sentinel animals to ensure that disease does not occur before repopulation of the farm with the original species of livestock.

Eradication of highly infectious diseases depends heavily on controlling animal movement. A classic example is the difficulty of controlling the spread of contagious bovine pleuropneumonia. By relatively unsophisticated methods of prohibiting cattle movement, slaughtering diseased and contact cattle, and administering crude vaccination, contagious bovine pleuropneumonia was eradicated from most parts of Western Europe by the beginning of the twentieth century, although sporadic outbreaks were continuing on the French-Spanish borders until the 1920s (Egwu et al, 1996). The disease, however, has persisted in some parts of Europe, and outbreaks have occurred recently in Portugal and Italy. It spread to South Africa from Europe into East Africa by Boer settlers who trekked their cattle to the Kenyan highlands around the turn of the century. The disease is now endemic in much of sub-Saharan Africa, and its incidence is increasing. Countries like Kenya, Uganda, Mali, Rwanda, Tanzania, and Botswana that were once free of the disease are now experiencing endemic disease. To be effective requires full cooperation from cattle owners and timely compensation payments needed to restock herds. This strategy may be impractical in developing countries with a pastoral economy. Bureaucratic problems leading to delays in paying compensation and political considerations are contributory factors in the continuing prevalence of the disease in Europe. Guidelines for the eradication of the disease from endemic regions and eventually around the world have been described and serve as a model (Egwu et al, 1996).

Identification and Disposal by Slaughter of Infected Animals From a Herd

Diagnostic tests are used to identify infected animals, which are then removed from the herd and disposed of by slaughter for salvage. Only those animals that are positive for the test are removed from the herd, and, depending on the particular disease, all remaining test-negative animals in the herd are retested at suitable intervals until all animals are negative on one or more tests. Animals found to be test positive at each test are removed and sent to slaughter. This method has been used for the eradication of diseases such as tuberculosis, brucellosis in cattle, enzootic bovine leukosis, Johne's disease, and maedi-visna in sheep. Financial compensation to the owner is commonly provided by the government for the eradication of diseases such as brucellosis, tuberculosis, and Johne's disease. The identification of infected animals depends almost entirely on diagnostic tests, which are not 100% sensitive and specific. Therefore this method, although highly successful, is not as reliable as the policy of destroying entire herds of animals for the eradication of foreign diseases.

Since Switzerland and Denmark eradicated bovine herpesvirus-1 in the last decade, attention has been focused on the eradication of the virus from the European Union. Switzerland and Denmark were able to eradicate the virus by test and removal procedures for serologically positive animals because of its low prevalence at the start of the eradication program. In countries with a high prevalence of disease, eradication is only economically feasible by the prevention of new infections combined with an increased rate of removal of infected animals. In 1998 the Netherlands began a compulsory bovine herpesvirus-1 eradication program. To make the Dutch farmers aware of their bovine herpesvirus-1 status, samples of bulk milk were taken from many dairy farms and tested for the presence of antibodies with an ELISA (Van Wuijckhuise et al, 1998).

In an individual herd, a disease caused by a specific pathogen can be eradicated by disposal of the entire herd (depopulation), followed by a period of vacancy of the buildings, and then by repopulation with animals from herds certified to be free of the infectious disease. Animals that are imported into a herd or into a country may be quarantined for a certain time and tested for the presence of infection before they are introduced into the herd. Pneumonia in pigs caused by *Actinobacillus pleuropneumoniae* and *M. hyopneumoniae* can be eradicated using this procedure.

When certain diseases caused by specific pathogens have been eradicated from a herd, the herd can be closed. In this case, no further live animals are introduced, which prevents the entry of unknown infected animals. Genetic improvement in the herd is achieved through artificial insemination, embryo transfer, and selection within the herd.

For some diseases, a combination of control procedures followed by eradication are used. For example, the prevalence of brucellosis in Canada was reduced by calfhood vaccination and serologic testing of herds to detect infected animals, which were removed and sent to slaughter. Vaccination prevented abortion and, although infection was still possible, the prevalence declined. When the prevalence was low, the vaccination of calves was deemphasized, serologic testing continued to detect and remove positively infected animals, and eventually eradication was achieved. A simulation model of different control strategies for ovine paratuberculosis found that vaccination of the replacement ewes was the most cost-effective strategy compared with testing and culling, vaccination and culling, and no intervention (Juste and Casal, 1993). Eradication of the disease can occur within 10 years even with a vaccine efficacy of only 30%.

Elimination of Infection by Treatment

Elimination of infection involves the treatment of infected animals that have been identified by clinical examination or diagnostic tests. Examples include the use of antibiotics for the treatment of sheep with footrot, cattle with leptospirosis, and cattle with mastitis caused by *S. agalactiae*.

Following eradication of the infection from a herd, area, or country, constant surveillance to prevent the entry of unknown infected animals into the area or the herd is necessary. For the notifiable diseases of the country, this requires a regulatory system that certifies that exported and imported

Downloaded From Vet-eBooks.com

animals are free of certain infectious agents. For the individual livestock producer who wants to purchase breeding stock, it requires an effective testing and certification system that certifies that the purchased animals are free of the disease and that they originate from a herd that has been free of the disease for a specified period.

Principles of Control

The inability to eradicate many infectious diseases totally leaves control or "living with the disease" as the most common alternative. The ideal objectives of control are to reduce both the prevalence of existing infections and the incidence of new infections as well as the morbidity and mortality rates from clinical disease. For example, staphylococcal mastitis of dairy cattle cannot be eradicated. However, the adoption of a reliable mastitis control program can reduce both the prevalence of existing infection and the incidence of new infections and clinical cases of mastitis. Similarly, acute undifferentiated diarrhea of newborn calves cannot be eradicated. Some calves always develop the disease, but the incidence of clinical disease can be reduced using the principles of control. These methods include the reduction of infection pressure, adequate colostrum, and the use of vaccines in the pregnant cow. The principles of control include the following.

Reduce Infection Pressure and Prevent New Infections

One of the most important principles of infectious disease control is to minimize the infection pressure on noninfected susceptible animals and to prevent new infections. This means the maintenance of a clean environment so that contamination of the feed and water supplies, bedding, and other materials with infectious agents is minimized. Dairy cows housed in a dirty environment may experience a high incidence of coliform mastitis caused by environmental pathogens. The prevalence of subclinical mastitis in dairy cattle caused by *S. agalactiae* and *S. aureus* are related to the infection rate in the herd and to the levels of sanitation and hygiene practiced during milking. In the ideal situation, infected animals that are known sources of the pathogens would be kept separate from susceptible animals. However, in herds of animals, this is often unrealistic. For example, in the case of the infectious enteric diseases of newborn beef calves, the dams are the source of the pathogens and separation of the calves from the dams is not practical. In such cases, control depends on the achievement of adequate colostral immunity and minimization of infection pressure when the calf is most susceptible. The environment of the animals must not be allowed to become heavily contaminated with pathogens shed by carrier animals. Calving grounds in beef herds can become heavily contaminated with enteropathogens because of the buildup of feces, which increases the risk of diarrhea in newborn calves. The control of *Cryptosporidium parvum* infection in calves is dependent on reducing the infection pressure with good management practices and attention to hygiene when handling infected calves (Harp and Goff, 1998). In groups of animals, high population densities or crowding must be avoided to control the spread of infection among animals. Feed and water supplies must be handled and situated to avoid fecal contamination. On the other hand, a controlled infection pressure may be useful. Low levels of contamination below those that result in clinical disease can result in effective immunization, as occurs in coccidiosis. In the case of respiratory disease in feedlot cattle, infection pressure may be controlled by minimizing the mixing of cattle from different sources. This is usually not practical in custom feedlots, however, in which cattle from many different backgrounds are assembled into pens.

An example of reducing infection pressure and preventing new infections in herds is nursery depopulation for the control of porcine reproductive and respiratory syndrome in swine herds. Control within a breeding herd is based on the observation that pigs commonly seroconvert to the virus during the nursery period. Pigs are seronegative shortly after weaning, but 80% to 100% are seropositive at 8 to 10 weeks of age (Dee et al, 1997). A control program based on a *nursery depopulation* consists of emptying the nurseries and moving *all of the pigs* to off-site finishing facilities or selling them as feeder pigs. This is combined with batch farrowing and weaning at intervals of at least 3 weeks. The nurseries are completely emptied and cleaned three times with hot water and disinfectant, the slurry pits are pumped out after each cleaning, and the facilities are kept empty for 14 days, during which time all pigs weaned are moved to off-site nurseries. After this the conventional flow of pigs into the cleaned facilities is resumed. The control program can cause significant improvements in both average daily gain and percentage mortality, but it will not eliminate the virus from the herd. Using a partial budget model to measure the profitability of nursery depopulation, the financial consequences indicate that it is profitable strategy to improve pig performance in herds affected with the virus. Additional income is generated by the increased number and weight of marketable pigs, as a result of their increased growth rate and decreased mortality. Lower treatment costs reduce overall expenses, but there are additional costs because of extra feed necessary to raise the additional pigs and the costs required to house the depopulated pigs. However, it is possible that the economical benefits are due to the control of other pathogens and not merely the porcine reproductive and respiratory syndrome virus.

The details for a nursery depopulation and clean-up protocol for the elimination of the virus are shown in Table 4-3 (Dee et al, 1997).

Management of Gilt Pool. Management of the gilt pool is the single most important strategy for long-term effective control. Controlling the infection in the breeding herd is a

TABLE 4-3

Nursery Depopulation and Clean-Up Protocol for the Elimination of the Virus

Day	Procedure
1	Empty all nurseries, off-site weaning, pump out slurry pits, clean and wash rooms with hot water (>95° C) and disinfect with formaldehyde-based product. Allow disinfectant water to remain in pits overnight.
2	Pump out pits, repeat washing procedure, and disinfect in phenol-based product. Allow disinfectant to remain in pits.
3-11	Allow facility to remain vacant.
12	Pump out slurry pits, repeat washing procedure, and disinfect with formaldehyde-based product.
13	Allow facility to remain vacant.
14	Resume conventional flow of pigs into clean nurseries.

prerequisite to controlling infection in the nursery and finishing pig groups. Strategies like partial depopulation and piglet vaccination are ineffective unless the breeding herd is first stabilized, which prevents piglets from being infected before weaning. Replacements are a major source of introduction of the virus and activating existing virus in the breeding herd. They also initiate the formation and maintenance of breeding herd replacements.

Subpopulations are subsets of naive or recently infected gilts or sows that coexist within chronically infected herds. These subpopulations perpetuate viral transmission in the breeding herd and farrowing units that ultimately produce successions of infected piglets before weaning. Modifications in gilt management that may minimize subpopulations include ceasing introduction of replacement animals for a 4-month period, beginning selection of replacements from the finishing unit, or introducing a 4-month allotment of gilts at one time.

Exposure to the virus in the breeding herd can be controlled by managing the gilt pool using two strategies. In one strategy, herds may be closed to outside replacements and replacement males and females are raised on the farm. In the other strategy, replacement gilts are held in an off-site holding facility from 9 to 12 weeks of age until breeding age at 7 to 7.5 months or even much earlier. This is combined with nursery depopulation as described previously. Before entry of the gilts into the herd they are serologically tested for evidence of seronegativity or a declining titer, which is required for entry into the herd. The gilts are isolated and quarantined for acclimatization for 45 to 60 days. This may be combined with vaccination twice, 30 days apart, after entering quarantine (Dee et al, 1998). This method reduces the risk of introducing potentially viremic animals into the existing population. The method selected depends on the production system, management capabilities, and facilities available on each farm. The introduction of younger gilts, in larger groups and less frequently throughout the year, is being recognized as the most effective method for introducing replacement stock to virus infected herds and long-term control of the disease.

Controlled Infection of Breeding Herd. The presence of subpopulations of highly susceptible breeding animals in the herd can be a major risk factor for maintaining viral transmission within problem herds and may explain recurrent outbreaks of reproductive failure. By intentionally exposing all members of a population to the virus, it may be possible to eliminate subpopulations and produce consistent herd immunity. In endemic herds, exposure of gilts to the virus before breeding is critical for prevention of reproductive failure. Seronegative replacement gilts can be introduced into seropositive herds at 3 to 4 months of age to allow for viral exposure before breeding. If the status is uncertain, quarantine and exposure to nursery pigs of the importing unit is a suitable policy if replacement gilts are brought in before they are bred.

Biosecurity. Biosecurity is any practice or system that prevents the spread of infectious agents from infected animals to susceptible animals or that prevents the introduction of infected animals into a herd, region, or country in which the infection has not yet occurred. Biosecurity, an integral part of any successful livestock enterprise, reduces the risks and consequences of introducing an infectious disease. The components of biosecurity, which include management and placement programs, farm layout, decontamination, pest control, and immunization, directly affect productivity and profitability.

For some diseases it is desirable to prevent the spread of infectious agents from a certain age group of animals to younger age groups, such as attempting to control the spread of the virus causing porcine reproductive and respiratory syndrome in pigs by depopulation of the nursery pens.

The introduction of new infections into herds can be prevented or minimized by purchasing animals directly from herds that are known to be free of a particular disease. The adoption of this principle requires awareness of the possibility of purchasing unknown infected animals and testing animals for the infection before entry into the herd. It may also require keeping the introduced animal in quarantine for several weeks after arrival before it is mixed with the other animals.

New infections can be prevented within herds or flocks by separation of the neonates from their dams immediately after birth and by rearing them in isolation from infected animals. This procedure for lambs, along with the culling of seropositive sheep, has been used for the control of ovine progressive pneumonia (Cutlip and Lehmkul, 1986). Many dairy producers now remove the calf from the dam immediately after birth and feed it colostrum rather than allowing it to remain with the cow for 3 days, as was the practice for many years. The rationale is that the calf will not become infected with the enteropathogens shed by the cow, but this has not yet been substantiated.

Caprine arthritis-encephalitis in goat herds can be controlled by removing the kids from infected herds at birth, avoiding any contact with the dam, and feeding cow's colostrum and milk (Nord et al, 1999). Seronegative groups are gradually established within each herd. When housed indoors the seronegative groups are kept segregated from the seropositive groups by compact pen fences. Total segregation of seronegative and seropositive groups, even at pasture, is of vital importance for the establishment of herds free from caprine arthritis-encephalitis virus infection. However, even with a strict control scheme, considerable reduction in prevalence of virus-positive animals rather than complete eradication is probably the most realistic aim for the first 2 or 3 years. To be declared free of the infection, a previously infected herd should test negative on at least three or four occasions at intervals of 6 to 12 months.

At least five categories of biosecurity in dairy herds have been described (Rauff et al, 1996):

Category 1: The highest biosecurity, in which replacement cattle were not purchased and animals were not taken to cattle shows or fairs.

Category 2: Herds in which producers did not purchase replacement cattle but did take their animals to shows and fairs.

Category 3: Herds in which producers purchased replacement cattle but isolated them on arrival to their farm.

Category 4: These are considered the riskiest herds, in which producers purchased replacement cattle and did not isolate them on arrival.

Category 5: Herds whose producers did not have sufficient information necessary to be classified.

Surveys of dairy herds in the United States indicate that about 50% of herds purchase replacement cattle but only 12% of those herds isolate them on arrival (Rauff et al, 1996). Most of the herds were biosecurity Category 1 (45.5%) or Category 4 (40%). Only 11% of dairy herds exhibited cattle from their herds at shows or fairs. Veterinarians need to work with their clients to develop a specific disease control and biosecurity protocol for each farm. The benefits of a rigidly enforced biosecurity program need to be stressed. Veterinarians can assist producers in developing methods to handle livestock and to purchase replacement stock by designing protocols that concentrate on general and specific aspects, such as design and construction of isolation rates.

Downloaded from Vet-e-Books.com

A closed system to prevent the introduction of infectious diseases into dairy farms is technically possible and is economical (van Schaik et al, 1998a). A closed dairy herd system could prevent the introduction of bovine herpesvirus-1, BVDV, leptospirosis, paratuberculosis, and salmonellosis and can be a good starting point for eradication of these infectious diseases from the herd. Limited field studies have found that closed dairy farms had a higher birth rate per 100 dairy cows, a lower average age at first calving, and lower costs for veterinary services (van Schaik et al, 1998b).

Biosecurity measures to prevent the introduction of infectious agents into herds is most advanced in the swine industry, where workers, visitors, veterinarians, and other service-oriented personnel may have to remove all of their street clothing, take a shower, and use clothing provided by the swine enterprise before they are allowed to enter the premises. In such high-security swine herds, no replacement breeding stock are purchased and all new gene pools may be introduced through artificial insemination.

The major routes through which an infectious agent can be introduced on to a farm follow:

1. Contact with other animals of the same species (e.g., purchased replacement stock)
2. Contact with other animal species that are potential carriers of the disease (e.g., sheep, goats, rats, and dogs in contact with cattle)
3. Transmission by humans (e.g., visitors, veterinarians)
4. Transmission by machinery (e.g., cattle trucks, manure spreaders, other tools)
5. Transmission by feedstuffs or water supplies (e.g., ditch water)
6. Transmission by air

Quarantine. A quarantine is a place or fixed period of isolation or restriction of the movement of animals. Animals being introduced into a herd or a country from another source herd or country may be quarantined in an isolation facility for a specified period during which the animals are monitored clinically or by laboratory testing for evidence of infectious disease. The objective is to ensure that the imported animals are not infected with infectious agents that could be transmitted potentially to animals of the importing herd or country. After a specified period of time, and if there is no evidence of infectious disease, the restrictions on the quarantined animals are lifted and the animals are allowed to mix with the importing herd or the general population. During the period of quarantine, transmission of infectious agents from the quarantined animals to the importing herd must be prevented by ensuring that feed and water supplies and personnel are kept separate from the nonquarantined animals. During outbreaks of highly contagious diseases such as foot-and-mouth disease, the affected farms may be quarantined for a fixed period during which animals from those farms cannot be moved to any other place, and unaffected farms may not be allowed to import animals until expiry of the quarantine measures.

Control of Wildlife Vectors. The control of some infectious diseases of food-producing animals, especially cattle, depends on control of disease in wildlife vectors that are reservoirs of infection for cattle. Tuberculosis in cattle is a significant problem in the United Kingdom because of the reservoir of *M. bovis* infection in badgers (Newell and Hewinson, 1995), and in New Zealand because of the reservoir of infection in the Australian brushtail possum (O'Neil and Pharo, 1995). In New Zealand the problem is confined to discrete areas, and spread is usually within those areas. The control scheme consists of measures to identify infected herds, to define the size of the problem, to contain the problem, and to eradicate the disease from vectors, cattle, and deer in most areas. The central cause of persistent disease nationally remains the possum, although other species may play a subsidiary role locally (Morris and Pfeiffer, 1995). The epidemiological characteristics of tuberculosis in cattle and the possums are now understood, and control strategies are based on reducing the prevalence in endemically infected possum populations and reducing the outward spread because of dispersal of pseudovertically infected juvenile possums. The use of badger vaccines in the United Kingdom is being explored as a method of control (Newell and Hewinson, 1995).

Reduction of Effects of Environmental and Host Risk Factors

A second major principle in the control of infectious disease is to reduce the effects of environmental and host risk factors that make animals susceptible to disease. Some common environmental risk factors include inadequate housing and ventilation of housed animals, rapid changes in weather, and sudden exposure to cold and windy weather. It is often difficult for even excellent livestock producers to manage uncontrollable environmental factors. In the continuing quest for more effective vaccines for the control of bovine respiratory disease, the importance of good management, housing, and husbandry must not be overlooked (Bryson, 1997). The host risk factors include failure of colostral transfer in the newborn animal, inadequate nutrition, deficiencies of trace minerals such as selenium and copper, genetic susceptibility, total lack of immunity because of no previous exposure to the antigen (either by natural infection or vaccination), age of animal (the young are more susceptible), animals that are stressed following prolonged, uncomfortable transportation, feed deprivation, immunosuppression, vaccination with live vaccines when animals are stressed, concurrent infections, and mixing animals of different ages and from different sources (as occurs commonly in commercial feedlots).

Chemoprophylaxis to Eliminate or Control Infection

The elimination of infection by chemotherapy or culling from the herd can reduce the prevalence of infection in the herd. One of the best examples of the successful application of this principle is the use of antibiotics for the control of bovine mastitis caused by the major contagious pathogens. The use of penicillin is highly effective for the treatment of cows infected with *S. agalactiae* during lactation. For cows infected with *S. aureus*, the use of long-acting penicillin at the end of lactation (dry cow therapy) is relatively effective. In both cases the use of antibiotics eliminates existing infections, and the dry cow therapy prevents new infections during the early part of the dry period. In a successful mastitis control program, both the prevalence of infections and the incidence of new infections decrease.

Metaphylaxis. Metaphylaxis is the mass medication of individual animals with an antimicrobial at a strategic time in order to prevent the onset of clinical disease. Antimicrobials are used for the control of pneumonic pasteurellosis, particularly in cattle that have just been introduced into a feedlot. The early onset of pneumonic pasteurellosis in cattle within a few days after arrival in the feedlot requires consideration of mass medication of all animals in a group as part of a health management program. Field trials indicate that administration of antimicrobials to calves at varying times on arrival in the feedlot can reduce subsequent morbidity and mortality from respiratory disease. The administration of antimicrobials to high-risk calves immediately after arrival is particularly effective under commercial feedlot conditions. Meta-

Downloaded from Vet-eBooks.com

analysis of the literature on mass medication for bovine respiratory disease indicates that prophylactic parenteral mass medication of calves with long-acting oxytetracycline or tilmicosin on arrival at the feedlot reduces bovine respiratory disease morbidity rates (Van Donkersgoed, 1992).

The injection of trimethoprim-sulfadoxine or oxytetracyclines on arrival can reduce morbidity and mortality from respiratory disease in high-risk calves. The administration of a long-acting preparation of oxytetracycline at a dose rate of 20 mg/kg BW IM to feedlot cattle on arrival can reduce the morbidity and mortality from respiratory disease. Both the IM and SC administration of oxytetracycline formulation are comparable to the IM administration of currently available oxytetracycline formulations after arrival in the feedlot. Tilmicosin, at 10 mg/kg BW SC given to calves immediately after arrival, significantly reduced the treatment rate for bovine respiratory disease during the first 5 days as well as during the first month of the feeding period (Vogel et al, 1998). The administration of tilmicosin to calves, either on arrival at the feedlot or 3 days later, reduced the treatment rate for respiratory disease in the first 30 days. The average daily gain was also improved in the treated group compared with the controls, and the feed conversion efficiency over the first 60 days of the feeding period was superior in the medicated group compared with the nonmedicated animals.

Mass Medication of Feed and Water Supplies. Medication of the feed and water supplies has given variable results because of the difficulties in obtaining adequate levels of antimicrobials in those cattle that most need them. In normal weaned beef calves at 6 to 8 months of age, blood levels of sulfamethazine of 5 mg/dl or greater can be achieved in 15 to 24 hours by providing medicated water at a dose rate of approximately 150 mg/kg BW. At 75 mg/kg BW the same blood levels are achieved by 72 to 84 hours. A standard recommendation is to provide 150 mg/kg BW for the first 24 hours and reduce the level to 75 mg/kg BW for the duration of the medication period, which may last from 5 to 10 days. A feed additive containing 700 mg/head/day of chlortetracycline and sulfamethazine from the day of arrival at the feedlot to day 56 of the feeding period improved average daily gain and feed conversion and reduced the incidence of bovine respiratory disease for days 0 to 28 and 0 to 56, the rate of relapses and mortality for days 0 to 56, and the incidence of chronic respiratory disease for days 0 to 28 and 0 to 56. Performance and health improvements attributed to the feed additive were cost-effective. However, medication of the feed and water supplies can result in a false sense of security, and the number of advanced cases of disease can actually increase.

Interferon Medication. Interferons are a heterogeneous family of cytokines that have antiviral, immunomodulatory, and cell growth inhibitory activities (Moore, 1996). Interferons are efficacious therapeutic agents for the treatment of several clinically important infectious diseases of food animals. None of the interferons is approved for use in food-producing animals.

Enhancement of Immunity Using Vaccination Programs. Vaccination is exposing an animal to an antigen derived from an infectious agent so that an immune response is stimulated and acquired resistance to that infectious agent is achieved before natural infection occurs. Several criteria must be considered to determine whether vaccination is either possible or desirable in controlling a specific disease (Tizard, 1996). The first is the absolute identification of the causal agent. Second, it must be established that an immune response actually can protect against the disease in question. Third, before using a vaccine, there must be assurance that the risks of vaccination do not exceed those associated with the chance of developing the disease in question. Thus the decision to use vaccines for the control of any disease must be based on considerations not only of the severity of the problem, but also of the prospects for its control by other techniques, such as removing or reducing the effects of risk factors.

When vaccines are used to control disease in a population of animals rather than in individuals, the concept of herd immunity should also be considered. Herd immunity is the resistance of an entire group of animals to disease conferred by presence in the group of a proportion of immune animals. Herd immunity presumably acts by reducing the probability of a susceptible animal meeting an infected one so that the spread of disease is slowed or terminated. If it is economically acceptable to lose individual animals from disease while preventing epidemics, it may be possible to do so by selective vaccination of only a proportion of the herd (Tizard, 1996).

Animals may be rendered immune to an infectious disease by *passive* or *active immunization* (Tizard, 1996). Passive immunization provides temporary resistance by transferring antibodies from an animal that possesses them from a natural infection or vaccination to an animal that does not. The transfer of colostral immunoglobulins is an example. Passive antibodies provide immediate protection that is short-lived because the antibodies are catabolized. The control of acute diarrhea in newborn calves can be aided by vaccination of the dam in pregnancy with vaccines containing antigens of *E. coli* 0157:H7, rotavirus, and coronavirus. The pregnant animal develops an immune response to these antigens and produces antibodies that are concentrated in the colostrum and subsequently transferred to the calf. Active immunization is the result of natural infection or vaccination, which involves the administration of an antigen to an animal so that it responds by developing a protective immune response that may be antibody-mediated, cell-mediated, or both. Reimmunization or exposure to infection results in a secondary immune response. Protection is not conferred immediately but usually requires several days or a few weeks; however, once established, it is long lasting and capable of restimulation.

The ideal vaccine should confer prolonged immunity to both the animal vaccinated and its fetus. It should be free of adverse side effects. It should be inexpensive, stable, adaptable to mass vaccination, and, ideally, should stimulate a response distinguishable from that resulting from natural infection so that vaccination and eradication may proceed simultaneously.

The classic vaccines can be divided into two groups according to the status of the organism or bioactive agent included as the antigen: live or killed (inactivated). The term "killed" is used when bacterial vaccines are discussed, whereas the term "inactivated" is used for vaccines used against viruses or toxins.

There are relative advantages and disadvantages of live and killed vaccines (Table 4-4) (Tizard, 1990). Two of the prerequisites of an ideal vaccine—high antigenicity and the absence of adverse side effects—tend to be mutually incompatible. Vaccines containing viable infectious agents stimulate the best immune response but have the potential to produce disease because of residual virulence, whereas the antigens in killed vaccines may be relatively poor immunogens but are usually much safer.

Live Vaccines. The advantages of live vaccines include the following: strong and long-lasting immunity, few inoculating doses required, administration possible by nonparenteral routes (e.g., intranasal), adjuvants unnecessary, less chance of hypersensitivity, and viral vaccines may stimulate interferon production.

The disadvantages of live vaccines include the following: systemic reactions because a mild form of the disease may occur, possibility of reversion to the virulent state by muta-

Downloaded From Vet-eBooks.com

TABLE 4-4

Advantages and Disadvantages of Live and Killed (Inactivated) Vaccines

	Live Vaccine	Killed (Inactivated) Vaccine
Advantages	Strong and long-lasting immunity; few inoculating doses required; effective by nonparenteral routes (intranasal, oral); less chance of hypersensitivity; may stimulate interferon	Unlikely to cause disease; stable on storage
Disadvantages	Systemic reactions caused by mild form of disease may occur; possibility of reversion to virulent state by mutation or recombination of a piece of genome with a mild strain of the pathogen; possibility of perpetuation of the vaccine antigen in the animal or environment; may cause abortion; limited shelf-life, requires defined temperatures for storage; possibility of contamination with adventitious agents	Possibility of incomplete inactivation; generally induces short-lived immunity; effective only by parenteral route, multiple doses may be required, which increases cost; hypersensitivity may occur because of antigenic modification; use of adjuvants in vaccines may cause local reactions at site of vaccination

tion or recombination of a piece of a genome with a wild strain of the pathogen, possibility of perpetuation of the pathogen in the animal or its environment, possibility of abortion in pregnant animals, limited shelf life, requirement of a defined temperature for storage, requirement of a biological system for vaccine production, and possibility of contamination with adventitious agents. However, the proper use of modified live virus vaccines does not have *immunosuppressive* consequences in healthy animals in which there is usually a significant antibody response to the administered antigen. Vaccination of healthy cattle with a modified-live BRSV vaccine does not result in adverse clinical reactions, leukopenia, alteration in blood leukocyte subsets, and decrease in phytomitogen-induced lymphocyte blastogenic responses (Ellis et al, 1990).

Killed Vaccines. The advantages of killed vaccines are that they are unlikely to cause disease because of residual virulence or reversion, and they are stable on storage.

The disadvantages of killed vaccines include the following: possibility of incomplete inactivation exists; they generally induce short-lived immunity; they must be given parenterally; generally a high antigenic mass is needed and therefore multiple doses are required, which increases cost; and they are often associated with an undesirable immune response such as hypersensitivity because of antigenic modification or contamination. Also, the use of adjuvants to increase effective antigenicity can cause severe local reactions that develop into small granulomas. These lesions can be unsightly and cause concern about condemnations at the time of slaughter.

The disadvantages of the conventional vaccines have created the need to develop vaccines based on a solid knowledge of elementary surface antigenic structures (epitopes or antigenic determinants) related to protection and immunopathology. This has led to an interest in developing second-generation vaccines. These new vaccines are characterized by the use of techniques involving recombinant DNA, monoclonal antibodies, and protein engineering (chemical synthesis of protein antigens). These techniques are commonly referred to as biotechnology.

Biosynthetic Vaccine. A biosynthetic vaccine is a formulation containing a noninfectious, protective subunit immunogen that is produced in or by a biological system. Isolated structural components of infectious pathogens, particularly proteins, are immunogenic and provoke protective immune responses with fewer undesirable side effects generally associated with whole-agent vaccines. A subunit vaccine that contains only those immunogenic components necessary to elicit a protective response and excluding others unnecessary for immunity has several attractive features. First, and of major importance, is safety; subunit vaccines lack infectious material, and no infection, either acute, persistent, or latent, can be established in vaccinated animals. This characteristic reduces complications arising from vaccination of immunocompromised or pregnant animals. Second, adventitious agents can be eliminated, thus preventing complications such as allergic reactions and immunosuppression from extraneous agents. Third, subunit vaccines are stable, allowing for wide distribution and prolonged storage. Another advantage of subunit vaccines is that vaccinated animals can be distinguished serologically from infected animals, which is a major advantage in disease control and eradication programs. The disadvantages of subunit vaccines at the present time include their high cost associated with research and development and the need to administer multiple vaccinations before protective immunity is established. Immunostimulants such as adjuvants are usually incorporated into subunit vaccines to improve efficacy.

Recombinant DNA technology is being used to produce live, genetically engineered vaccines, such as the vaccinia-vectored vaccines. Vaccinia virus was one of the first viruses into which foreign antigens were inserted and shown to be capable of inducing immunity to the foreign antigen (Babiuk et al, 1990). Such technology has the potential to improve the efficacy of vaccines for infectious diseases and improve animal production.

Efficacy of Vaccines

The veterinary practitioner is often asked for advice about the use of vaccines for the control of infectious diseases of food-producing animals. There is probably more controversy and uncertainty about the efficacy of these vaccines than about almost any other topic in livestock production. Livestock producers are exposed to a wide variety of advertising from biological manufacturers who claim that their vaccines can provide protection against clinical disease. The producer expects the veterinarian to be knowledgeable regarding the use and efficacy of specific vaccines but is generally unaware that reliable data

Downloaded from Vet-eBooks.com

showing efficacy against naturally occurring disease may not be available to the veterinarian or are nonexistent. Producers usually assume that licensure of the vaccine is synonymous with vaccine efficacy. All of this places the veterinarian in a difficult position; the veterinarian is asked to prescribe and dispense vaccines for which there are no valid efficacy data.

The Canadian Animal Health Institute's *Canadian Compendium of Veterinary Pharmaceuticals: Biologicals and Specialties* (ed 6, 1999) lists more than 40 vaccines for the control of bovine respiratory disease and more than 10 vaccines for the control of acute diarrhea in calves. How is the veterinarian, or the livestock producer, supposed to select the most effective and economical vaccine(s) from this list of products, for which efficacy data are scant or not available? On what basis should the veterinarian select a vaccine from these lists? It should be based on a combination of efficacy, potency, safety, and cost. However, although they may be safe and relatively inexpensive, there is widespread concern among veterinarians that some of these vaccines are not efficacious. There is also a need to ensure safety of biologicals used in veterinary medicine (Evermann, 1996). Contamination of vaccines with viruses may occur, and sensitive detection systems must be applied to ensure quality control.

Field observations by veterinarians and critical reviews of the literature (Perino and Hunsaker, 1997) have suggested that the vaccines that appear to lack efficacy are those intended for the control of enteric and respiratory disease complexes of cattle. It appears that, for certain diseases, not all currently available vaccines are effective. For other diseases, there are wide differences in effectiveness among vaccines produced by different companies. In other cases, there may be considerable difference in effectiveness among serial lots of the same product. A review of the literature of the field efficacy of vaccines intended for the control of bovine respiratory disease published from 1972 to 1996 found 521 articles, and 183 were deemed relevant to the objective. Only 22 articles were considered to be of acceptable experimental design (Perino and Hunsaker, 1997). Most efficacy studies are based on extrapolation from experimental challenge experiments rather than on randomized clinical field trials under naturally occurring conditions (Higgins, 1997). Hemophilosis in feedlot cattle in western Canada is considered to be the most significant cause of mortality in fall-placed weaned beef calves despite routine single immunization of calves with a commercial *H. somnus* bacterin on arrival (Van Donkersgoed et al, 1990a). A field evaluation of the efficacy of two vaccines against pneumonic pasteurellosis in sheep being shipped from New Zealand to Saudi Arabia found no clear evidence of either vaccine resulting in a lower incidence of deaths or lesions because of pneumonia (Black and Duganzich, 1995). The vaccines are effective in the laboratory, but they are ineffective under naturally occurring conditions or the results are conflicting. Conversely, the vaccination of cows and heifers with a BRSV vaccine before parturition may unexpectedly increase milk production and first insemination conception rates (Ferguson et al, 1997). In first parity cows, vaccination had a beneficial effect on milk production during the first 14 weeks of lactation, indicating that there was a reduction in subclinical illness and an increase in dry matter intake in these cows, compared with herd mates. Second parity cows vaccinated against BRSV before calving had improved first insemination conception rates.

In some cases the vaccine may be ineffective because the antigens used in the manufacture of the vaccine may not provide optimal protection against even closely related field strains of the organisms. For example, a pentavalent leptospiral vaccine containing *Leptospira interrogans* serovar *hardjo-prajitno* did not provide protection against experimental challenge with *L. hardjo-bovis* serovars (Bolin et al, 1989). Renal carriers, with periodic urinary shedding of the organisms, were established in vaccinated and control animals after they were challenge exposed. Fetal infection, stillbirths, and birth of weak calves also occurred in both vaccinated and control cows.

The efficacy of vaccines for farm livestock has been an issue. It has been suggested that the problem of inadequate vaccine efficacy is a result of the following: (1) the reliance of the licensing agency on efficacy data generated by the manufacturer (who has a vested interest in the data), (2) the acceptance by the licensing agency of efficacy data from studies that were inadequately designed or did not provide results that could be correlated significantly with protection against the naturally occurring disease, (3) the lack of influence of data from independent laboratories, which are contrary to data on which licensure is based, (4) inadequate monitoring of the efficacy of vaccines after licensure, and (5) the unavailability of efficacy data used in licensure for peer review. Furthermore, the lack of awareness of livestock producers and veterinarians concerning the current limitation of the licensing authority further contributes to the seriousness of the problem.

The problems related to the efficacy of vaccines used in farm livestock need to be addressed by all individuals and agencies concerned with veterinary medicine. Veterinary practitioners, vaccine manufacturers, governmental agencies, diagnostic laboratories, veterinary colleges, and vaccine users all have a stake in ensuring that vaccines are safe and effective.

In Canada, it is generally assumed that the biologics licensed by the Animal Health Division, Food Production and Inspection Branch, Agriculture Canada, are safe and can stimulate protection against naturally occurring diseases in vaccinated animals (Alexander, 1989). However, there is considerable field experience suggesting that some vaccines are not effective. Outbreaks of acute respiratory disease occur in cattle that have been vaccinated with a variety of respiratory disease vaccines. When these outbreaks occur, it is difficult to document that the vaccine was ineffective for a number of reasons. It is often difficult to obtain a definitive, causative diagnosis for the reasons described earlier. It is difficult, if not impossible, to determine whether the vaccine was used as prescribed, the vaccine was stored properly and maintained its potency, and risk factors were present that overwhelmed the immune response.

What is the definition of vaccine efficacy? Efficacy could mean prevention of the disease in question or control at an economic level. It could also mean that it is economical to use the vaccine, because vaccinated animals may be more profitable than unvaccinated animals. The essence of any vaccine must be that it is safe and capable of eliciting a protective response in the targeted host. This could mean protection from clinical disease or protection from infection by the pathogen, and a criterion for protective efficacy must be established for each disease for which a vaccine is to be developed. Protection does not mean that the vaccine constituents are immunogenic or antigenic, or that they elicit neutralizing antibodies. Although correlations between an in vitro serum neutralizing antibody and protection against disease do exist for some diseases, there are other diseases in which neutralizing antibody activity and protection from disease are not well correlated. For some diseases, cell-mediated immunity (CMI) is more important. Protective immunity can be established only by challenge of the vaccinated host for which the vaccine is intended with the respective pathogen under conditions resembling those of natural infection. Challenge models are an important part of vaccine efficacy testing, along with assessment of vaccine-induced immune responses and field trials. However, the ultimate test of any vaccine for the veterinary practitioner,

Downloaded From Vet-eBooks.com

livestock producer, and the animals is protection or disease sparing, following proper use of the vaccine in field situations in which natural transmission of pathogens occurs. Although laboratory challenge models are an approximation of this situation, they are, by definition, artificial and often fail to duplicate the multiplicity of factors that comprise disease following exposure to pathogens. Naturally occurring dose, frequency of pathogen exposure, and the kinetics of animal-to-animal transmission in a herd are three such factors that are difficult to duplicate in challenge models but obviously could affect the outcome of a test of vaccine efficacy.

Expected Benefits of Vaccination. Vaccination programs are designed to potentiate the immune system of the host toward a unique, specific antigen and to prevent clinical disease caused by that specific antigen. For example, vaccination against infectious bovine rhinotracheitis in cattle is expected to provide protection against clinical disease and to protect the fetus of pregnant cattle. The control of transmission of disease within herds is one of the objectives of an effective vaccine, and transmission can be measured experimentally. Using Aujeszky's disease as an experimental model, it has been shown that vaccinating pigs twice significantly reduces disease transmission (DeJong and Kimman, 1994). In unvaccinated groups the estimated maximum number of secondary cases per infectious individual (the basic reproduction ratio R0) was 10.0. In contrast, the reproduction ratio for the vaccinated groups was 0.5. Thus it is possible to measure transmission experimentally. Ideally, such measurements should be obtained for all vaccines intended to eliminate etiological agents causing infectious diseases, either on a single farm or in a country. The potential of a vaccination program to eliminate infection from the host population and the proportion of hosts that must be vaccinated to achieve elimination are related to the basic reproduction number of the pathogens or parasite and to the impact of the vaccine. The impact of the vaccine is a measure of the take of the vaccine and the duration of protection. Duration of protection should be a major consideration in the development of new vaccines (Woolhouse et al, 1997). The interval between repeat vaccinations is related to vaccine impact, host life expectancy, and the basic reproduction ratio. For a pathogen with a high basic reproduction number, and where available vaccines have low or moderate impact, it may not be possible to eliminate infection regardless of how frequently hosts are vaccinated.

Mastitis vaccines are expected to eliminate chronic intramammary infections, prevent the establishment of new intramammary infections, and reduce the frequency and severity of clinical disease (Sordillo et al, 1997). But vaccines currently available do not reduce consistently the incidence of new intramammary infections or eliminate chronic mastitis. However, some mastitis vaccines have effectively reduced the incidence of clinical mastitis. For example, recent development of the R mutant vaccines for Gram-negative mastitis should prove to be beneficial for the control of coliform mastitis in well-managed dairy herds (Sordillo et al, 1997).

HUMORAL IMMUNITY. The protective immune response to a vaccine may be due to the presence of circulating antibody (humoral immunity), the actions of sensitized T-lymphocytes (CMI), the presence of antibody on mucosal surfaces (mucosal immunity), or a combination of these factors. Assessing vaccination with serology is attractive. Unfortunately, measuring circulating antibody is not necessarily synonymous with protection. For most diseases, it is not clear what level of antibody is required for protection, nor are standardized serological methodologies used in all laboratories that would allow comparison of results between laboratories. In addition, some pathogens persist in a latent form despite a host immune response. An excellent review of the theory behind diagnostic serologic testing and the strategies for interpreting the results of these tests is available (Tyler and Cullor, 1989).

CELL-MEDIATED IMMUNITY. Immunological evaluation of vaccines has depended largely on the measurement of an antibody response in the serum of recipient animals. This approach works well for diseases prevented in large part by humoral immunity but ignores the contributions of CMI or the contributions made by mucosal immunity in providing protection against many infectious diseases. As a result of this approach, certain vaccines have been marketed that produced an antibody response but failed to protect vaccinates in the field from disease. In a rational approach to vaccine development, some questions must be addressed when assessing the development of CMI against a specific disease. Does CMI have an important role in providing protection against the disease? What are the CMI responses that develop after vaccination or natural infection with the infectious agent, and how can these responses be measured? Which antigenic components of the infectious agent are targets of the protective CMI responses? Which CMI effector functions provide protection against the disease? What vaccination strategy (antigen delivery system, adjuvant formulation) induces the most protective CMI response against the infectious agent? Many diseases require that a CMI response develop in the host to provide adequate immune protection. Extensive knowledge of the CMI responses to infectious agents is required when a rational approach to improved vaccine development for these diseases is attempted (Clough and Roth, 1995). The importance of CMI against a specific disease may be examined by determining that induction of an active antibody response or the acquisition of passively acquired antibody to the causative agent does not correlate well with protection against clinical disease. It is usually assumed that if antibodies do not prevent clinical disease, then other immune mechanisms (cell mediated or mucosal) must be important for protective immunity (Clough and Roth, 1995).

The importance of CMI in providing protection against specific diseases may be assessed by suppressing a specific arm of the immune system and evaluating the severity of disease after subsequent challenge exposure.

Measurement of CMI can be accomplished using several different assays, including delayed hypersensitivity, leukocyte migration inhibition, adoptive transfer, lymphocyte proliferation, cytokine release, and cytotoxicity assays (Clough and Roth, 1995).

The CMI response after natural infection is not necessarily the same as that induced by vaccination. The duration of vaccine-induced CMI may differ from the duration of CMI induced by natural infection. In general, the duration of vaccine-induced immunity has not been well defined. Most veterinary vaccine studies have detected initial vaccine efficacy, but the immune responses beyond several weeks after vaccination have not been monitored. In nearly all vaccine studies, protective immunity over time is determined by challenge-exposure or serological methods, and few studies have measured CMI responses over an extended period (Clough and Roth, 1995).

Identification of protective microbial antigens is important in implementing a rational immunological approach to vaccine development. Knowing the protective antigens facilitates the selection of vaccine strains for whole cell vaccines. The strain must express the protective antigens and stimulate solid immunity to those antigens. The type of antigen that elicits a protective immune response varies widely among infectious agents. Thus careful selection of the ap-

Downloaded From Vet-eBooks.com

propriate antigens for inclusion in these vaccines is critical to the efficacy of the final product.

The method of antigen delivery may be as critical to the efficacy of a vaccine as the selection of protective antigens to include in the vaccine. Antigen presentation influences the types of immune responses that are generated in host animals, and the type of immunity favored should correspond to the immune mechanism that has been identified as protective. Current research aimed at increasing the CMI response to vaccines include improved adjuvant formulation, generation of vaccine vectors, and the development of bioengineered delivery systems.

LACTOGENIC IMMUNITY. For some important diseases of swine and cattle, lactogenic immunity is important. An excellent example is transmissible gastroenteritis of swine. The disease is caused by a virus and is the major cause of neonatal diarrhea in piglets, causing up to 100% mortality in piglets under 2 weeks of age. Recovery from natural infection imparts a high degree of resistance to reinfection, but active immunization cannot be induced in time to protect neonatal piglets when they are most susceptible. Neonatal pigs are dependent on passive immunity transferred from the sow's colostrum and milk (lactogenic immunity, coproimmunity). Commercial vaccines have limited efficacy under simulated field conditions. Numerous studies have emphasized the importance of IgA antibodies in colostrum and milk in passive immunity. Sows inoculated with virulent virus orally secrete IgA antibodies in colostrum and milk and provide a high degree of protection to their piglets. However, it has been difficult to attain comparable colostral and milk IgA antibodies using attenuated live virus vaccines, probably because of limited replication of the virus in fewer enterocytes. Vaccination of sows with attenuated live transmissible gastroenteritis virus or a recombinant virus vaccine failed to provide complete protection to suckling pigs after challenge exposure (Park et al, 1998).

Approval of Vaccines. Although national departments of agriculture may be responsible for licensing vaccines, licensing authorities do not conduct clinical field trials to evaluate vaccines against naturally occurring diseases. Currently, the vaccines are approved on the basis of data supplied by the manufacturers, who usually claim efficacy based on serological responses following vaccination of host animals and protection against experimentally induced disease in a host animal and in vitro tests. These test results usually cannot be correlated with protection against naturally occurring diseases. Furthermore, the data submitted by the manufacturer to the licensing agency involve privileged information and are not available to the veterinary profession at large for peer review. It seems unjustifiable not to disclose the efficacy data to veterinarians who must recommend the use of the vaccine to the livestock producer. Furthermore, when veterinary research workers conduct well-designed field trials and find that a particular vaccine is not efficacious, the information can be ignored by the licensing agency and the vaccine continues to be sold.

Until recently, the biologics manufacturers did not conduct scientifically designed field trials on typical livestock farms using randomly assigned, unvaccinated control animals along with vaccinated animals to show protection against naturally occurring diseases. The manufacturers have contended that livestock producers are reluctant to permit the use of control animals. They claimed that producers sometimes charge the manufacturers unfairly for losses that occur during the study. The manufacturers also state that, because the incidence of many diseases is low and the occurrence too difficult to predict, this type of testing requires too many animals, which makes the trial expensive and prohibitive because of the limited market for food animal vaccines. However, there are signs of progress. Biologics manufacturers have now begun to support well-designed field trials to evaluate the efficacy of vaccines against naturally occurring diseases (Van Donkersgoed et al, 1990b). Also, when the need for field trials with concomitant controls is explained to producers, they cooperate and participate in the evaluation of vaccines and other biologics. The evolution of the vaccines for bovine pneumonic pasteurellosis is an example of the value of intensive and focused research on the pathogenetic and microbiological mechanisms of a disease entity.

There is a widespread belief among vaccine users that efficacy can be determined accurately through extensive field usage of a vaccine against naturally occurring disease in the absence of control animals. This belief may be acceptable for those diseases that are clearly defined and relatively easy to diagnose, such as blackleg. With the more complex problems, however, such as diarrhea and pneumonia, accurate field evaluation of a vaccine without good experimental procedures and design, including adequate numbers of randomly assigned control animals in the same population, is difficult and often leads to erroneous conclusions. For example, an apparent decrease in the losses caused by acute diarrhea in a beef herd or by respiratory disease in feedlot animals following vaccination of all animals in either situation in 1 year compared with the previous year or feeding period may not be related to the use of the vaccines. There is a lack of understanding of why the incidence of diarrhea in beef calves varies from herd to herd, from year to year, and within the same calving season in large herds. In addition, the fact that it occurs in some animals and not in others necessitates that well-designed field trials be conducted if the results are to be meaningful and can be applied to other herds in general.

The herd effects in trials of animal biologics must be considered (Waltner-Toews, 1989). Even in well-designed field trials and with all the modern tools of veterinary epidemiology, considerable difficulty is commonly encountered in making the definitive, causative diagnosis of clinical cases that occur in both vaccinated and unvaccinated control animals. For example, how is the cause of acute diarrhea determined in a particular group of calves from which two or more enteropathogens were isolated from the feces of affected calves born from cows vaccinated with a vaccine intended to prevent diarrhea caused by the same pathogens? The same applies for acute undifferentiated bovine respiratory disease in feedlot cattle that are vaccinated with an *M. haemolytica (P. haemolytica)* vaccine.

Meta-analysis of various vaccines for the control of specific diseases is being done now. The analysis controls for all the relevant variables that affect vaccine efficacy comparisons. For example, a meta-analysis of the various commercial vaccines available for a 12-year period for the control of pneumonic pasteurellosis in cattle has been published (Srinand et al, 1996). Such analysis allows for an objective comparison of the efficacy of several vaccines. Box 4-2 offers some possible approaches to resolving the problem of vaccine efficacy.

It could be argued that governmental authorities (licensing bodies) should not be given the power to deny access by the livestock industry to new products based on efficacy in the field regulations. There is no single, perfect trial. Only by the use of multiple, properly designed trials, carried out under field conditions, can the efficacy for many products be assessed. The biologics manufacturers should be required to ensure there are no major problems with the product, and the livestock industry, including producers, veterinarians, and epidemiologists, then can assess properly vaccine efficacy.

BOX 4-2

Approaches to Resolving the Problem of Vaccine Efficacy

1. The vaccine user should be informed that the licensing agency determines efficacy on the basis of the data generated by the manufacturer.
2. Licensing regulations should require that vaccines, before licensure, be shown to be efficacious in properly designed studies. The results of these experiments should have proven correlation with protection against the naturally occurring disease in the host animals. The other tests, including serological responses, protection against experimentally induced disease, and certain in vitro tests are valid to use for this purpose only if it can be shown that their results correlate significantly with protection in the host animal against naturally occurring disease.
3. Vaccines should be evaluated following licensing. An objective and open evaluation of licensed biologics is needed to provide the vaccine user with information necessary to make informed decisions regarding vaccine use. For example, the approval of the vaccine for the control of pneumonic pasteurellosis has been evaluated by veterinary clinicians who conducted field trials with unvaccinated control animals. The results were published in the Canadian veterinary literature. The same has been done for the bovine respiratory syncytial virus vaccine and others.

Adverse Vaccine Reactions. During the process of development of a vaccine, the manufacturer must show that the vaccine stimulates an immune response and that it is safe for use in the target animals. Since the development of combination vaccines for use in livestock, there have been reports of adverse reactions associated with the use of some vaccines. Most reports are anecdotal, making it difficult to assess mechanisms by which certain vaccine components, or combinations thereof, may cause adverse reactions. Combination vaccines containing viral and bacterial antigens are commonly used in veterinary practice and have been associated with adverse reactions (Ellis and Yong, 1997). It is suspected that the presence of endotoxin or other bacterial components may interact with adjuvants to cause an enhanced pathological inflammatory response in some individuals (Ellis and Yong, 1997). Vaccination of calves between 3 and 31 days of age with a combination of multiple-antigen vaccines containing known quantities of endotoxin can induce evidence of an inflammatory response characterized by a fever, increased total white blood cell counts, and absolute neutrophil counts, without clinical signs of illness (Allen et al, 1996).

Vaccine Assessment Checklist. If efficacy data are not available from the vaccine manufacturer, the practitioner then must assess the effectiveness of the vaccine based on whatever clinical research on the vaccine has been published. A vaccine assessment checklist can be used by the practitioner to make an informed decision about recommending the use of a certain vaccine (Ribble, 1990). The important items in a vaccine assessment checklist are shown in Box 4-3. In addition to this checklist, the veterinarian must consider all relevant circumstances in the herd on a regular basis and determine how effective the vaccine might be in that herd compared with another.

Design of a Vaccination Program. A number of factors should be considered when providing recommendations for the use of vaccines and vaccine schedules, including those in Box 4-4. Deciding to recommend the vaccination of any of the food-producing animal species for protection against an infectious disease primarily depends on the probability of infection occurring and causing economically important clinical disease without vaccination. Also, the availability of an efficacious vaccine that can provide protection so that the incidence of clinical disease is lower than if the animals were not vaccinated is an important factor. For each of the infectious diseases that are likely to occur in a particular area, there is usually some epidemiological information available that can be used to predict the probability of infection and disease occurring. This information can be applied to the herd under consideration. Ideally, a cost-benefit analysis would be performed, but, under most practical conditions, the information required for such an analysis is neither available nor reliable. As a result, most veterinarians justify the use of a vaccine based on their assessment of the probability that the disease will occur at a certain incidence if the animals are not vaccinated and that vaccination will provide varying degrees of protection and be cost effective. Obviously, there is a need for more reliable information on the probable incidence of disease with and without vaccination in herds with varying levels of management and risk factors.

Guidelines for the use of biologics in domestic animals are issued periodically by the Council on Biologic and Therapeutic Agents in the United States. The guidelines are intended to document currently accepted protocols for vaccinations, based on the best available scientific information (Council Report, 1994). However, these guidelines are not based on the results of randomized field trials under naturally occurring conditions.

Time of Vaccination and at What Intervals. For most vaccines, both primary and secondary vaccinations are recommended for optimal protection. In general terms, the primary vaccination is the first time the vaccine is given, followed by a second vaccination usually 10 to 28 days later. Two vaccinations at that interval usually cause a higher titer 10 days after the second vaccination compared with that after only one vaccination. Most recommendations in the literature are for two vaccinations for the primary vaccination. Whether the higher titer is more protective or more economically beneficial is uncertain. In general, most primary vaccinations for the commonly occurring infectious diseases of food-producing animals are given at least 2 weeks before the expected occurrence of disease. Young animals are usually vaccinated after the colostral immunity has waned. For infections that cause fetal disease, the breeding female should be vaccinated at least 3 weeks before breeding.

The vaccination of the pregnant female in late gestation is an effective method for the passive immunization of the newborn against commonly occurring infectious diseases (Saif and Fernandez, 1996). The widespread occurrence of rotavirus antibodies in the colostrum led to strategies for maternal rotavirus vaccination to boost lactogenic immunity and transfer passive antibodies to the neonate through colostrum and milk (Saif and Fernandez, 1996). The variable success of maternal rotavirus vaccines in the field is influenced by vaccine dose, strain of virus, inactivating agent, adjuvant, route of administration, and environmental rotavirus exposure levels. The use of genetically engineered rotavirus-like particle vaccines in cows to boost antibodies in mammary secretions shows promise and possesses potential advantages over existing vaccines.

Administration of modified-live viral vaccines can boost systemic humoral and cellular responses to BRSV and bo-

BOX 4-3

Vaccine Assessment Checklist

1. Has the vaccine been laboratory and field tested in randomized, controlled trials? This requires the results of testing in the laboratory and field, and often these are not available.
2. Were the control groups concurrent or historical? Were control groups of animals randomly assigned at the same time as the vaccinated groups? Historical control groups (those not vaccinated in previous years) are unsatisfactory for comparison.
3. How were the trial animals challenged? In a laboratory study of the efficacy of the vaccine, assess how closely the challenge model approaches the natural disease and whether the results can be extrapolated to the field situation. In field trials, note whether the controls became clinically affected, and note the incidence of clinical disease.
4. Was the measure of outcome meaningful? The outcomes should be easily measurable so that there is clear evidence that the vaccine prevents clinical disease. Outcomes include morbidity and mortality caused by the disease in question and production measures, such as average daily gain. Often, morbidity rates are actually treatment rates based on the number of animals that became sick and were treated. Thus the morbidity rate by itself may not provide a true indication of whether the vaccine protected the animals against the specific disease compared with the controls. The ideal situation would be to make a precise clinical and laboratory diagnosis of the diseases that occurred in both the vaccinated and unvaccinated animals. The serological response in vaccinated animals is often used as measure of efficacy, but it really does not indicate whether the vaccine prevents disease or improves production.
5. Were the biology and epidemiology of the disease considered?
6. Was the vaccine assigned randomly? Some type of randomization procedure is necessary so that each animal has an equal chance of being assigned to the vaccinated or control group.
7. Were blinding techniques used to reduce bias? Both the vaccinated and control groups of animals should be handled similarly, and the animal attendants responsible for the detection and treatment of sick animals should not be able to distinguish the vaccinated animals from the controls. This means that the method of identification, such as an ear tag, is identical in both groups and that the vaccination status of each animal is not revealed until the end of the trial.
8. What other potentially important biases are evident? Some potential biases occur in almost every field trial, and their significance must be assessed.
9. How likely was the result a chance finding? Rather than depend on the statistical significance of the results, it may be more meaningful to estimate the magnitude of the vaccine effect and the accuracy of that effect.
10. What are the differences between the trial animals and animals in a private veterinary practice? How relevant are the results of the field trial to herds in a private practice?

vine herpesvirus-1 in cows. Neonatal calves can be immunologically primed by vaccination at 10 days of age with modified-live virus vaccine based on virus-specific memory cells persisting in most calves until weaning (Ellis et al, 1996a). Vaccination of pregnant cattle with the intranasal vaccine for bovine herpesvirus-1 provides protection of the calves against the highly fatal form of the infection, which can occur in newborn calves (Mechor et al, 1987).

Vaccination of newborn calves under a few days of age with a modified-live bovine herpesvirus-1 and parainfluenza-3 virus vaccine has been associated with a high mortality (Bryan et al, 1994).

The effects of the presence of maternal antibodies in young farm animals on active immunization have been suggested as a cause of vaccine failure, but it is not documented. The vaccination of pregnant cows 4 months before calving results in colostral titers in calves, which can be enhanced by vaccination of the calves at 50 to 53 days (Troxel et al, 1997).

For feedlot cattle, the ideal procedure is to vaccinate them at least 2 weeks before being placed in the feedlot and mixed with other cattle. However, under commercial feedlot conditions, in which cattle are bought from auction marts and sent directly to the feedlot, the animals are invariably vaccinated on or shortly after arrival.

A common question about vaccination schedules for food-producing animal herds is the frequency with which animals should be revaccinated upon receiving their primary vaccination. Should dairy cows, beef cows, breeding sows, and ewes be revaccinated annually for protection against commonly occurring diseases if they were vaccinated once or twice when they were young? Based on the principles of immunology, a booster vaccination or revaccination usually is given annually or sometimes biannually depending on the disease being considered, the nature of the vaccine, the immunogenicity of the antigens, the duration of immunity provided by the vaccine, and the degree of infection pressure that is anticipated. For some diseases of cattle, for example, unless booster vaccinations are given or reinfection occurs to stimulate an anamnestic response, herd immunity wanes in 2 to 3 years and booster vaccinations should be considered. A similar situation applies in swine herds, in which sows are vaccinated for some diseases before or during each pregnancy. However, some of these practices are based on empirical observations; there is often no reliable published information on which to base a recommendation to revaccinate every few years or during every production cycle.

Vaccines are sometimes used during a herd epidemic in an attempt to prevent additional new cases among unvaccinated animals. All the in-contact normal animals are vaccinated based on the assumption that they have not been infected already by contact with the clinically affected animals. In outbreaks of anthrax, for example, the vaccination of all in-contact animals is highly effective for the prevention of new cases. The same applies for outbreaks of blackleg in unvaccinated cattle. The use of vaccines in the face of an outbreak of acute bovine respiratory disease depends on the

Downloaded from Vet-e-Books.com

BOX 4-4

Design of a Vaccination Program

1. What are the risks of infection and clinical disease occurring in the animals in question without vaccination?
2. What are the potential economic losses associated with the clinical disease in unvaccinated animals?
3. What risk factors for the disease are present in the herd or are likely to be present in the future, and can they be removed or modified as part of the control program?
4. Can the disease be prevented or controlled economically and practically in the herd under consideration without the use of vaccines?
5. What type of immunity is required for protection of the disease(s) under question? Is it humoral, local, or cell mediated, and what type does the vaccine stimulate?
6. What information is available about the efficacy of the vaccine, and how much protection can the vaccine provide in the circumstances under consideration compared with not vaccinating? How successful has the vaccine been in the past in the herd under consideration? Can the vaccine prevent both clinical disease and infection? What are the results of a crude cost-benefit analysis based on the expected economic losses associated with morbidity and mortality in the vaccinated and nonvaccinated groups, considering all costs associated with the vaccine and the vaccination procedure?
7. If vaccination of the newborn is being considered, does the presence of colostral immunity minimize the effects of the vaccine?
8. If the vaccine under consideration is a live vaccine, are there any potential hazards associated with its use in the animals to be vaccinated? Modified live virus vaccines are potentially abortigenic and should not be used in pregnant animals. The use of modified live virus vaccines can result in the shedding and spread of the vaccine virus to other animals, but this is an unlikely occurrence.
9. What is the duration of immunity provided by the vaccine? How often must the animals be revaccinated?
10. Should the vaccine ever be used during an epidemic of the disease in the herd in an attempt to prevent additional new cases?

suspected cause of the disease, the class of animals involved, and the potential for long-term economic losses. In an outbreak of infectious bovine rhinotracheitis in an unvaccinated dairy herd, the potential for abortion is high and vaccination of all animals, including vaccination of the pregnant cows with a nonabortigenic vaccine, is recommended. The use of respiratory virus vaccines or the *M. haemolytica (P. haemolytica)* vaccine in the face of an outbreak of acute respiratory disease in recently arrived feedlot cattle does not make biological sense. Many of the animals are under stress, some are incubating the disease, and vaccination actually may cause an increase in the incidence of disease.

Vaccination of Wildlife Vectors. The control of bovine tuberculosis in the United Kingdom is a major problem because of the reservoir of *M. bovis* infection in badgers (Newell and Hewinson, 1995) and in New Zealand because of the reservoir of infection in the Australian brushtail possum *(Trichosurus vulpecula)* (O'Neil and Pharo, 1995). The possibility of controlling the disease by vaccination of cattle or farmed deer is unpopular because of the potential compromise of existing diagnostic tests. However, the vaccination of badgers to reduce the risk of transmission to cattle is an attractive option and now has been adopted as a potential control strategy (Newell and Hewinson, 1995). An initial strategy appears to involve optimization of bacille Calmette-Guérin (BCG) vaccination or the cloning of mycobacterial antigens into BCG. Given a suitable delivery system, aerosol vaccination of possums with the BCG vaccine combined with other control measures may be a suitable method of reducing the spread of *M. bovis* from wildlife to domestic animals (Aldwell et al, 1995).

Recommending a Vaccine and a Vaccination Schedule. As part of a comprehensive, year-round, health management program, veterinarians have the opportunity to make recommendations about the selection of vaccines and the vaccination schedule. The veterinary practice can educate clients about the need to vaccinate and when to vaccinate through regular newsletters. This method is effective because it prompts many questions from producers, which results in contact between the veterinarian and the producer. More importantly, however, veterinarians must become familiar with the herd, identify and assess the importance of risk factors, monitor the disease incidence, anticipate when the infectious diseases are to occur, make appropriate control recommendations (including the management techniques to reduce risk factors), and recommend the vaccines to be used and the vaccination schedule. Recommendations should be submitted in a written report, which may include observations about disease control made by the veterinarian during farm visits. The recommendations should include the following:

- *Which diseases* are being controlled by vaccination
- *Which animals* should be vaccinated including all age groups
- *Which vaccine* should be used
- *When* the vaccines should be used during the lifetime or production cycle of the animal
- *Frequency of vaccination* or when a booster vaccine should be given

The level of protection that can be expected from the vaccine should be estimated and explained. Producers should be encouraged to record the date on which they vaccinated the animals and the brand name and batch number of the vaccine used. It is remarkable how easy it is to forget vaccination dates or whether certain animals were actually vaccinated. It is also important to advise producers about the logistics of the use of the vaccine, how it should be stored, whether unused portions can be used at another time, the route of administration, the proper use of needles and sy-

Downloaded From Vet-e-Books.com

ringes, and the hazards of chemical sterilants when using a live vaccine. With the possibility that certain infectious diseases such as bovine leukosis can be transmitted by the use of hypodermic needles, it may be necessary to use a *new needle* for each animal. When disease for which the animals are vaccinated occurs in vaccinated animals, the veterinarian should investigate the problem, attempt to make a clinical and laboratory diagnosis, communicate the results to the vaccine manufacturer, and explain to the producer the possible causes of the apparent failure of the vaccine and the disease control program. Veterinary records of herd investigations assume high priority in such occurrences.

The effect of vaccines and other injectables like antimicrobials on the formation of injection site lesions in food-producing animals is now a major concern (Van Donkersgoed et al, 1999a). Injection site surveys in feedlot cattle in Canada and the United States have found injection site lesions in primal beef cuts, which are a major cause of economic loss in the beef cattle industry because of losses in trim, devaluation of cuts, and consumer dissatisfaction from eating tough beef. The occurrence and severity of lesions may vary with location of injection. They are less severe in the blade than in the butt or round because the products are introduced intermuscularly (between muscles) in the neck because of the presence of numerous fascial planes. The intermuscular location and the excellent lymphatic supply in the neck may result in accelerated absorption of products and rapid healing. A high incidence of intramuscular lesions associated with the use of clostridial bacterins has resulted in recommendations to administer these vaccines subcutaneously in the neck. The use of chemically altered and modified-live virus vaccine combinations given intramuscularly in primal cuts is also associated with a high incidence of lesions, which may be due to the presence of oil-based adjuvants in the vaccines. Myositis, lameness, and paraparesis have been associated with the use of an oil-based adjuvant bacterin administered intramuscularly (McAllister et al, 1995). Vaccination into paravertebral muscles is risky because inflammation may extend through intervertebral foramina.

Compliance of the Animal Owner with the Recommendations of the Veterinarian. The success of any animal health management program is limited by the willingness of the producer to implement any of the program components. Several factors influence this willingness, but in most cases the predominant considerations are about the effectiveness of the program ("Does the herd need it and will it work?") and about its cost; the producer must have confidence that implementing the program will be effective and that the program is valuable. The program should provide a return on their investment, or at least they should be confident that the program will reduce potential financial losses.

Surveys of vaccination practices in dairy herds indicate that a large percentage of dairy cows and heifers are not vaccinated against bovine virus diarrhea at all or improperly vaccinated (Rauff et al, 1996; Carruthers and Petrie, 1996). In 1993 to 1994, outbreaks of fatal mucosal disease occurred in dairy herds in Canada and the United States. Field investigations revealed that affected herds had not been vaccinated or had been vaccinated improperly by failing to provide a booster vaccination 2 to 4 weeks after the initial inactivated vaccine was given. Veterinarians could be more effective in providing specific vaccination recommendations and infectious disease control programs to their dairy producers as part of health management programs. In a survey of Saskatchewan dairy farms in 1994, only 34% of the dairy herds were vaccinated against BVD virus, compared with a reported 58% of dairy herds in the United States and Ontario in which, at a minimum, the heifers were vaccinated (Carruthers and Petrie, 1996). Surveys of beef cow-calf producers have found that veterinarians have an excellent opportunity to advise producers about infectious disease management, especially vaccination programs (Sanderson and Gay, 1996).

Producers expect their veterinarians to help assess the degree of risk reduction provided by the program; essentially, will the disease-control program be effective and cost effective? The veterinarian must be familiar with the local disease conditions and any factors in the producer's herd that might alter (either increasing or decreasing) their risk. The challenge for the veterinarian is how to effectively communicate the risk so producers will want to adopt the program. Each herd visit is an opportunity to present this information verbally, but providing concise specific written recommendations may increase producer understanding and acceptance of recommendations. The written recommendations may be general as in articles in a practice newsletter sent to all producers in your practice. But compliance may be increased if specific recommendations are made for the farm in the form of a "preventive prescription." The owner must be fully informed by the veterinarian about the importance of vaccination, which vaccines to use, when to use them, and their limitations. The veterinarian should provide explicit written recommendations and monitor compliance by asking the owner if the animals were vaccinated, on what date, and with which vaccine. The veterinarian must show leadership and be responsible for monitoring the health management in the herd.

Whether the producer accepts the program or not, the veterinarian may have an obligation to educate the producer about the merits and limitations of the preventive program. In human medicine, education of the patient is often ineffective in increasing compliance. Large-animal practitioners have an advantage over their human colleagues because they actually visit their clients rather than wait for patients to return to them. This provides veterinarians opportunities to reinforce their message about adopting preventive measures. Although education may not increase compliance, client education programs are probably valuable in maintaining the acceptance of procedures by current users. Using education to improve compliance is most effective when information is presented in a variety of ways and when there is continual reinforcement of the message. Making individual and group contact (such as producer meetings), giving written as well as verbal recommendations, and using examples of some successful programs or failures by other producers are all strategies that can be used to try to improve compliance.

If producers do not accept all or part of a disease prevention program, should veterinarians alter their recommendations until a program is reached that the producer will accept? What components can be removed before the program reaches a point when it is unlikely to be effective? This problem became an actual concern in Ontario in 1993 (Carman et al, 1998). In that situation, many producers apparently had been reluctant to administer a double primary immunization series when killed BVDV vaccines were used. The reasons often presented for lack of compliance to appropriate vaccination procedures were the additional cost and inconvenience of handling animals twice. When some of these "partially" vaccinated herds had severe problems with BVD, questions were asked about whether veterinarians should have permitted producers to adopt an ineffective vaccination protocol. Should veterinarians permit this type of situation to occur or should they refuse to administer a vaccination program that they know will be ineffective? Veterinarians may have a legal as well as an ethical responsibility for the failure of inadequate programs.

Downloaded from Vet-eBooks.com

Proper implementation of vaccination protocols is necessary to optimize efficacy of vaccines. Periodic reviews of the management practices in a herd are necessary to ensure that the vaccinations are actually done. In some situations the employees responsible for vaccinations actually may not vaccinate the animals or may vaccinate them inadequately (Amass and Scholz, 1998).

Economic Analysis of Vaccination. An economic model of the costs and benefits of vaccination has been proposed based on its application to the control of listeriosis in sheep in Norway (Vagsholm et al, 1991). Four items of information are needed: (1) the cost of a clinical case, which includes the cost of treatment and the average cost of mortality (average case-fatality rate multiplied by the value of the animal), (2) the annual total cost of vaccination of each animal, (3) the expected incidence of the disease, and (4) the efficacy of the vaccine.

The incidence of disease at which vaccination should be recommended is given by the equation:

$$EI > VC/(DC \times VE)$$

where *EI* is the expected incidence, *VC* is the annual cost of vaccinating each animal, including any veterinary fees associated with vaccination, *DC* is the cost of a clinical case, including treatment and average cost of mortality (average percentage case-fatality rate multiplied by the average cost of the animal), and *VE* is the efficacy of the vaccine, given by the following:

$$VE = \frac{1 - (\text{Number of diseased vaccinated animals})}{\text{Number of diseased unvaccinated animals}}$$

The derivation of the equation is as follows: (Vagsholm et al, 1991). The basic premise of the model is that vaccination should prevent losses that are larger than or equal to the costs of vaccination. This is expressed by the equation:

$$(RI \times DC) > VC \qquad (4\text{-}1)$$

where *RI* is the proportional reduction in annual incidence of disease resulting from vaccination, *DC* is the cost of a clinical case, including treatment and average cost of mortality (average case-fatality rate multiplied by the average cost of the animal), and *VC* is the annual cost of vaccinating each animal, including any veterinary fees. This expression can be rewritten as follows:

$$RI > (VC/DC) \qquad (4\text{-}2)$$

Equation 4-2 indicates that the proportional reduction in disease incidence that is required to make vaccination beneficial is a function of the ratio of the cost of a vaccination to the cost of a disease case. To estimate the expected incidence (EI) at which vaccination would become beneficial, the efficacy of the vaccine (VE) must be estimated, as given above. Vaccination should be recommended when the expected incidence (EI) is larger than the reduction in disease incidence (RI), defined as the ratio of the cost of a vaccination to the cost of a disease case divided by the efficacy of the vaccine:

$$EI > (RI/VE)$$

Substituting for *RI* from Equation 4-2, the incidence of disease at which vaccination should be recommended is given by the equation:

$$EI > VC/(DC \times VE)$$

Because the estimated costs of vaccination and disease are average values, the incidence of disease at which vaccination should be recommended can be determined according to variations in the costs of vaccination and the value of the animal, which may vary widely. A table can be structured that lists the expected percentage incidences of disease above which vaccination would be economically beneficial according to the cost of vaccination and the value of the animal.

The disease under consideration and the expected efficacy of a vaccine to control that disease influence the choice of a vaccine, and the formulation of a control program may or may not include the use of a vaccine. For some of the causally defined diseases, such as rabies, erysipelas, and the clostridial diseases, the vaccines available are usually effective and reliable. For others, such as leptospirosis in cattle, some of the vaccines available may not be effective because the antigens used in the vaccines are not specific enough to stimulate immunity against the field serotypes of leptospira causing the disease. For complex diseases not causally defined, such as acute undifferentiated diarrhea of calves and acute bovine respiratory disease of feedlot cattle, the vaccines available are often not effective. In both these cases, several different pathogens in combination with a variety of risk factors are often the causative factors.

Surveillance of Disease Prevalence

The prevalence of an infectious disease in a herd can be monitored indefinitely as a method of control. The control of Johne's disease in a herd is an excellent example of such continued surveillance. The first herd diagnostic step in a control program is to test all animals over 2 years of age and to consider culling all seropositive animals. After the ELISA-positive animals are culled from the herd, a second ELISA can be done on the entire herd again. An alternative is fecal culture, which is more expensive but detects animals missed by the ELISA. It is suggested that every third or fourth test should be a fecal culture. The frequency of testing and the types of tests used depend on factors such as the type of farm enterprise and the use of the animals, the estimated prevalence of infection, the owner's perception of the importance of the disease and how it has affected productivity, the willingness of the owner to invest in the costs of the tests, how quickly the owner wishes to begin a control program, and the eagerness of the owner to control the disease.

When the incidence of infection in a herd is low, continued progress towards certification that the herd is free of infection is a desirable goal. This is achieved by continued testing of the herd and testing replacement animals that are being introduced to the herd. A model herd certification program for Johne's disease was adopted by the U.S. Animal Health Association in 1993. The goal of the program is to establish uniform herd certification standards among the states. Identification of herds free of infection is vital to preventing spread of infection nationally and internationally. Certification of laboratories in performing the diagnostic tests such as being able to culture the organism is an important part of the program. The model herd certification program consists of using the ELISA and an organism detection test such as fecal culture on an alternating basis annually on all animals in the herd more than 20 months of age. Herds are given levels of certification based on the number of herd negative tests up to level 5. After attaining a level 5 Johne's-free certification, herds can maintain certification by retesting annually with either a serum antibody test or organism detection-based test.

Testing herd replacements before they are nominated for breeding (15 months of age) would be desirable, but the available tests are unlikely to detect subclinically infected animals at that age. Herds become infected by the introduction of unknown subclinically infected animals. The estimated risk of purchasing an infected animal from an auction mart of cattle dealer is 10% based on the overall

Downloaded from Vet-eBooks.com

prevalence of infection in the cattle population. Ideally, purchased herd replacements should be obtained from certified paratuberculosis-free herds. If these are not available, the next best option is to purchase from herds that have had no recent history of clinical disease. Then a prepurchase plan should be arranged with the seller to test the animals, and the costs should be determined. If the seller is unwilling to cooperate with a prepurchase testing as a condition of sale, the buyer may wish to purchase the animal and quarantine it until testing on the farm is completed. The ELISA is recommended for purchased animals, but replacement heifers 12 to 15 months of age are unlikely to be seropositive, and fecal culture would improve the accuracy of testing.

When the prevalence of disease in a herd or geographic area has been reduced to a low level or even eliminated, a surveillance system is desirable to monitor the infection rate and to prevent the introduction of unknown infected animals into the population. This can be established by requesting that imported animals be certified free of specific diseases and be placed in quarantine for specific periods, combined with diagnostic testing to ensure that they are negative for the disease in question. Bulls destined for artificial insemination units are to be tested for several infectious agents and must be found negative before they are allowed entry (Howard et al, 1990).

In countries with national programs for the eradication of a disease such as bovine virus diarrhea in dairy herds, the testing of bulk tank milk for the presence of antibodies is an excellent diagnostic aid for detection of infected herds that have not been vaccinated (Fredriksen et al, 1998). In Norway, a national program was introduced in 1992 to eradicate BVDV. No BVDV vaccines are used, and all milk-positive herds are followed up by examination of pooled milk samples from heifers and, if antibodies are detected in these, also by examination of pooled blood samples from calves. The presence of antibodies in blood and milk is always the result of natural infection.

Mass screening of livestock herds for selected infectious agents can be done using ELISA methods on sera (Behymer et al, 1991). The data provided from mass screening of livestock sera over a certain period can be used to detect emerging or silent disease, chronic or acute infections, effectiveness of vaccines, and duration of specific antibody activity. This information can be used by veterinarians to give advice on the treatment of diseases, vaccine programs, production and reproduction, and culling.

The prevalence of infectious diseases can be monitored on many herds in a geographical area and correlated with epidemiological determinants. A rabies surveillance system annually monitors the occurrence of rabies in wildlife, domestic animals, and humans in the United States (Krebs et al, 1997). The reported cases are a crude indication of the occurrence of the disease and do not indicate the extent of viral infection among wildlife or domestic animals in any region. The cases reported are based only on those cases of rabies that were diagnosed in the laboratory and reported to the Centers for Disease Control and Prevention. Many rabid animals are never observed and thus are untested and undetected. The information is useful for the implementation of vaccination campaigns and control programs. Within broad geographical regions of the United States, rabies infections in terrestrial mammals can be linked to distinct virus variants, which are identified by reaction with panels of monoclonal antibodies or by patterns of nucleotide substitution determined by genetic analysis. This allows monitoring of the spread of virus variants geographically and within and between species.

The provision of a comprehensive animal-health surveillance program that provides an early-warning system for the introduction of new diseases into a country is a function of national animal health regulatory agencies of many countries. In New Zealand, a key component of the surveillance program is a network of Animal Health Laboratories that are situated at regional centers throughout the country and staffed by a team of well-trained veterinary diagnosticians (Sanson and Thornton, 1997). The costs associated with the surveillance are substantial, but so are the benefits. The system is necessary in the event of the introduction of a new disease and the ability to satisfy the export requirements of animals and animal products. The introduction of *S. dublin* into New Zealand cattle herds, for example, would have a substantial impact on the cattle industry and would be a public health concern. With the use of simulation modelling of such an occurrence, the time to diagnosis is a function of the number of farms in the clinical state per week and the probability of diagnosis. The median time to first diagnosis under the current surveillance program regime was 4 weeks under all three epidemic scenarios, when there would have been only one or two infected premises. In contrast, the median time to initial diagnosis under the reduced surveillance scheme varied from 33 weeks under the worst-case scenario to greater than 78 weeks under the least case epidemic scenario. Any reduction in funding allocation of such an activity in countries that are heavily dependent on agricultural exports affects the laboratories' ability to conduct the tests required to make a diagnosis.

In Canada, the Canadian Animal Health Network (or CAHNet) was established in response to requests from WHO to increase animal disease surveillance (Inch, 1997; Kellar and Inch, 1998). The goal is to ensure that animal disease does not impede trade. The network will gather and disseminate information about animal diseases that exist within or beyond the borders of Canada. The network will coordinate federal, provincial, and private efforts with regard to trade-sensitive OIE list B and C diseases that historically have not been the mandate of federal disease surveillance. The network links animal disease surveillance partners in Canada. All Canadians involved in domestic animal production, livestock producers, veterinary practitioners, government veterinarians, veterinary colleges, researchers, exporters, and importers are network members. The surveillance program comprises three broad categories: data gathering, data evaluation, and knowledge communication (Kellar and Inch, 1998). Once the analysis of the data is completed, the information is communicated to partners through a bulletin and other publications such as the *Canadian Veterinary Journal*. The *CAHNet Bulletin* is published regularly on the Internet (http://www.cahnet.org/commun.htm) and in hard copy.

The identification of individual animals is an integral part of any successful disease surveillance program. Being able to trace the origin of an animal examined in the abattoir or to identify animals that have been in contact with animals in an epidemic of disease is vital to the program. In Canada the federal government identified, recorded, and monitored about 95% of calves through the national herd, from farm to slaughter (Inch, 1998a). The identification program was an integral part of the eradication of brucellosis and tuberculosis in cattle in Canada. The Livestock Identification Working Group has the mandate for the identification of all livestock species (Inch, 1998a). Because of major public health concerns over bovine spongiform encephalopathy, most of the identification efforts are now being directed to the beef and dairy cattle industries. Since the early 1990s, the Health of Animals Act in Canada has provided the Governor in Council with the authority for "establishing and governing a national identification system for animals that provides for standards and means of

Downloaded From Vet-e-Books.com

identification." For the year 2000, cattle industry representatives have agreed to collaborate with the federal government to establish standards in the areas of tag conformation; control of tag numbering and distribution; premises identification; sites and methods of tag capture; database design, capabilities, integration, and access; and audit and promotion.

The identification database, central or distributed according to the needs of the industry, will reside within the industry's complete control (Inch, 1998a). Each owner will be represented by an individual electronic file that bears his or her address and other details, along with the tag series received. Each service sector site, such as feedlots, auctions, abattoirs, and artificial insemination units, will have a file in the system, carrying identifiers similar to those recorded for individual owners. The system will be configured on the basis of tag, owner, geographical location, or any other parameters recorded. The system will be have the potential of identifying GIS coordinates and a premises code, as a means of facilitating automation and disease control efforts. In a fulminating disease outbreak, the federal government may have to control disease that has spread over many premises across several provinces, but for each instance the tracking process will be the same. The system will have captured where the animal was tagged, and, by reference to all tag series issued to that site, a list of potential contact animals will be obtained.

The surveillance and the study of disease geographically will be enhanced by the use of GIS, which provides the technology to study associations between environmental exposures and the spatial distribution of disease (Vine et al, 1997). A GIS is a powerful computer mapping and analysis technology that allows large quantities of information to be viewed and analyzed within a geographical context.

Genetic Selection for Resistance to Infectious Disease

Because of the persistent difficulties of controlling infectious diseases with the conventional methods described, there is interest in using selective breeding programs to enhance natural resistance. The term *natural disease resistance* refers to the inherent capability of animals to resist disease when exposed to pathogens, without prior exposure or immunization. The ultimate goal of most studies of natural resistance is to breed selectively to increase herd resistance to disease. Some examples of natural resistance to infectious disease include brucellosis and K88+ colibacillosis in pigs in which some strains of pigs are resistant to infection. Poultry breeders have applied successful selective breeding programs to produce stock with increased genetic capability to resist specific diseases. The possibility that cattle could be selected for resistance to mastitis has been a subject of consideration for many years, but little progress has been made. However, there is some evidence for a genetic basis for disease resistance and, in spite of low heritabilities for disease traits, genetic variation for disease incidence is economically important and justifies some consideration in breeding programs.

Genetic improvement leading to disease resistance achieved by both conventional breeding techniques and recently developed techniques in molecular biology may contribute considerably to reduce the costs of infectious disease (Müller and Brem, 1996). The various strategies that provide transgenesis to improve animal health have been discussed and reviewly briefly. The application of gene transfer in livestock depends on the acceptance of this technology by the public as well as the introduction of appropriate laws permitting the use of transgenic animals in animal production.

CHAPTER 5

Investigation of Disease Outbreaks and Suboptimum Productivity in Herds

CHERYL WALDNER

Food animal veterinarians are sometimes presented with disease outbreaks and unexplained changes in herd productivity. To investigate these outbreaks, the veterinarian must take on the role of medical detective (Schwabe et al, 1977). The resulting field of medical detection has become known as "shoe-leather" epidemiology, and it can be one of the most interesting and challenging aspects of herd medicine. Veterinarians who successfully resolve outbreaks or reverse downward trends in productivity provide a unique and invaluable service to their clients.

Opportunities to investigate herd problems are overlooked sometimes in busy rural practices. The veterinarian may focus too much attention, for example, on addressing the client's concern about the perceived failure of a specific pharmaceutical or vaccine rather than the underlying herd problem (Ribble et al, 1998). Why are opportunities to investigate outbreaks and changes in herd productivity often missed? Some herd owners may be reluctant to admit that they are having a serious herd problem. In other cases the herd owner may not recognize the severity of slowly escalating herd losses, particularly during busy and stressful times such as calving. Also, many herd owners do not recognize the potential of their local veterinarian to assist in diagnosing and resolving herd-level productivity problems.

By recognizing and pursuing opportunities to examine disease and productivity losses, practitioners cannot only help their clients with the current problem but also can promote the importance of veterinary herd health services. Significant herd-level problems are often identified from the history of a single animal presented to a clinic for examination and treatment. At other times, the veterinarian will detect changing patterns in drug sales or individual animal problems in a particular herd. Opportunities to follow up the problem at the herd level should not be dismissed without some consideration. A successful herd outbreak investigation can often be the first step in a long-term production and health management program in a herd. After working through a disease problem many herd owners recognize the benefits of good herd record keeping and the implementation of health management protocols.

The depth of the investigation should be justified by the economic importance of the herd problem (Radostits et al, 2000). An adequate and thorough herd investigation requires a great deal of time and can be expensive. Intensive investigations are most necessary when the determinants of disease are not well understood or several determinants are interacting to increase the risk of disease in a herd, and additional information is necessary to plan appropriate control measures.

The diagnosis of herd-level problems requires many of the same skills used in the examination and treatment of individual animals. These include a systematic approach to history taking, physical examination, and pathology as well as adequate knowledge of nutrition, microbiology, toxicology, immunology, genetics, and animal behavior. In addition, the investigator must be a skilled observer and have a good understanding of the livestock industry, herd management, and the basic tools of epidemiology (see Chapter 2). Industry knowledge, experience, and preparation are necessary to first differentiate correctly the normal and unusual patterns of herd health and productivity and then identify the risk factors associated with the abnormalities.

No single protocol can be applied to investigate and resolve all herd problems. The variety of concerns investigated is too large. There are, however, some basic principles that are useful for both the investigation of epidemic disease outbreaks and the examination of suboptimal herd productivity. These basic principles, with minor variations, have been reported in many sources (Schwabe et al, 1977; Kahrs, 1978; Lessard and Perry, 1988; Ribble et al, 1998) and are presented in this chapter.

OBJECTIVES

The broad objectives of the clinician are to halt the progress of disease, determine the reasons for the outbreak, institute corrective measures, and recommend procedures to reduce the risk of future outbreaks (Martin et al, 1987). These objectives can be achieved most consistently by differentiating the characteristics of affected and unaffected animals within the study population and by observing, recording, and analyzing the distribution of the disease with respect to time, place, and other potential exposure factors and environmental influences (Kahrs, 1978).

Risk factors are characteristics of the host, agent, or environment associated with an increase in the probability of disease or reduced performance. Risk factors can be manipulated to resolve the outbreak or improve herd production and profitability. For example, some risk factors for impaired fertility in beef cattle include body condition at calving, bull performance, reproductive tract infections, and nutritional deficiencies (Wikse, 1988). The risk factors over which management has control and that can be altered to affect disease rates or production levels are sometimes referred to as *key determinants* (Wikse et al, 1992; Sanderson and Christmas, 1997). Nutrition is an important key determinant of reproduction in beef cattle.

PROCEDURES FOR INVESTIGATING DISEASE OUTBREAKS

To achieve the objectives of a disease investigation in a herd, the investigator must systematically work through the following questions (W5): what (and how much)? who? when? where? and why (Gregg, 1996; Ribble et al, 1998)?

The herd owner invites the clinician to the farm to stop the problem, not just describe it. From the time of initial contact, an initial hypothesis regarding the cause of the outbreak will begin to develop. When appropriate, action should be taken to stop the epidemic based on the working hypothesis even before the investigation is complete. For example, in cases in which exposure to a toxin is suspected, the animals should be moved or alternative food or water sources provided to minimize any additional exposure. The veterinarian and herd owner should work together to minimize further losses as soon as possible.

Define the Problem (What?)

The first and most critical task early in the investigation is to *clearly define the problem* (Ribble et al, 1998). This is often one of the most difficult parts of the investigation. The initial complaint can encompass many different types of health and production issues. The investigator might be presented with clinical disease, subclinical disease, impaired performance, negative trends in productivity, inadequate profitability, or potential public health concerns related to food safety or environmental issues. Establishing a working definition of the problem as early as possible creates a focus or starting point. This definition will be reworked continually as the investigation progresses and more information becomes available.

An outbreak of a single disease must be differentiated from the simultaneous occurrence of many unrelated conditions. Case definition becomes very important early in the investigation. A case as an animal, group of animals, or herd having the characteristics associated with a disease or a deviation from productivity targets (Lessard, 1998). The defining characteristics are selected by the investigator and can include attributes such as clinical signs, test results, or individual traits such as age, breed, sex, or other distinguishing features. The simplest and most objective criteria are usually the best for the working case definition, particularly if there is more than one person participating in the investigation (Gregg, 1996). A simple, easily recognized and applied definition facilitates the consistent reporting of cases by the herd owner, other farm workers, and cooperating veterinarians.

Most field investigators compare diseased animals with animals not affected to identify exposures that may have contributed to the outbreak. The potential for inclusion of animals with unrelated conditions can be minimized by defining the problem as precisely as possible. This definition is critical when comparing cases with noncases to determine the importance of potential risk factors for disease. The inclusion of unrelated cases can result in errors in recognizing factors that might have contributed to the outbreak (Lessard, 1988). Case definition can be particularly challenging in retrospective field investigations. For example, one of the challenges to investigating a midgestation abortion storm, in a beef herd that had not been pregnancy tested before the outbreak, was differentiating between cows that aborted and those that failed to conceive (Waldner et al, 1999). Low pregnancy percentages for beef herds and late abortions can be associated with very different risk factors.

Establish the Existence of an Outbreak or Suboptimal Herd Production (How Much?)

Once a working case definition is established, the owner's complaint and the existence of an outbreak can be verified. To determine if the outbreak is real, the productivity and disease frequency in the herd can be measured and compared with published or historical expectations or to the performance of other neighboring herds with similar management. Some investigators have suggested that a change in disease risk, mortality, or production in excess of 2 standard deviations (SDs) from the mean or expected level can be considered an outbreak and should be investigated (Martin et al, 1987; Lessard, 1988).

The definitions of *outbreaks* and *epidemic* often overlap. As with the term *epidemic*, reference to an outbreak suggests both an unexpected problem and that an expected threshold for that problem has been exceeded (Toma et al, 1999). An *outbreak* as the occurrence of events (disease, impaired productivity, or both) in a population, clustered in time and space, the incidence of which is markedly in excess of the expected incidence (Lessard, 1988). Because the expected incidence of different diseases varies, an extensive outbreak investigation could be triggered potentially for as little as one case. One animal with evidence of a reportable foreign disease would trigger a large regulatory investigation.

Most outbreaks are identified and reported by the herd owner. The determination of what is presented to the veterinarian is dependent on the individual owner's threshold of concern (Ribble et al, 1998). The extent of the underlying problem can vary dramatically among different herd owners. Large problems can go unreported, whereas disease losses with accepted or expected rates can be alarming for some herd owners (Wikse et al, 1992). The expenditure of time and resources on the investigation of epidemics that do not exist can be minimized by first confirming the existence of an actual outbreak (Lessard, 1988). However, convincing the concerned farmer that there is "no problem" can be extremely difficult and often requires a great deal of patience and persistence on the part of the veterinarian. Seemingly frivolous concerns should never be dismissed without adequate information.

Orient the Problem: Characteristics of the Animals Affected, Time, and Place

Given that there is sufficient evidence to proceed with an investigation, the next steps are to answer the questions of which animals or groups are affected (*who*), *when* did they became affected, and *where* the affected animals were and are located (Radostits et al, 2000). This information is used to group animals within the investigation herd using these three factors: *host characteristics*, such as age, sex, and breed; *time*, particularly the date of onset; and *place or location* of affected animals or groups of animals (Smith, 1995).

Define the Groups of Animals Affected Within the Herd (Who?)

The amount of information available varies greatly among herds, depending on management, animal identification, and record-keeping practices. The clinician should collect all available information on the diseased animals, including identifying brands, tags (plastic and metal), or tattoos; age, sex, breed, and color; use; origin (purchased or born on farm); sire and dam; feed and water source; pastured, yarded, or housed; stage of reproductive cycle or gestation; lactation status; parity; clinical, pathological, or laboratory signs; processing, vaccination, and treatment history; and

Downloaded from Vet-eBooks.com

status of exposure to other potential risk factors (Lessard, 1988). A detailed individual animal listing or inventory is very useful but often not readily available.

Where herds are managed in distinct groups, much of this information can be collected and entered at the group level rather than individual animal. When collecting information about groups of animals, the investigator should ask if there are any exceptions. For example, data obtained for a group of yearling heifers in a cow-calf herd may not reflect the two older cows kept in the group to calm the younger animals. The information collected should include observations on unaffected as well as affected animals within the herd (Lessard, 1988). In some cases, information on neighboring herds can also be very useful. Have other herds within the area experienced similar problems recently? Information can be collected through phone interviews, written questionnaires, herd visits, and examination of the herd inventory and production records.

Orient the Problem in Time (When?)

Understanding the time sequence or temporal pattern of disease provides many important clues about the origin of disease in the herd (Lessard, 1988). A well-constructed graph (or *epidemic curve*) can help describe the pattern of disease. Epidemic curves have been used to describe the pattern of a number of important diseases, including the onset of shipping fever in feedlot cattle (Fig. 5-1). The clinician should consider whether this is a new or a long-standing problem in the herd. Have the numbers of new cases increased, stabilized, or peaked and started to decrease? The time of onset of each case (x-axis) should be plotted in appropriate intervals against the number of cases recognized at each time interval (y-axis). The best time interval to summarize the data varies with the accuracy of the records and intensity of the outbreak and may be hours, days, weeks, or even months. Other critical factors, including recent additions and changes in herd management, feeding practices, or the environment, when indicated on the epidemic curve, help the clinician visualize the time sequence of events.

From the epidemic curve, some inferences can be made about whether the problem is endemic in the herd, represents epidemic disease, or is a sporadic occurrence. An *endemic* disease occurs at a consistent level in the herd with only minor fluctuations over time (Fig. 5-2). The percentage of animals affected may be very low or include most of the herd. *Epidemic* is a relative term used to describe disease within a given time interval that is clearly above its expected rate of occurrence. A disease is *sporadic* if it occurs rarely and follows no regular pattern (Smith, 1991) (Fig. 5-3).

Epidemic curves can be used to identify periods of high exposure risk (Lessard, 1988). The pattern of disease can suggest whether the problem resulted from a single point source exposure or whether the occurrence of cases is better described by an infectious agent moving from one animal to the

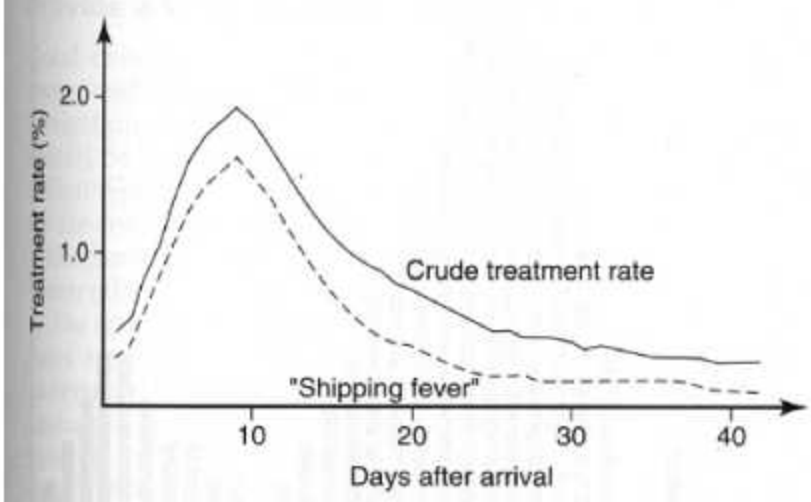

FIG. 5-1 Summary epidemic curves of crude treatment rate and "shipping fever" treatment rate for 106 pens of feedlot cattle. FIG. 5-3 Epidemic curve illustrating a sporadic disease problem in a cow-calf herd.

Downloaded from Vet-eBooks.com

next. The slope of the curve suggests whether the whole group was exposed at one time or if there were multiple exposures over a certain period. For example, an epidemic curve that has a relatively short time span of new cases and a dramatic upward slope is consistent with a *point source* exposure to the causative agent (Gregg, 1996) (Fig. 5-4).

A less steep upward slope followed by a more defined down slope and often one or more additional peaks can suggest a *propagated* agent (Gregg, 1996) (Fig. 5-5). The pattern of the curve may suggest an infectious agent moving between animals and groups of animals. The shape of the curve reflects the incubation pattern from infection to the time the animal becomes contagious and the timing and number of opportunities for transmission (Radostits et al, 2000). The incubation period for an infectious disease can often be estimated from analysis of the pattern of clinical onset data (Lessard, 1988).

Where the information is available, the location and identification of the first case *(index case)* can provide valuable epidemiological clues about the source of infection in the group. Identification of the index case can be extremely important in cases where an exotic or reportable disease is diagnosed. In these cases an intensive "trace back" will be initiated by the investigating regulatory agency to determine the origin of the first sick animal and potential contacts with other herds. Determining the amount of time from when the animals were first observed sick until they were found dead can also be very useful, when this information is available. Where treatment records are limited, however, the available information is often restricted to the date of death.

Examine the Spatial Pattern of Disease (Where?)

It is necessary to determine where affected animals were housed and pastured in relation to unaffected animals (Lessard, 1988). This often requires a detailed sketch or map of the farm and surrounding area. The clinician must also understand if and how the herd was organized into separate management groups. One common example is the division of dairy heifers into separate groups and facilities based on age and reproductive status. Information on the occurrence and timing of movement of groups of animals between different housing facilities or pastures is important, as is any information on the movement of animals between different management groups. The location of management groups in relation to neighboring herds and the potential frequency of contact with neighboring herds should also be examined.

A simple way to describe location is by preparing a *point map* of the farm (Thrusfield, 1995). A sketch of housing facilities, corrals, pastures (including details of cross fencing), feeding facilities, and watering sources should be prepared. Any potential areas of concern including chemical storage areas, garbage dumps, or industrial facilities should be noted (Lessard, 1988). The location of each management group at the time of the outbreak can be overlaid on the map and the location of individual cases. This map can be used as a visual aid for detecting patterns of disease and developing hypotheses about the location of exposure. A series of maps showing animal movements and pattern of disease over time can also be used.

Summarize and Analyze the Herd Data (Why?)

Data to answer the previous questions (what, how much, who, when, and where) are collected from many different potential sources, including interviews, questionnaires, herd visits, laboratory reports, and herd production and health records. The analysis begins with organizing and summarizing the data for the entire herd. The next step is to quantitatively describe the breed and age structure of the population, the physical examination, and laboratory results and then characterize the problem using descriptive statistics. Herd average morbidity, mortality, and productivity level should be calculated and then repeated for groups of individual animals identified within the herd. Hypotheses are made about the key determinants of disease or low productivity in the herd by comparing the risk of exposure between groups of diseased and nondiseased animals or, alternatively, by comparing the risk of disease in groups of exposed and nonexposed animals. The methods used to measure disease, the appropriate tools to measure the association between risk factors and disease, and finally the application and in-

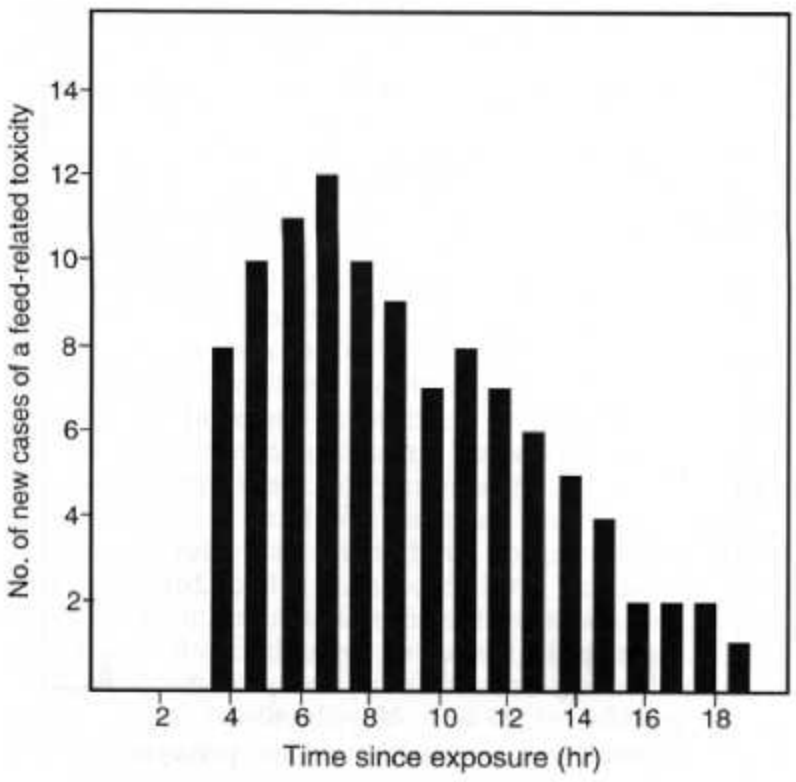

FIG. 5-4 Epidemic curve illustrating a point source disease outbreak in a feedlot.

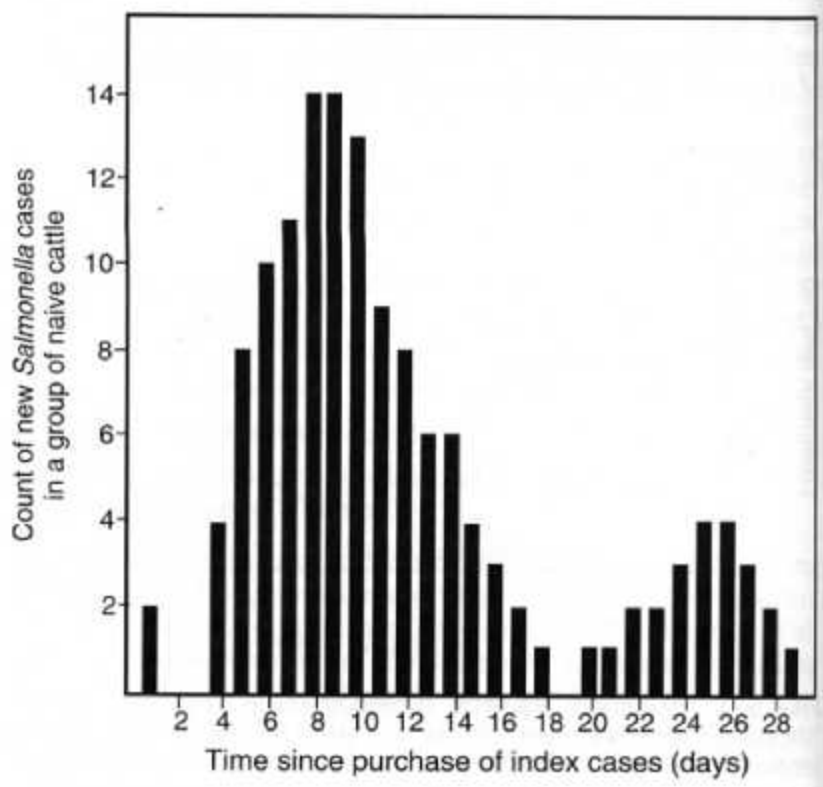

FIG. 5-5 Epidemic curve illustrating a propagated infectious disease epidemic in a cow-calf herd.

Downloaded from Vet-eBooks.com

terpretation of statistical tests have been covered briefly in Chapter 2. Measures of association are reviewed near the end of this chapter.

The results of the initial analysis often suggest factors that are determinants of disease risk or productivity problems in the herd. Methods based on *Mill's canons* for inductive reasoning can be used to identify and rank the importance of factors contributing to the outbreak (Martin et al, 1987). One strategy is to identify the factors that are common to most or all diseased animals and evaluate whether these factors may have contributed to disease ("method of agreement"). Were most or all of the affected animals of the same breed, age, or sex? Were they pastured together, or were they given the same ration?

The second and perhaps most successfully used investigation technique is the "method of difference." Many factors are examined to determine what is different about the animals that are diseased. Initially, rates of disease can be compared across different age, breed, or management groups within the herd. This method is frequently also used to interpret laboratory results. The diseased or affected animals should have a significantly higher frequency of positive test results than their unaffected herd mates if the test reflects an important risk factor for the disease.

When the conditions in which disease occurs are similar to those in which disease does not occur, with the exception of one factor (or group of factors), the presence or absence of this factor (or group of factors) may increase the risk of the disease. Variation in the occurrence of disease with the intensity or frequency of the suspected exposure factor ("method of concomitant variation") can provide additional evidence that the factor may be an important risk factor for disease. This principle is often applied when a nutritional or toxicological problem is suspected. The animals that were most exposed to some potential toxin should, in most situations, exhibit more profound clinical signs than those exposed to less of the same substance.

The comparisons just mentioned form the initial foundation for the answer to the final question: *why did the outbreak occur?* Sometimes these comparisons identify one or more key determinants for the disease outbreak or herd productivity problem. Other times this process targets specific questions that can be addressed by obtaining additional information from the herd owner or through focused laboratory testing. Several rounds of collection of additional data and analyses can be required with complex herd problems.

Provide a Written Report to the Herd Owner

Good communication must be maintained with the herd owner and other consulting veterinarians throughout the investigation. Preliminary reports summarizing initial findings should be issued within a few weeks of the initial herd visit. A final report can be issued later when all laboratory analyses are completed. A professional, clearly written document is necessary to communicate effectively the results and recommendations coming from the investigation.

The report must be written for the intended audience. Most reports are prepared for the herd owner. To make the report understandable to the intended audience, it must be well organized, concise, and explain the findings and recommendations of the study without excessive scientific or industry-specific terminology (Gardner, 1988; Lessard, 1988). The report should contain the following sections (Gardner, 1988; Ribble et al, 1998):

- Background to the investigation and the initial complaint
- Objectives
- Legal land location of the herd
- History
- Methodology
- Description of the facility and herd management
- Results of clinical and pathological examinations
- Laboratory results
- Summary of data analysis
- Discussion of results and diagnosis
- Assessment of financial impact of the problem
- Recommendations
- Appendices, including copies of relevant laboratory reports

Tables and graphs should be used to summarize results when possible. The best graphs convey no more than one idea (Altman, 1991). Elaborate special effects can clutter the presentation and make the data more difficult to understand. The recommendations should be presented with sufficient detail to avoid confusion (Gardner, 1988). Both short- and long-term recommendations may be necessary. The potential costs and benefits should be explained to the herd owner.

Occasionally herd-level problems involve liability issues that eventually may end up in litigation. Examples of potential legal cases include herd losses from feed or water contaminated with toxins, purchased replacement stock that are carriers for disease, and adverse reactions to pharmaceuticals. The written report should contain sufficient information so that the veterinarian can explain and defend the investigation results as many as 10 or more years after the original problem. Unusual or unique herd investigations should also be considered for peer-reviewed scientific publication.

Follow-Up Investigation

Relatively few complex problems are completely resolved with a single report. Many investigations are done retrospectively with insufficient information to reach definitive conclusions. In these cases, protracted herd health and productivity monitoring and occasionally planned follow-up studies are required to address outstanding questions. Structured observational studies can be used to define the importance of suspected risk factors. Study types include cohort, case-control, and cross-sectional designs (Smith, 1991; Thrusfield, 1995). Where there is a rapid solution to the problem and control measures can be introduced, follow-up field studies may be required to determine if the control measures are effective. In some cases, a planned randomized clinical trial is the best way to determine the success of specific recommendations. The appropriate intensity of the follow-up studies will be determined by the importance of the problem to the individual producer or to the industry in general. Planned field studies require a large amount of time and can be very expensive (Perry, 1988). Consultation with an epidemiologist before initiating a field study helps ensure the study design meets the intended objectives.

DATA GATHERING: INITIAL CONTACT, THE HERD VISIT, AND COLLECTION OF SAMPLES

The basic process of defining the problem, orienting the problem by animal, time, and space, and analyzing the data is common to all outbreak investigations. The steps often overlap in time and parts of the process may have to be repeated to resolve the problem successfully. The practice of outbreak investigation requires preparation, organization, and communication skills from the initial contact with the herd owner through implementation of the recommendations in the final report. Some practical suggestions for a structured and consistent approach to field investigations

Downloaded from Vet-eBooks.com

are presented below; however, no one approach applies to all situations.

Initial Contact and Preparation for the Herd Visit

Most herd investigations begin with a phone conversation, from questions raised over the counter at the clinic or during some other routine procedure. Herd owners should be encouraged to *describe the problems in their own words*. Good listening skills are very important, and questions should be asked only for clarification. The information will be biased if the interviewer excessively directs or monopolizes the conversation.

Herd problems should not be diagnosed by phone or "over the counter." Veterinarians should be reluctant to offer comment on economically significant herd-level problems without at least one herd visit. Although many herd owners can describe the problem well, incomplete or misleading secondhand information could result in inappropriate recommendations and leave the veterinarian potentially liable for the well-intentioned "free advice" (Ribble et al, 1998).

If this is the first visit to the farm, the investigator needs to collect some background information including complete name and address of the herd owner, the legal land description of the farm, and all important phone numbers. Have other veterinarians been working with the herd? If so, find out who and when. Previous examination or laboratory testing reports from the herd should be retrieved, if possible, and copied to save time during the herd visit.

Communication and preparation before the herd visit can optimize the limited time available on the farm. The client should be encouraged to gather all potentially relevant herd records before the planned visit. These may include herd record books, sales receipts, calendars, invoices for purchased feed, and other data depending on the type of operation. Some clinicians suggest having the client fill out a preliminary questionnaire covering basic herd background information. The initial questionnaire should include information such as the herd inventory and recent changes, breed and age distribution of the herd, management groupings, and feeding and vaccination practices. This background information will allow better planning of what and how many animals need to be examined and the number and type of appropriate laboratory samples.

The visit should be arranged so that everyone who works with the animals can be present at some point during the day. In addition to the herd owner, the clinician can obtain important information from other family members and farm workers. Also, if possible, the veterinarian should arrange to examine the herd in their "home pen" or usual location before they are disturbed and confined for detailed examination. It is often easier for a "stranger" to walk or ride through and examine the animals when the animals are actively grazing or just after they have been fed. The clinician can observe the group with minimal disturbance to the animals. This is an excellent opportunity to make observations of both animal behavior and herd management. If there are no nearby handling facilities, a second visit may have to be scheduled during some routine management procedure, such as pregnancy testing, vaccination, or branding, to facilitate detailed examination. More than one herd visit might be necessary to make both the necessary herd- and individual-level observations.

A "crude" working case definition can be constructed from the information provided during the initial contact. The investigator can save time, particularly for unusual or complex problems, by briefly reviewing the current literature on the known risk factors for the problem before the herd visit. A *path model* is a diagram summarizing the current understanding of the risk factors for the disease or productivity problem under investigation. Several good examples including path models for neonatal mortality in beef herds (Wikse et al, 1992), impaired fertility in beef cattle (Wikse, 1988), and factors affecting weaning weights (Sanderson and Christmas, 1997) have been published.

In addition to listing risk factors for the disease, the path model depicts the known information about the interrelationship between risk factors and their effects (Hancock and Wikse, 1988). Among other things, these diagrams help communicate to the herd owner that herd problems usually have more than one cause, that many areas of management may be deficient, and that infectious agents are usually only one part of the problem (Wikse et al, 1992). This review process also serves as a listing of the most likely risk factors. A complete investigation that evaluates the extent of involvement of all probable risk factors in the herd is necessary to provide sound recommendations for resolving the outbreak. By taking the time to review the potential risk factors for disease before the herd visit, the chance that either some area of herd management or the collection of important samples is overlooked will be decreased.

Preparation for the visit is important. In many cases there will be only one opportunity to examine the animals closely and to collect samples. An animal health technician can help organize sample collection and ensure everything is properly labeled and packaged for transport. The proper sample collection equipment should be packed in sufficient quantity to allow for surprises and accidents during the herd visit. The laboratory should be contacted before the visit (several days if possible) to verify the manner of sample collection, quantity of sample, type of container to be used, and packaging and transportation recommendations. Many private laboratories have sample collection containers and transportation packages that they will provide on request to their clients as part of their service fee or for a small additional charge.

The practice of herd investigation differs in some ways from routine ambulatory practice. A list of useful equipment not always carried for individual animal calls might include notebooks and pens for logging visit notes and samples collected; a calculator and possibly a laptop computer and printer; a good camera, pocket cassette recorder or video camera; a measuring tape, weigh tape, and calf weigh scale; ear tags and applicators; livestock markers; a current county or municipal district map; and a portable photocopier. A *photocopier* can save substantial time spent abstracting records and minimize the number of errors. The laptop computer and printer are also useful. Some veterinarians have expressed concern about the difficulties in getting paid full value for time at home spent entering records and doing records and nutritional analysis. Doing some of this work on farm and together with the herd owner can increase their appreciation for the time and effort required to complete the analysis.

Herd Visit

The examination of the herd includes collection of additional history, clinical examination of individual animals from the herd, necropsy examination of dead or euthanatized animals, observation of herd management and examination of the environment, collection of samples for laboratory examination, and examination of the herd records. This series of steps is a general guideline only, and the steps often overlap each other. This data-gathering process is followed by descriptive and analytical epidemiological evaluation of

Downloaded from Vet-eBooks.com

the results (Radostits et al, 2000). The objective of the herd visit is to determine first how the affected or diseased animals differ from those that are not affected, and then which of the factors that differs among these groups can be altered by intervention to decrease the risk of disease. The unique characteristics of the group of animals that is affected become a focus of the examination. Nutrition, management, and the environment are examined in relation to this group of animals.

Detailed written notes of all observations are important for constructing a meaningful and accurate report for the herd owner. Few things destroy a clinician's credibility faster with a herd owner than making a substantial mistake in describing the herd owner's operation. *All records should be in ink, dated, and signed.* A *camera* and *video camera* can be important aids in documenting observations. Pictures are a valuable memory aid and a great tool for client education and presentations to producer groups. If the case potentially involves litigation, date (and time stamp) the photos or video if possible. A record should be maintained of where and when the pictures were taken and a detailed voice narration on the video should include a description of what was observed. If a digital camera is used, the admissibility of the pictures as evidence should be discussed with a legal expert in the local area.

Cameras can be useful, particularly for recording somewhat subjective observations such as body condition score (BCS) and farm hygiene. Pictures from two different dates can be compared to monitor change over time. When trying to show the relative size of an object in a photograph, include a marked standard reference in the picture (e.g., a ruler, meter stick, or person of a known height). If individual animal identification is important, try to include the ear tag and brand, if applicable, in the photo. If it is impossible to have everything in the same picture, consider having someone hold or place a small sign or card in the picture with the necessary information. Video cameras are an excellent tool for recording behavioral or postural abnormalities and, sometimes, unusual sounds.

History. Always start from the beginning. The information was probably discussed during the initial contact, but this is an important opportunity to verify the phone conversation notes. Find a quiet and comfortable place such as the kitchen table or the office and have the herd owners restate the presenting complaint in their own words. The herd owner should be encouraged to present the events in chronological order if possible. The time sequence or time between events is crucial. Any unclear references should be clarified. The interviewer must avoid interrupting unnecessarily and "jumping to conclusions" during questioning (Ribble et al, 1998).

A list of questions prepared for the problem under investigation can help ensure nothing is overlooked during the interview—particularly for those who are gaining experience in this field. Although strict adherence to standardized questionnaires is necessary for most observational research designs, this same strict adherence to a prepared questionnaire can hinder the outbreak investigation process. No standard questionnaire fits every situation, and attempts to follow a preformatted series of questions interfere with the chronological order of the story (Ribble et al, 1998). Preliminary discussions with the herd owner and occasionally a simple previsit questionnaire can be used to prepare a list of required information to be obtained during the interview. This list can be used as a check sheet after the farmer has told his or her story to fill in some of the areas not covered in the initial contacts.

History-taking is an art and a science. Interview questions should be presented carefully. Below are several guidelines for collecting both oral and written information from the herd owner (Armstrong et al, 1994):

- "Open-ended questions" should be used when possible.
- Scientific language and industry jargon should be avoided.
- Ask for only one piece of information at a time.
- Avoid using double negatives in questions because they are confusing.
- Be cautious of "emotionally loaded" or "leading" questions that would suggest one answer is better than another.
- Questions should contain unambiguous, clear time references.

If questions are not presented carefully, the herd owner will in many cases be tempted to give the "correct answer" or the answer he or she thinks is more "socially acceptable" and not what actually happened. For example, when trying to evaluate the effectiveness of a particular treatment, written records or firsthand observation of actual treatments supplemented by a determination of the total amount of drug used often is more revealing than questions about what dose and frequency of administration was used. The quick and easy answer to a question about treatment protocol might be the information written on the side of the bottle—whether or not this was the actual amount given.

The use of "aids to recall" can improve substantially the accuracy of information obtained in the interview (Armstrong et al, 1994). Encourage the herd owner to verify dates and numbers using herd records or the kitchen calendar (Ribble et al, 1998). Often people have difficulty remembering brand names of the specific drug, vaccine, electrolyte, milk replacers, or mineral mix they used. Some props to help stimulate recall might include a list of drug names or a binder with examples of labels or packaging.

Much of the interview should be focused on collecting the owner's observations and not interpretations. First, ask the herd owner to describe what has happened in as much detail as possible (Radostits et al, 2000). However, after the required information has been recorded, give the herd owner opportunity to present his or her interpretation of events. He or she may present a possible cause or connection the clinician did not consider.

The history should include information on the herd owner, the history of the operation, and the type and number of animals. In addition to basic name and address information on the herd owner, inquire about off-farm jobs because this could be a potential source of risk in some herds. For example, the person who works in another herd or at an auction market could bring disease back into his or her own herd. The herd owner, any employees, and the families should also be questioned tactfully about concurrent illnesses if zoonotic disease or simultaneous exposures to toxins are potential threats (Ribble et al, 1998). This must be done cautiously so as not to alarm anyone unnecessarily.

The specific questions asked vary with the species, type of management, and type of problem; however, some general areas should be considered in all types of investigations. The disease history should include the following:

- Information on the present disease or productivity problem, including chronology, severity, and duration
- Estimates of the morbidity or treatment rates, case fatality, and population mortality rates
- Prior treatment; any prophylactic or control measures attempted
- Potential for exposure through introductions to the herd
- Any recent transportation of animals or transient introductions to the herd
- An assessment of herd culling practices.

The management history should include an assessment of nutrition quantity and quality, a record of recent changes

Downloaded from Vet-eBooks.com

in diet, any supplements used, and the availability and quality of drinking water. Other factors that must be discussed include reproductive management, past and present reproductive performance, and the breeding history of the herd (i.e., in-breeding, line breeding, cross-breeding programs). The vaccination and parasite control programs should be recorded. Many other general management factors, including the adequacy of hygiene, ventilation, drainage, feeding and watering equipment, opportunity for exercise and other equipment maintenance (milking machine maintenance), can be important. As climatic factors can be associated with many types of disease, local climatic information should be obtained first from the herd owner and verified, if necessary, with detailed records from area meteorological stations.

Clinical examination of individual animals from the herd. In many outbreak investigations, it is often not possible to confine and examine individually every animal in the herd. The distant visual examination of different groups in the herd during feeding or grazing is a valuable tool that should not be overlooked or minimized. The visual examination from a distance has been described and is outlined here (Radostits et al, 2000; Wilson, 1992). Both general observations of the group and individual observations should be recorded. Data should include identification, breed, color, sex, and approximate age where possible for individual animals showing notable clinical signs. If individual animal notations are not possible, count the number of animals in the group showing specific signs. The total number of animals and location of the group should also be included in the field notes.

The *visual examination* should include an assessment of the following:

- Behavior, mental status, temperament, and exercise tolerance
- Degree of crowding, dominance, and aggression problems within the group, and the access to and availability of bedding, food, and water
- Voice, respiration rate and character, coughing, and unusual noises or discharges
- Appetite, mastication, and swallowing; abdominal shape or contour (bloated, gaunt)
- Defecation (frequency, consistency, straining) and urination
- Reproductive status, signs of estrus or mounting activity, discharges from the reproductive tract, maternal behavior, udder conformation, and lactation status
- Posture, gait, and progression of movement
- Body weight and condition score; relative frame size and conformation
- Skin and hair coat (health and cleanliness)

Body condition scoring is an extremely useful technique that has been applied successfully to dairy and beef cattle, horses, and sheep as well as other species. Body condition is affected by energy intake, environmental demands, lactation demands, and parasitism. Body condition scoring can be done visually from a short distance where cattle cannot be confined to permit palpation. Visual appraisal is comparable to palpation except when cattle have long hair (Wikse, 1988).

Other clues to the nutritional status of the herd can be found during observation of the group. The amount, consistency, and appearance of fecal material can verify diet composition and provide information on recent changes or accidental ingestions. Fecal consistency can provide information on the amount of dry hay relative to silage, green grass, or concentrate. Fecal content can also reflect recent grain overload or exposure to environmental toxins such as crude oil spills.

Several types of herd problems may be difficult to detect and quantify if the animals are closely confined. A potential herd lameness problem is best initially assessed through observation of the group. Observation of group behavior can also be an important supplement to the investigation of herd reproductive problems. Suboptimal reproductive performance sometimes can be associated with lameness because of inhibited mounting activity and expression of estrus. Bull libido is not assessed as part of routine breeding soundness examination but can be informally assessed in beef herds by observing bull activity on pasture during the early part of the season. Timing of the observations is important. Early morning and evening visits are often the most productive. If a problem is suspected, a more formal service capacity test can be applied (Barth, 1997).

The *detailed examination* of individual animals has been well documented in other textbooks and is not extensively reviewed here. Each animal can be examined individually if warranted by the severity of the problem or if the examination can be combined with other routine processing activities. If this approach is not practical, subsets of severely affected, moderate or mildly affected, and not apparently affected animals from the herd can be examined. Examining the "normal" animals first should minimize the potential for transmitting disease within the herd. There are no specific guidelines for how many animals should be examined; however, a minimum of 12 (8 affected [4 severe and 4 mild] and 4 normal animals) are suggested. Targeting the first few animals that became sick and all recent additions to the herd has also been suggested (Martin et al, 1987).

If all animals are examined individually, a complete herd inventory can be compiled including identification, breed, sex, and approximate age. If the animals are not identified individually, some form of permanent individual identification such as ear tags can be placed during the examination or routine processing. Also, the reproductive status of the herd and BCS the animals should be recorded if possible. If bred cows are not pregnancy tested, this should be done as soon as practical. If the complaint involves reproductive failure, breeding soundness examinations should also be done on any bulls. This individual animal listing and record of reproductive status is particularly important if the problem could require monitoring over time. This inventory information provides an important baseline for further study in the herd.

Necropsy examination. A detailed guide on necropsy techniques for food-producing animals is available (Andrews, 1986). Detailed instructions for necropsy examination are not presented, but some general concepts applicable to multiple examinations and outbreak investigations are included. Necropsy information is particularly important for improving the case definition where clinical signs are vague and nonspecific. *All* available animals that have died should be examined whenever possible. One or two cases from a major disease outbreak might not be representative of the underlying problem. Where the value of individual animals are low, the herd owner might also be willing to sacrifice a small number of affected animals for a complete necropsy examination. If the value of individual animals is high, the herd owner might consent to the euthanasia of one or two chronically diseased animals where the prognosis for recovery is poor.

The investigation of abortion outbreaks and the laboratory examination of the fetus and placenta deserve special note. The approximate gestation age of the fetus should be estimated. The time of loss can be an important clue for infectious etiological agents. Tables associating crown-rump length and gestation age have been published for cattle and

Downloaded from Vet-eBooks.com

sheep (Kirkbride, 1986). Few causes of abortions have distinctive gross pathology, making laboratory examination necessary in almost all cases. Where possible, submission of the entire fetus and placenta to the laboratory is preferred to examination in the field. Fetal postmortem diagnoses are made more difficult because many fetuses are retained *in utero* after death and are often severely autolyzed before expulsion. Autolysis can obscure histological lesions and make recovery of the causative organisms impossible.

Where possible, all samples from the outbreak should be submitted to the same laboratory. The clinician might also request that only one pathologist examine all submissions relating to a single investigation. This should improve communication and consistency and make it easier to see trends in the data. If multiple laboratory submissions are made, the clinician should summarize the data in a quantitative manner. What proportion of the animals examined had the lesion of interest? What proportion of the herd does this represent?

A consistent protocol for sample collection, attention to labeling, and log of all samples collected helps ensure nothing is lost or forgotten. The amount, appropriate sample container, storage, preservation, and shipping instructions for nonroutine samples should be verified with the laboratory before the herd visit. For example, should the sample be placed in a glass or plastic container? Should the sample be shipped frozen, on ice, or at room temperature? Special care should be taken with samples for microbiology to optimize the survival of the suspected pathogen and minimize overgrowth of contaminants. Samples for toxicological analysis can be contaminated easily during collection or degrade very rapidly if the wrong container or preservative is used. Small errors can result in misleading and inaccurate laboratory results.

Banking tissue samples for future analysis is appropriate if the factor to be analyzed is stable for a known period and if the cost of collection and storage is not prohibitive. It is much better to collect tissue that will not be examined than to miss important samples. Questions raised later in the outbreak investigation could require histology on tissues not originally examined, toxicological analysis of a liver sample, or immunohistochemistry to confirm the presence of an infectious agent. Small pieces of formalinized tissue for histology, for example, do not add much to the cost of the investigation and require little if any additional storage space. Frozen tissue samples can be analyzed later for some types of toxins or trace mineral content.

Extra care should be taken in necropsies that are part of herd outbreak investigations in which large economic losses have occurred. One option is to have the herd owner transport some or all of the cadavers to a regional diagnostic laboratory where the examinations can be conducted by a pathologist under the more controlled conditions of the laboratory. Where this is not practical or possible, the examinations must be completed in the field using the best possible practices. The challenge to necropsy technique and documentation is most likely to come from litigated cases.

A *camera* can be used to record subtle clinical and pathological abnormalities. The identity of the subject animal, the date, a size reference scale marker, and the identity of the pathologist should be included in each photograph in which litigation is a potential issue. The laboratory should be notified before the samples are shipped if the case may involve litigation. Many laboratories have special "chain of custody" protocol documentation that assists in ensuring any sample results will be admissible in court. The common errors made in necropsy examinations that must be avoided in "medico-legal" necropsy of livestock include the following (Wobeser, 1996; Jaffe, 1991):

- Incomplete examination (failure to examine the brain)
- Inadequate documentation (no written report or photographs)
- Too much delay between the examination and preparation of the report
- Failing to collect samples for supplementary analysis (microbiology, histology, or toxicology)
- Improper collection of samples (inappropriate samples, unsuitable containers, insufficient preservation, inadequate labeling)
- Accidental damage to specimens (contamination with spilled gastrointestinal content or improper or rough handling of fragile tissues)
- Confusion of artifacts (autolysis or histological damage from freezing confused with important pathological lesions)
- Failure to consult with other experts
- Bias resulting from too much emphasis placed on the case history

Occasionally, tissues from "normal" animals within the herd may be required as controls or for determinations of trace mineral, heavy metal status, or parasite load. Animals sent to slaughter either for the commercial market or for in-home use should be considered as potential sources of material for this type of comparative analysis.

Observation of herd management. Many other chapters in this textbook are devoted to the detailed discussion of herd management in specialized livestock production systems. This section outlines some general points that should be considered in most herd outbreak investigations. Many veterinarians are reluctant to be perceived as criticizing the management skills of their clients. Often the management assessment consists of the simple notation "good management" (Hancock and Wikse, 1988). If there is an outbreak in the herd by definition, however, there must be some level of deficiency in management. Few common disease problems require only the infectious agent to cause substantial herd losses. Almost all outbreaks or suboptimal productivity problems result from many factors, including management. The objective of the investigation is to identify the risk factors that can be changed to resolve the current herd problem.

Questionnaires traditionally have been used to attempt to objectively evaluate herd management. Questions having yes or no or other short answers are commonly used to simplify the form. This process often provides only a superficial evaluation of potentially important risk factors. For example, many management questionnaires ask whether cattle are vaccinated for infectious bovine rhinotracheitis. This would seem like a relatively straightforward question. However, a "yes" answer provides no information on what type of vaccine was used, when it was administered, and if label directions were adequately followed to optimize the chance of an adequate immune response.

To evaluate herd management completely, the clinician must *see* how things are done. Herd management cannot be evaluated completely during a single visit. Several visits may be required to understand the operating procedures in a herd. Planned management checks do not always provide a complete picture of herd management. Herd management, for that visit, might be what the owner thinks the clinician wants to see rather than what is done routinely. The best management assessments are often collected informally as part of an ongoing process where the investigating veterinarian works with the livestock owner on a regular herd health program. Ongoing assessments provide a reference for identifying changes in herd management. Management changes may be important risk factors; however, those changes that preceded the outbreak need to be carefully differentiated from those that occurred later.

Downloaded from Vet-e-Books.com

Evaluating the nutritional status of the herd. The nutritional status of the herd is a critical area of management and often one of the most difficult to evaluate retrospectively. Disease or suboptimum productivity can result directly from inadequate nutrition such as starvation, white-muscle disease and selenium/vitamin E deficiency, or laminitis in dairy cows from rumen acidosis. Poor herd nutritional management can also contribute indirectly to many productivity and health problems. Protein-energy malnutrition during the final weeks of gestation has been associated with the failure of passive transfer in beef calves and the resulting increased risk of calf scours.

The objective of a nutritional evaluation is to determine if the feeding management in the herd could have contributed to the problem under study. Is the nutrition program adequate for the type of animal and environment? Expensive laboratory analysis alone will not address these objectives. Chemical analysis of the feedstuffs is important; however, this single report provides very little information about what is actually ingested by average animal and how much variation there is between animals.

Feed inventory. Before collecting any feed samples, the herd owner should prepare an inventory of all forages, grains, and purchased supplements. Individual lots of homegrown feed are listed by type and composition, approximate date harvested, and quantity. All purchased feeds should be listed by date of purchase, source, type and composition, and amount. Copies of all feed tags (analysis and instructions for use) or the supplier contact numbers for all commercially prepared feeds or supplements should be collected. The clinician should record which of these feeds are being used now and which have been used in the past. Any unused feed from the period when the herd problem was first noticed should also be identified. The amount of available feed stores can be verified during sample collection. Does the amount of feed on hand realistically reflect the reports of the amount fed?

Feed quality. The *visual appearance* and *physical characteristics* of the feed observed during sample collection should be recorded. Odor, color, stage of maturity, presence of foreign material (garbage, weeds) and physical form provide information necessary for proper interpretation of the feed analysis. Was the hay weathered before storage and is there any evidence of mold? Record the lengths of the silage chop and estimate the moisture content. Milk fat, rumination, cud chewing, and salivation are all decreased by chopping silage too fine (Holland and Kezar, 1995). Note the relative stem-to-leaf ratio or grain-to-forage ratio in the stored feedstuff. Chop length and moisture content should be measured in the field when possible for silage and total mixed rations. Silage pH can also be measured in the field.

Feed quality can be affected by many factors, including the following (Swecker and Thatcher, 1988):

- Weather conditions during the growing season
- Deficiencies and potential excesses of nutrients and minerals in area soil (low copper and high molybdenum regions)
- Plant maturity and moisture content at harvest time
- Application of organic acid during harvest to retard mold formation
- Ammoniation at harvest to improve protein content
- Method of storage (square, round bales or stacks; covered shelter, tarps, or no protection; upright stave silos, upright "oxygen-limiting" silos, bunker or pit silos, and bags)
- Problems with the moisture content of stored feed often resulting in heat damage or mold development
- Damage during final processing (particle size, excessive heating)
- Incorporation of feed additives (ionophores, hormones, antibiotics, buffers, minerals, pellet binders, antioxidants, vitamins, flavoring agents).

Sampling techniques. Good sample collection technique is important for a meaningful chemical analysis. The samples submitted for analysis must be "representative" of what is being fed. There can be considerable variation in the quality of feedstuffs from different fields or from feeds harvested at different times during the growing season. Proper equipment is also necessary to get an adequate sample. A good quality core sampler is required for hay sampling and an auger or probe for grain and concentrates. Silage and haylage are often the most difficult to sample representatively at a single point in time. Silage is collected by taking several grab samples from different parts of an open pit or at different times from multiple points on a moving conveyor belt. There might be substantial differences in quality in different parts of the pit or silo. To get some information from the entire pit or silo, many herd owners will collect samples from each load during ensiling and then freeze the samples for later analysis. Additional sampling of the final or total mixed ration provides a check on the adequacy of the mixing process and the actual composition compared with the "paper ration." The collection of the samples from feed storage and handling equipment may be useful particularly for cases where feed-related toxicity, such as mycotoxins, is suspected. The collection of "old feed" samples from equipment has been described (Hancock et al, 1988).

Pasture sampling is done relatively infrequently but occasionally may be necessary for the investigation of metabolic disease or trace mineral deficiencies (Hancock et al, 1988). Composite grass and composite legume samples should be representative of the major species in the pasture. If more than one soil type is present, separate samples should be collected from each soil type. The samples are best collected by cutting the plants near the roots with scissors to minimize soil contamination. Separate soil and ground water samples may also be appropriate if environmental contamination of the pasture is being considered. Toxic plants can be photographed and then collected and dried for identification by an expert in that area.

Visual inspection of the pasture is important. Is the pasture natural or cultivated domestic grass or legume? Is the amount of forage adequate for the number of animals on the pasture? There are formal methods of monitoring pasture growth and availability and grazing capacity that are not reviewed here. The location(s) of water sources and evidence of use by livestock on pasture should also be examined and recorded. The clinician should note the location and availability of any supplemental feed sources, whether mineral and salt are offered in block or loose form, whether the supplement appears fresh and is protected from the elements, and finally whether there is any evidence of recent intake.

Submission for laboratory analysis. Collect, pool, and mix thoroughly 5 to 10 samples for grain or concentrate and 20 individual samples for hay or silage from each lot of feed before submission to the laboratory. Silage samples should be placed in airtight plastic bags, stored on ice, and shipped to the laboratory as soon as possible. Do not divide hay samples after collection and before submission to the lab. Separation of the leaves and stems can result in very different results among the subsamples. The lab should be instructed to dry and grind the *entire sample* before analysis (Swecker and Thatcher, 1988; Holland and Kezar, 1995). Some laboratories only process a subsample of what has been submitted unless otherwise specified.

The feed testing laboratory should be consulted before the samples are submitted. There are a number of chemical analysis packages to select from. Feed analysis can be very

Downloaded from Vet-eBooks.com

expensive. The selected package should answer only the questions of interest. The clinician should also understand the limitations of all the requested tests. Commercial feed laboratories vary greatly in their internal quality control procedures and the types of analytical, estimation, and calculation procedures used.

Common analyses and laboratory procedures. One of the standard procedures for feed chemistry is proximate analysis. *Proximate analysis* is a set of wet chemistry procedures including dry matter content, crude protein, ether extracts (lipids and fats), ash (mineral content), and crude fiber (cellulose and lignin) (Holland and Kezar, 1995). Nitrogen-free extract (sugars, starch and some of the hemicellulose and lignin) and total digestible energy are estimated from the proximate analysis. Some of these wet chemistry procedures are still used in routine forage analysis.

Crude protein analysis reflects the total nitrogen content of the feed and alone can be misleading because it gives no indication of what percent of the protein might be unavailable because of heating damage (Holland and Kezar, 1995). An additional analysis must be requested for unavailable protein. If the amount of bound protein from heat damage is greater than 12%, the available protein and not crude protein should be used in ration evaluation calculations.

Energy can be expressed many different ways (NRC, 1996). Digestible energy (DE) is the total energy of the feed less the energy lost in the feces. DE overestimates the value of high-fiber feedstuffs. Total digestible nutrients (TDN) are similar but adjusted for digestible protein. Metabolizable energy (ME) is total energy adjusted for fecal energy, urinary energy, and gaseous energy losses. The ME can be used as a reference unit and starting point for the preferred system based on net energy (NE) (NRC, 1996). Net energy is ME minus the heat increment from fermentation and nutrient metabolism. Net energy is commonly partitioned to the energy required for maintenance (NEM), gain (NEG) and lactation (NEL). Net energy values are preferred for formulating rations because they account for major losses in digestion and utilization of the feed (Holland and Kezar, 1995).

The Van Soest method is the preferred technique for cell wall determination (Holland and Kezar, 1995). The sample is processed first to separate the soluble portion (sugars, starch, pectins, lipids, protein, soluble carbohydrates, and nonprotein nitrogen, water-soluble vitamins, and minerals) from the insoluble portion or cell wall fraction (neutral detergent fiber [NDF]). NDF (cellulose, hemicellulose, lignin, and silica) increases with the maturity of the forage at the time of harvest. NDF is negatively correlated with *dry matter intake* and is used to estimate DMI (120/% of NDF). Acid detergent fiber (ADF) remains after processing with an acid detergent. The ADF is negatively correlated with the *digestibility* of forage and is used to estimate the energy value and digestibility of feed.

Calcium, phosphorus, and other major minerals can be analyzed using wet chemistry, atomic absorption spectroscopy, or colorimetric procedures, depending on the laboratory.

In recent years, near infrared reflectance spectroscopy (NIRS) has become common. The computer compares the reflectance spectra of previous forage samples analyzed by wet chemistry with that of a new feed sample and estimates fiber, protein, mineral, and energy. NIRS can provide rapid low-cost forage and grain analyses but variation in the consistency of sample collection, storage, drying, grinding, and mixing can all affect the quality of the result. The accuracy of the result, however, is most dependent on the number of wet chemistry samples from similar forage or grains used to develop the calibration set for the system (Holland and Kezar, 1995). The calibration set used will depend on how the feed sample was described on the submission form. Proper description of the submitted sample is necessary for an accurate result. For example, submitting a 90% grass:10% alfalfa mix as a "clover hay" will result in inaccurate results using NIRS. NIRS should not be used on concentrates, mixed forages, and total mixed rations (TMRs).

Ration evaluation. The laboratory results should be examined promptly. If any of the values are substantially different from what was expected, the laboratory, in most cases, will recheck the analysis. Most laboratories will hold the original sample for a short time after the results are completed. Both the "as received" and "dry basis" values on the feed analysis report should be examined. Some computer ration evaluation programs use "dry basis" and some use "as fed." Ration evaluation programs suitable for dairy, beef, and swine are readily available and can be used with a laptop computer on farm to assess the adequacy of the ration under the observed environmental conditions. Working through this process together with the herd owner, when possible, improves his or her understanding of nutrition and his or her understanding of the time required and the value of the work.

Measuring average daily intake. A limitation of ration evaluation is the failure to obtain an accurate estimation of average daily intake. First, what and how much feed is being offered to the livestock? In some herds, weights of feed delivered each day are recorded. If possible, verify the accuracy of the scale. In most cases, however, this information is not available, and one or more representative sections of the feed in the bunk should be weighed and extrapolated based on the dimensions of the bunk. A portable calf birth weight or milk scale can be used with 5-gallon pails to weigh the feed offered in individual bunks. This type of scale can also be used to weigh a sample of small square bales. Larger feedstuffs such as round bales or a load of silage potentially could be weighed at a local truck scale.

The second task is to determine how much feed is actually consumed. This should be measured and not estimated whenever possible. This can vary greatly depending on climatic conditions for any particular day. Because the amount of feed offered will vary depending on the previous days consumption and environmental conditions, have the farmer record how much is offered over several days and determine the average value. Intake then can be estimated by weighing any leftover feed just before the next feeding (weigh back). Given the number of animals in the pen, the average intake can be determined. Feed intake within the pen can also vary dramatically among animals. The amount of variation depends on bunk management and the variation in animal age, size, and type within the group. Accurate determination of feed intake is necessary for a meaningful ration evaluation but often requires substantial time and effort on the part of both the herd owner and clinician. These figures can be roughly verified by comparing the above estimates with feed inventories and invoices from feed companies.

Feed bunk management. Feed bunk management is also an important aspect of nutritional management. Variations in the dimensions, materials, and size of the feed bunk; the timing and frequency of feeding; method of feed delivery; the presence of salt or mineral in the bunks; practice of "top-dressing"; and finally the person doing the feeding can all influence average group intake and extremes within the group (Swecker and Thatcher, 1988). The necessary amount of feeding space varies with the size of animals, number in the group, and whether feed is available "free choice" or limit fed. The available bunk space should be measured, particularly if crowding or competition appears to be a problem. Ice or mud around the bunk or waterer can affect intake adversely. The feed in the bunks should be fresh, clean

Downloaded From Vet-eBooks.com

smelling, thoroughly mixed, and free of mold and other foreign material (Fetrow, 1993). Old spoiled feed in the bunk also decreases intake. Feeder design and feed storage conditions will affect the amount of feed wastage. The feed wastage should be estimated, since this information will be needed for most computer ration evaluation programs. The method of delivery for feed supplements is also important to note. The amount of micronutrients consumed will be less on average with free choice than for force-fed livestock in which micronutrients are mixed with concentrate, silage, or a TMR.

Water quality and availability. Water quality and availability are important determinants of livestock health and feed intake. The ratio of animals to waterers in each pen should be noted. The clinician should observe animals using the water source and record any evidence of crowding or dominance behavior, stray voltage, physical access, or footing (mud, manure buildup, or ice) that appears to be limiting access to water. The investigator should determine if all automatic waterers are working properly. Is dugout, pothole, or stream water pumped to a trough, or do the animals actually enter the water to drink? Is the water clean and free of offensive odors, or are there substantial amounts of mud and manure suspended in the water because of animal movements? Is algae growth an obvious problem?

Water sampling for livestock use should include an assessment of total dissolved solids (TDS), sulfates, nitrites and nitrates. TDS in excess of 5000 ppm can reduce water intake and result in diarrhea in all classes of livestock (Jaikaran, 1993). High sulfate levels (>1000 ppm) can interfere with copper status (Larson et al, 1995) and increase the risk of polioencephalomalacia (Radostits et al, 2000). Bottles for water sampling should come directly from the laboratory where possible. Improperly cleaned containers can contaminate the sample. This is particularly important for trace mineral or organic analysis. Proper sampling technique, special preservatives, and rapid transportation are required for samples being tested for potentially volatile components. The laboratory should be contacted in advance if tests outside the routine potability parameters may be required.

Reproductive management assessment. The most practical and widely used approach to assessing reproductive management has been to ask questions during an interview or to use a written reproductive performance questionnaire. Much of the necessary information is record-based and therefore lends itself to this approach. Many of the factors involved in successful reproductive management of the herd, however, are best evaluated through on-site observation. Records analysis may, for example, target heat detection or artificial insemination (AI) technique as a potential problem. Both heat detection and AI technique can be evaluated by examining a series of reproductive indices if the records are complete and accurate. Heat detection and AI techniques can be reported verbally, but herd owners may be reporting what they think the veterinarian wants to hear rather than what is actually happening. A herd visit to observe estrus detection, semen storage, handling, and thawing techniques might be necessary (Williamson, 1987). The most reliable first-hand observations and assessment of reproductive management are probably casual observations made by the veterinarian across a number of regular herd health visits. The skills required for successful management of parturition, dystocia, and neonatal resuscitation and routine processing are also difficult to evaluate without on-site observation.

Other management problems. Depending on the type of operation, many other areas of management might have to be assessed through on-farm visits. For example, in dairy herds without observing milking procedures first hand (both morning and evening if different milkers are involved), it may not be possible to understand the origin of some mastitis problems in a herd. On-site observation is the best way to determine how cows are being assessed for mastitis, how consistently udders are cleaned and teats are dipped, whether or not the liners are allowed to slip, how well the milking machine is maintained, and whether cows are being overmilked. Recently digital video cameras have been used successfully in milking parlors to monitor and time milking procedures. The milking staff should be notified that a camera is being used.

Management deficiencies are also well-documented contributors to perinatal mortality. For example, stocking density, sanitation, rotation of feeding sites, use of shelters, wintering cows on the calving ground, and mixing of heifers with mature cows can all contribute to perinatal losses in beef calves. A walk-through of the calving and nursery facilities is usually necessary to understand calving management in the herd and assess many of these somewhat subjective issues.

Animal handling and processing techniques may be important. A number of questions should be considered and are answered best by observing processing procedures. Are the animals handled with minimal stress? Are injections given correctly? At the end of processing, does the amount of product used correspond to the number of animals processed and the label dose? How many new needles were used compared with the total number of animals processed? Are biologicals reconstituted, administered, and stored according to label directions? Are recommended implanting or castration techniques correctly applied?

All facets of management can be difficult to evaluate objectively. Hygiene can be a particularly difficult area because of the herd owner's sensitivity to what is socially desirable. Livestock owners who are questioned about their barn cleaning or bedding practices might volunteer what they try to do rather than what actually happens. For example, someone might report putting fresh bedding out twice a week. The size of the bedding pack and the cleanliness of the area can be used to verify this information. A count of the straw bales on site can also be compared with the amount of bedding used and the period over which it will be needed to further support or raise questions about the self-assessment. Without time spent on the farm listening and watching, many management problems will not be detected.

Examination of the environment. As with the assessment of management, the clinician requires an understanding of the husbandry and needs of individual species and classes of livestock to identify potential environmental risk factors. Climate, housing, population density, and air quality are all important determinants of disease risk and herd productivity and should be assessed individually for both housed and pastured groups within livestock operations.

Climate. Some classes of livestock can adapt to severe extremes of climate. Most, however, do not tolerate rapid changes in the weather conditions without some associated risk. Historical weather data, to supplement verbal reports from the herd owner, can usually be obtained from local meteorological stations for a modest fee. In addition to actual data on weather extremes and changes, the interactions of the climate with other characteristics of the animals' environment, including topography, drainage, and ventilation, can be important factors. Actual pen size, for example, can be dramatically reduced by snow cover or poor drainage (Ribble et al, 1998). A field that should be of adequate size for a given number of animals can be overcrowded and highly contaminated during certain times of the year because of water accumulation or high snow drifts.

Downloaded from Vet-eBooks.com

Population density. A numerical assessment of population density should not be calculated from the total space in the pen but from the usable space at the point in time preceding the outbreak. The range of numbers of animals in the group through the critical period should be determined and not just the average or the number at the time of the herd visit. Herd visits should be made as soon as possible after a herd problem is identified, since problematic environmental conditions are sometimes transitory. Crowding and environmental contamination can be important determinants of exposure to infectious agents by increasing the opportunity for effective contact between agent and host resulting in disease (Spangler, 1988). Topography can also be an important risk factor to consider. In addition to the direct effects on drainage, topography can affect prevailing wind conditions, exposure to wind-chill factor, and, rarely, environmental toxins (Waldner et al, 1998). Ground level and aerial photographs and topographical and local municipal or county maps are all useful for recording environmental observations.

Housing and shelter facilities. The location and type of shelter within the outdoor pen should be recorded. Sheds, porosity fencing, other types of windbreaks, and wooded areas are all used by various types of operations. Portable calf sheds (if used properly) can help minimize the high levels of contamination that often occur in these highly frequented areas. The ground conditions are also very important to livestock health and production and should be recorded. Is the ground grass covered, a dry dirt lot, a lot bedded with straw or wood shavings, or a paved dry lot? Or is the ground covered with stagnant water, deep mud, and manure? The importance of these factors varies with the class of livestock, but poor ground conditions adversely affects productivity for all species. The type and amount of bedding are important to the ground conditions, but bedding management can also affect dust levels in the pen. Air quality is particularly important in dry lots and feedlots where dust levels can potentially affect the occurrence of respiratory disease.

The clinician should walk around the perimeter of the farm and ask about any potential problems areas. Some potential environmental risks to consider are the location of carcass disposal sites, garbage dumps, fuel and chemical storage areas, and nearby industrial or mining facilities. Also, the potential for insect and predator problems on the pasture should be considered.

Good ventilation and temperature and humidity control are critical to maintaining health and productivity in housed livestock of all species. The objective evaluation of indoor ventilation may require the assistance of an expert in this area. Many parameters typically are measured depending in part on the type of animal being housed and include minimum and maximum temperature, number of air changes per hour, humidity and condensation, location and size of air inlets and fans, and presence of drafts. Specialized monitoring equipment can be used to measure levels of many suspected problem gases including ammonia, hydrogen sulfide, and carbon monoxide. Other factors to be evaluated for indoor environments include sanitation and hygiene, type and condition of the flooring, barn cleaning and waste disposal system, stall or crate design and dimensions, bedding type and adequacy, ease of movement for both animals and attendants within the unit, and adequacy of the lighting. In dairy barns, for example, at any given time more than one half of all cows lying down should be chewing their cud. If a large number of cows are standing and chewing their cud, there may be a problem with the stanchions or freestalls.

Laboratory sampling and analyses. Sampling for laboratory examination is a valuable tool for ruling out or confirming the diagnosis, determining and defining risk and exposure factors, predicting the necessity for and appropriate level of intervention, and, eventually, assessing the success of the attempts to control the problem (Hancock et al, 1988). Laboratory testing usually is the most expensive part of the investigation. Undirected "fishing expeditions" are particularly expensive and rarely productive. Tests should be selected based on whether the results are likely to directly affect management decisions (Hancock et al, 1988). Appropriate samples might include blood, milk, feces, urine, nasal and ocular swabs, biopsies or tissue samples from slaughter animals or cadavers, other fluid samples, and feed, water, and soil samples. Necropsy, feed, and water sampling has been discussed previously.

Several factors influence how successful laboratory sampling protocol will be at achieving the objectives just outlined. The type of sample selected must be appropriate for the question being asked. The animals chosen for sampling must not bias the results, and the number must be sufficient to answer the question with a reasonable degree of certainty. The samples must be collected using the appropriate technique and collection equipment, stored properly, and delivered to the laboratory before sample quality is compromised (Hancock et al, 1988).

Finally, the laboratory test selected must have acceptable measurement error, accuracy, and precision and must be able to discriminate adequately between "normal" and affected individuals. (See Chapter 2 for a complete discussion of the limits and interpretation of laboratory results.) To meaningfully interpret the test results, the laboratory should be able to provide the sensitivity and specificity of a particular test and define how the value for the normal cut-off has been established. To accurately assess sensitivity and specificity there must be a "gold standard" for the test being evaluated. Several good additional references are available that discuss the interpretation of diagnostic test results (Martin, 1988; Sackett et al, 1991).

Introduction to sampling principles. The cost of most analysis often prohibits laboratory testing of every animal in the herd. How then should the animals be selected for laboratory sampling? Sampling theory is based on the principle idea that a representative group can be selected from a population of individuals, and that characteristics of the population can be estimated from this group. *Probability sampling* is a deliberate, unbiased process in which each sampling units in a group has a known probability of being selected. The most common form is *simple random sampling*. In this case, each member of the population has an equal chance of being selected. To select a simple random sample, the clinician must know the size of the study population before sampling begins.

How can the clinician make sure each individual has an equal opportunity of being selected? To select a simple random sample from a population of a given size (N), the *random number generator* on most computer spreadsheet packages can be used to produce a list of random numbers equal to the required sample size (n). The calculation of required sample size is considered in the next section. The spreadsheet program generates a column of (n) random numbers between 0 and 1. The spreadsheet formula is used to multiply each of these numbers by "N." For the random number 0.859 and n = 100, multiply 0.859 and 100 to get 85.9, round the product up to the next whole number (86), and pick the 86th animal on the list or the 86th animal through the handling system. The next number generated by the computer may be 0.246. This number is multiplied by 100 and rounded off to 25. The 25th animal on the inventory list or the 25th animal processed then would be selected. Repeat the process and keep moving down the list until there is a complete list of sample subjects equal to the

Downloaded From Vet-eBooks.com

number suggested by the sample size calculation. *Random number tables* can also be used to generate the necessary list of animals for sampling.

The process just explained can be modified to account for selection of subjects from divisions within the larger population *(stratified sampling)*. Stratified sampling would be appropriate to ensure the selection of some animals from each age or management group within the herd. The process described above is repeated within each age or management group. The appropriate sample size is calculated using the number of animals in that age or management group within the herd.

On the surface, formal probability sampling appears tedious and complicated. Many herd owners and veterinarians will ask, "Why not just select a *convenience sample* or the first 20 cows that walk in the chute?" Ease of accessibility or any other factors that made the sample "convenient," however, also will bias the resulting factor estimate. Intentional or purposive samples selected because they are "typical" of the average within the population are also biased because the subjects are clustered around the mean and do not adequately represent the variation within the target group.

The best compromise, if herd size is not known exactly before sampling begins, is to use *systematic sampling*. Systematic sampling involves the selection of animals at equal intervals. The first animal is selected randomly from within the first interval. If 10% of 100 animals are required, a number between 1 and 10 is randomly selected. If this number were 6, then the 6th, 16th, 26th, 36th, and up to 96th animals through the chute would be sampled.

Sample size determination. Probably the most common question and often the most difficult to address is "How many samples are necessary?" There is no single correct number of samples suitable for every situation. If sample-associated uncertainty in the results is unacceptable, then every animal in the herd must be tested. This is rarely practical because of time and cost considerations; therefore a sample of total population is tested to estimate the population value. The required number of animals is based on (1) the acceptable degree of uncertainty in the final estimate, (2) the expected prevalence of the factor of interest, or, for continuous measurements, the variation in the factor within the population, and finally (3) the size of the population examined.

The number of samples required also depends on the question being asked. The three most common questions addressed within a single population include the following:

- Estimate the prevalence of a disease or characteristic
- Detect the presence of some factor or disease
- Estimate the mean (or median) of some measurement in the population

Sampling to estimate the prevalence of disease in a population. Suppose, for example, a clinician wanted to determine what percentage of a herd of 500 head of beef cows was serologically positive for *Neospora caninum* and could not afford to test the entire herd. The sample size is estimated initially based on a theoretically infinite population and then adjusted to the required sample size for the number of animals in the group of interest (Thrusfield, 1995). The sample size estimate is determined for a given level of precision or an interval on either side of the estimate within which the true prevalence will fall for some predetermined level of confidence. By convention, many sample size estimates are calculated with a 95% confidence interval.

The formula for a 95% confidence interval is as follows (Thrusfield, 1995):

$$n = \frac{1.96^2\, P(1 - P)}{d^2}$$

in which

n = the sample size for an "infinite" population
P = the expected prevalence in the population
d = largest acceptable difference from the true prevalence

The estimated prevalence (P) sometimes can be found in the literature, or previous experience might suggest a suitable estimate. If there is no available information, use 0.5. This provides the most conservative or largest estimate of sample size for the bounds and confidence level used in the calculation.

Given the *N. caninum* example, a prevalence of 10% could be predicted in the population and a 2% error on either side of that value might be acceptable. The 1.96 value in the formula is used for 95% confidence interval calculation:

$$n = \frac{1.96^2(0.10)(1 - 0.10)}{(0.02)^2} = 864$$

The last step in the calculation is to adjust this infinite population estimate (n) for the number of animals in the population under study (N). If n is very small compared to N (roughly less than 5%), then n_{adj} will approach or equal n (Thrusfield, 1995):

$$n_{adj} = (N \times n)/(N + n)$$

The infinite population estimate from the previous *N. caninum* example was 864, which is more than the number of cows in the herd. This infinite population estimate is adjusted for herd size using the above formula:

$$n_{adj} = (250 \times 864)/(250 + 864)$$
$$n_{adj} = 194$$

A sample of 194 of the 250 cows is needed to be 95% confident that (over a large number of repeated trials) the prevalence of serologically positive animals is within ±2% of the sample estimate. The formulas just provided are based on approximate methods. More exact methods are also available (Levy and Lemeshow, 1999).

There are a number of commercial software and shareware packages available to perform these calculations. To use the programs, however, the clinician must understand the required information and the limitations of the results. One of the most popular is a program called EPITABLES within Epi Info, from the Centers for Disease Control and Prevention (CDC) in Atlanta, Georgia. Instructions for obtaining the software are presented in Chapter 2. A second program available free of charge on the Internet is Win Episcope 2.0 available at http://www.zod.wau.nl/genr/epi.html.

Often other factors determine how many samples will be analyzed. Cost, weather conditions, time available to collect the samples, facilities for collection, and the interest of the herd owner all affect how many can be collected. If a fixed number of samples is collected, it is possible to calculate a confidence interval for the herd prevalence and present the precision of the estimate. Using the previous example, suppose only 25 of the 250 cows were tested and 4 were serologically positive. The 95% confidence interval for the apparent prevalence could be calculated as follows (Hancock et al, 1988):

$$\textit{Apparent or test prevalence } (P) = 4/25 \text{ or } 0.16$$

$$\text{95\% confidence intervals (CI) for } P = P \pm 1.96 \times \{[P \times (1 - P)/n] \times [(N - n)/N]\}^{-2}$$

$$\text{95\% CI for } P = 0.16 \pm 1.96 \times \{[0.16 \times (1 - 0.16)/25] \times [(250 - 25)/250]\}^{-2}$$

$$\text{95\% CI for } P = 0.16 \pm 0.14$$

$$\textit{Apparent or test prevalence } (P) = 0.16 (\text{95\% CI, } 0.02 \text{ to } 0.30)$$

Downloaded from Vet-eBooks.com

Confidence intervals provide information about the precision of the estimate. "If the underlying statistical model is correct and there is no bias, a confidence interval derived from a valid test will, over unlimited repetitions of the study, contain the true parameter with a frequency no less than its confidence level" (Rothman and Greenland, 1998). Roughly translated, the clinician would be 95% confident, based on 4 positive samples out of 25, that the proportion of serologically positive cows in the herd was between 0.02 and 0.30.

Apparent prevalence and true prevalence. In the previous example, serological status, and not actual disease prevalence, was estimated. If the actual disease status of the herd was required, the clinician would also have to account for laboratory error. The laboratory results only reflect the *apparent prevalence* and do not account for the limitations in the ability of the laboratory test to discriminate between truly affected and nonaffected animals. (See Chapter 2 for information on the interpretation of laboratory tests.) Given the sensitivity and specificity of the test, the apparent prevalence, and the sample size, the *true prevalence* and 95% confidence intervals can be estimated. A shareware program called True Prevalence within Survey Toolbox (available at http://www.ausvet.com.au/surveillance/toolbox.htm) can calculate true prevalence from the data shown previously (Cameron, 1999).

Sampling to compare the prevalence of disease between two groups. In herd outbreak investigations, laboratory sampling is often targeted to identifying the *differences between groups*. The sample size necessary to do this depends on the confidence limit and power required for the test, or the estimated value and the variance of the proportion or prevalence of animals with the attribute in each of the two groups being compared. A good estimate of the expected prevalence in at least one of the groups should be obtained from previous data, a literature search, or expert opinion. The value for the second group, if unknown, should reflect the smallest important difference between the first and second groups being compared. The variance of a proportion in which there are only two possible outcomes (a binomial outcome such as "diseased" or "not diseased") is equal to $[np(1 - p)]$ where n is the number in the group and p is the expected prevalence in the group (Altman, 1991).

The *confidence limit* is often set at 95%, but frequently used values range from 90% to greater than 99% to minimize the chance of *type I error* (α). A type I error occurs when subsequent data analysis suggests (often because of sampling error) that a real difference between the groups exists and there is none. A *type II error* (β) occurs when a real difference exists between the groups being compared and this difference is missed or is considered nonsignificant often because of sampling error (inadequate sample size). The *power* $(1 - \beta)$ is often initially set at 80% but can be set higher (90% is also used commonly).

The shareware programs Epi Info and Win Episcope 2.1 can be used to calculate the sample size for comparing prevalence between two groups. The serological status of two groups of replacement heifers could be compared to assess the effectiveness of a control program for *N. caninum*. If the prevalence in the untreated group was 25% or higher, how many heifers should be sampled to determine if the prevention program worked? In this example, an "effective program" might result in a prevalence of 10%. The sample size calculator for Win Episcope 2.0 suggests that 98 heifers from each group should be tested to detect this difference with 95% confidence and 80% power.

Sampling to compare the prevalence of disease between two groups (case-control studies). In herd investigations the clinician often needs to compare the test results between affected (cases) and unaffected (controls) animals to determine whether some risk factor has contributed to the observed disease problem in the herd. If the number of cases is limited, there are some statistical advantages to having more controls than cases up to a ratio of about 4 controls to 1 case. To calculate the necessary sample size, the number of controls per case and an estimate of the prevalence of exposure in the control group are required. The estimate of exposure in the baseline population should be made from previously published work when available. The smallest important relative change in exposure between cases and controls will then determine the sample size. This value is estimated by the *odds ratio* (see Chapter 2). The clinician must decide if a risk factor that is two times more common in the cases than controls is important or if it is only important if it is substantially more common in the cases. A larger sample size is required to detect smaller relative differences. Confidence intervals and power must also be specified. Both Epi Info and Win Episcope 2.0 can be used to calculate the required sample size for case-control comparisons.

To determine if *N. caninum* serological status was a risk factor for an abortion outbreak in a particular herd, the clinician could collect serum samples near the time of abortion. Additional samples should also be collected from up to four control cows for every aborted cow. The power of the analysis is slightly increased by having more controls than cases. Reports in the literature suggest that the relative difference in abortion risk between serologically positive and negative cows can differ by 8 or higher during an outbreak. The literature also suggests the background percentage of cows that are serologically positive could be up to 10%. If 12 aborted cows and 48 controls are tested, an odds ratio of at least 8 could be measured with 90% confidence and a power of 80%.

Sampling to detect the presence of some factor or disease in a population. Testing might be conducted to determine whether or not disease is present in a group of animals. Because no test is perfect, the veterinarian can never be 100% sure there is no disease in the herd. To be 100% confident that no animals are positive for the disease, every animal must be tested. If some defined level of uncertainty in the result is acceptable, however, probability sampling methods can be applied, as explained earlier for the estimation of disease prevalence.

The following formula can be used either to calculate the minimum number of animals to be tested from a group of a given size to detect disease above a specified minimum frequency or, conversely, to calculate the probability of finding one infected animal given a specified sample size from a larger group of known size. The calculations depend on both the expected frequency of the disease in the population and the desired confidence level. The following formula can be used to estimate either the required sample size (n) or p_1 (the probability of finding one affected animal) (Thrusfield, 1995):

$$n = [1 - (1 - p_1)^{1/d}][N - (d/2)] + 1$$

in which

N = the size of population under examination
d = the minimum number of animals that must be detectable within the population
n = the size of sample required to detect at least one affected animal
p_1 = is the probability of finding at least one affected animal in the group

Consider a herd of 150 beef cows to be screened for bovine leukemia virus status. There have been no confirmed clinical cases in the herd. Some Holstein cows occasionally have been brought into the herd from auction marts to serve as "nurse-cows" for abandoned calves. How many cows

Downloaded From Vet-eBooks.com

would have to be tested to detect a 5% seroprevalence if the minimum acceptable probability of finding at least one affected animal is 95%?

$$n = [1 - (1 - p_1)^{1/d}][N - (d/2)] + 1$$

in which
$N = 150$
$d = 0.05 \times 150 = 7.5$
n = the size of sample required to detect at least one affected animal
$p_1 = 0.95$
$n = [1 - (1 - 0.95)^{1/7.5}][150 - (7.5/2)] + 1$
$n = 49$

The FreeCalc program, which is part of the shareware program Survey Toolbox (Cameron, 1999), can calculate sample size for the detection of disease and can also account for both the sensitivity and specificity of the diagnostic test in the calculation. The sensitivity and specificity of some tests may vary with the stage of the disease. A test that performs well for detecting animals that show clinical signs may not do an equally good job of detecting disease carriers (Spangler, 1988). For example, serological and culture techniques are much more reliable for adult animals showing clinical signs of Johne's disease than for younger animals that may have no symptoms but may be carrying the organism and potentially contaminating the environment.

Sampling to estimate the mean of some value in the population. The sample size calculations presented up to this point have examined examples in which the animals have or do not have the disease in question or are positive or negative on some diagnostic test. Different formulae and information are required to estimate the mean of some continuous measurement in the group, such as trace mineral levels or average daily gain. An estimate of the expected SD, an accepted level of error in the mean, and the size of the population from which the sample is collected are required (de Blas et al, 1999):

$$n = [N \times Z^2 \times SD^2]/[(N - 1) \times d^2 + Z^2SD^2]$$

in which
n = estimated sample size
Z = Student's t-value for an expected confidence level
SD = expected SD
N = population size
d = selected accepted error (precision)

This formula could be used to calculate how many animals should be tested to estimate the whole blood selenium status of a group of 60 beef cows. Often the most difficult number to estimate is the expected SD. Ideally, previous local data would be available; however, this seldom happens. This value can be crudely estimated from the range of normal values reported by the laboratory. Many laboratories have developed a normal range based on the results of a reference set of representative "normal" animals. The samples are analyzed and the normal reference range is set at approximately ±2 SDs of the mean of these samples. One published normal range for whole blood selenium is 0.200 to 1.200 ppm (Puls, 1994). If this includes ±2 SDs, then 0.250 ppm [(1.200 − 0.200)/4] should be a useful approximation of the SD for the calculations.

The next number required is Z or the Student's t-value for an expected confidence interval. In most cases, a 95% confidence interval is used, which is equivalent to a Z value of 2.00 (Altman, 1991). This value can be obtained from the tables at the back of most statistics books. The value d or the maximum acceptable error should be based on the expected mean and the degree of precision required for the estimate. The maximum accepted error is 0.100 ppm for this example.

$$n = [N \times Z^2 \times SD^2] \times [(N - 1) \times d^2 + Z^2SD^2]$$
$$n = [60 \times (2.00)^2 \times (0.250)^2] \times [(60 - 1) \times (0.100)^2 + (2.00)^2(0.250)^2]$$
$$n = 18$$

Win Episcope 2.0 can be used to calculate the number necessary to estimate a mean given the expected SD, the population size, and the selected accepted error (precision) for a given confidence interval (usually 95%).

Sampling to compare the means of two groups. When evaluating the importance of a risk factor in a herd investigation, the clinician may need to compare the means of two different groups. For example, is selenium status an important determinant of poor calf health? This question could be addressed by collecting samples from sick and healthy calves and then comparing the average whole blood selenium between the two groups. To determine how many animals to sample from each group, the following information is necessary:

- An estimate of the mean for one of the groups. (If comparing cases and controls, the expected normal value for the population should be used.)
- An estimate of the mean for the second group. (In this example, the cut-off level between deficient and normal could be used. If comparing calf weights between two groups, the second value could be estimated after considering the minimum important difference in weight between the two groups.)
- An estimate of the standard deviation.
- The confidence level and power for the sample.

Win Episcope 2.0 can calculate the sample size for comparing means. For the selenium example, to detect a difference between a normal group (mean = 0.300 ppm) and a deficient group (mean = 0.080 ppm) with an estimated SD of 0.250 ppm (see previous section) at 95% confidence with 80% power, samples should be collected from 23 sick and 23 healthy calves.

Sample size calculations: why not just use 10% or 10 animals per group? The previous examples demonstrate that 10% of each group or 10 animals per group is often not enough to answer a question with the level of confidence and power needed to make defensible, economically important herd management decisions. The cost of laboratory analysis, however, often practically limits the numbers of samples analyzed far below what the sample size calculations suggest is required. The calculations are not absolute or perfect. Different computer programs may use different formulas and provide different answers. Many of the inputs are based on subjective judgments and the values used vary from one clinician to the next. Calculated sample sizes are not absolute requirements but rather guidelines for planning data collection. Before spending substantial amounts of time and money on laboratory analysis, the necessary sample size should be determined. This estimate can minimize the chance of collecting either not enough samples or more samples than necessary for the level of confidence required in the final results.

Serum banks in herd investigations. In many investigations, there is only one opportunity to collect laboratory samples from the herd during the critical timeframe. Because of the laboratory costs, the clinician cannot possibly direct the laboratory to analyze the samples for every potential question that could arise during the investigation. If the expenses for sample collection are less than analysis, one potential answer is *serum (or sample) banking*. Samples are collected and stored with sufficient precautions so that they can be analyzed later with minimal loss of sample integrity and quality.

Serum, if processed correctly, can be stored almost indefinitely for future analysis. A single serum sample can be

Downloaded from Vet-eBooks.com

tested for a wide variety of constituents such as immunoglobulins, trace elements, toxins, hormones, enzymes, and genetic markers (Moorehouse and Jones, 1981). Whole blood samples sometimes can be stored for future assay of some trace elements or toxins.

Most often, serum samples are used to diagnose viral or bacterial infections. The use of paired samples to compare acute and convalescent titers is one of the most commonly referenced applications of serology. In some investigations, however, the disease episode may be long past before the samples are collected (Collins, 1991). Most of the limitations of this process accompany the serological test itself. Some antibodies are transient and are detected only if the samples are collected immediately following the infection. With other tests, cross-reacting antibodies make interpretation difficult. False-positive reactions can also be caused by nonspecific inhibitors, agglutinins, or unstable red cells. False-negative reactions can occur because of immunological tolerance to the agent, poorly timed collection, or masking of results by nonspecific inhibitors (Moorehouse and Jones, 1981). Some recently developed antigen capture ELISA tests have fewer limitations than paired sera comparisons.

Careful attention to animal identification, sample labeling, and documentation is required to create a useful serum bank. Minimal sample identification should include breed, sex, age, location, date of collection, and herd size (Moorehouse and Hugh-Jones, 1981). Where possible, blood samples should be collected from the entire herd. A subsample then can be selected for initial laboratory analysis. If whole herd sampling is not practical, the method of selecting the test group should be recorded.

Ideally, a sufficient amount of blood should be collected so that 3 to 5 ml of sera can be stored per animal. If the sample could be assayed potentially for trace element concentration (e.g., zinc), the collection equipment and storage containers must be chosen carefully so the sample is not contaminated. The freshly collected blood should be allowed to clot at room temperature and then stored horizontally for several hours at 4° C before separation of the serum by centrifugation at 2000 to 3000 rpm for 10 to 15 min (Moorehouse and Hugh-Jones, 1981). The serum is removed using clean Pasteur pipettes. Cross-contamination between samples must be avoided. Some sera can be refrigerated for immediate use. The remaining sera should be frozen in 0.5- to 2.0-ml aliquots for later testing.

Conventional standard deep freezes average about −20° C, and for many serum constituents, deep freezes provide adequate preservation for short-term storage of less than 3 to 6 months. If the freezer temperature remains constant, sample quality can be maintained for up to 2 years (Moorehouse and Hugh-Jones, 1981). For prolonged storage, samples should be frozen as soon as possible after collection below −60° C. Options for long-term storage include ultra-low temperature deep freezes available at some laboratories and storage in liquid nitrogen. Hemolysis and bacterial contamination of the samples must be avoided because of resulting enzymatic destruction of serum immunoglobulins. Thawing and refreezing also increase the destruction of serum constituents. Samples should be tested as soon as possible after thawing to minimize proteolysis (Moorehouse and Hugh-Jones, 1981).

Interpreting diagnostic panels and the results of "fishing expeditions" in herd investigations. When faced with a new or unusual problem with no immediately obvious solution, there is a temptation to run a panel of diagnostic tests or to submit samples of everything for everything and see what comes up positive (the "fishing expedition"). See Chapter 2 for a discussion of the risk of false-positive results that can occur when running batteries of tests on individual animals. The risk of a false-positive result increases further when batteries of tests are used on groups of animals. A group of five tests, with an individual test, false-positive risk of 3% repeated on five animals, has a combined risk of greater than 50% for one false-positive result when used on the group. Unless the test has a specificity of 100% (and very few do), the high risk of false-positive results from using the laboratory to "fish" for an answer makes this practice very dangerous. The laboratory tests should be chosen and the results must be interpreted using the information presented in Chapter 2 (the clinical signs and other laboratory results) and considering the effect of herd size and the number of samples collected. Additional discussion of the interpretation of diagnostic tests at the herd level is covered by Martin (1988).

Examination of the herd records. The details of what records are required and what information may be available for a particular type of operation have been reviewed in Chapter 3. Additional details on the form and interpretation of herd records are given in the individual chapters for each species and production class. The quality and completeness of records vary greatly between operations. Some herds have complete, individual animal, computerized record systems, and some may appear to have little or no record of animal health and productivity.

The most challenging, and all too frequently encountered, situation occurs when there are apparently few or no herd records. Potential sources of information may include veterinary service, supply, or drug bills; auction mart receipts; old calendars, pocket diaries, and calving books; feed and supplement bills; financial records of animals bought and sold; and bulk tank receipts showing somatic cell count and bacterial numbers (Hancock and Wikse, 1988). Record quality can be a serious problem, and an informal "audit" of the records for accuracy might be useful. For herds that do not have a current inventory list, chute side collection and recording of animal identification, color, breed, age (actual or approximate), and BCS should be considered and can be performed during routine processing.

Records analysis should be performed with a laptop on farm with the herd owner present. If the investigator has questions, the herd owner may be able to answer them and the herd owner gains an appreciation for the time required to perform the analysis. This may not always be possible depending on the extent of the problem and available herd records. For more complicated problems in larger herds, it may be necessary to copy the herd records and have them entered into a software program for detailed analysis. Manual entry of individual animal data is sometimes impractical. Some software programs provide user-friendly outputs using only downloaded data from third-party agencies or summary records entered at the herd level. For DHI herds, it is usually possible to obtain a computerized herd production history. This data then can be directly imported into the common herd analysis programs. Electronic data sharing can save considerable time over that required for manual data entry and analysis.

The records can be analyzed and compared to information from other herds to determine if and how the herd performance differs from expectations. Comparisons can be made to other area herds; state or provincial averages; breed association or dairy herd improvement services reports; published production and health monitoring studies; suggested targets for production; and the historical performance of the herd being examined. The appropriate benchmarks against which to compare production vary between farms because of economic constraints, physical restrictions, time and management limitations, and other individual differences. The targets for performance change over time for a particular herd as these constraints change.

DATA ANALYSIS: EVALUATING RISK FACTORS FOR DISEASE AND SUBOPTIMUM PRODUCTIVITY

One of the most commonly calculated measures of disease for outbreak investigations is the attack rate. The attack rate is the proportion of the group that is affected during a given period. The attack rate can be compared between those that are and are not exposed to each individual potential risk factor. To easily visualize this comparison across many different risk factors, an *attack rate table* (Table 5-1) is used to help identify the exposures most likely to be associated with disease.

The application of the appropriate statistical test allows the clinician to determine if the difference between exposed and nonexposed animals is statistically significant (Lessard, 1988; Gregg, 1996). To apply statistical methods, the investigator must clarify the hypothesis being tested and then define the *null hypothesis* or statement that the effect or association of interest is zero. For example, the hypothesis might be that low BCS is associated with increased risk of nonpregnancy. The null hypothesis would be that there is no association between BCS and pregnancy status. The next step assesses the likelihood that the data (or more extreme data) could have been obtained if the null hypothesis were true (or there really was no association). In the example presented in Table 5-1, cows with a BCS <2.5 were significantly less likely to be pregnant than those cows with a BCS >2.5 ($P < .0001$).

The correct selection and application of the statistical test is necessary for meaningful interpretation of the *P*-value. The *P*-value is derived from the resulting test statistic. The *test statistic* is a value that can be compared with the known distribution of what is expected when the null hypothesis is true or there is no association. The *P-value* is the probability under the null hypothesis that the test statistic computed from the data would be as extreme or more extreme than the observed value, assuming there is no source of bias in the data collection or analysis. Statistical testing is discussed in Chapter 2, but the redundancy is justified to some extent by the frequent misinterpretation of the *P*-value. The *P*-value is not the probability that the observed effect arose by chance. This interpretation too often leads to the incorrect belief that if the observed effect is not due to chance, then it must be real (Altman, 1991).

Many times in herd investigations, the number of animals is relatively small, particularly when differences between groups within herds are examined. Often a relationship between a risk factor and disease is strongly suspected, but nothing comes up "statistically significant" (or $P < .05$). This does not prove that the null hypothesis is true (or that there is no association), only that there is not sufficient evidence to reject it. To fully interpret the importance of risk factor data from herd investigations, additional information is needed. Some measure of the magnitude of effect or the strength of the association between the exposure (or grouping factor of interest) and disease must be calculated. The magnitude of the association and the confidence intervals suggests whether there is a tendency towards an effect that might not be significant simply because of the small sample size and resulting low power of the statistical test.

The importance of different risk factors can be compared objectively by measuring the magnitude of the association between each exposure and the outcome of interest or disease. The two common indices used to measure the magnitude of effect are the relative risk and odds ratio (see Chapter 2). To review, the *relative risk* is the ratio of the risk (or cumulative incidence or attack rate) of disease in the animals exposed to the factor of interest to the risk (or cumulative incidence or attack rate) of disease in those that were not exposed. Relative risk can be used when there is complete information about the entire herd.

	Diseased	Nondiseased	
Exposed	a	b	a + b (all exposed)
Nonexposed	c	d	c + d (all nonexposed)
	a + c (all diseased)	b + d (all nondiseased)	

Relative risk = $[a/(a + b)]/[c/(c + d)]$

TABLE 5-1

Sample Attack Rate Table for an Investigation of Infertility Problem in a Beef Herd

	Exposed Animals				Unexposed Animals			
Suspected Risk Factors	No. Affected (Not Pregnant)	No. Not Affected (Pregnant)	Total No.	Attack Rate (%)	No. Affected (Not Pregnant)	No. Not Affected (Pregnant)	Total No.	Attack Rate (%)
Bull 1	6	30	36	16.7	6	18	24	25.0
Bull 2	6	18	24	25.0	6	30	36	16.7
Body condition score <2.5	11	4	15	73.3	1	44	45	2.2
New feed supplement	8	32	40	20.0	4	16	20	20.0
Purchased replacements	3	17	20	15.0	9	31	40	22.5

Downloaded from Vet-eBooks.com

If the relative risk is less than 1, then the exposure is associated with a decreased risk of disease. If the relative risk is equal to 1, then there is no association between exposure and disease. If the relative risk is greater than 1, then the exposure is associated with an increased risk of disease. The farther the relative risk is from 1, the stronger the mathematical association is between the exposure and disease. If the 95% confidence interval includes 1, then the association is not statistically significant. The relative risk provides more information than the *P*-value alone for interpreting the data in Table 5.1. Cows with a BCS <2.5 were more likely (RR, 33; 95% CI, 5 to 234) to be nonpregnant than those cows with a BCS ≥2.5. The relative risk estimates the strength of the association, and the confidence interval relates the precision of the estimate.

The *odds ratio* can be used to measure the association between exposure and disease for any study type, but it is the method of choice for expressing the magnitude of effect in case-control comparisons. Case-control comparisons are very useful for interpreting laboratory data in herd investigations. The odds ratio (sometimes called the cross-product ratio) is the odds of being exposed to some potential risk factor of interest among the cases divided by the odds of being exposed among the controls. The odds ratio can also be defined as the ratio of the cases to controls among the exposed subjects divided by the ratio of cases to controls among the unexposed subjects. If, in herd investigations, the outcome of interest is relatively rare (<10%), then the odds ratio offers a good approximation of the relative risk of disease in the exposed compared with the nonexposed animals.

	Diseased	Nondiseased	
Exposed	a	b	a + b (all exposed)
Nonexposed	c	d	c + d (all nonexposed)
	a + c (all diseased)	b + d (all nondiseased)	

$$\text{Odds ratio} = [(a/c)/(b/d)] \text{ or } [(a/b)/(c/d)] = ad/bc$$

The interpretation of the odds ratio is similar to that of relative risk. If the odds ratio is less than 1, then the exposure is associated with a decreased risk of disease. If the odds ratio is equal to 1, then there is no association between exposure and disease. If the odds ratio is greater than 1, then the exposure is associated with an increased risk of disease. If the 95% confidence interval includes 1, then the association is not statistically significant. The odds ratio tends to overestimate the strength of relationship between exposure and disease in herd investigations, particularly if the outcome is common (>10%). The data in Table 5-1 can also be interpreted using an odds ratio. Poor BCS was associated with an increased risk of nonpregnancy, since nonpregnant cows were more likely (OR, 121; 95% CI, 12 to 1193) to have a BCS <2.5.

The calculation of confidence intervals for either the relative risk or the odds ratio is useful for interpreting small data sets. Formula for confidence intervals for both the relative risk or odds ratio can be found in many different sources. Most of the calculations can be done with a handheld calculator, but Epi Info and Win Episcope 2.0 can also be used. With very small data sets, exact calculations can be obtained from most software programs that are more accurate than the formulas suitable for manual calculation.

Because of the increasing availability of computers, difficulties with formulae and calculations are no longer the major factors limiting the application of appropriate statistical analysis; however, the clinician must interpret the results correctly. "Statistically" significant does not equal "clinically" or "biologically" significant. A very small association can be statistically significant if the sample size is high enough. Strong associations are sometimes missed if the number of animals is too small. Finally, a strong and significant statistical association between a factor and disease does not prove causation without additional information.

To assess causation, the practitioner must evaluate a number of other factors, including the time sequence of events. The time of exposure for any suspected risk factor should also be plotted on the epidemic curve. Any factor suspected to cause disease must precede the onset of the disease in time. This time relationship between suspected risk factor and outcome can be difficult to verify, however, particularly when disease outbreaks are investigated retrospectively.

Analysis of Multiple Risk Factors

The preceding section outlines the basic analytical tools required for herd investigation. These tools alone, however, often limit the investigator to analyzing one risk factor. These simple techniques do not allow the investigator to account for the interactions of multiple risk factors in disease and productivity failure. In field investigations, all of the known risk factors for the outcome of interest must be considered in formulating recommendations for control. If only one risk factor is examined, and another important factor that is unmeasured or unaccounted for is differentially distributed between the two groups, the results of the analysis could be biased and misleading. Other potential risk factors can be accounted for by limiting characteristics of the animals compared, by matching some characteristics of the animals compared, or by using stratification or various types of multiple regression analysis. These more advanced analytical methods are beyond the scope of this chapter. The clinician should consult a veterinary epidemiologist for assistance with analysis of complex data sets involving multiple risk factors. Faulty investigation design or analysis can result in inappropriate advice and potentially substantial losses in herd productivity.

SUMMARY OF INVESTIGATIONS, RECOMMENDATIONS, AND CONTROL STRATEGIES

The objective of the investigation is to identify the risk factors for disease or suboptimal productivity in the herd and then to control the problem by targeting the factors under management influence. The clinician needs to explain why the outbreak occurred. At the completion of data analysis, the most likely risk factors can be identified and used to formulate a working hypothesis or diagnosis of "best fit" (Ribble et al, 1998). The working diagnosis should consider risk factors, sources of exposure, modes of transmission, and the exposure period where applicable (Lessard, 1988). In some cases, this information is sufficient to proceed with detailed recommendations for control. In other cases, further work is required.

Sometimes the required further work is simply additional laboratory analysis indicated by the initial results. In other investigations, planned observational studies are necessary to address specific questions raised during the investigation. Earlier in this chapter, the potential for supportive epidemiological studies to investigate the importance of potential risk factors was introduced. In the following sections, the basic observational study designs (cross-sectional,

Downloaded From Vet-e-Books.com

case-control, and cohort) and the advantages and limitations of each approach are introduced.

Follow-up Observational Studies

Cross-Sectional Studies

In a cross-sectional study, data on the risk factors of interest (exposures) and disease outcomes of interest are collected simultaneously. The cross-sectional study is a snapshot of the exposure disease relationship at some particular point in time. Because all of the information is collected together over a relatively short period, this is often the least complicated and least expensive of the observational study designs. The major limitation of the cross-sectional study design, however, is that there is often no way to determine whether the risk factor preceded the disease in the animals being studied. For example, a poor BCS should be evaluated as a potential risk factor in a herd that had recently experienced high stillbirth losses. If the information on body condition is limited to observation of the cows after calving season is completed, the clinician will have difficulty verifying the time sequence of events. Did the low BCS contribute to the losses, result from dystocia-related postpartum metritis, or occur because of unrelated, poor postpartum nutrition? Cross-sectional studies are useful for examining factors that do not vary over time, such as the association between the degree of eyelid pigmentation and the risk of pinkeye in cattle.

Case-Control Studies

When the case-control approach is used, the risk of exposure to one or more risk factors of interest is compared between cases of the disease (or productivity deficit) in question and controls selected from the population at risk. Case-control studies are well suited for retrospective analysis of clinic or hospital-based records and are very efficient for examining rare outcomes. Accurate case definition and careful thought on the selection of appropriate controls is necessary to minimize bias in the results. Since exposure status is usually determined after disease status, there may be some difficulty in establishing whether exposure preceded disease. Case-control designs are often used in herd investigations in which it is possible to sample most or all of the cases, but it is not practical or possible to sample all of the nonaffected animals. Case-control methods could be applied to assess the association between failure of passive transfer and a neonatal scours outbreak by examining the concentration and amounts of serum immunoglobulins between calves with scours and healthy calves matched on calf age.

Cohort Studies

For cohort studies, two or more groups within a herd or larger population are defined according to their exposure status for some risk factor of interest and followed to determine the occurrence of disease (or productivity deficit) in each group. Because exposure status is known at the start of the study, the timing and directionality of events should be clear. When done prospectively, cohort studies can provide good quality data; however, this study design can be time consuming and expensive.

Cohort studies require extensive efforts to minimize loss to follow-up and the bias that can result if all study subjects are not included in the final analysis. Cohort studies can also be difficult when disease is recorded at a very low frequency. If the outcome of interest is rare, a very large study population might be required to achieve adequate statistical power unless the study is conducted within a high-risk population. If historical records are very good, cohort studies sometimes can be performed retrospectively. For example, available herd records could be used to compare the pregnancy rates between two different AI technicians. The herd records could be used to identify all cows inseminated by each of the technicians. The records then could be used to follow the individual cows forward from the time of insemination to determine the proportion of each group that became pregnant. Finally, the relative risk could be calculated to compare the proportion of pregnant cows for each of the two technicians.

Follow-up Investigations

No investigation is complete without a *written report* prepared for the herd owner as described earlier in this chapter. This written report may have to be supplemented with the results of later laboratory tests or longer-term field studies to identify risk factors. The case definition may need to be revised and the results from the investigation herd compared with other herds in the surrounding area (Lessard, 1988).

Clinicians should consider their responsibilities to the larger livestock industry (legal and ethical) as well as the immediate concern with improving health and productivity in this one herd (Ribble et al, 1998). If the disease is *contagious*, the investigator must consider what risk the herd poses to other livestock producers in the area and consult with the herd owner on minimizing the potential for transmission beyond the herd. If the exposure could potentially cause *food residues*, the investigator should contact the appropriate authorities for direction and advise the herd owner of his or her legal and ethical responsibilities. If the disease is potentially *reportable*, the appropriate regulatory officials should be consulted as soon as possible. If the losses are extremely severe, the herd owner should be advised to consider his or her short- and long-term goals and to get advice from a financial counselor before deciding between potential alternatives for control.

For economically significant herd problems, the investigation should not end with the identification of important risk factors and the recommendations for control, particularly where control or treatment are not well understood. Where the effectiveness of proposed control measures cannot be predicted with certainty, one infrequently used but potentially invaluable strategy for evaluating the effectiveness of control measures in the herd is the randomized controlled trial. Controlled field trials have been used, for example, to examine the impact of copper supplementation on weight gain in calves from a herd showing clinical signs of deficiency (Naylor et al, 1989).

Randomized Controlled Trials

The randomized controlled trial (RCT), sometimes referred to as a clinical trial, is a valuable tool for assessing the effectiveness of herd treatment and control procedures. Volumes have been written on the design and analysis of randomized controlled trials, and these details are beyond the scope of this chapter. This section is intended to introduce this tool, provide some references for further study, and suggest that consultation with a veterinary epidemiologist before planning or implementing the trial could save both time and expense.

The RCT is a field trial in which the subjects are distributed using a formal randomization scheme into a treatment and control group(s). Randomization is used to minimize the potential influence of other risk factors on the

Downloaded From Vet-e-Books.com

study results. The performances of the treated and untreated control group are compared to estimate the effect of the treatment procedure. Sometimes the control group is treated with the current best practice rather than no treatment at all for ethical reasons and to minimize the potential for economic loss and animal suffering as a result of the trial. For the results to be valid, the assessment should be made blind to the treatment status of the animal, the control group should be current and not historical, no other biases should be apparent, and the role of chance should be assessed using appropriate statistical analysis (Ribble, 1990). A complete understanding of the randomization process, appropriate unit of analysis, and analysis of data, including withdrawals and incomplete data, are necessary to minimize potential misinterpretations.

CONCLUSIONS

This chapter outlines the principles of herd outbreak investigations. All outbreaks and all livestock operations are different. There is not one particular format of investigation that will cover all possible situations in the field. The process is not followed in any particular order, and individual steps are often repeated many times before the information necessary to implement a successful control process becomes apparent. However, a basic outline for approaching disease outbreaks and investigations of suboptimum productivity is provided. The mathematical techniques presented here supplement the information presented in Chapter 2. With the availability of computers and software, the mathematical analysis required to investigate disease in populations is no longer tedious, time consuming, and inaccessible to field practitioners. The techniques introduced in this chapter are relatively basic, however, and situations requiring more complex analysis will be encountered that require consultation with an epidemiologist.

CHAPTER 6

Health and Production Management in Dairy Herds

PAMELA L. RUEGG

OVERVIEW OF THE DAIRY CATTLE INDUSTRY

The dairy industry is a large and dynamic segment of the agricultural economy of many nations. In 1999, cash receipts from marketing's of milk exceeded $23 billion in the United States. In Canada the dairy industry ranks third in the agricultural sector behind grains and red meats. In recent years there have been remarkable changes in the structure of the dairy industry of developed countries. These changes include continued restructuring of the industry through reduced herd numbers, increased herd sizes and adoption of specialized management practices that encourage higher productivity. Societal trends such as increased urbanization, changes in food preferences, and unease with biotechnology will contribute to continued evolution of this industry.

While dairy herd numbers have decreased, consumption of dairy products continues to increase. In the 3-year period between 1995 and 1998, U.S. commercial disappearance of milk increased by 4.3% (Fig. 6-1). The majority of milk is consumed in the form of manufactured products such as cheese. There is strong consumer demand for convenience foods that include cheese as an ingredient. While consumption has increased, milk prices paid to the producer have stagnated. One result of stagnate milk prices has been increased farm productivity and larger herd sizes (Weersink and Tauer, 1991). In the United States the dairy industry is restructuring at a rapid pace. Dairy cow numbers have been declining since peaking at 24.1 million cows in 1940. Since 1991, dairy herd numbers have decreased by about 5% per year and in 1998, there were approximately 9.1 million cows located on 117,000 dairy farms. To meet the continued demand for milk, productivity has increased on the remaining farms. Between 1999 and 2000, per cow milk production increased by 196 kg to reach 8257 kg per cow. In the United States another response to stagnate milk prices has been an increase in the number of cows per herd. As a consequence, an ever-increasing percentage of milk is being produced on larger dairy farms. According to the U.S. Department of Agriculture, in 2000, 50% of dairy herds milked less than 50 cows, 42% milked 50 to 199 cows, and only 8% milked more than 200 cows. The volume of milk production looked markedly different with only 10% of milk produced by herds of less than 50 cows, 37% of milk produced by herds of 50 to 199 cows, and 53% of milk produced by herds of more than 200 cows. In a number of other countries, including Canada, the dairy industry functions under a supply management policy. Consequently, herd numbers and herd size demographics are more stable. In 1996, there were 30,926 dairy farms in Canada with an average herd size of 54 cows per farm. Only 1.5% of Canadian farms milked more than 123 cows.

Holsteins are the predominant breed of dairy cow, comprising 93% and 85% of U.S. and Canadian dairy herds, respectively. Jerseys are the next most popular breed (4.1% of U.S. herds) followed by Guensey (1.7%). The remaining 1.2% of herds are distributed among Ayrshire, Brown Swiss, Milking Shorthorn, and other breeds.

Another trend is the increased centralization of dairy farming in specific geographic locations. In Canada, 81% of dairy farms are located in Ontario and Quebec, 14% in the Western provinces, and 5% in the Atlantic Provinces. In the United States in 2000 the top five dairy states accounted for 53% of total milk produced. Continual increases in productivity and herd size have resulted in California becoming the leading milk-producing state. California and Wisconsin alone—19.29% and 13.99%, respectively—produce approximately 33% of U.S. total milk production, followed by the next three states: New York (7.1%), Pennsylvania (6.6%), and Minnesota (5.7%). Between 1991 and 1996 most states reduced milk cow numbers. The Western states were a notable exception to this trend. During this time period, cow numbers increased in Arizona, Idaho, and New Mexico by 23%, 38%, and 88%, respectively.

As dairy farms increase in size, the ability to attract, train, and manage labor becomes increasingly important. On small dairy farms, much of a dairy producer's time is spent performing actual physical tasks, such as milking, growing crops, and handling animals. As farms increase in size, the farmer's attention must be directed toward managing people and processes. Many successful stock handlers have personality characteristics that are not easily transferable to the people management process (Seabrook, 1984). It becomes necessary to delegate many tasks to others. Continued advances in the sciences of genetics, nutrition, reproduction, milk quality, and health management encourage farmers to learn to depend on others more for advice. These trends are also influencing veterinary practitioners that serve dairy farms. The specialization occurring on dairy farms is encouraging many dairy practitioners to develop specialized services and skills to meet the industry needs.

While the number of large dairy herds is increasing, dairy farming remains a family-based business. The 1995 U.S. Census of Agriculture reported that 86% of U.S. farms are sole family proprietorships and less than 1% are non-family-owned corporations. As herds expand, they often become structured as family partnerships or family corporations (Stahl et al, 1999). Small single-family dairy farms of less than 80 cows often require creative production or marketing techniques to generate adequate farm income. Low-input dairy operations based on grazing or production of certified organic milk are ways that some smaller farms are attempting to market and produce milk at low cost or to obtain a higher milk price. Organic dairy farming is a small but grow-

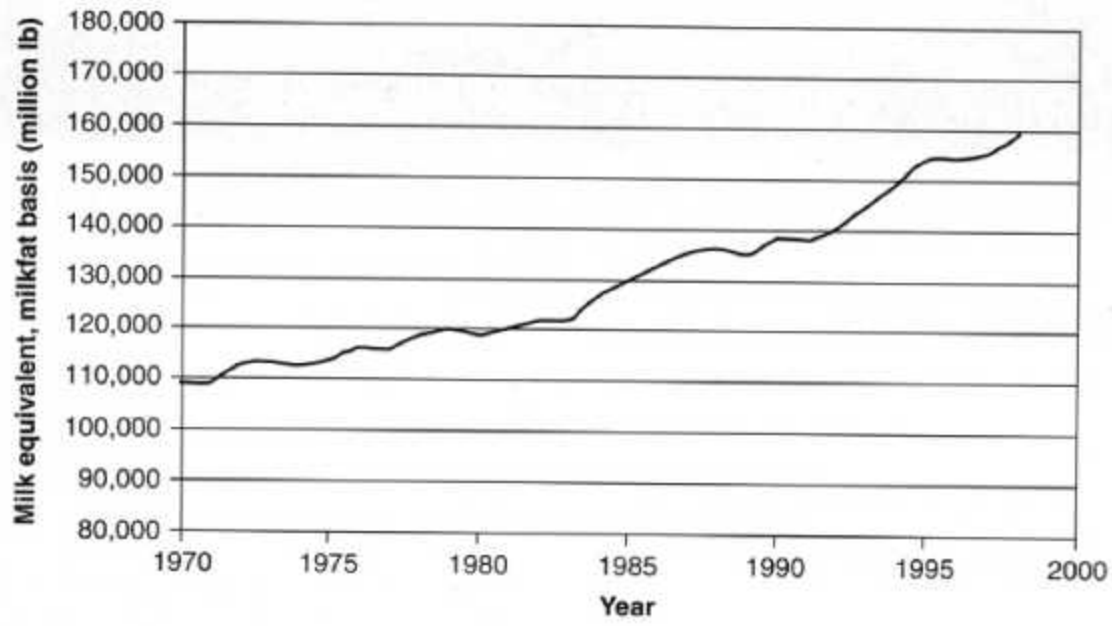

FIG. 6-1 U.S. commercial disappearance of milk.

ing segment of the dairy industry that markets milk to meet increasing consumer demand for organically produced milk. The market for organic dairy products is especially strong in the European Union (E.U.) (Vogl and Hess, 1999). The number of farmers using intensively managed grazing systems to provide forage to their cattle has also increased. Intensive grazing systems are promoted to reduce labor and purchased feed costs on smaller dairy farms.

Large dairy farms have an advantage in fixed production costs and tend to adopt production enhancing management techniques at a higher rate (Table 6-1). The adoption of bovine somatotropin (bST) is a good example of this phenomenon. In the United States, recombinant bST has been approved and marketed since 1994. In 1996 the National Animal Health Monitoring System (NAHMS) reported herd adoption rates of bST by farm size: 6.5% (operation of less than 100 cows), 18.5% (100 to 199 cows), and 31.9% (200 or more).

In past years, types of housing and milking systems were limited. Most cows were housed in confined stall-barn type facilities and allowed access to pasture according to seasonal conditions. Today most animals continue to have access to pasture, but the choice of housing system is much more diverse. In 1995 dairy operators surveyed by NAHMS reported that 24.4%, 61.4%, 47.2%, and 59.6% of lactating cows had access to free stalls, tie stalls (or stanchion), drylots, or pasture, respectively. The current design of cow housing is markedly different than in the past. Barns were traditionally designed to maximize operator comfort. In 2001 most new free stall facilities are built to maximize natural ventilation. In the past, barns were often located in a sheltered location. Barns are usually located in open fields or on hilltops to ensure adequate airflow and to optimize cow comfort. The type of milking facility is also evolving; whereas many operations report using tie stall or stanchion milking facilities, the majority of cows (55%) are now milked in milking parlors.

A wide variety of milking parlors are in use. Most parlors are highly mechanized and have been designed to minimize the amount of labor required for operation. Automatic milking machine take-off units are commonplace, and large parallel and rotary-style parlors have been designed to require minimal human input. The ultimate low-labor milking systems are the automatic milking systems ("AMSs" or "robot systems"). AMSs are designed to clean teats before milking, attach milking clusters, extract milk, detach the milking unit, spray post-milking teat disinfectant, and clean the equipment between cows. A number of AMSs are in use in Europe and Canada. In the United States AMSs are expected to be attractive to small, financially sound, well-managed, single-family dairy farms that wish to minimize labor needs.

On most farms, harvested milk is cooled before storage in refrigerated bulk tanks or milk silos. Milk is generally picked up on a regular basis (either daily or on alternate days) and transported to the processor by tanker trucks. Some of the largest farms have dispensed with bulk tanks. On these large operations (generally more than 1000 cows) milk is piped directly from the milking parlor through a precooler into a tanker truck that transports the milk to the processor when the tank is full. This type of farm often milks cows continuously throughout the day and night. Milk that is immediately transported to processors has an advantage in freshness compared with milk that is held on the farm until pickup.

The definition of "high-quality" milk is evolving. Milk quality is traditionally defined by the somatic cell count (SCC) and bacterial count in prepasteurized bulk tank milk. In all developed nations, regulatory officials set allowable maximums for SCC. Since 1986 allowable limits for SCC and bacteria have been gradually lowered. The current upper limit for bulk tank SCC is 750,000 and 500,000 cells/ml in the United States and Canada, respectively. The E.U. SCC maximum is 400,000 cells/ml using geometric means as the basis for calculation. In the United States, the Centers for Epidemiology and Animal Health surveyed 35% of U.S. milk supply from 1994 to 1997 and reported a geometric mean value of 297,000 cells/ml. Dairy herds with SCC greater than 400,000 cells/ml have been demonstrated to have a higher risk of violative antibiotic residues (Ruegg and Tabone, 2000). Many industry experts in the United States expect the regulatory limit for SCC to be lowered in future years.

Artificial insemination (AI) through the commercial distribution of frozen semen is the preferred method of reproductive management on most dairy operations. In fact, 45% of U.S. dairy operators in 1996 reported that no breeding bulls were present on their farms. An additional 35% of operations reported that they had one bull, and only 20% of farms reported more than two breeding bulls. In most of these operations the breeding bulls are used after unsuccess-

ful attempts at AI. The use of genetically elite sires has contributed to more than 150 kg/year increases in genetic merit for milk production (Funk, 1993). Declining fertility has accompanied advancements in genetic merit. It is common for dairy farms to record herd conception rates of less than 50%. Technologies such as embryo transfer, rapid hormonal assays, controlled breeding programs that use reproductive hormones, and the use of ultrasound are used increasingly on modern dairy farms. Advice by specialized veterinary practitioners is essential for farmers to sort through the complexity of reproductive choices available.

Nutritional research has advanced rapidly, especially in areas such as rumen physiology and lipid metabolism. Lactating dairy cows are generally fed either a component based ration (forages and grain are fed separately) or a total mixed ration (TMR) (forages and grain are mixed and fed together). The basis of a successful nutritional program is the determination of nutrient content of the ration ingredients through laboratory testing, formulation of nutritionally sound diets, and assurance of adequate intake of required nutrients through feed bunk management. Maintaining a stable and healthy rumen environment is difficult with component-based feeding systems, and many herds prefer TMR-based diets. TMR diets are generally based on mixing stored forages (usually haylage or corn silage) with grains (such as high-moisture corn or soybeans) and by-products such as cottonseed or locally available commodities such as citrus pulp, brewers grains, or bakery waste. On larger farms, cows are often grouped and fed diets specifically formulated to meet their production and metabolic needs. Many farms use the expertise of professional nutritionists to formulate rations.

Both farmers and their consultants routinely use computers on dairy farms. In the NAHMS Dairy '96 study, the use of on-farm computers for record keeping was reported by 15% of dairy operations but involved 37% of cows. Records were kept for an additional 13% of cows using off-farm computers. Computers are used for a variety of purposes, including monitoring milk yield. In 1996 almost 60% of dairy operations used record-keeping systems through dairy herd improvement (DHI) organizations (Losinger and Heinrichs, 1996). All DHI organizations use on-farm computers for data entry and summarization. Milk weights can be downloaded from computerized milking systems that weigh and record milk yield or can be entered at the farm by DHI technicians after manually weighing the milk. Both DHI enrollment and on-farm computer use have been associated with increased herd productivity (Losinger and Heinrichs, 1996). Computers are an integral portion of nutritional management on dairy farms, and virtually all professional ration balancing is performed using specifically designed computer software. Many large dairy farms use on-farm ration balancing software to reformulate TMR diets when ingredients are changed or moisture content is reassessed. Notebook and handheld computers are increasingly part of the veterinarian's toolkit when they visit the dairy. There are many specialized spreadsheet programs that are used by dairy veterinarians for farm problem solving. Electronic devices are available to automatically identify cows, record milk weights, record movement, monitor estrus behavior, detect changes in milk conductivity, report body temperature, and monitor feeding activity. "Fuzzy logic," herd simulation programs, and decision support software are being explored for a variety of situations including manure management, grazing programs, disease control, and replacement management.

Most producers continue to raise their own replacement animals, but an increasing number of large dairy farms contract with specialized heifer growing operations (Table 6-1). Virtually all newborn heifer calves are fed colostrum within the first 24 hours of life. Colostrum is hand-fed to most calves to ensure adequate intake of immunoglobulins. The use of mastitic- or antibiotic-containing waste milk has been related to high mortality rates (Losinger and Heinrichs, 1997). Many producers feed milk replacer to decrease the potential transmission of infectious disease. Today's Holstein heifers are heavier and taller at the withers than shown in published standards from years past (Heinrichs and Losinger, 1998). Efficient replacement programs endeavor to calve Holstein heifers that weigh 550 kg at 22.5 to 25 months of age. A variety of health management programs are used to reach this goal, including deworming and the use of oral coccidiostats, supplemental selenium, and ionophores.

Societal and Governmental Issues Related to the Dairy Industry

Changes in the dairy industry are occurring worldwide (Table 6-2). Between 1991 and 1995, North American milk production increased slightly. Mexico had the largest per-

centage increase in milk output in North America. The developing economies of South America and Asia also recorded large increases in production. Favorable climates and investments in the dairy infrastructure are leading to significant expansion of dairy production in Brazil and Argentina. As national economies expand and personal income rises, milk consumption tends to increase. Dairy production is well suited for developing economies, since cattle can convert forages and by-products into highly nutritious animal protein. Supply management policies contributed to a small decline in net milk production in the European Union. Dramatic decreases in production were seen in the transitional economies of Eastern Europe and the former Soviet Union. More than 95% of milk produced in New Zealand and Australia (Oceania) is used in manufactured products that are exported. Seasonal production systems based on low-cost grazing and limited supplemental feed contribute to a relatively low cost of production in these countries. The ability to export dairy products at low cost played a role in the large increase in milk production seen in this region.

Milk is a bulky and perishable commodity that tends to be consumed domestically. In 1989 to 1994, only 5% to 6% of total world milk production was traded. However, trade in dairy products continues to be a contentious issue. Virtually all developed countries maintain restrictions on imports in order to protect their local dairy industries. Most countries also subsidize exports of dairy products. The United States and Canada share about 8% of total world dairy exports. Since passage of the North American Free Trade Agreement (NAFTA), the United States has become a net exporter of dairy products to other NAFTA countries. However, trade in dairy products is an extremely small part of the dairy economy. In 1998 exports contribute to less than 3% of all U.S. milk produced. Trade in dairy products between North America and the European Union is limited because of domestic market protections.

A number of health and production issues are used as surrogate trade barriers, such as differences in sanitary standards for milk production between developed and nondeveloped countries. Differences in societal values between countries may create differing policy decisions regarding animal health and welfare. One example of policy difference is the use of recombinant (rbST) for production enhancement. In 1993 U.S. regulatory officials approved the use of bST to increase milk production of adult dairy cattle based on scientific evidence of safety of milk for human consumption. U.S. regulatory officials recognized the potential for minor side effects in cows supplemented with bST but concluded that any potential effects could be controlled by existing management techniques and would not adversely affect the overall health of the national dairy herd. In 1999 regulators in Canada and the European Union used the same data to reject applications for licensure of bST in their countries. The Canadian and E.U. regulators confirmed that milk from bST-supplemented cows was safe for human consumption but concluded that potential side effects (such as increased mastitis) were unacceptable compromises to the welfare of their national herds. Other contentious topics include management issues such as tail docking, the use of reproductive hormones, and concerns about diseases with zoonotic potential. It is likely that the veterinary community will play an increasing role in public debate regarding these ethical and public health concerns.

In developed countries, the primary goal of governmental policy is to provide consumers with safe and hygienic dairy products. Tremendous advances in productivity and efficiency of production have caused surplus dairy production in all major dairy-producing countries. On an economic basis, therefore, the objective of most governmental dairy policy is to preserve the stability of the domestic dairy industry and to maintain an adequate income level for dairy farmers. Policies used include: (1) direct price supports (the purchase of commodities at announced intervention prices), (2) direct income payments and input subsidies, (3) product use subsidies, (4) import restrictions (tariffs, quotas, and licenses), (5) supply management, and (6) trade restrictions (Blayney and Fallert, 1990).

Worldwide trends are toward relaxed trade barriers and reduced governmental expenditures to agriculture. In the United States, dairy farm support programs have been based on maintenance of a minimum milk support price through

Downloaded From Vet-eBooks.com

governmental purchases of butter, cheese, and skim milk powder; import quotas and export subsidies and classified pricing programs based on federal and state milk marketing orders. In recent years, reduced U.S. government involvement has created more volatility in milk price. As a result, some dairy farmers are attempting to manage risk through the use of futures contracts. The Canadian government also uses price supports, import tariffs, and classified pricing programs. In addition, Canada attempts to balance supply and demand through the use of milk production quotas. Supply management programs are effective in reducing surplus dairy production but can limit productivity growth of individual farms and produce entry barriers for new farmers (Beck et al, 1991). In both the United States and Canada, these programs are constantly under review and undergoing immense reform to reduce government spending.

In all countries with major dairy industries, indirect subsidies continue in the form of low-interest loans, crop insurance, water and land policy, agricultural research and extension programs, and the maintenance of government diagnostic laboratories. These programs are justified on the basis of maintaining a healthy, affordable, and abundant food supply for the nations' consumers. Veterinary practitioners are affected directly by the economic health of the industries that they serve. As governmental spending continues to decline, dairy farms need to improve the efficiency of production. Preventive medicine programs contribute to enhanced profitability for dairy farms and healthy rural economies. Dairy health and production management programs are essential for the efficient production of high-quality dairy products.

The continued need for improved efficiency has created a number of challenges for dairy farmers. Although farm processes are increasingly automated, many tasks remain dependent on physical labor. One challenge in recent years has been the availability of affordable high-quality farm workers. To meet this challenge, farm managers are increasingly turning to non–English-speaking workers. Farm labor needs in the western United States have been filled by workers from Mexico and Central America for many years. Midwestern and Eastern dairy farms are increasingly using the same source of labor. As a consequence, on many dairy farms, labor needs are met by personnel with limited English. Learning to cope with cultural differences and diverse training needs can be difficult. The need to devise standard operating procedures (SOPs), treatment protocols, and consistent quality standards is an opportunity for veterinary practitioners to expand their services to meet the emerging needs of the dairy industry.

Worldwide, population growth continues to increase the demand for food while urbanization continues to exert pressure on farmland. Many developing nations are attempting to balance agricultural development with sound environmental stewardship. A desire to protect fragile environments while meeting critical needs for food and stable agricultural economies often causes tension. In developed countries an increasingly affluent population that is often several generations removed from any farm contact may view common agricultural practices with concern. Many current agricultural issues have arisen from these points of tension. The general public increasingly views biotechnology and genetic manipulation with skepticism. While technologies such as transgenic dairy animals may be viewed by some as potential new markets for dairy products, critics may view these concepts as risky experiments. Opinions about animal welfare and animal rights are also sharply divided.

Most dairy producers recognize that profitable dairy production is based on meeting the biological and physical needs of the dairy animal. Good dairy farmers pride themselves on the care that they provide for their animals. Cow housing and handling facilities are designed primarily to meet the needs of the cow ("cow comfort") and secondarily to provide a comfortable working environment for animal handlers. Without personal farm experience, the perceptions about animal welfare are increasingly shaped by media descriptions about isolated incidents of mismanagement. Many welfare activists are distrustful of large farms and may unfairly consider them to be "factory farms" that don't adequately provide for individual animal health and behavioral needs. The American Humane Society Association has stated that: "Animal welfare is improved when livestock managers adhere to the following: (1) caring and responsible planning and management; (2) skilled, knowledgeable and conscientious stockmanship; (3) appropriate environment design; (4) considerate handling and transport; (5) access to wholesome and nutritious feed; and (6) humane slaughter" (American Humane Society Association, 2000). It is unlikely that many farmers would disagree with these broadly stated recommendations, but attempts to legislate acceptable and unacceptable production methods (such as prohibitions on dehorning or tail docking) are considered unacceptable intrusions into individual farm management systems. Veterinarians and animal production specialists will be called on increasingly to educate the public and mediate societal discussions regarding acceptable animal production practices. It is always incumbent on the livestock veterinarian to recognize the welfare aspects of food-producing animals and to promote agricultural practices that enhance the well-being of the animals. Sound health management programs are the best way that veterinarians can minimize animal disease, promote animal welfare, and provide an economically sound environment for dairy farm families and their employees.

ANIMAL AND HERD PRODUCTIVITY

Productivity of Individual Cows

In developed dairy regions the genetic potential of commercial dairy cows is very high because of widespread use of AI. The genetic potential for milk yield is unlikely realized for most dairy cows in these regions. In 1999, 85% of farm income on Wisconsin dairy farms was obtained from milk sales (Table 6-3). However, the productivity of an individual cow exceeds the value of the milk she produces. The productivity of an individual cow is the sum of the value of the milk she produces, the value of her offspring, and her individual market value when she exits the herd. Many factors influence individual cow productivity. The value of the milk may be determined in part by its composition and the type of products it is used to produce. Breed, nutrition, and stage of lactation can significantly impact the composition of milk. There is an inverse relationship between milk yield and milk composition; higher producing breeds generally produce milk with a lower percentage of components. Typical milk and fat composition for the major breeds of cattle are shown in Table 6-4. Holsteins have become the predominant breed because of their ability to produce high milk volume. Colored breeds become more attractive when productivity is defined based on specific component yields. For example, the production of approximately 2 lb of milk protein would require production of either 50 lb of 3.9% Jersey milk or 63 lb of 3.1% Holstein milk. The market value of the components varies nationally and regionally based on pricing programs and the market use of the milk (i.e., consumed as fluid milk or used to produce cheese, butter, or other products). The type of ration that is fed also significantly influences milk composition. The feeding of well-balanced

Downloaded From Vet-e-Books.com

forage-based diets generally leads to a higher percentage of milk fat than the feeding of high concentrate diets.

Individual cow productivity is also based upon longevity and the proportion of the cows' lifetime spent producing milk in contrast to time spent nonproductively. Nonproductive periods include the period from birth until first parturition and dry periods before subsequent calvings. Management decisions regarding replacement and reproductive programs can have a large impact on productivity. Heifers must be managed to reach appropriate breeding size by 13 to 15 months of age to maximize lifetime production. Milk yield is related to stage of lactation. Milk yield increases rapidly after calving, reaches a plateau about 40 to 60 days after calving, and then gradually declines at a rate of about 5% to 10% per month (Fig. 6-2). The rate of decline in milk yield is less in younger animals compared with older cows. Milk yield of primiparous cows may actually surpass milk yield of multiparous animals during late lactation. Reproductive management is vitally important to ensure that the largest proportion of a cow's total lifetime production is spent during early high-producing stages of lactation rather than late lower-producing periods. Decisions regarding reproductive efficiency often involve complex issues such as the effect of production-enhancing technologies (such as bST); the herd veterinarian is ideally suited to help the producer sort through these issues.

Milk yield increases with age. Production of first lactation animals is generally about 15% lower than second lactation animals. Productivity continues to increase with parity until about the sixth lactation; these aged animals may produce up to 25% more milk volume compared with first lactation cows. Health disorders or other management problems that reduce longevity have a negative impact on productivity.

Herds that depend on grazing generally have cyclical patterns of both milk production and milk composition. Milk yield increases when pastures are abundant (often midspring and early fall). A simultaneous decline in milk fat may occur because of lower fiber levels in the highly succulent forages. Some grazing herds attempt to increase milk component values and hybrid vigor by crossbreeding. A typical cross would be to breed high-yielding Holsteins to high-component Jerseys.

On most dairy farms the market value of offspring is limited. In 1999 the sales of calves accounted for 4% of total cash farm income of Wisconsin dairy producers (Table 6-3). Male calves are sold for either veal or dairy beef production. Female animals are most valuable as replacement animals for the dairy herd. The cost of raising replacement stock is not usually well documented and can be influenced by feed costs, mortality rates, growth rates, and reproductive management. As farms are required to become more efficient, health management programs for youngstock become vitally important. Diseases that result in reduced growth rates or excessive mortality can reduce the overall efficiency of the herd. Considerable inefficiency exists in youngstock programs. The NAHMS study estimated preweaning mortality of U.S. dairy calves to be 10.8% and the average age at first calving was reported to be 25.8 months (NAHMS, 1996). A small number of registered herds aggressively market and sell elite genetic stock. On some of these farms, profits from the sale of embryos, bulls, and other elite animals (such as cloned offspring) may exceed profits from milk volume. On these farms, preventive veterinary care and excellent reproductive programs are justified to protect the value of individual animals.

The last aspect of productivity is the market value of the cull dairy animal herself ("market cattle"). About 5% of total cash income of Wisconsin dairy farmers was accounted for by the sale of cull dairy cows (Table 6-3). Approximately 95% of culled dairy cattle are sold for slaughter purposes (NAHMS, 1996). The remaining 5% are sold to other dairy farms for production purposes. The value of cull dairy cows is relatively small compared with the value of milk and fluctuates according to beef production cycles. It is obvious that market cattle, which leave the dairy herd in better body con-

dition, have higher market values than animals that leave in lighter condition. Large variation in carcass weights of culled dairy animals has been reported to occur between farms (Seegers et al, 1998). Factors that influence carcass weight include the reason for leaving the herd and the stage of lactation when the animal leaves the herd. Animals with chronic, debilitating diseases may continue to lose weight if they are retained within the dairy herd, whereas animals culled for reproductive inefficiency or subclinical mastitis may gain weight. Carcasses from culled dairy cattle are also considered to have the highest risk for antibiotic residues. Attention to culling practices and the development of SOPs for market cattle is an area that is ripe for attention from production medicine veterinarians.

Numerous diseases and management errors can affect individual productivity of dairy cows. A flow chart of factors affecting lifetime productivity is shown in Fig. 6-3. One role of the production medicine veterinarian is to maximize individual animal well being and productivity to ensure the long-term viability of the dairy operation.

Productivity of the Dairy Herd as a Unit

Net farm income is related to dairy farm productivity but is not the sole determinant of profitability (Fig. 6-4). The profitable management of a dairy herd is the result of sound business decisions and financial management combined with optimum animal care. It is only under these circumstances that the dairy herd can achieve a sustainable level of production. It is incumbent on the dairy veterinarian to encourage and promote the adoption of management techniques and preventive health care programs that enhance animal well being and allow the farm to meet its business objectives. In small farms, veterinary care is often directed at individual animals and the veterinarian is often the actual provider of technical services. As farms expand, the dairy veterinarian needs to become involved in defining systems and SOPs that allow the easy application of preventive health care programs to groups of animals. In many instances technical services (such as vaccination, hoof care, and individual animal treatments) are carried out by farm staff that have been trained to deliver treatments defined by the herd veterinarian.

Factors influencing individual animal productivity were discussed earlier. On a herd basis, ideal standards of performance and disease goals for dairy herds can be stated (Table 6-5). It is important, however, that the cost of measures used to meet performance targets not exceed the value achieved by reaching the target. One role of veterinarians serving the dairy industry is to help the producer evaluate the cost versus the relative benefit of production technologies, preventive health care programs, and management choices.

Nutritional Management

The importance of understanding applied dairy nutrition cannot be overemphasized. In most dairy herds, nutritional management is the most important determinant of herd productivity. Feed costs account for the largest proportion of variable costs for most dairies. Many common production-limiting diseases of adult dairy cattle are caused at least in part by errors in nutritional management (Table 6-6). The relationship between nutrition and productivity begins at birth. Dairy herds that reported mean age at first calving of less than 27 months and mean body weights at first calving of more than 545 kg have been shown to have higher mean milk production (Losinger and Heinrichs, 1996). The dairy feeding system must be designed to deliver necessary nutrients to each cow at the correct stage of lactation to maintain optimum productivity (Linn et al, 1996). The choice of a feeding system is associated with both herd size and production level (NAHMS, 1996). Three general types of feeding systems are used currently by dairy farmers: total mixed rations (TMRs), component feeding, and management intensive grazing (MIG). Each of these systems, when implemented correctly, can deliver adequate nutrients for a highly productive dairy herd. Each system has its own inherent challenges in the achievement of optimum productivity.

The use of TMR feeding systems has increased as more herds have adopted free-stall or dry-lot housing facilities. TMR diets have several advantages (Linn et al, 1996): cows consume the desired proportion of forages, reduced risk of digestive upset, increased feed efficiency, ability to use by-product feeds, greater accuracy in diet formulation, and reduced labor needs. The performance of herds using TMR diets can be impacted adversely by errors in ration formulation and feed delivery. Some common errors include: inadequate or nonexistent forage testing, variation in forage dry matter, variation in dry matter intakes, overmixing of diets that causes inadequate fiber levels, and overfeeding or underfeeding energy to late lactation cattle. When TMRs are fed, nutritional mistakes are often spread across the entire group

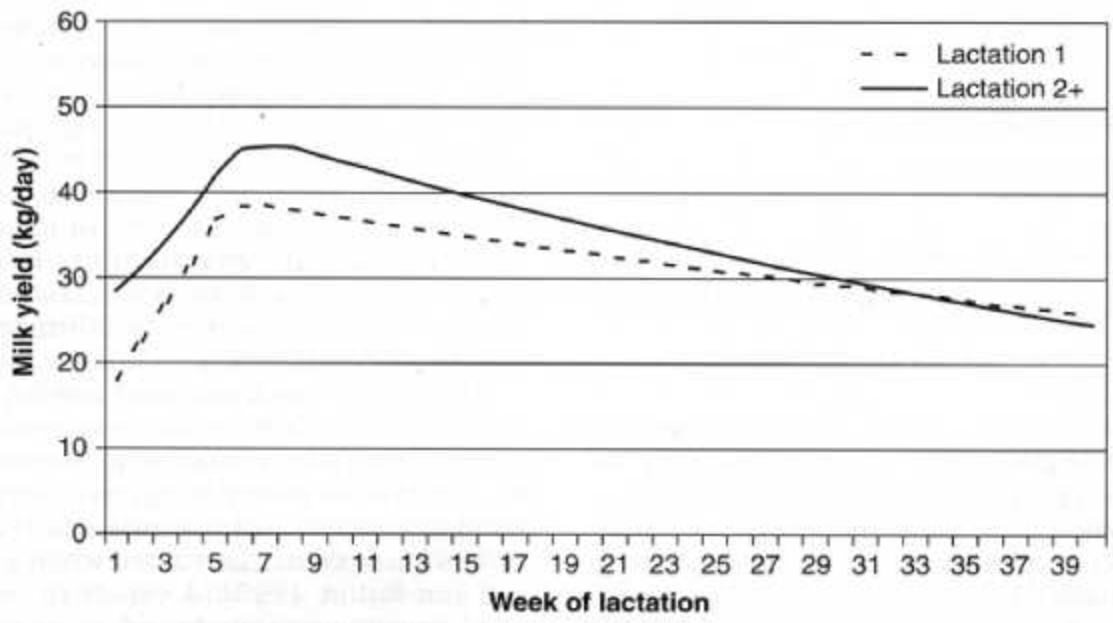

FIG. 6-2 Classical idealized lactation curves of dairy cows.

Downloaded from Vet-eBooks.com

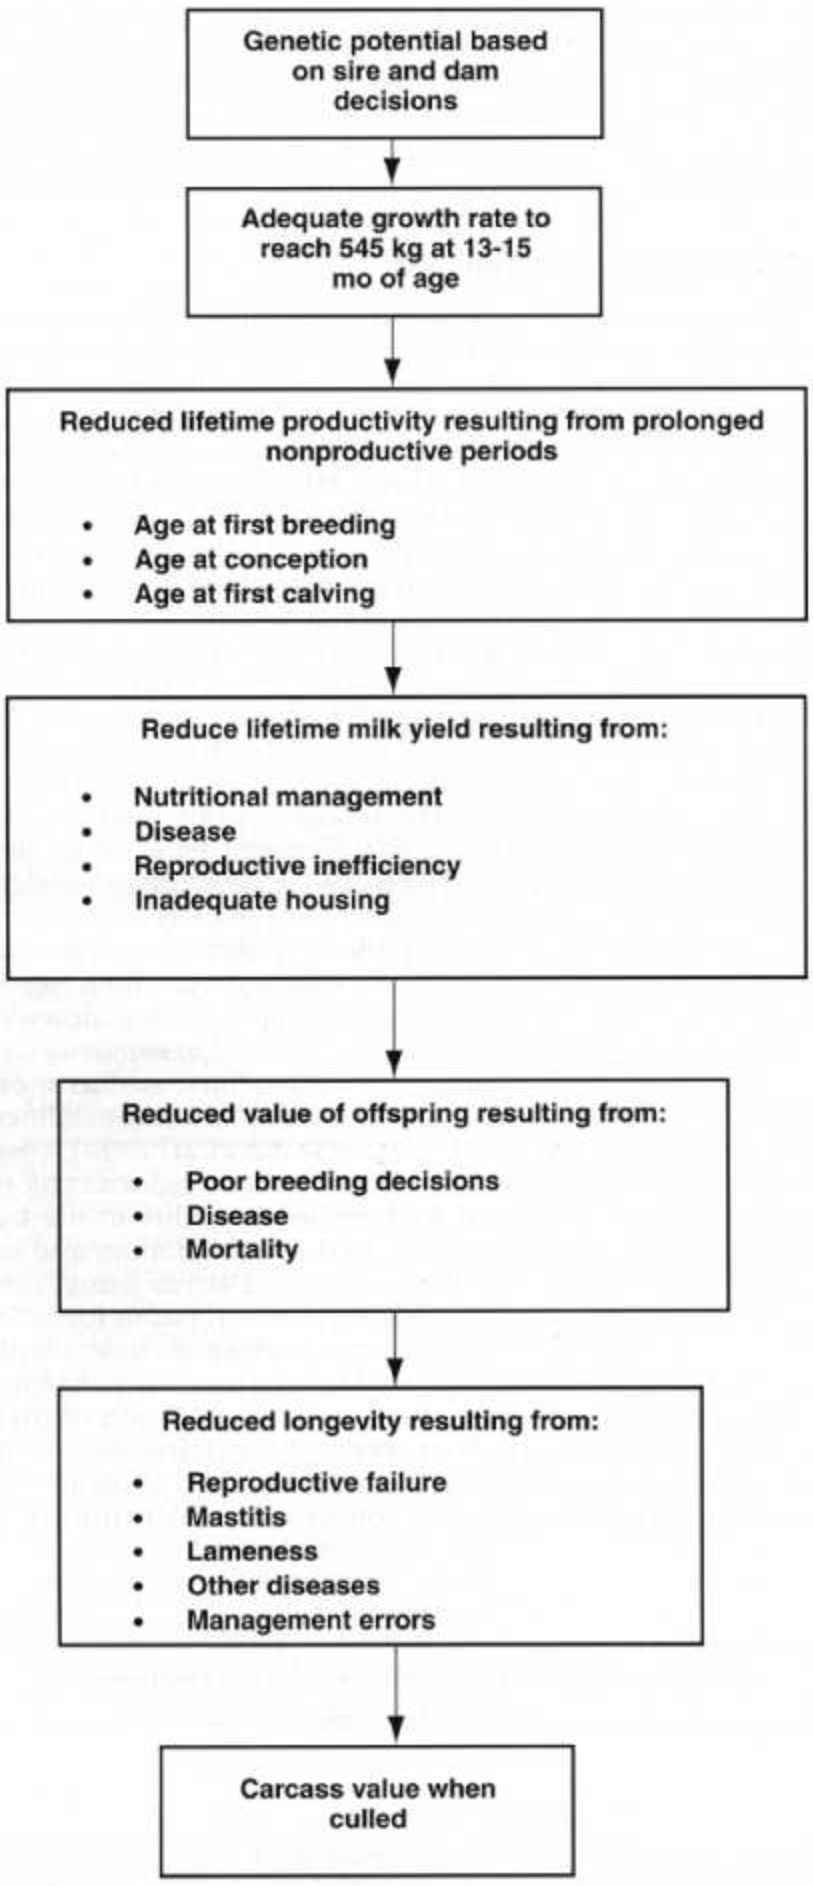

FIG. 6-3 Factors affecting lifetime productivity of an individual cow.

or herd receiving the diet. Health management programs of herds that receive TMR diets should include systems to monitor the adequacy of the ration formulation and delivery.

Component-fed herds receive grain and forage separately. Farms using these systems are often housed in tie-stall facilities. However, herds using AMS technology employ mechanized grain feeding as an incentive for cows to enter the milking robot. The successful operation of a component feeding system depends on the maintenance of a stable rumen environment while meeting the nutritional needs of modern, high-producing dairy cows. Advocates of component feeding emphasize the ability to meet the production and metabolic needs of individual cows throughout their production cycle.

Pasture-based forage systems are used in many dairy regions of the world. Management-intensive grazing systems can be used to meet the needs of modern dairy cows. In some regions of the world (such as New Zealand and Australia) pasture-based systems are the predominant method of feeding dairy cattle (Mueller, 1998). In these truly pastoral systems, nutrition is often the most limiting factor for the achievement of optimum productivity. These regions may experience significant annual variation in productivity because of year-to-year differences in growing conditions. Some herds use seasonal dairying to match pasture conditions with the energy needs of early lactation cows. Attention to reproductive management is critical for herds that attempt to breed all cows within a defined period. Production management programs for herds using MIG systems must include programs to control bloat, hypomagnesemia, and copper and selenium deficiency. Pastured cattle may walk considerable distances to harvest forages. Therefore a system to monitor and minimize lameness must be included in the health delivery system.

Reproductive Management

In most dairy herds, reproductive management is a key determinant of overall productivity. The reproductive program is the most common reason for scheduled herd visits by dairy veterinarians and is a recognized area of expertise. The dairy herd veterinarian can improve herd productivity significantly by designing and implementing sound reproductive management programs that include cost-effective strategies to meet farm goals. Farm goals for reproductive management programs must be designed individually, but all farms need to breed cows successfully to reduce involuntary culling related to reproductive failure. Reproductive disorders are the most common and costly reason for premature culling of dairy cows (Seegers et al, 1998; NAHMS, 1996). In conventional dairy herds that calve throughout the year, reproductive management can influence productivity through the following: production losses because of cows milked in later, lower-producing stages of lactation; production losses because of long dry periods; culling losses; reduced genetic potential because of the use of natural service sires; reproductive inefficiencies because of delayed age at first calving; and excessive labor and therapeutic costs associated with the reproductive program. Conception rates have decreased as herd production has increased (Fricke, 1999). High production has been related to an increased rate of double ovulations and twinning in some studies (Fricke and Wiltbank, 1999). Some herds have returned to extensive use of natural service sires to ensure that cows conceive promptly. In these herds veterinarians need to include breeding soundness exams and bull management programs in health management programs to ensure continued herd productivity.

Herds that use a seasonal calving strategy often restrict the period of calving to increase productivity and labor efficiency. Induced parturition is one strategy used to ensure that most cows calve during the desired period. An increased incidence of retained placenta and related reproductive disorders has been demonstrated when induction is used (Morton and Butler, 1995). A variety of hormonal protocols are used in some regions to aid in breeding synchronization.

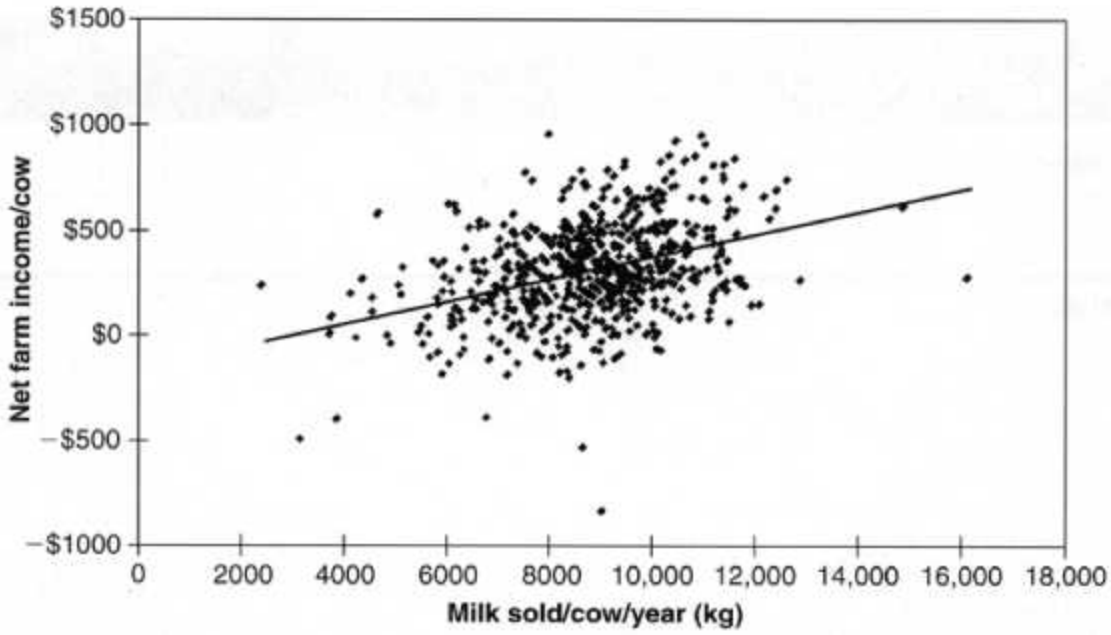

FIG. 6-4 Net farm income versus milk sold per cow for 620 Wisconsin dairy farms in 1999. (Data from Gary Frank, Center for Dairy Profitability, College of Agricultural and Life Sciences, University of Wisconsin, Madison.)

The expertise of the herd veterinarian is vital to successful use of these technologies.

Replacement Management

Calf and replacement heifer programs contribute to herd profitability in several ways and are described thoroughly in Chapter 9. Herd productivity can be impacted negatively by high mortality of replacement animals. The highest morbidity and mortality rates on dairy farms generally occur before weaning. On many farms the most significant causes of preweaning death are infectious diseases of the digestive and respiratory systems. These disorders can be controlled by well-designed health management programs that define the care and housing of the dam during the periparturient period, SOPs for the calving process, and the application of proper preventive measures (including sound nutritional programs) for the newborn calf. Healthy calves can achieve growth rates that allow them to be bred at 13 to 15 months of age and maximize the potential productivity of the overall dairy herd.

Disease Incidence

There are a number of ways that disease can reduce herd productivity. Increased culling, reduced milk or protein yield, increased adult cow mortality, and reduced reproductive efficiency are all potential outcomes of diseases of dairy cattle. Historically most veterinary attention was directed toward diseases with obvious clinical symptoms. Metabolic diseases such as milk fever and displaced abomasums (DAs), infectious diseases such as bovine viral diarrhea (BVD), and clinical mastitis were common problems for dairy farmers. Cows affected with clinical disease often exhibit a profound reduction in milk production. The duration of acute clinical syndromes is often short, but the effects of the disease may persist throughout the entire lactation. Early lactation is the highest risk period for many diseases. Disease events during early lactation may reduce peak milk yields and therefore contribute to lower total lactational yields. While management errors and lapses in biosecurity still cause epidemics of these clinical syndromes, the nature of disease has changed on many dairy farms. Through advances in animal husbandry and health management programs, many farms have minimized clinical syndromes associated with infectious and metabolic disease. The trend toward larger agricultural units and shrinking profit margins has encouraged veterinarians to shift from treatment of clinical disease in individual animals toward optimizing herd or group productivity through reduction of subclinical disease. Subclinical diseases such as mastitis, acidosis, and laminitis have emerged as major limitations to productivity on many farms. The changing nature of disease has created some diagnostic challenges. The beginning of an epidemic of clinical disease is usually readily apparent because of an unexpected increase in clinical disease to a level obviously greater than normal. The beginning of an epidemic of subclinical disease is not usually defined clearly. There is often a lag between the beginning of a problem and the recognition of its effects on the herd. In many instances veterinary practitioners must rely on indirect indicators such as SCCs, changes in body condition score (BCS), or alterations in milk component ratios to identify the beginning of an outbreak of subclinical disease. The inability to identify subclinical disease and the long duration of these syndromes allow these diseases to have considerable impact on herd productivity.

Herd Size

There is a well-demonstrated relationship between productivity and herd size. In the NAHMS Dairy '96 report, rolling average milk production for Holstein operations increased from 7487 kg for herds with less than 100 cows to 8788 kg for herds with greater than 200 cows. One reason for this relationship is the greater willingness for larger operations to adopt production-enhancing technologies (Jackson-Smith and Barham, 2000). In the United States, larger farms are more likely to adopt technologies such as TMR or bST (Table 6-1). Smaller farms tend to focus on technologies such as MIG to reduce feed costs and improve profitability.

Government policies can substantially impact herd size. Countries such as Canada that have adopted supply management systems effectively limit the annual income that a farm can achieve from the sale of milk. In this instance, achieving high individual farm milk yields may increase the efficiency of milk production (by meeting the farm quota for

TABLE 6-5

Suggested Performance Targets for Dairy Cattle

Parameter	Target
REPRODUCTIVE PERFORMANCE	
Mean age of first calving (mo)	22-24
Mean intercalving interval (days)	365-405
Mean interval calving to conception (days)	85-125
Mean length of lactation (days)	305
Mean length of dry period (days)	45-65
Culling rate for reproductive inefficiency (%/year)	<10
Abortion rate (%/year)	<2
MILK PRODUCTION AND NUTRITION	
Deviation in daily milk production (kg drop/day/cow)	<2.5
Deviation in daily group milk production (kg drop/day)	<2.5
Ratio of primiparous milk yield to multiparous milk yield (%)	80-85
Fat tests <3.0 (% monthly)	<10
Deviation in daily dry matter intake (kg drop/cow/day)	<1
MASTITIS PREVALENCE	
Prevalence of linear scores ≥4 (%/mo)	<15
Incidence of new linear scores ≥4 (%/mo)	<5
Bulk tank somatic cell count (cells/ml, monthly)	<200,000
Individual cow somatic cell count (cells/ml, monthly)	<150,000
Number of new clinical cases/100 cows/mo	<2
DISEASE AND CULLING	
Calf mortality (% under 28 days of age)	<5
Culling rate (%/year)	<30
Prevalence of lameness (%/mo)	<5
Incidence of milk fever (% of multiparous cows calved/mo)	<10
Incidence of retained placenta (% of cows calved/mo)	<5
Incidence of left displaced abomasum (% of lactating cows)	<5
Incidence of ketosis (% of fresh cows/mo)	<15

volume, fat, or protein with less cows) but may reduce total farm income by limiting alternative farm income from the sale of replacement heifers, breeding animals, or steers. Under these circumstances the producer must carefully evaluate management decisions to ensure that higher milk yields do not cause reduced total farm income.

As herd sizes increase, some efficiencies of scale are recognized, especially regarding fixed costs such as barns and milking parlors. Herd size has a smaller impact on variable costs such as feed and veterinary expenditures. Many extremely large farms are highly specialized and contract with neighbors for feed and services such as heifer rearing. One challenge for the expanding dairy herd is to identify a reliable source of skilled labor. Labor needs are often reduced with increased specialization and automation.

The amount and productivity of pasture can influence the size of herds that use grazing. Pasture growth is influenced by soil fertility, plant type, weather, and the grazier's skill in managing animal density. In these herds productivity is determined by balancing the ability of the pasture to produce nutrients against the ability of the cows to produce milk. The size of both grazing and confinement herds are increasingly impacted by competing demands for land. In many traditional dairy regions, urban sprawl is a threat to farm growth and increasingly veterinarians are asked to participate in the planning process for farm expansions. In many communities, veterinarians also fill a local role in helping farmers educate local governments about common farm practices.

Composition of the Herd

The composition of the herd influences herd productivity. The proportion of the herd that is producing milk compared with nonproductive stock (dry cows, calves, heifers, and bulls) has an obvious impact on total herd productivity. Herd composition is the result of a number of interrelated management decisions, such as culling policy, rate of reproductive success, rate of disease, replacement management, and long-term goals regarding herd size. The ability of a herd manager to cull animals can have a significant impact on herd composition. If the pool of available replacement animals is small, many farmers are reluctant to cull aggressively. When numerous replacement heifers are available, culling may intensify, leading to a younger herd. In countries where herd production is not limited, such as in the United States, long-term plans regarding expansion often influence herd composition. A herd that is planning to grow without purchasing animals may eliminate all unforced culling and thereby end up with an older herd. Alternatively, some growing or start-up herds prefer to purchase only nonlactating cattle to reduce the risk of purchasing animals with infectious diseases such as contagious mastitis or BVD.

TABLE 6-6

Common and Sporadic Diseases and Control Procedures in Dairy Herds

Disease or Production Procedure	Monitoring Techniques	Management	Primary Prophylactic Methods		Zoonotic-Potential
			Nutritional Intervention	Medication or Vaccines	
PREGNANT HEIFER OR COW					
Fat cow syndrome	Body condition score and test nonesterified fatty acids	Group and feed dry cows separately and according to needs	Yes	May need to provide supplemental propylene glycol or glycerine	No
Parturient paresis	Breed predisposition and risk increases after first episode, fresh cow SOP should include frequent observation	Feed low-potassium forages to dry cows; control the cation-anion balance and feed anionic salts if needed	Yes		No
PERIPARTURIENT COW (1 WEEK BEFORE AND AFTER CALVING)					
Parturient paresis	Fresh cow SOP should include frequent observation for staggering, or recumbency in cows every few hours for first 48 hr	Oral Ca^{+} gels to at-risk cows	Yes	Treat with calcium salt in first stage of milk fever	No
Retained fetal membranes and septic metritis	Placenta and/or malodorous discharge visible, straining in some	Adequate dietary intake of selenium and vitamin E, avoid hypocalcemia	Yes	Treat with antibiotics if septic	Yes, if brucellosis is suspected
Udder edema	Edema along belly and up escutcheon; udder swollen, very hard, milk normal	Premilk before parturition only if necessary to relieve pressure		Treat with diuretics Consider induction of parturition	No
Left-sided displacement of abomasum	Clinical evidence of inappetence, ketonuria, and decreased milk production	Feed diet balanced to provide adequate effective fiber; maintain dry matter intake	Yes		No
Simple indigestion	Clinical evidence of inappetence in rumen hypomotility	Avoid rapid dietary changes or poor quality feeds	Yes	Ensure energy intake to avoid ketosis	No

TABLE 6-6

Common and Sporadic Diseases and Control Procedures in Dairy Herds—cont'd

Disease or Production Procedure	Monitoring Techniques	Management	Primary Prophylactic Methods		Zoonotic Potential
			Nutritional Intervention	Medication or Vaccines	
EARLY LACTATING COW (1-8 WK)					
Primary acetonemia	Screening of urine of high-risk cows for ketones	Control BCS, adapt rumen slowly to high energy diets	Yes	May supplement diet with propylene glycol or glycerin	No
Hypomagnesemia	Observation of cows daily	Avoid high-fat diets or ammoniated forages	Yes	Supplement diet with magnesium	No
Postparturient hemoglobinuria	Checking of phosphorus status	Ensure adequate dietary phosphorus	Yes	Avoid feeding of rape, cabbage, or other cruciferous plants	No
Subclinical laminitis	Observation of hoof wall or sole lesions with or without lameness	Avoid rumen acidosis and balance carbohydrate levels, provide adequate cow comfort	Yes	Administer foot baths; balance the concentration of fiber in the diet; trim feet regularly	No
Right-sided displacement of abomasum and cecal dilatation	Early detection of illness	No reliable preventive technique; assess nutritional status	Yes	Feed a balanced diet and feed roughage during dry period to ensure rumen fill	No
NEWBORN CALF (BIRTH TO WEANING)					
Acute diarrhea caused by *E. coli*, rotavirus, coronavirus, *Cryptosporidia* spp.	Daily observation for clinical disease, checking serum immunoglobulin or protein levels at 24-48 hr of age	Ensure adequate obstetric assistance at birth, if necessary, hand-feed 4 L of colostrum in first 12 hr	No	Vaccinate pregnant cow with vaccines containing K99+ *E. coli*, rotavirus, and coronavirus antigens	Yes for *Cryptosporidia*
CALF (WEANING TO 6 MO OF AGE)					
Unthriftiness and suboptimum growth rate caused by subclinical parasitism	Monthly body weight and height; fecal egg and oocyst counts; observation of diarrhea, weight loss	Feed adequate diet to support optimum growth rate; pasture rotation to avoid massive larval infection	No	Strategic use of anthelmintics, ionophores, and coccidiostats dependent on local epidemiology	No

Downloaded from Vet-Books.com

Enzootic calf pneumonia	Observations for paroxysmal, harsh upper respiratory tract coughing, and tachypnea	Provide clean, dry, well-ventilated, individual calf housing	No	Medicate feed with tetracycline for few weeks during period of convalescence if appropriate; develop herd-specific vaccine recommendations	No
Infectious bovine rhinotracheitis, clostridial diseases, leptospirosis, brucellosis, bovine viral diarrhea	Observation of fever, dyspnea, cough; sudden death myositis; red urine, mastitis, abortion; diarrhea and mucosal erosions	Develop a calf biosecurity plan	No	Develop herd specific vaccine recommendations	Yes for leptospirosis and brucellosis
HEIFER (6-15 MO OF AGE)					
Supernumerary teats	Inspection at 6 months of age	Remove all supernumerary teats surgically	No		No
Traumatic reticuloperitonitis		Feed hay from string-tied bales only; all concentrates should be passed over a magnet	Yes	Administer reticular magnet to all heifers nominated as herd replacements	No
Suboptimum growth rate	Measurement of height and weight monthly and comparison with standards	Ensure adequate nutritional intake or delay mating heifers until optimum mating weight achieved	Yes		No
Coccidiosis	Observation for diarrhea, dysentery, poor growth	Provide hygienic housing conditions	No	Routinely feed ionophores	No
Bovine viral diarrhea	Observation for diarrhea (sporadic cases: most die); serology for titers and detection of persistently affected animals to be culled	Develop a heifer biosecurity plan	No	Modified live vaccines; test herd additions for persistent infection before purchase	No
Clostridial disease	Observation for sudden deaths and typical lesions	Performing special techniques for some diseases, such as controlling liver fluke for black disease; clean castrations and tail docking	No	Vaccinate with eight-way vaccine if not done earlier; vaccinate before tail docking or castration	No
Intestinal helminthiasis	Regular observations of performance, especially if on pasture; fecal examination for worm eggs	Establishing pasture management to avoid heavy larval infestations	No	Strategic dosing with anthelmintics	No

Common and Sporadic Diseases and Control Procedures in Dairy Herds—cont'd

Disease or Production Procedure	Monitoring Techniques	Management	Primary Prophylactic Methods		Zoonotic-Potential
			Nutritional Intervention	Medication or Vaccines	
DISEASES OF DAIRY CATTLE NOT NECESSARILY RELATED TO THE PRODUCTION CYCLE					
Infectious Diseases					
Respiratory					
Pneumonic pasteurellosis	Sudden onset of fever, cough, dyspnea, toxemia	Maintain adequate ventilation; avoid stresses of handling and transportation of cattle shows; develop biosecurity program	No	Consider use of antimicrobials in an epidemic; develop specific herd vaccine recommendations	No
Viral interstitial pneumonia (bovine respiratory syncytial virus)	Sudden onset of dyspnea, cough, fever, not toxemic; wheezes over lungs, elevated body temperature	Same as for pneumonic pasteurellosis	No	Treat secondary bacterial infections; develop specific herd vaccine recommendations	No
Infectious bovine rhinotracheitis	Sudden onset of fever, cough, dyspnea	Same as for pneumonic pasteurellosis	No	Vaccinate calves at 6 months of age and cows annually	No
Lungworm	Observe for chronic coughing in calves	Manage pastures to minimize larval contamination	No	Administer strategic treatment with appropriate anthelmintics; monitor irrigated pastures	No
Atypical interstitial pneumonia	Not possible; put pilot one or two cattle on suspect pasture	Restrict dust in barn	No	Feed monensin if allowed before turn out on pasture	No
Enteric					
Winter dysentery	Explosive herd outbreak, severe diarrhea; brief, nonfatal illness	Sanitation and hygiene; effective manure disposal	No		No
Salmonellosis	Diarrhea and toxemia; fecal serotest for *Salmonella dublin* carriers	Sanitation and hygiene; check for asymptomatic carriers	No	Vaccinate as appropriate	Yes
Coccidiosis	Diarrhea, dysentery	Sanitation and hygiene; avoid crowding and fecal contamination of feed	No	Mass medication of feed and water for large herds raising many herd replacements	No

Downloaded from Vet-eBooks.com

Bovine viral diarrhea	Acute diarrhea or abortion infection is ubiquitous		No	Vaccinate breeding females at least 3 weeks before breeding	No
Johne's disease	Chronic diarrhea	Eradication by identification and culling of infected animals	No	Don't feed waste milk or pooled colostrums to calves; separate calves from dam; ensure hygienic calving environment; vaccine available in some areas to control disease	No
Intestinal helminthiasis	Diarrhea, wasting, egg counts	Pasture management, improved husbandry	No	Strategically administer of anthelmintics, if economical	No
Bovine papular stomatitis	Fatal illness with profuse mucopurulent ocular nasal discharges, ophthalmitis, oral mucosal erosions, terminal encephalitis, lymphadenopathy	Avoid contact with lambing ewes	No		No
Bovine malignant catarrh	Fatal illness with profuse mucopurulent ocular and nasal discharges, ophthalmitis, oral mucosal erosions, terminal encephalitis, lymphadenopathy	Avoid contact with lambing ewes	No	Very sporadic disease; no control program warranted	No
Foot-and-mouth disease	Herd affected; lameness, sore mouth, milk yield drop	Prevent introduction of carrier animals into countries where disease does not occur	No	Eradication by slaughter of herd and contact herds in free countries; vaccination in countries where disease endemic	No
Bluetongue	Clinically identical with chronic bovine virus	Avoid introduction of infected animals; insect control	No	Cattle are significant carriers for sheep	No
Skin and feet					
Warble fly infestation	Lumps under skin		No	Regular strategic use of insecticides	No
Pediculosis	Itching, dandruff, hair rubbed; lice visible; some blood loss; seasonal	Thin cattle most susceptible	No	Regular use of insecticides	No
Fibropapillomas	Observe for appearance of warts	Isolate infected animals	No	Autogenous or proprietary vaccines usually used as treatment	No

Common and Sporadic Diseases and Control Procedures in Dairy Herds—cont'd

Disease or Production Procedure	Monitoring Techniques	Management	Primary Prophylactic Methods		Zoonotic-Potential
			Nutritional Intervention	Medication or Vaccines	
DISEASES OF DAIRY CATTLE NOT NECESSARILY RELATED TO THE PRODUCTION CYCLE—CONT'D					
Pseudocowpox; mammillitis	Observe for characteristic lesions on teats	Strict hygiene in milking parlor	No	Iodophor teat disinfection preferred	No
Ringworm	Obvious skin lesions of scabs and alopecia	Sanitation, hygiene; avoid overcrowding	No	Griseofulvin if allowed	Yes
Dermatophilus infection (mycotic dermatitis)	Tenacious, widespread scabs; hair loss	Treat or remove affected animals	No	Individual medication of each affected animal with antibiotics to remove source of infection	No
Footrot	Lameness, crack in foot cleft, swelling	Provide well-drained, stone-free alleyways	No	Daily foot bath using zinc sulfate or copper sulfate	No
Digital dermatitis (Mortellaro's disease, hairy foot warts)	Lame cows; distinctive lesions, hind feet, proximal to plantar/palmar interdigital space; circular, raised, proliferative, red, pungent, painful, filiform papillae protrude from surface	Observe for lameness and examine feet for lesions	No	Topical oxytetracycline spray for individual cases; footbath for treatment and control of groups of animals	No
Sudden death diseases					
Clostridial diseases	Sudden death; may be swollen leg (blackleg, malignant edema); hemoglobinuria (bacillary hemoglobinuria)	Dispose of infected carcasses properly	No	Vaccinate all animals for clostridial diseases in endemic areas	No
Anthrax	Sudden death	Dispose of infected carcasses properly	No	Vaccinate all animals for anthrax in endemic areas	Yes
Nervous system					
Haemophilus	Number of cattle affected with somnolence, recumbency, blindness; synovitis, pneumonia, pleurisy, endometritis	Survey constantly, treat early, avoid stress	No	Vaccinate in outbreak; vaccinate calves annually before weaning; consider mass medication in face of an outbreak	No

Downloaded from Vet-Books.com

Listeriosis	May be number affected; observe for neurological signs, especially circling	Cease feeding ensilage; may be source of infection	Yes, poorly ensiled forages	Avoid poorly ensiled forages	Yes, if raw milk is consumed
Rabies	Posterior paralysis, slack jaw, dribbling saliva, choking; occasionally maniacal	Avoid contact with wildlife	No	Vaccinate in endemic area	Yes
Other					
Infectious keratoconjunctivitis	Lacrimation, photophobia, keratitis	Fly control	No	Treat with long-acting tetracyclines	No
Brucellosis	Monitor abortion rate; greater than 2%, check cows serologically with agglutination test for brucellosis; cull positives	Eradicate by test and slaughter	No	Vaccinate calves in initial stage of eradication program; adult vaccination permissible in some countries	Yes
Leukosis	Serological testing	Eradicate by test and slaughter; maintain closed herd	No	Avoid multiple use of needles or other equipment that comes in contact with blood	No
Leptospirosis	Abortion storms, mastitis, hemoglobinuria in calves	Avoid contact with carrier animals; hygiene and water control	No	Control rodents and deer populations; frequent vaccination in endemic areas	Yes
Tuberculosis	Regular herd or area testing	Cull reactors; quarantine until tests clear; prevent introduction of infected animals	No	Avoid contact with wildlife in areas where disease is endemic	Yes
Actinomycosis	Observe osteomyelitis of bones of jaw	Cull affected animals quickly; disinfect feed troughs	No		No
Actinobacillosis	Observe myositis of tongue	Treat or cull quickly; disinfect feed troughs	No		No
Contagious bovine pyelonephritis	Red urine, fatal subacute illness	Cease natural breeding; isolate affected animals; hygienic disposal of contaminated bedding	No	Prophylactic treatment with penicillin in high-risk situation	No
Anaplasmosis	Wasting disease, with fever peaks; monitor by complement fixation test	Insect control; prevent infection through careful disinfection of instruments	No	Vaccines widely used in endemic areas best procedure	No

BCS, Body condition score; *E. coli, Escherichia coli; SOP,* standard operating procedure.

Downloaded from Vet-eBooks.com

These herds are often composed of almost all first lactation animals.

Stage of Lactation

Ideally, herds that calve on an annual basis maintain an average 150 days in milk. This goal is derived from a calving interval of 365 days that is composed of a 305-day lactation and a 60-day dry period. In this instance 8.3% of the herd would calve and dry off each month, causing stable herd population and efficient milk production. Herds that calve seasonally or semiseasonally to coordinate peak milk yield with seasonal pasture conditions do not attempt to reach this goal. The goal in those herds is to calve in a narrow time frame, and the stage of lactation will progress as the season progresses.

Age

The age of dairy cattle influences herd productivity. It is reasonable for the manager of a herd that is composed primarily of younger animals to have lower expectations for milk volume. The distribution of age groups within a herd is related to the risk of acquiring a number of disease syndromes. Mastitis and reproductive inefficiency are more prevalent in older age groups. Some diseases (such as milk fever) are uncommon in first lactation animals. The production medicine veterinarian should take into account the proportion of animals that are at risk for disease when setting appropriate targets of herd performance. Herd age can change as the result of disease events or management decisions. When involuntary culling is increased through disease, herd age may decrease because of reduced longevity. When reproductive performance is poor, herd age may actually increase because of a reduced pool of replacement animals. Herd age should also be considered when grouping and feeding decisions are made. Social dominance in groups of cattle is based on age. In many confinement operations, grouping younger, first-lactation animals separately from older animals has been shown to increase feed intake and improve productivity.

Environmental Conditions

Even in the best housing situations, environmental conditions can affect herd productivity. Higher producing cows have larger dry matter intakes, generate more internal heat, and are less tolerant of high ambient temperatures. Weather conditions that combine high ambient temperatures and high humidity without periods of cooling generally cause depressed dry matter intakes and reductions in milk yield. The increased concentration of dairy farming in regions that experience considerable periods of high temperatures has resulted in more seasonal variation in milk output. Farmers have adopted a variety of systems to combat heat stress. Many new facilities are constructed with large open sides (often greater than 4.3 m high) and ends. These modern facilities often use fans and cooling systems to keep cows comfortable. Older enclosed facilities can be retrofitted with tunnel ventilation systems to provide adequate air movement.

Drying Off and Dry Cow Management

The dry period is recognized as an important portion of the overall management cycle of dairy cattle and is an important component of herd productivity. Most successful dairy producers recognize that the dry period is not the end of a lactation cycle but the beginning of the next lactation. Risk factors for most postpartum diseases of dairy cows occur during the dry period, with clinical signs of disease becoming evident after calving. Diseases such as hypocalcemia (milk fever), hypomagnesemia, udder edema, ketosis, DA, and mastitis all often begin during the dry period. Dairy health management programs focus many preventive practices such as vaccination, hoof care, and nutritional monitoring during this period.

The length of the dry period influences milk yield in the subsequent lactation. When milk yield ceases, nonsecreted milk is absorbed and udder secretory cells are rapidly lost. This process (termed "involution") is usually complete within about a 2-week period after milking is terminated. Immediately before calving, hormonal changes initiate rapid proliferation of milk secretory cells. The length of the dry period can influence the proliferation of secretory cells. The recommended dry period is 6 to 8 weeks. Dry periods of less than 40 days have been demonstrated to reduce milk yield in the following lactation (Dias and Allaire, 1982). In one study, a dry period of 4 weeks resulted in about 2.5 kg/day less milk compared with a 7-week dry period (Sorensen and Enevoldsen, 1991). Dry periods that are too long often lead to excessive weight gain and reduced production efficiency. Both short and long dry periods are most common when breeding dates are uncertain because of either bull breeding or inaccurate (or missing) reproductive records.

The process followed for ending a lactation should be well defined. Cows should be dried off by abrupt termination of milking followed by appropriate intramammary dry cow treatment. High-yielding cows can be dried off successfully in the same fashion, but it may be necessary to reduce milk yield rapidly by temporarily limiting access to water for 12 to 24 hours. Water intake should not be limited during periods of heat stress. Cows that are receiving bST should receive their last injection no later than 3 weeks before the expected dry date. BCS at dry off should be within the target range of 3.00 to 3.25 (on a 5-point scale). Cows that are overconditioned should not lose weight during the dry period, but a moderate amount of condition can be added safely to underconditioned cows (<3.00).

Culling Program

Decisions regarding cow removal can significantly impact productivity of the dairy herd. Culling rates can vary dramatically between herds. In 1995 U.S. farmers reported an adult cow removal rate of about 27.8% (24% sold, 3.8% died) (NAHMS, 1996). A study from England reported an annual culling rate of 23.8% (22.0% sold, 1.8% died) for 1990 to 1992 (Esslemont and Kossaibati, 1997). The rate of disease has a strong correlation with culling rates. Fertility, mastitis, and lameness are commonly reported reasons for cow removal. In some instances culling is increased because of disease control programs; in England 7.4% of culling was related to control programs for bovine spongiform encephalopathy (BSE). Culling is an important aspect of controlling other diseases such as bovine tuberculosis, brucellosis, Johne's disease, and chronic mastitis caused by some contagious mastitis pathogens. When culling is excessive because of disease, the farmer cannot select cows to cull based on productive potential and herd productivity may be affected adversely. Cow culling practices are reviewed thoroughly in Chapter 7.

Quality of Labor

The final aspect of farm productivity is the managerial ability of the dairy farmer. A dairy farm is a complex system that

Downloaded from Vet-e-Books.com

requires the ability to make numerous interrelated decisions about animals, crops, people, and financial management. Farm owners need to be able to devise monitoring systems that enable sound decision-making based on realistic data. Successful farm managers are also good at understanding how and when to seek advice. On small farms dependent on family labor, the herd owner is often responsible for all aspects of farm management and animal handling. On large farms the ability of the herd owner to employ animal handlers with excellent stockmanship can determine herd productivity. Regardless of farm structure, the relationship between animal handlers and cows can influence milk yields (Seabrook, 1984).

INTERACTION BETWEEN HEALTH AND PRODUCTION

A dairy farm is a complex interrelated system that requires a great deal of coordination to achieve optimum productivity. Each day, the dairy farm manager is required to make decisions about subjects as diverse as environmental stewardship, financial management, cow health, and personnel management. Almost every management decision has the potential to either directly or indirectly impact farm productivity and profitability. In addition, some farm conditions such as weather cannot be controlled by the farmer. For example, a farmer may elect to plant a new variety of corn to use as silage after harvest. Seasonal growing conditions may cause nutrient values or yields that are considerably different than expected. At this point the farmer may need to add grain to the diet to meet nutrient requirements of the cattle. The addition of grain may increase feed expenses (and limit available capital for other farm operations) and potentially reduce effective fiber levels. With lower fiber levels, subacute ruminal acidosis may develop in some groups of cattle, causing reduced yields, increased lameness, and increased culling. Cows may experience excessive body condition loss and reduced conception rates. Eventually, there may be inadequate numbers of replacement animals available to maintain herd size unless heifers are purchased from an outside source. Purchased animals may introduce contagious diseases unless an effective biosecurity plan is in place. Multiple and seemingly unrelated decisions on dairy farms can produce a cascade of effects that affect farm productivity and ultimately farm profitability.

The dairy health and production management program is one mechanism that allows for consistent assessment and discussion of the farm situation. There are a multitude of issues that the production medicine practitioner should recognize, and the cause of problems is not always the most obvious risk factor. For example, dry cow management and housing are often neglected during periods of farm expansion. One manifestation of inadequate dry cow management may be an increase in mastitis of recently fresh cows. The first impulse may be to review milking procedures for fresh cows or to revise early lactation protocols. In reality, many environmental mastitis infections are acquired during the dry period and manifest as clinical mastitis after calving. Appropriate intervention therefore needs to be directed at the high-risk periods immediately after dry off and immediately before calving. Ideally, the production management program would include a proactive assessment of dry cow needs before the expansion occurs.

The interconnectedness of the dairy farm system often results in decision making based on imperfect knowledge. In many instances farmers manage the separate enterprises (crops, replacement herd, milking cows, financial, and personnel) without full consideration of the impact of one decision on the entire system. Sometimes simple financial tools such as partial budgets are used to assess the economic impact of management decisions. Other times, simple computer spreadsheets are used to predict the effect of management changes to the entire herd. In some instances computer simulation models have been developed to forecast the outcomes of management changes to the entire farm system. Computer simulation is based on a thorough understanding of the underlying processes and the use of realistic assumptions that apply to the situation under study. At some point computer simulation will probably be used in the field on a regular basis to aid in farm decision making. The variety and complexity of current farm management systems have slowed the commercial application of computer simulation. It is currently possible to download spreadsheets for farm financial decision making from a variety of university-related Internet sites. In the future it is likely that some form of Internet-based computer simulation program will be available for farm use.

Frequency of Disease in Dairy Cattle

An important factor that influences herd productivity is the amount and type of disease that the dairy herd experiences. The frequency of diseases of dairy cattle has been a topic of numerous research reports. Most reports have been either prospective or retrospective reports describing disease conditions on one or more commercial dairy herds. Virtually all studies have documented the relationship of disease to the production cycle of dairy animals and have noted the interrelationships among diseases and risk factors. Many of the reports have estimated the cost of disease, and some have estimated the cost of preventive measures. A number of reports conclude by summarizing performance targets and acceptable levels of disease for the reference population of herds in their studies. The information contained in these observational studies is an important component of the knowledge base of health management practitioners because the basis of disease control programs includes the following:

- Knowledge of the frequency of disease
- Information about the biological effect of disease
- Information on the effectiveness of various control procedures

It is important to note, however, that the information included in many of these studies is incomplete, and direct extrapolations of survey information to individual herds should be made cautiously. The design of the study can contribute to inaccuracy of disease estimates. Retrospective studies are generally based on retrieval of computerized records of some sort from either an official production recording system or on-farm computer software. These studies often lack a common case-definition for diseases and have the assumption that all diseases are diagnosed and recorded on an equal basis. Given that episodes of severe clinical disease are more memorable than episodes of mild disease, the likelihood of recall bias in these studies is high. Most studies that depend on producer estimates of disease, not surprisingly, have significantly lower estimates of disease compared with estimates derived from prospective studies.

Incidence rates in prospective studies are generally estimated based on routine recorded observations of the dairy producer and his or her veterinarian. The frequency of clinical disease is generally reported as either lactational incidence rates or percentages of the at-risk population affected. The term "lactational incidence rate" is generally defined as

Downloaded from Vet-e-Books.com

the number of cows with at least one occurrence of disease during a lactation divided by the number of cows at risk for the lactation, expressed as a percentage (Dohoo et al, 1983). Recommendations for uniform reporting of clinical diseases have been proposed (Kelton et al, 1998). For retrospective analysis using historical data, lactational incidence risk is recommended. For current analysis (such as herd health monitoring), a true incidence rate (number of cases of disease divided by number of cow-days at risk for disease) is recommended.

Most studies differentiate between new and recurrent cases, but the definition of a new case often varies considerably between studies. When referring to reported disease estimates, the practitioner should always make note of the definition of the population considered to be at risk since it can considerably influence the applicability of the disease estimate, especially if differential risks apply to the disease. A good example of differential risk is the consideration of the at-risk population for milk fever. Since the risk of milk fever is known to increase with parity (Dohoo et al, 1984), the acceptable (or "target") baseline rate of milk fever in a herd composed entirely of first lactation animals should be considerably lower than in a herd composed of older animals.

Practitioners should consider other herd- and animal-specific risk factors when assessing the performance of a health management program. Dohoo et al (1984) evaluated the effects of age, season, and sire on the occurrence of the common diseases of Holsteins in Ontario, Canada. There were linear increases with age observed for milk fever, mastitis requiring intramammary therapy only, cystic ovaries, and foot and leg problems. No consistent age patterns were found for retained placenta, reproductive tract infection, abomasal displacement, teat injuries, digestive disorders, and abortions.

Environmental conditions also influence the risk of disease occurrence and should be considered when setting goals for a herd. Heat stress influences health and reproductive performance. In the United States it is well known that the levels of clinical and subclinical mastitis increase during periods of hot and humid weather. Similar cyclical trends linking poor reproductive performance to periods of heat stress have been recognized recently, even in traditional Midwestern dairy regions.

Most studies report only incidence rates of common, easily diagnosed, clinical diseases such as mastitis, lameness, milk fever, retained placenta, or DA. The frequency of subclinical disease is much more difficult to discern. The cost of obtaining subclinical disease information is inflated by the need to use screening tests (such as culture or somatic cell counts for mastitis, or fecal culture or enzyme-linked immunosorbent assay tests for Johne's disease) for diagnosis. The lack of repeated testing leads to the reporting of prevalence rather than incidence for many subclinical diseases. Estimates of the frequency of sporadic or endemic infectious diseases (such as listeriosis, infectious bovine rhinotracheitis, or leptospirosis) are also sparse. There is zero tolerance for some diseases that have serious consequences for public health. The occurrence of even one case of BSE, brucellosis, rabies, or tuberculosis in areas thought to be free from those conditions is cause for immediate action by veterinarians and regulatory officials. Most national disease control programs depend on surveillance by local veterinary practitioners.

Within the constraints just noted, knowledge of the frequency of disease is important for the veterinary practitioner. Table 6-7 shows a summary of recent reports of disease frequency of adult dairy cows in commercial dairy herds. Whitaker et al (2000) monitored 340 herds in southern England between April 1998 and March 1999. The average herd size was 133 cows, and average milk production was 6620 kg. This study was prospective and used explicit case definitions for the diseases of interest. Type of housing was a risk factor for both mastitis and lameness. It is interesting to note that considerable variability was noted between farms for many conditions. The incidence rates for the lowest and highest quartile of herds were 1.0% and 21.0%, 13% and 70%, and 5.8% and 50.3% for assisted calvings, mastitis, and lameness, respectively.

Data was retrieved from on-farm computerized record systems supported by the Northeast DHI for two studies (Gröhn et al, 1995, 1998). Both retrospective studies were conducted in commercial herds composed primarily of Holsteins and located in New York. The lactational incidence of several common diseases was reported (Table 6-7). The herds tended to be large (mean herd size of 323 for Gröhn et al [1995]; median herd size of 500 for Gröhn et al [1998]) and high producing (mean milk yield was 10,265 kg for Gröhn et al, 1998). Estimates of some diseases (ketosis, DA) were similar between studies, but differences in lactational incidence were noted for mastitis, milk fever, and metritis. Mastitis was only recorded if it required treatment, so differences in treatment protocols and selective recall likely resulted in underreporting of this condition. The exclusion of primiparous animals from the first study (Gröhn et al, 1995) probably accounted for part of the observed differences. This study noted significant interrelationships between diseases. Milk fever, metritis, and abomasal disorders increased the risk of ketosis. Cows diagnosed with ketosis had twice the risk of metritis, and cows diagnosed with retained placenta had more than six times the risk of metritis compared with cows that did not experience these disorders. Retained placenta and ketosis were significant predictors of abomasal displacement. The effect of milk yield on the risk of disease was the primary objective of this study, but higher milk yield was not identified as a risk factor for any disease except mastitis and ovarian cyst. This finding supported earlier work (Dohoo et al, 1984; Erb, 1987) that found little evidence that high levels of milk production predispose dairy cows to diseases other than milk fever. High milk yield was not a risk factor for veterinary-assisted dystocia, retained placenta, metritis, cystic ovary, clinical milk fever, clinical ketosis, left-sided displacement of the abomasum, and clinical mastitis (Erb, 1987).

The relationship between milk yield and disease occurrence was also studied in Finnish Ayrshire cows (Rajala and Gröhn, 1998). This study relied on data from the Finnish health data recording system and followed cows that calved during 1993. Animals included in this study were from small farms (only 9.3% of the herds had 25 or more calvings during 1993) with moderate production levels (mean 305-day milk yield was 6715 kg). The study population by parity was 33.5% (parity 1), 23.8% (parity 2), 17.1% (parity 3), and 25.6% (parity 4+). In this population, increased milk yield was found to increase the risk of acute mastitis, ovarian cysts, and anestrus in older cows. Higher milk yield increased the risk of milk fever in parity 2 cows but not in other age groups.

The differences in results between studies of Finnish Ayrshires and New York Holsteins were attributed by the author to differences in farm size and management (Grohn, 2000). Confounding issues, such as the preferential retention of high-yielding cows in the herd, may contribute to the perception of a relationship between yield and disease. High-yielding cows are more likely to be retained within the dairy herd and to receive veterinary treatments if ill when compared with low producers (Grohn, 2000).

Data collected from on-farm computers were used to describe the frequency of disease occurrence in registered Holstein herds located in British Columbia, Canada (van Dorp et al, 1999). The average herd size was 110 cows, and most cattle were housed in free stalls and fed a TMR. This study noted that most diseases occurred during the first 30 days of lactation and that the occurrence of early lactation disease tended to increase the risk of other diseases later in lactation. Udder edema was more common in first lactation animals and was a risk factor for mastitis, metritis, and cystic ovaries. Milk fever was directly associated with the risk of DAs. Seasonal effects were shown for the risk of mastitis, retained placenta, metritis, cystic ovaries, ketosis, and foot rot.

It is interesting to compare the occurrence of disease among vastly different production systems. Esslemont and Kossaibati (1996) and Frei et al (1997) reported disease occurrence in selected herds in England and Switzerland. The reported rates of mastitis and milk fever were remarkably close even though the herd populations varied significantly. The average herd size and milk yield was 152 cows and 6000 L for the English herds compared with 15.5 cows and 4400 kg (estimated) for the herds included in the Swiss study.

A number of well-known risk factors for disease have been defined by earlier studies. Bendixen et al (1986) reported risk factors for dystocia in Swedish red and white (SRB) and Swedish Friesian breeds (SLB). Parity (first parity animals had a higher risk), breed (SLB had a higher risk than SRB), sex (male calves had a higher risk), and previous history of dystocia were among the risk factors that were identified. Bendixen et al (1987) also identified an increased risk of retained placenta associated with breed, age, occurrence of milk fever, dystocia, twinning, and the birth of male calves.

The recurrence of disease was reported for 8782 pairs of lactations in Israeli Holsteins that were followed for 8 years (Markusfeld, 1987, 1990). Annual milk yield in this population raged from 7000 to 10,000 kg. The crude risk ratio for recurrence was 2.1 for twinning, 16.7 for milk fever, 3.1 for ketonuria, 1.7 for retained placenta, and 1.7 for metritis.

The frequency of common diseases of adult dairy cattle was reviewed through a complete literature search of articles that spanned 26 years (Kelton et al, 1998). The median and range of lactational incidences were reported: milk fever (6.5%; 0.03% to 22.3%), ketosis (4.8%; 1.3% to 18.3%), left DA (1.7%; 0.3% to 6.3%), cystic ovarian disease (8.0%; 1.0% to 16.1%), lameness (7.0%; 1.8% to 30.0%), and clinical mastitis (14.2%; 1.7% to 54.6%).

The dairy practitioner requires knowledge about the frequency of calfhood morbidity and mortality. The National Dairy Heifer Evaluation Project, sponsored by NAHMS, reported retrospective data on 1811 dairy farms and prospective surveillance data on 921 U.S. dairy farms (NAHMS, 1996). Preweaning calf mortality was 8.4% and 6.8% for the prospective and retrospective data, respectively. Diarrhea accounted for 52.2% of mortality, followed by respiratory disease (21.3%), trauma (2.4%), joint and navel disease (2.2%), and other or unknown causes (21.9%). Morbidity during the first 3 weeks of life was attributed to pneumonia (25%), diarrhea (29%), and umbilical disease (29%), according to data obtained from 410 dairy calves born in 1990 on 18 commercial dairy herds in New York (Virtala et al, 1996).

In summary, baseline measures of disease for a variety of management systems have been reported. This knowledge is an important starting point for the establishment of health and performance targets on dairy farms. The dairy practitioner is responsible for integrating knowledge of the specific dairy herd farm with existing knowledge about disease to derive appropriate health management programs for the farms that he or she serves.

Influence of Disease on Productivity

The effects of disease on animal productivity have been described extensively (Morris, 1997). Alterations at the individual animal level include reductions in the nutritional, metabolic, and physiological status of the diseased animal leading to reduced productive capabilities (Fig. 6-5). These reductions initially occur at the individual animal level but can ultimately lead to reductions in productivity of the entire herd. The effects of disease on productivity can be direct (such as mastitis causing a profound reduction in milk yield) or indirect (such as reduced locomotor ability leading to reduced feed intake, thus causing reduced milk yield). The interrelationship between diseases occurring in early lactation can also lead to a cascading effect that ultimately leads to lowered productivity. Data obtained over a 12-month period from 1374 Holstein lactations in 31 commercial dairy herds in New York State demonstrated that periparturient disorders often occur as a complex (Curtis et al, 1985). For example, cows diagnosed with parturient paresis were at increased risk of retained placenta, complicated ketosis, and mastitis. Cows with veterinary-assisted dystocia and retained placenta were at increased risk of metritis.

Only short-term direct effects on production are usually considered in most studies of the effects of clinical disease on productivity. The most documented direct effect is the effect of mastitis on milk yield. One review of this relationship examined 20 studies composed of at least 250 lactations per study (Hortet and Seegers, 1998a). This study concluded that a single case of clinical mastitis resulted in a milk yield loss of 300 to 400 kg/lactation. A high variability of loss was noted; approximately 40% of clinical cases were associated with negligible loss, 30% of clinical cases led to a loss of 150 to 250 kg, and 30% of clinical cases led to losses of 950 to 1050 kg. Milk yield losses of 200 to 300 kg/lactation were noted for primiparous cows. This study also noted that mastitis cases occurring in early lactation were associated with higher losses (450 to 550 kg) compared with cases that occurred later.

The effect on the lactation curve of diseases that occur in early lactation is an important reason for the development of sound preventive medicine programs for early lactation. An extremely difficult dystocia was demonstrated to reduce milk, fat, and protein yields by 704 kg, 24 kg, and 21 kg, respectively, compared with yields of cows that calved without assistance (Dematawewa and Berger, 1997). Significant reductions (6% to 7%) of peak milk yield were noted in lactations in which a cow had a retained placenta or ketosis (Rowlands and Lucey, 1986). In cows with ketosis, the decline in milk yield was slower in later lactation and no overall difference in 305-day milk yields was noted. The lactation curve is determined by initial production, peak milk yield, and persistency. Low initial production may reflect poor nutrition, inadequate management, poor dry cow management, or periparturient disease problems. The slope of the curve following peak production is generally referred to as persistency. Persistency can be defined as the extent to which peak milk production is maintained. As discussed earlier, innate persistency is not highly variable, so a reduction in peak milk yield can have long-lasting effects on productivity. Heifer lactations tend to be more persistent than those of older cows. Cows from higher producing herds have high peak milk yields and are more persistent than lower producing cows. Adverse environmental conditions (especially heat stress) can also alter the shape of the lactation curve.

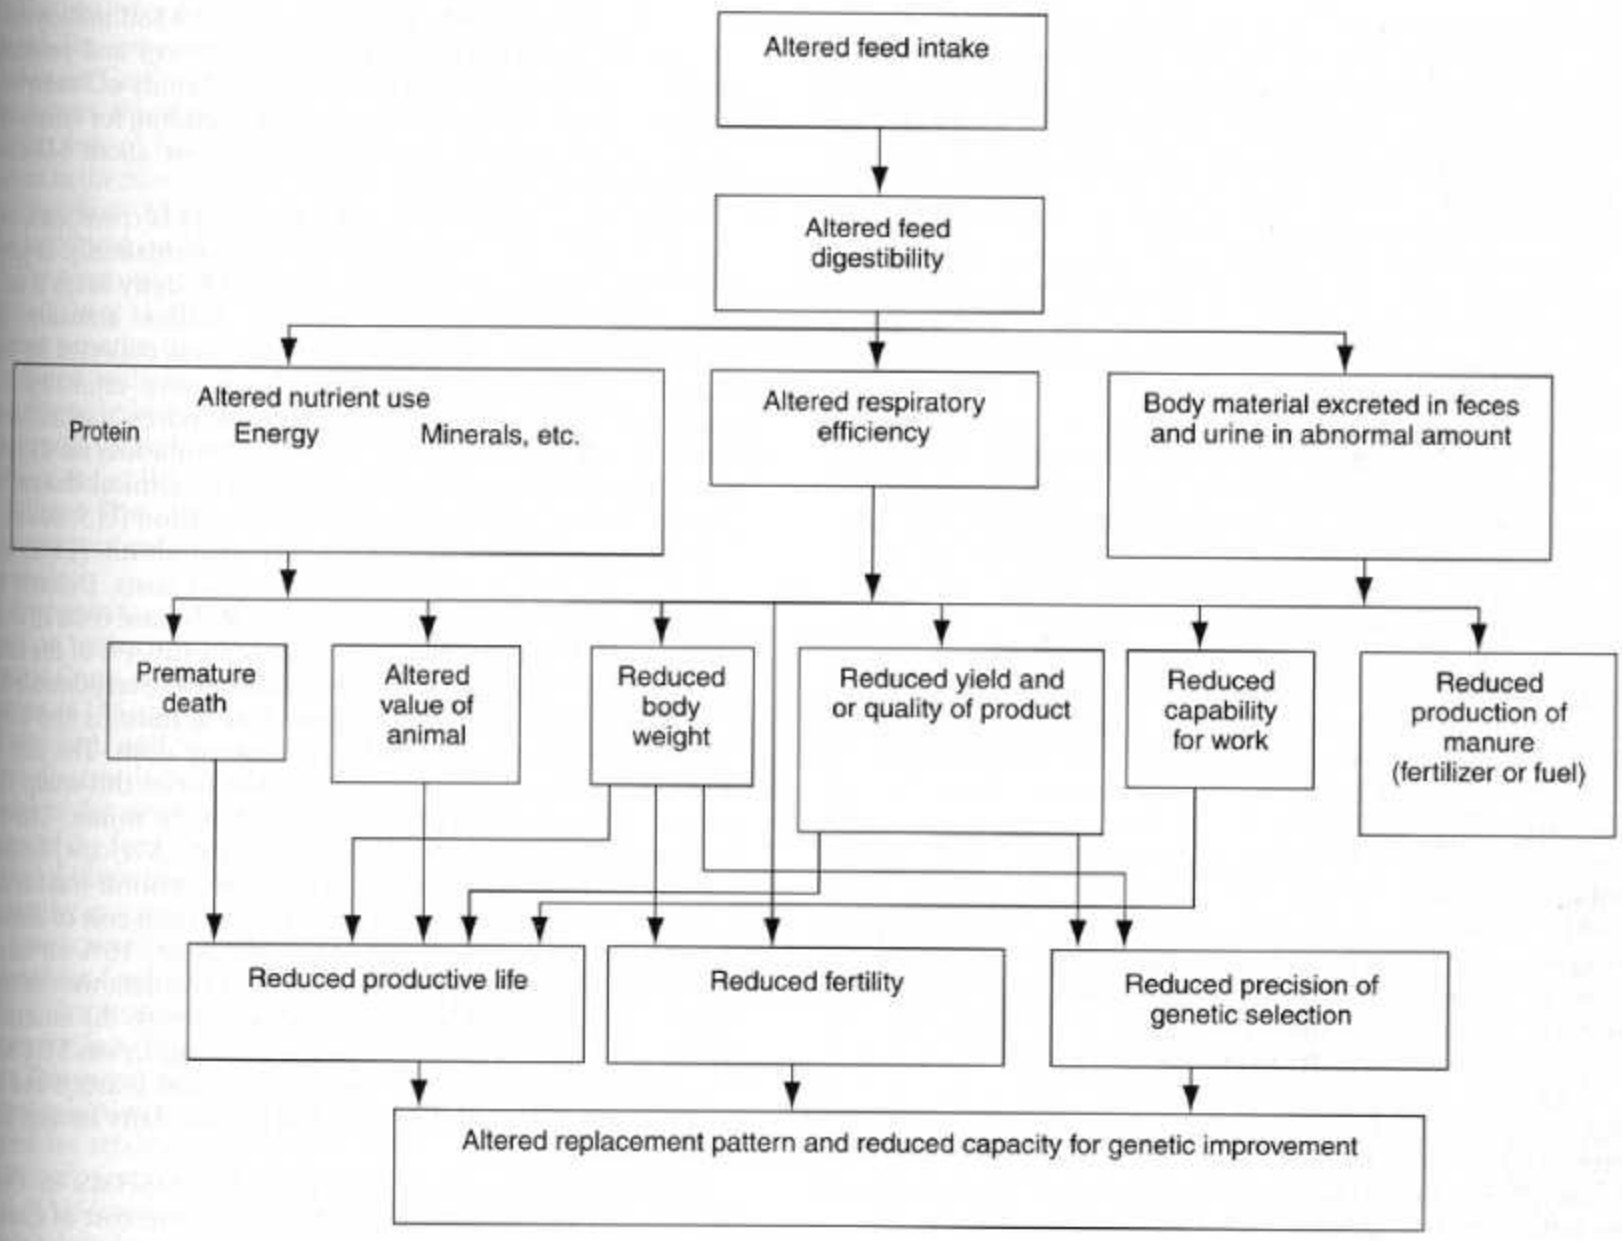

FIG. 6-5 Effect of disease on productivity. (Adapted from Morris RS: How economically important is animal disease and why? In Dijkjuizen AA, Morris RS: *Animal health economics*, Sydney South, Australia, 1997, University of Sydney.)

The method of production recording has an influence of estimates of production loss caused by disease. Automatic milk meters that record daily milk production for each cow enable the detection of deviations from normal performance. Through the use of daily milk weights, subclinical disease can be detected 2 or more weeks before its clinical appearance (Lucey et al, 1986). Significant differences in milk yield have been detected between 1 week before and 1 week after clinical diagnoses were observed for ketosis, hypomagnesemia, lameness, and mastitis cases after peak milk yield. Milk yield declined for as long as 2 to 4 weeks before diagnosis of disease. Total losses in milk yield associated with ketosis or hypomagnesemia were as high as 60 to 70 kg. Daily milk losses varying between 1.0 to 5.3 kg have been found for Finnish Ayrshires affected with clinical mastitis, ketosis, milk fever, and lameness (Grohn, 2000). In some instances, total lactational yields were not affected by short-term reductions in daily yield.

A number of common diseases of dairy cattle have been shown to influence lactational milk yields. A study of Holstein cows in Ontario indicated that milk fever, retained placenta, abortion, and other diseases were detrimental to milk production (Bigras-Poulin et al, 1990). Metritis and ovarian cysts had a positive effect on concurrent milk production because of increased number of days of lactation. A positive effect of diagnosis of ovarian cysts on total milk yield in the concurrent lactation was followed by a detrimental effect on milk production in the subsequent lactation. Retained placenta caused a 7% reduction of 305-day milk yields in one study composed of 1594 lactations occurring in 732 British Friesian, Ayrshire, and Holstein crossbred cows (Rowlands and Lucey, 1986). This study did not note any significant associations among hypocalcemia, hypomagnesemia, dystocia, or endometritis and milk yield.

Studies about the relationship between lameness and milk yield have been equivocal. Increased and decreased milk yields have been associated with lesions in specific regions of the hoof. A tendency for increased lameness in high-yielding cows has been noted in some studies. While it seems reasonable that lameness is associated with reduced milk yield, continued research is needed to fully explain the relationship.

Losses resulting from subclinical disease are not as apparent as losses from clinical disease but are often considerable. The best described relationship between subclinical disease and productivity is the effect of subclinical mastitis on milk yield. A review of 19 papers concluded that each twofold increase in SCC above 50,000 cells/ml caused a loss of 0.4 and 0.6 kg milk/day in primiparous and multiparous cows, respectively (Hortet and Seegers, 1998b). Total lactational milk yields were estimated to be reduced

Downloaded From Vet-eBooks.com

by 80 kg for primiparous and 120 kg for multiparous for each twofold increase in the geometric mean SCC over 50,000 cells/ml. Other subclinical diseases have also been related to reduced productivity. Subclinical Johne's disease is estimated to reduce lifetime milk production by 3926 kg (Hutchinson, 1996). Over 40% of the reduced production occurred during the final lactation of affected cows.

Veterinary literature largely supports the concept that many clinical and subclinical diseases adversely affect milk yield. Improved productivity of the dairy herd is a strong incentive for many dairy producers to participate in health and production management programs.

The ability to successfully reproduce is a necessary component of productivity. Diseases that delay or prohibit conception have a negative effect on herd productivity by prolonging the time that cows spend in lower producing stages of lactation, by reducing the number of offspring for replacements or for sale and by increasing the likelihood that the animal will be culled prematurely. Many reasons for declining conception rates have been considered. Some genetic studies have reported antagonistic correlations between production traits and health disorders, implying that selection for yield causes deterioration in health and fertility (Pryce et al, 1998). Several diseases have been associated with conception rates. The likelihood of conception was reduced by 14%, 15%, and 21% for cows that experienced retained placenta, metritis, or ovarian cysts, respectively (Eicker et al, 1996). Mastitis, metritis, and ovarian cysts reduced the likelihood of cattle being bred for the first time. Postpartum diseases that prolong negative energy balance in early lactation probably also have a negative effect on reproductive performance through alterations in hormonal activities.

The effect of disease on longevity has been investigated. A large proportion of cow culling is considered involuntary (driven by disease, injury, or death) rather than for reasons of low production. The premature removal of a cow from the herd reduces lifetime milk yield. Reproductive failure and mastitis are consistently recorded as the top two reasons for culling. A culling rate of 22.1% was recorded for 340 British dairy herds (Whitaker et al, 2000). The top four reasons recorded for culling were infertility (25.3%), mastitis (16.3%), lameness (7.7%), and age (16.7%). A separate British study of 50 dairy herds recorded an overall culling rate of 23.8% (Esslemont and Kossaibati, 1997). Poor fertility accounted for 36.5% of removals followed by management policy (11.5%), mastitis (10.1%), BSE (7.4%), and lameness (5.6%).

In France, the probability of a cow being culled was higher for cows that experienced mastitis, teat injuries, or udder disease (Beaudeau et al, 1995). Cows with metritis or cows experiencing early abortion also had poor survival. In New York, metritis did not influence culling, but mastitis, milk fever, retained placenta, DAs, ketosis, and ovarian cysts were found to affect culling significantly (Gröhn et al, 1998).

In general, disease influences productivity by reducing milk yields, decreasing reproductive performance, and limiting the length of productive life. Veterinary practitioners involved in production and health management programs are likely to have a considerable opportunity to improve the productivity of the farms that they service.

Estimate of the Costs of Dairy Cattle Diseases

The aggregate and individual cost of disease has been estimated with varying precision at a number of levels. Disease costs include outlays for veterinary services and products and disease-related reductions in productivity. The cost of veterinary services and products is more easily estimated than the cost of reduced productivity. In 1993, U.S. producers spent an estimated aggregate sum of $580 million dollars (about $60/cow) on veterinary services and products (USDA, 1993). A smaller, more detailed study of Pennsylvania producers estimated that annual spending for veterinary supplies and services was $2606/farm or about $43/cow from 1986 to 1990 (Miller et al, 1993).

When the cost of reduced productivity is considered, estimates of the cost of disease increase dramatically. In general the aggregate cost of disease for U.S. dairy herds is estimated to exceed several billion dollars annually. In California, disease and economic data was collected for the NAHMS (Sischo et al, 1990). Costs were estimated for death, culling, weight loss, veterinary services, medication, disposal, labor, calves born dead, and milk loss on 43 randomly selected dairy herds. The cost of clinical disease in California was estimated to be $1.75 million (U.S. dollars) or $112/cow/year. Culling (52%) and death (24%) accounted for a large proportion of total costs. Diseases of adult cows accounted for 93% of total disease costs in contrast to calf disease, which represented only 4% of the total disease costs. Diarrhea and pneumonia were responsible for 86% of costs of calf diseases, and clinical mastitis and infertility accounted for 53% of cow disease costs. The cost of subclinical disease was not accounted for in this study. The cost of disease prevention was relatively minor. The 43 herds in the study spent about $172,000 ($11/cow) for disease prevention. Most of the cost of prevention was for the purchase of drugs and biologics. Of the total cost of disease prevention, 55% was spent on medication, 16% for labor and 29% for veterinary services. When the data were extrapolated to the entire California dairy industry, the estimated cost of clinical disease and disease prevention was $118 million for the 1-year period studied. Clinical mastitis and infertility were estimated to cost California dairy farmers $53 million a year.

Economic data were collected for NAHMS in Ohio (Miller and Dorn, 1990). In this study the cost of disease was estimated to be about $152 per cow-year, and the cost of prevention was an additional $21 per cow-year. The proportion of costs attributable to specific diseases was mastitis (26%), infertility (13%), pneumonia (5%), lameness (5%), dystocia (5%), milk fever (4%), left displacement of the abomasums (4%), and death (3%). Most of the cost of disease occurrence was due to deaths, culling, and stillbirths followed by milk loss, drugs, biologics and veterinary services, body weight loss, labor, and carcass disposal. Most of the prevention costs were for drugs and biologics, followed by veterinary services and labor input. When preventive expenditures not attributed to a specific disease were included, the annual total health-related cost was $188/cow.

Estimates of the costs of specific diseases have been generated, particularly for mastitis. Using unpublished NAHMS data, Wells et al (1998) estimated the annual aggregated sum of individual producer costs of mastitis for U.S. producers to be $1.5 to $2 billion. The loss from subclinical mastitis was estimated to be $960 million. Clinical mastitis was estimated to cost California dairy producers $27 million annually (Sischo et al, 1990). The cost of a case of clinical mastitis has been estimated at $104/case for California producers (Sischo et al, 1990) and $107/case for Ohio producers (Hoblet et al, 1991). The cost of clinical mastitis was estimated for both mild ($139/case*) and severe ($433/case*) mastitis in English dairy herds (Kossaibati and Esslemont, 1997). Most of the losses for clinical mastitis are attributable to discarded milk.

*Converted from pounds sterling at $1.40 U.S. dollars per pound.

Downloaded From Vet-e-Books.com

The cost of a number of other diseases has been estimated. The cost of a DA was estimated to be about $250 to $400/case (Geishauser et al, 2000). Losses consisted of treatment costs, discarded milk, decreased milk yield, reduced fertility, loss of body weight, and increased risk of culling. Losses to the North American dairy industry were estimated to range from $55 million to $220 million depending on the lactational incidence rate.

The economic impact of Johne's disease has been estimated (Ott et al, 1999). Herds that were positive for Johne's disease experienced an economic loss of almost $100/cow compared with herds without Johne's disease. Most loss was due to reduced milk production and increased cow replacement costs. When the prevalence of Johne's exceeded 10% of the cull cows, economic losses were greater than $200/cow. The cost of Johne's disease to the U.S. dairy industry was estimated at $200 million to $250 million annually.

Productivity, prevention, and treatment losses were used to estimate the cost of several diseases (Guard, 1994). Costs were estimated for milk fever ($335/case), ketosis ($145/case), left displacement of the abomasum ($340/case), and lameness ($302/case). The occurrence of these diseases is related to management issues such as the design of the stalls or barns, manure handling, and the adequacy of the feed formulation and delivery system. The incidence of these diseases is minimized in herds with sound preventive management practices.

Losses caused by a number of production diseases were estimated for English dairy herds (Kossaibati and Esslemont, 1997). This study used a survey of 10 veterinary practices to determine fees, treatment costs, and typical treatment protocols. This survey also included costs for farm labor and estimated reductions in yield. The cost (in U.S. dollars) was estimated for retained placenta ($416/case), mild milk fever ($70/case), severe milk fever ($216/case), and digital lameness ($336/case). This study estimated that ill health cost English dairy farmers approximately $8825/100 cows/year.

It is apparent that disease is a considerable cost to the dairy industry. Studies have consistently indicated that much more money is expended on disease treatment than on prevention. Prevention of disease is cost effective. One study demonstrated that each marginal dollar spent on veterinary services and supplies returned $3.22 in additional revenue from milk production (Miller and McSweeny, 1993). The challenge for the dairy practitioner is to effectively communicate and market preventive health care practices to their clients. Current and developing trends within the dairy industry will make the need for effective preventive health management programs even more acute. Fewer herds are truly isolated and more animals are housed in larger units, thus the risk of acquiring infectious disease is increasing. In addition, the cost of subclinical disease has not been recognized fully. Defining and implementing practices to promote healthy and productive cattle should be the goal of every dairy veterinarian.

Other Potential Causes of Economic Loss in Dairy Herds

The dairy practitioner should be concerned about other, less obvious potential losses than those just described. A number of diseases of dairy cattle have zoonotic potential (Table 6-6). The loss of public confidence in the purity and integrity of the food supply could be catastrophic for the dairy industry. The European experiences with BSE should be considered when farm practices and regulatory procedures are reviewed. The linking of new variant Creutzfeldt-Jacob disease (nvCJD) with the ingestion of beef has devastated the British beef industry and cost agriculture its' credibility with European consumers. While North America has not experienced BSE, other food safety and welfare issues could reduce the public confidence in the dairy industry. Food safety is not an issue that most producers spend much time worrying about. However, human pathogens such as *Listeria monocytogenes*, *Salmonella* spp., and *Escherichia coli* O157:H7 are known inhabitants of the dairy ecosystem. *Listeria* and *Salmonella* are pathogenic in cattle and can be shed in milk. They are regularly found in unpasteurized bulk tank milk, and exposure can occur through ingestion of raw milk or raw milk products. *Salmonella* and *E. coli* O157:H7 are common fecal contaminants of carcasses. One role of the veterinary practitioner is to educate farmers about food safety and to promote practices to ensure that food products are derived from healthy cattle.

Another emerging issue is the change in societal ethics regarding animal welfare. Consumers are increasingly interested in the conditions in which animals are raised and are especially concerned about perceived suffering. Although the dairy industry is generally regarded positively, the handling of recumbent cattle, housing of veal calves, and concern about humane slaughter practices are issues that animal activists are pursuing. A proactive approach by everyone involved in the dairy industry is needed to ensure that animals are handled humanely throughout their entire productive lifespan.

Monitoring the Frequency and Economic Impact of Dairy Cattle Diseases

The vast majority of animal disease monitoring is done on an individual herd basis by the local practitioner working with on-farm record systems. About 60% of U.S. dairy herds belong to production reporting programs such as DHI. The primary focus of these programs is to collect and collate information to be used in genetic proofs of dairy sires. Although genetic progress and production is assessed and compared across herds through the use of DHI systems, a comprehensive system to collect and collate health information has not been devised. On-farm disease reporting is tremendously difficult because of issues such as case definition, the recording of recurrent disease, and the determination of at-risk populations. Many farms have only handwritten record systems, and some do not identify all the animals with unique identification. Attempting to introduce monitoring programs in herds that are lacking proper cow identification or record systems can be extremely frustrating. Dairy record systems are addressed in Chapters 3 and 7, but the importance of a complete record system cannot be overemphasized. The existence of a record system does not always lead to information that is useful in making management decisions. For a record system to be used, there must be a method to routinely summarize pertinent production and disease indices and a forum for discussions between the practitioner and the farmer. Ideally, a method of benchmarking herd performance against peers should be available. In some instances, data from regional or national databases can be used if local data are not available.

Most countries with developed dairy industries have some sort of surveillance system based on collecting farm level data from a selection of farms and extrapolating that information to the U.S. herds. In the United States, NAHMS is an active surveillance system, based at the farm level, with the goal of generating data for statistically valid estimates of incidence and prevalence and costs of various diseases of livestock and poultry (Kaneene and Hurd, 1990; Hurd and Kaneene, 1990). NAHMS data are useful for identifying overall industry trends but are generally too

Downloaded from Vet-eBooks.com

far removed from an individual farm to be used as benchmarking data.

In Canada, a variety of farm surveillance programs are in use. The Animal Productivity and Health Information Network (APHIN) was established at the Atlantic Veterinary College in Charlottetown, Prince Edward Island (Dohoo, 1992). The Quebec Dairy Herds Health Improvement (ASTLQ) Project (Bouchard et al, 1997) was established with the following objectives:

1. To build a data bank in animal health for dairy cattle.
2. From the data bank to calculate health indices and associations between reproduction, production, disease, and culling.
3. To compare herds with regard to the indices calculated and to classify them as "healthy" or "sick."
4. To create tools to calculate and interpret the indices.

The programs just mentioned have been useful tools for farmers, veterinarians, and other consultants and have contributed to the enhanced decision making for farms served by the programs. It is likely that Internet-based database systems that are constantly accessible to farmers and their consultants will replace most existing systems in the near future. Internet-based systems have an advantage in allowing data entry on the farm and allow for multiple access to real-time data.

The access to farm-based information is the foundation of a sound production management and health program. The ability to access farm data quickly and easily enhances the likelihood that realistic data will be used in the problem-solving and decision-making process. As local systems become available, farm benchmarking can be a valuable tool for motivation of dairy clients.

ROLE OF THE HEALTH MANAGEMENT PROGRAM

The adoption of preventive health care programs for dairy herds has been promoted for at least 25 years. The desire to continually improve efficiency and the recognition of disease as a contributor to reduced productivity are the primary reasons that many herds have adopted health management programs. The universal goal of health management programs should be to assure the optimum care and well being of the dairy animals and therefore to reduce losses in productivity caused by disease and management errors. The provision of these conditions is expected to lead to profitability for the dairy business and ultimately to contribute to the well being of the farm owner and employees. The veterinarian delivering health management programs will likely fill a variety of roles depending on the interests, expertise, and availability of other local experts. Multiple resources such as specialized extension services, industry personnel, and private consultants are available to dairy producers in some regions. In other regions, the dairy industry infrastructure may not be as developed and the local veterinary practice may be the primary provider of many services. Regardless of available resources, the scope of the dairy health management program can be extensive (Fig. 6-6). In some instances the veterinary practitioner may be both the initiator and the deliverer of services. A typical example would be an assessment of herd reproductive status leading to the adoption of a reproductive management program. In other instances the veterinary practitioner may serve as the coordinator of services from specialized consultants or industry personnel. An example of such a role is when the veterinarian routinely reviews feed delivery programs of rations developed by a specialized dairy nutritionist. Some veterinarians also play the role of "animal experts" in health management programs when the farmer deals with non-farm-based consultants such as bankers, architects, or environmental assessment personnel.

Virtually all dairy farms have some contact with veterinarians. Veterinarians are a well-regarded source of information for health care decisions. Of dairy producers surveyed for the NAHMS Dairy '96 study, 78% regarded the veterinarian as a very important source of information for health care decisions. Only 2.3% of producers considered veterinarians as not being an important source of health care information. Nutritionists were the next most important source of health care information, but only 39% of producers considered them to be very important and 27% considered them as not being an important source of health care information. Veterinarians are a frequent presence on dairy farms, and the frequency of farm visits increases as herd size increases (Fig. 6-7). The frequent presence of veterinary practitioners on dairy farms is unique among agricultural professionals and gives veterinarians an advantage in understanding farm processes and personnel.

Although health management programs have been promoted for a number of years, the primary use of veterinarians by dairy producers continues to be individual animal care. In the NAHMS survey of dairy producers, the top five reasons veterinarians visited farms were: (1) individual animal diagnosis and treatment (listed by 96% of respondents); (2) provision of drugs and vaccines (88%); (3) vaccination consultation and services (77%); (4) reproduction consultation and services (74%); and (5) herd diagnostic services (51%). Only 27% of producers listed nutritional consultation and only 14% listed housing or ventilation as reasons for veterinary visits.

Considerable evidence exists that the delivery of health management programs remains a growth area for many dairy practices. The adoption of many routine preventive health care practices by dairy farms continues to be below expectations. Adoption rates of a number of practices were reported for U.S. herds (NAHMS, 1996). In spite of almost universal promotion of many routine mastitis control procedures for over 25 years, only 77%, 58%, and 89% of farms reported the use of universal dry cow therapy, premilking teat dipping, and postmilking teat dipping, respectively. Only 71% of farms reported that all antibiotic treatments were recorded. Universally recommended practices, such as dipping navels of newborn calves and vaccination against BVD, were reported by only 53% and 71%, respectively, of overall survey respondents.

A survey of veterinarian and producer perceptions regarding herd health services was performed in Saskatchewan, Canada (Giger et al, 1994). Farmers that identified themselves as participating in herd health programs had more frequent, regularly scheduled visits by veterinarians to their farms compared with herds that did not participate in herd health programs. Producers that participated in herd health programs indicated that they received more advice and services in areas of reproduction, nutrition, and mastitis control compared with farmers who were not enrolled in a herd health program. Reproductive services were considered to be the major component of the herd health program. This finding agrees with studies performed earlier (Goodger and Ruppanner, 1982; Wise, 1987) showing that reproductive services were the primary component of herd health programs. There is some indication that a gap exists between the perception of services offered by veterinary clinics and the perception of services received by producers. In the Saskatchewan survey the veterinary clinics indicated that they offered "fairly comprehensive" nutritional services, whereas the producers indicated that they only "occasionally" received advice on nutrition. A high proportion of farmers (60%) indicated that

Downloaded from Vet-e-Books.com

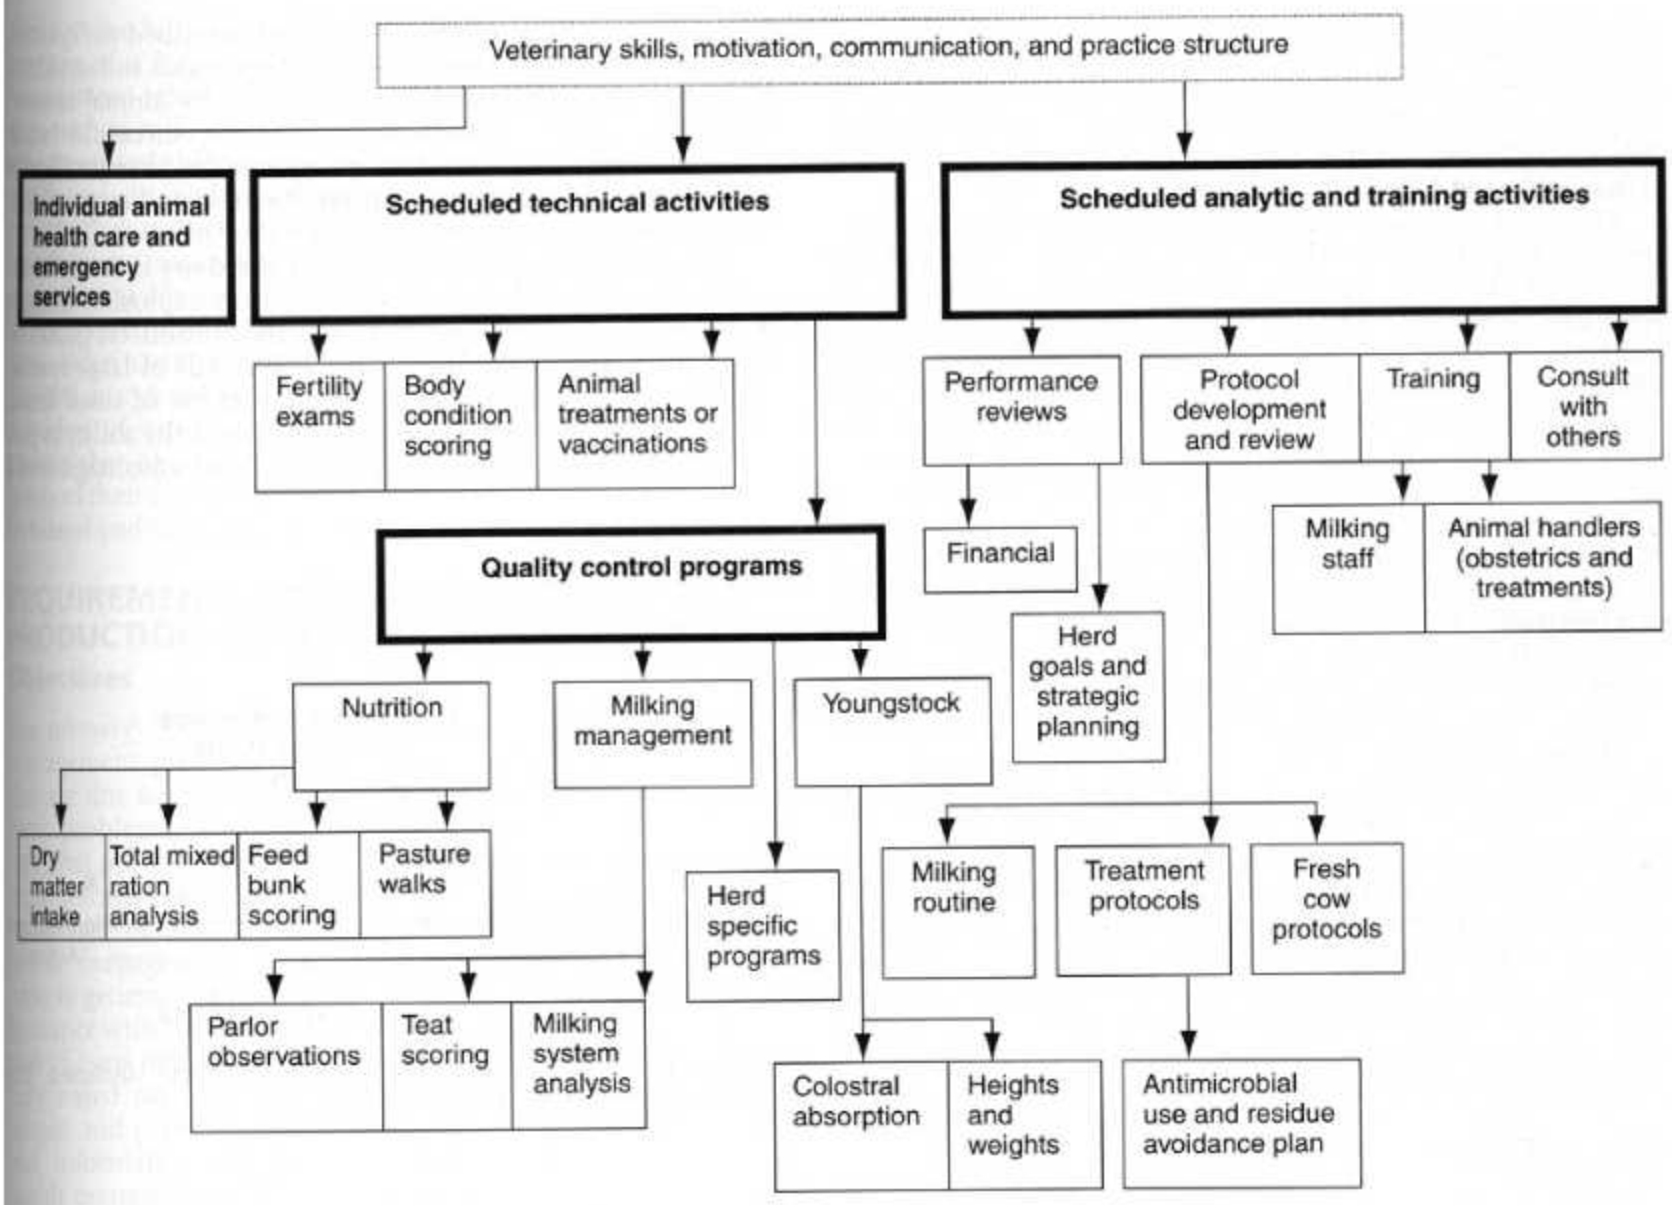

FIG. 6-6 Components of a dairy health and production management program.

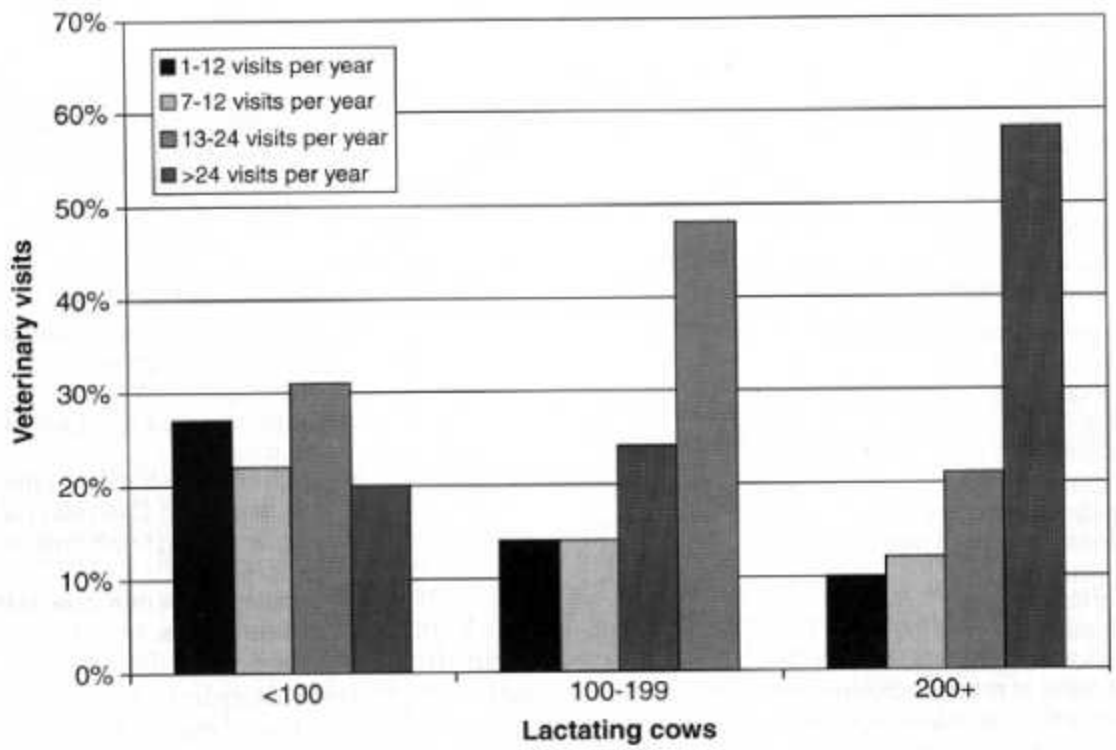

FIG. 6-7 Frequency of veterinary visits to dairy farms by herd size.

Downloaded From Vet-eBooks.com

their veterinarian was rarely or never involved in the analysis of herd records. This finding agrees with a survey of progressive Wisconsin dairy farmers involved in a milk quality management program (Ruegg, 2000). Only 40% of the herds in this survey indicated that they routinely consulted their veterinarians regarding milk quality.

The slow uptake of health management programs appears to be an issue in developed dairy regions throughout the world. In the United Kingdom a survey of veterinary practices indicated that the practice operators considered herd health programs very beneficial, but only about a third of the practices were offering them (Wassell and Esslemont, 1992). The lack of farmer motivation was the primary reasons listed for the lack of adoption of these programs. Farms were more likely to adopt herd health programs when a disease or fertility problem existed on their farm. These findings emphasize the importance of communication and marketing skills as a component of the skill set of veterinarians involved in health management programs.

A health management feedback cycle consists of an interrelated series of events and decisions based on the acquisition of performance data, the analysis of the current status of the herd, and resulting actions to correct or prevent problems. The health management cycle has been described (Fig. 6-8; Fetrow, 1993). A major limitation to the success of many health management programs is a breakdown in consistent implementation of health management plans. One reason that implementation may be difficult is that the successful execution of health management plans is often dependent on the motivation of others rather than of direct actions of the veterinarian themselves (Fig. 6-9). The ability to convince and motivate dairy producers and employees is a function of marketing and effective communication of health management programs. Marketing has been described as "synchronizing the business aspects of his or her goods and services so that they are understood and desired by animal owners" (Herrick, 1989). Veterinarians offering successful health management and production programs are often excellent at understanding the needs of their clientele and communicating the success of the programs that they offer.

The continuing restructuring of the dairy industry in developed countries and the information explosion through the Internet have changed the way that producers gather information and make decisions. The needs of large specialized dairy farmers are different than those of small farms. Large farms tend to have specialized labor, the ability to purchase large volumes of supplies at a cost advantage, and

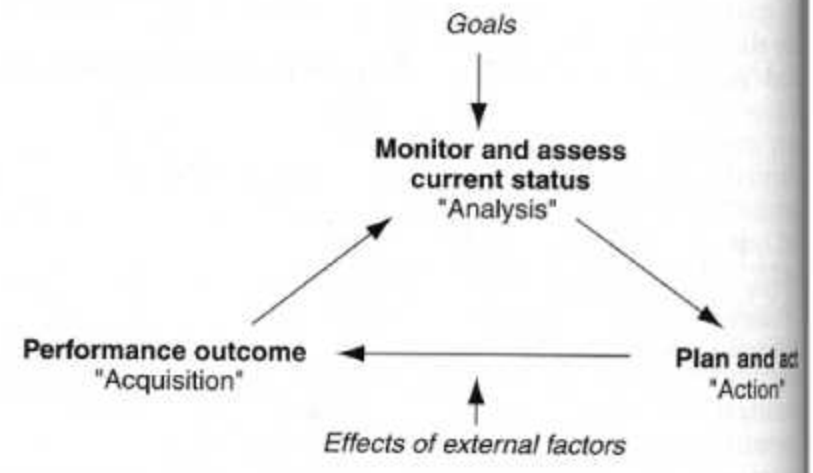

FIG. 6-8 Health management feedback cycle. (Adapted from Fetrow J: *Bov Prac* 27:88-101, 1993.)

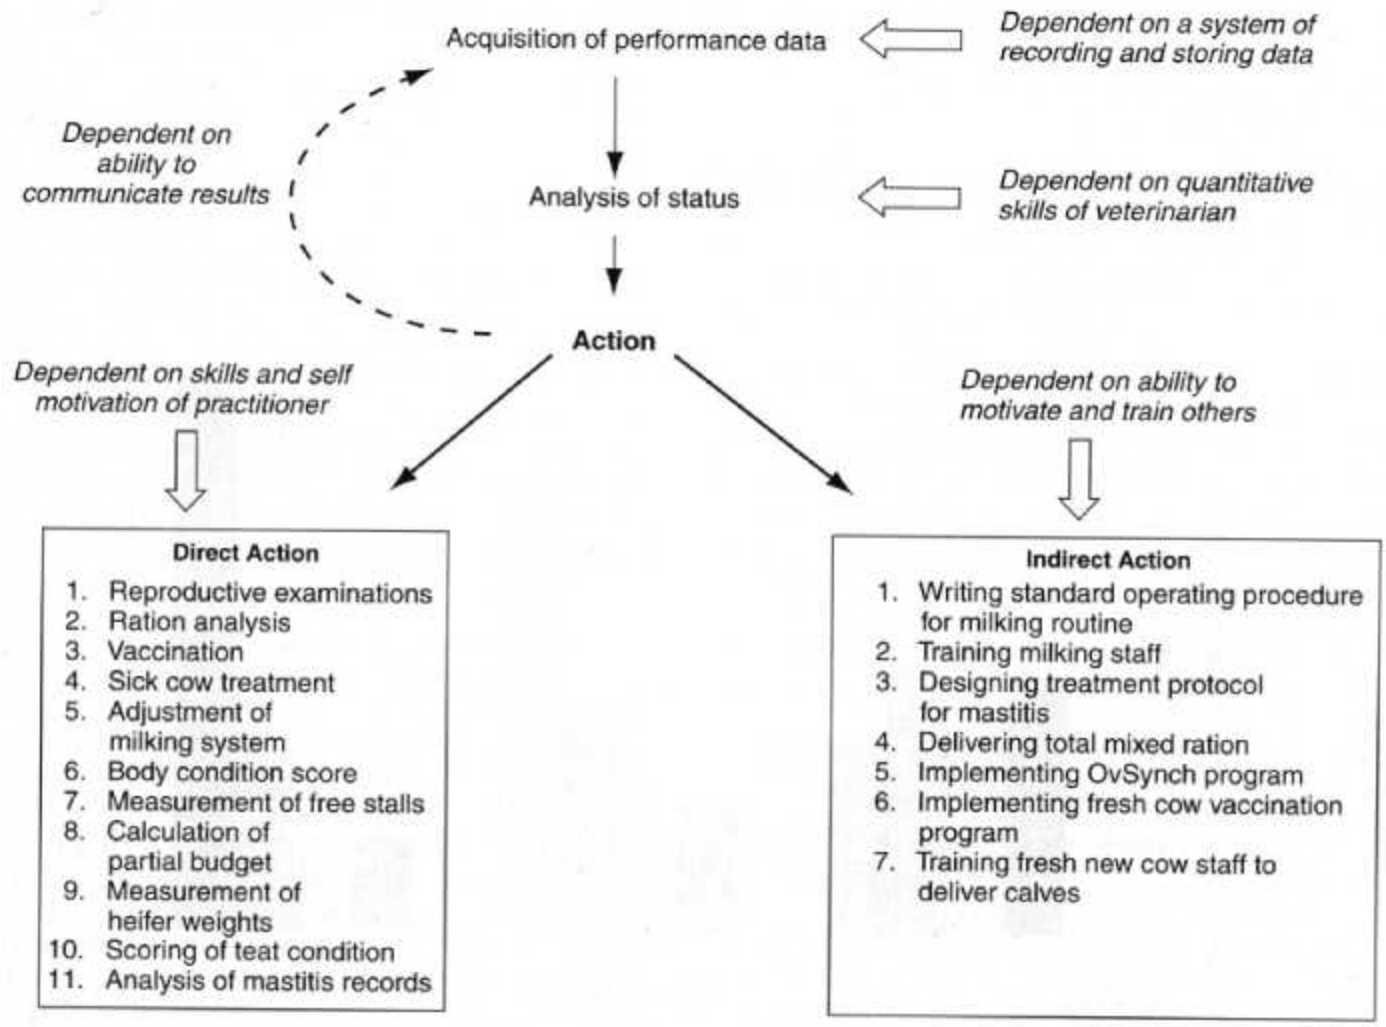

FIG. 6-9 Implementation of dairy health management programs.

Downloaded from Vet-eBooks.com

need for scheduling and consistency (Nordlund, 1998). The operator of a large dairy generally spends more time on management-related functions rather than labor-oriented tasks such as milking. These large producers have considerable access to information about management and animal health and are likely to directly contact recognized subject experts when specific needs arise. Large dairy producers also have frequent contact with industry representatives, including technical service veterinarians and professional nutritionists employed by large feed and pharmaceutical companies. Veterinarians who provide only clinical services directed at individual cows risk becoming marginalized as providers of information and management advice. Veterinarians that have developed specialized skills to meet the needs of their clients are extremely valuable as purveyors of unbiased and objective advice.

REQUIREMENTS OF A DAIRY HEALTH AND PRODUCTION MANAGEMENT PROGRAM

Objectives

The primary objective of a dairy health and production management program is to minimize productivity losses that are due to disease, nutritional disorders, and management problems. An additional objective should be to ensure that preventive health and management practices are economically justified. It is probably safe to assume that all herds can benefit from biologically and fiscally sound health management programs. The health management cycle is generally predicated on comparisons of herd performance with predetermined performance goals. The selection of herd performance goals should be considered carefully based on the farm environment, motivation of the farmer, and presence of adequate resources (labor, capital, and information sources) to succeed. The structure of health management programs is generally unique to each farm but is minimally composed of scheduled herd visits that are usually a combination of routine reproductive examinations, review of selected herd performance records, and decisions and actions related to specific herd management issues.

Targets of Performance

A number of widely recognized performance targets have evolved as industry standards over the years. Examples of such targets are shown in Table 6-5, and more specific descriptions of acceptable performance are explained in individual chapters of this book. The performance targets reflect herd standards of performance that are perceived as indicators of successful herd management. Although there is tremendous value in recognizing these standards, the dairy practitioner needs a thorough understanding of the strengths and limitations of these targets.

Performance targets are useful as comparison values for herd performance and as a starting point to initiate discussions about potential areas for improvement. To use a performance target, it is necessary for a herd to have a record system that allows for the generation of comparable herd indices. The veterinarian must also understand how the targets were calculated and must be able to define the appropriate at-risk population to include in the statistic. An understanding of the inherent distribution and biologic variation of the value is also important. In many instances, performance targets have been calculated as arithmetic averages. Arithmetic averages are useful indicators of herd performance when the contributing data are normally distributed and have a reasonable degree of variation. Many production data (such as milk, fat, and protein yields) meet these criteria. Arithmetic averages of skewed or widely varying data do not adequately reflect herd or group performance. Many reproductive indices and values such as SCCs are not distributed normally, and erroneous conclusions about herd performance may be made if averages alone are used to make management decisions. Appropriate frequency distributions are often much more useful for these type of data.

Performance targets should be reviewed at appropriate intervals with realistic expectations regarding the amount of time it takes to effect change in an index. For example, management actions taken to reduce days to first calving would require at least 9 to 10 months to become apparent. A more timely value such as age at conception would more rapidly reflect current management changes. Performance targets should also be amended periodically as industry conditions warrant.

Performance targets can be used to help generate individual herd goals. Goals should not be imposed by the veterinarian but should be agreed on mutually by farm decision makers. Frequent communication and reassessment of goals is an important component of successful health management and production programs.

Minimal Informational Needs

It is extremely important that a system of unique individual cow identification exists. Without this prerequisite it is impossible for a health management program to succeed. Permanent methods of identification include tattoos, color sketches, and hot and freeze branding. The most common methods of animal identification are ear tags, collars, and branding (hot or cold). Increasingly, farms are using electronic identification through the use of transponders on ankle bands or neck straps. The most common use of transponders is identification of cows in the milking parlor to record daily milk weights. Permanent, unique implantable transponders are available and will likely be adopted eventually throughout the industry. At a very minimum, data must be recorded on birth dates, breeding dates, calving dates, and periodic milk yield data. Under ideal circumstances, summarized data should be available for the nutritional program, disease occurrence, and financial performance.

Record analysis is a necessary component of the health management cycle (Fig. 6-8). A health management program without the inclusion of a system to track the success and failure of management decisions is doomed to failure. Most or all DHI systems now allow for the electronic access to performance data, and a variety of computerized systems for individual herd management are used throughout the industry. In many instances, dairy producers and veterinarians are not effectively using existing information sources. The development of information-guided decision-making habits is one hallmark of successful health management programs.

Characteristics of Participants in Successful Health Management Programs

Although health and production management programs are probably beneficial for all dairy farms, not all dairy producers or veterinarians are well suited for participation in them. The commitment to a successful health management program is somewhat analogous to the adoption of a strategic plan. In a survey of strategic planning by family businesses, four reasons were identified for why most family businesses were lacking one (Klinefelter, 2000):

1. **Requires sharing information.** In many instances the commitment to a health management program requires not

Downloaded from Vet-e-Books.com

only the sharing of information but also creating of a forum that allows for the generation and discussion of appropriate herd information. In many instances the adoption of a health management program will require time dedicated to analysis and discussion of herd management data. For some herds, recognizing the value of paying for consultative time rather than specific tasks (such as fertility exams or individual animal services) is difficult. The investment in a herd management program is a longer term and less obvious investment compared with the immediate returning of learning whether or not a cow is pregnant. For some farmers it is also difficult to share sensitive information about the financial performance of their business, and in other instances farms are lacking necessary data. A good relationship consisting of trust and mutual respect between the herd veterinarian and the farm owner is a necessity for a successful health and production management program.

2. **Requires the senior management to respond to the ideas of others and defend their own ideas.** Ideally, the producer participating in a health management program has clear, long-term goals for their farm that include constantly looking for new ways to improve the efficiency of production while maintaining product quality and animal health. The producer must believe that attaining herd performance goals will increase the profitability of their business. Producers must also believe that their veterinarians have the expertise to be a credible source of information. Excellent herd managers often read about or observe new management practices of their peers and should be willing to discuss their ideas with their veterinarian. Likewise, many dairy producers are extremely innovative, and the herd veterinarian should be willing to listen and effectively respond to their suggestions. One important communication skill of successful dairy veterinarians is the identification of the "teachable moment"—the time when a farm is most receptive to introduction of a new management idea. An example of a "teachable moment" would be deciding when to initiate discussion of a new milker-training program. Producers are likely to be more receptive to such a program if they believe that their herd will show immediate benefit from it. A herd that is experiencing mastitis or increased bulk tank SCC (BTSCC) will probably be more receptive to such a program compared with one that is currently satisfied with their milk quality.

3. **Increases the opportunity for conflict as a result of differences of opinion.** Most dairy farms are family businesses that have evolved based on decisions of a single individual or family partnerships (husband-wife, father-son, or siblings). As farm owners take on new roles related to management, their traditional role of providing labor (such as milking or feeding cows) are often delegated to others. In some instances no clear mechanism exists for feedback from farm staff regarding the impact of health management programs on their daily jobs. The introduction of practices that have to be implemented by farm staff who may not understand or appreciate the reasons behind the action can be frustrating and self-defeating. In these instances, both active (verbal disagreement) and passive (failure to implement a task or quitting a job) conflict may arise. The same scenario can occur when farm owners disagree with the recommendations of the herd veterinarian but do not have a mechanism to disagree. In these instances the veterinarian may believe that the owner has agreed to implement a program, but progress is impeded because of unresolved issues related to unstated differences of opinion.

4. **Requires a commitment to the plan versus the typical entrepreneurial style of keeping options open.** The successful implementation of a health management and production program requires commitment, such as dedication of time, labor, and capital toward implementation of the program. Farmers who say they are committed to a program but do not designate people to specific tasks or spend money on execution of the program are clearly not convinced of its value.

Producer attitudes and long-term goals are extremely important for the success of a health and production management program. It is obviously more difficult to motivate producers who are planning to exit the dairy industry compared with producers with long-term plans to remain within the industry. In fact, the development of a sound exit strategy should be included in health management programs of terminal dairy farms. There are also some conditions that may delay the introduction and implementation of health management programs. It is important to remember that most dairy businesses are based on family management, therefore many personal issues can influence the performance of the dairy farm. Personal issues such as substance abuse, family disagreements (such as divorce or intergenerational issues), or family tragedies (such as accidents or death) are sporadic distractions from management of the dairy for some producers. The veterinarian is usually a member of the local community and therefore should use awareness of such issues when promoting the adoption of health management programs.

In some instances the farmers are fully convinced about the need for a health management program, but other influences may temper their enthusiasm. Sometimes the client simply does not understand the relationship between suggested interventions and the potential outcome. For example, a farmer may not intuitively understand the link between dry cow housing conditions and clinical mastitis in early lactation. In this instance effective education and a mechanism to demonstrate causality are vital to the success of the program. Many farmers are highly kinesthetic and learn best with a hands-on approach. Visits of neighboring and demonstration farms may help these farmers better understand the need to adopt a practice. Other farmers may rely on the experiences of local key influencers to guide their opinions. In this instance a forum for exchanging ideas between farmers must be available. On some farms, financial limitations make it difficult for farmers to justify what they (or their bankers) may view as unnecessary investments. A carefully justified partial budget may help convince the farmer or the financial partner of the need for a program.

In general, farmers who are successful in implementing health and production management programs are generally numerically literate and business oriented. These farmers are usually willing to listen to advice and make informed decisions based on all available evidence.

Enthusiasm and Competence of Dairy Veterinary Practitioners

The skills and enthusiasm of the veterinary practitioner are an integral component of the health management program. Veterinarians who are successful in offering health and production management programs have to believe they have something to offer the farmer, have the time and ability to offer it, can make a convincing case of its value, and are able to know when to modify practices. Production-oriented dairy practitioners needs to be able to expand the focus of the knowledge and skills that they have already acquired and be able to generate enthusiasm and commitment from their clients for intervention in areas that their clients may not recognize as problems. Health and production management programs are most successful when the skills and motivation of the veterinary practitioner are equally matched by those of the producer (Fig. 6-10). When the skills and

Downloaded From Vet-eBooks.com

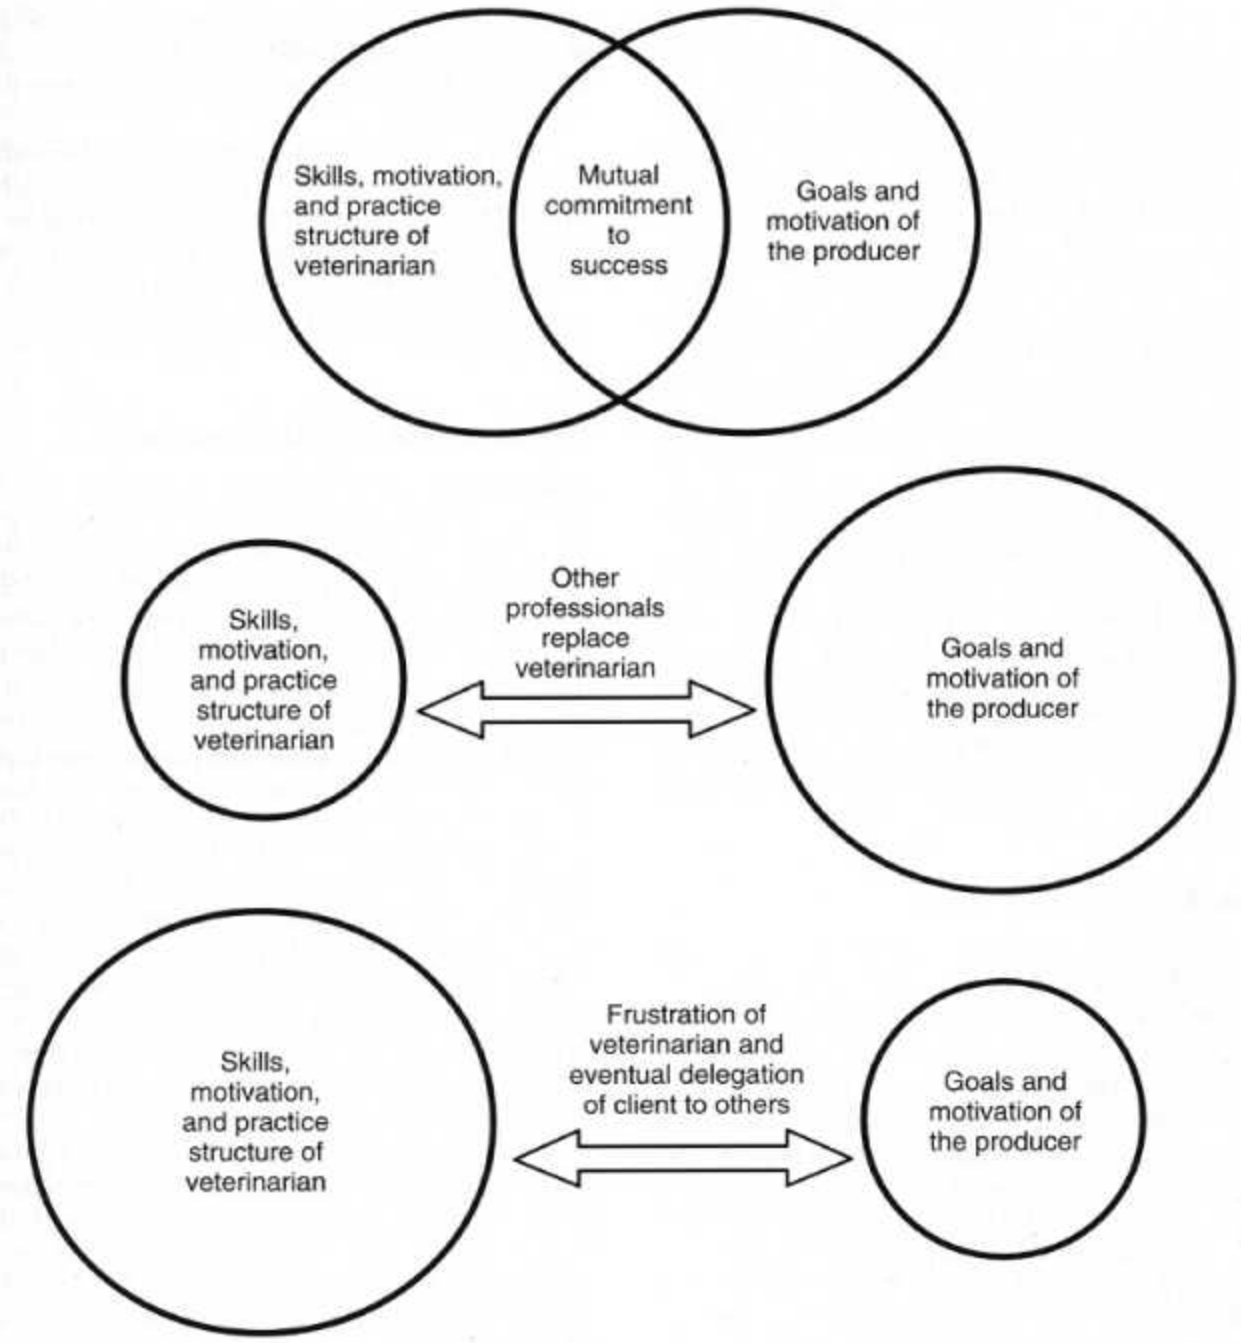

FIG. 6-10 Influence of veterinarian and producer skills and motivation on success of health and production management programs.

motivation of the veterinarian exceed the goals and resources of the producer, the veterinarian will likely feel frustrated and reduce their commitment to the client, sometimes eventually delegating the client to other veterinarians or agri-service professionals. On some farms the producer goals exceed the capabilities (either knowledge or time) of the veterinarian with whom they work. In this instance the producer will likely identify other professionals to supply the desired services.

Clients expect dairy veterinarians to be extremely competent in traditional skills involving diagnosis and treatment of individual animal disease. They also expect the veterinarian to be highly skilled at reproductive examinations and to be able to perform many routine technical tasks such as obstetrical procedures. Veterinarians who offer health and production management programs must also acquire a range of knowledge that extends beyond traditional veterinary skills. Knowledge of the principles of dairy cattle nutrition, milk quality and milking systems, reproductive management, and housing systems—and an understanding of the dairy industry itself—are essential. The dairy veterinarian needs to understand how to acquire and analyze appropriate data and how to communicate its value. The veterinarian must also have an appropriate mechanism for charging clients for time spent on analysis and consulting rather than procedures or services. Another important attribute of veterinarians who offer successful production and health management programs is an ability to communicate with other agri-service providers. This attribute is especially important as farms enlarge and acquire more specialized consultants. Gaining the mutual respect of other agricultural professionals is an excellent mechanism for building a reputation within the dairy community.

SYSTEMS FOR MONITORING HEALTH AND PERFORMANCE

The basis of a health and production management program is the use of a record-keeping system that allows for easy acquisition and analysis of data. Data that are not measured, recorded, and accessible cannot be used in management of the herd. In most instances the record system must be able to chronologically record individual animal events such as calving history, disease events, treatments, reproductive events and examinations, and animal characteristics such as BCS and SCC. The details of record systems are described in Chapter 7. The choice of a record-keeping system tends to vary by farm size, the level of producer education and

Downloaded From Vet-eBooks.com

computer literacy, and the availability of a critical mass of users and support staff within a given region. Most monitoring systems can be characterized broadly as one the following: (1) manual (handwritten) card systems, (2) on-farm computer programs, (3) DHI, or (4) DHI and on-farm computer. Regardless of the type of system used by a farm, the monitoring system should meet certain criteria. A comparison of the relative strengths of the various types of systems is presented in Table 6-8. Ease and timeliness of data entry are important so that the monitoring system remains relevant to the day-to-day operations of the dairy. One important function of record systems is the generation of action lists (due to calve, due to dry, etc.). This function is critical in large herds in which cattle are not individually known by the animal handlers and can be overlooked easily. Most systems also provide for a minimal level of herd analysis, such as the generation of timely performance reports for production, reproduction, and disease. Some programs can also generate statistics, such as medians, standard deviations, regression analysis, and process control charts, which are useful for herds that desire advanced analytic capabilities. It is important for the record-keeping system to be flexible and allow the producer and veterinarian to understand and modify the formulas that are used to generate herd performance indices.

Handwritten Card Systems

Handwritten record systems that use individual cow cards for each animal are the most common record system for many small farms. In these systems, each cow has her own card on which events such as calving, breeding, disease, reproductive examinations, and other items are entered. This basic system has been sufficient for many small herds for a number of years because of the relatively small amount of data to be recorded, summarized, and reported. Data entry using these systems is simple, especially for events related to reproductive examinations or treatments, because the producer usually simply carries the card to the cows and records the information as it is generated. The generation of action lists requires a manual examination of each cow card and is generally performed by the producer before herd visits. It is difficult for veterinarians to access data and to generate reports or assess problem areas because there is usually only one copy of the data and the producer needs to maintain the data on the farm. The generation of herd-level indices for benchmarking is also difficult because of the amount of time required to assess each cow card physically.

A lack of farmer motivation and difficulty in demonstrating financial benefits of the program has been identified as one reason that farms do not participate in structured health management programs (Wassell and Chamberlain, 1994). The inability to summarize herd records easily on farms with manual record systems probably contributes to this problem.

On-Farm Computer Systems

Computers were originally used on farms in bureau-type systems designed to provide the veterinary practitioner with a database from which to generate selected indices and herd summary data. Bureau systems required farmers to record data on paper record sheets that were picked up by the veterinarian or a technician. The data were entered into centrally located mainframe computers. Much like the DHI systems of the time, these programs were developed to allow the veterinarian to generate paper reports that could be discussed with the producer each month. Some systems, such as DAISY (Stephens et al, 1979) and FAHRMX (Bartlett et al, 1986) were used to build databases for epidemiological research about disease. Although a tremendous amount of information about disease and performance was learned from these systems, the lack of timely turnaround has limited the widespread implementation of these programs. Bureau and on-farm systems were compared on Ontario dairy farms (Menzies et al, 1988). Farmers invested more time and generated more information with computers located on farms than with bureau-based systems.

The next generation of herd management software was developed to be used on microcomputers located at the farm. Programs such as VAMPP (Noordhuizen et al, 1986), DairyCOMP 305 (Goodger, 1987), and DairyCHAMP (Udomprasert and Williamson, 1990) continue to be developed and used on many farms throughout the world. Veterinarians and consultants also use numerous spreadsheet and goal-setting programs.

In 1996 computers (on-farm or bureau systems) were used to manage about 50% of U.S. cows (NAHMS, 1996). A variety of systems are available, including systems for indi-

vidual cow management (i.e., dairy herd management software), herd or group management (parlor management software or nutritional software), financial accounting systems and communication packages for Internet access. Individual cow management programs are generally organized like handwritten records with computerized cow cards available to record events and items for each animal. Computerized record systems have advantages over handwritten records in virtually every facet with the exception of data entry. Farms that use computers have been demonstrated to produce more milk compared with herds not using computers (Losinger and Heinrichs, 1996).

Differences exist among the software packages that are currently marketed, and the farm owner should select a program that meets his or her management needs, level of computer literacy, and projected future requirements. The herd veterinarian is often faced with using computer programs on different farms. The practitioner must understand the formulas used in the various programs and assist the producer in proactively defining appropriate indices to monitor herd performance.

Dairy Herd Improvement Association Recording Systems

DHIs began as milk-recording systems set up to provide for comparisons of performance among offspring of service sires used in AI programs. For over 50 years these programs have contributed greatly to genetic progress and productivity in developed dairy regions such as Canada and the United States. The generation of bull proofs remains an important function of these organizations, but they have evolved to be the major provider of management information for about 60% of all dairy farms in the United States and Canada. Another function of DHI systems is to provide data for research and extension programs to foster improvements in the efficiency of production.

DHI systems are based on accurate cow identification, periodic (usually monthly) measures of individual cow yield and components, and recording of appropriate events and items. The data are collected on the farm by a DHI technician or sent electronically to a centralized database, and the amount of information sent to DHI varies by farm. The farmer receives reports with herd summary information. On most farms, milk weights and individual cow data (such as calving and breeding dates) are entered directly into notebook computers and a report is generated before the technician leaves the farm. More extensive reports incorporating component and SCC data are sent after the milk samples have been processed at a central laboratory.

Assuming that data have been recorded and entered accurately, the data submitted to DHI can be used to generate numerous herd reports. Farmers receive a variety of reports depending on their interests and the DHI system to which they belong. Summary reports, action lists, and individual cow data are available. Typical data on a standard herd summary report may include the following:

1. Daily average milk, fat, and protein yields
2. Standardized herd performance measures, such as management level milk or 150-day milk
3. Fat and protein percent
4. Production, income, and feed cost summary
5. Yearly rolling herd averages (RHAs) (milk, fat, and protein)
6. Summarized test day averages for past 12 months
7. Times milked
8. Days in milk
9. Length of lactation
10. Average number of days dry

Reproductive summary data generally include these estimates :

1. Days open to first service
2. Distribution or mean number of days to conception (usually by parity and stage of lactation)
3. Conception rate or services per pregnancy
4. Calving interval and/or projected calving interval
5. Heat detection indices

Herd summary data are usually also available for subclinical mastitis (based on SCC data), heifer management, and genetic progress. Individual cow reports are also available.

Most DHI processing centers have developed programs that allow for the electronic exchange of data and the generation of customized reports. Both commercial and proprietary herd management software can be used to interact with most DHI processing centers. Producers that wish to use the DHI herd management software can enter data directly into their farm computers, transmit the data online to a centralized database, and design and receive customized action lists and reports. In many systems it is also possible to compare herd performance with anonymous peer herds. Web-based systems are also available. These systems have greatly improved the timeliness and usefulness of DHI data. Veterinarians and consultants can access the data and generate reports before herd visits. The ease of data access and report generation allows the development of easily sustainable health- and performance-monitoring programs. The combination of a farm-based computer for daily data entry and the centralized DHI database for herd comparison can be a powerful tool for the dairy practitioner interested in optimizing health and performance of dairy herds.

Use of Computers in Health and Production Management Programs

Computers are an integral component of the health management feedback cycle, and the use of computers enhances the ease and sustainability of most health and production management programs. Veterinarians have a role in assuring accurate data acquisition, focused and useful herd analysis, and knowledge-based management action. The acquisition of data without analysis or action is a waste of resources and is usually unsustainable. The dairy veterinarian who wishes to have an impact on herd performance recognizes that the key to motivating accurate data collection is the use of the data to stimulate action and improve herd performance. One role of the veterinarian is to ensure that collected data are used in a timely manner. The veterinarian not only uses data but also generates data. Therefore the veterinarian can set a good example by recording or entering diagnosis and treatment data into the appropriate record system whenever possible. Accurate data collection is most likely when the producer is using the data frequently and understands its value. The veterinarian should not generate excessive data for which they do not have a system of summarization and reporting. Although many aspects of data acquisition are still based on manual recording systems, automated data collection systems are increasingly used. Automated data collection systems are currently used for collecting individual cow data on milk yield (periodic or daily), conductivity (for mastitis detection), and cow activity (pedometer data used for heat detection). Mottram (1997) projects that automated systems will be used in the future to monitor health and metabolic status of dairy cows. On some larger herds automated collection systems are used to summarize group or herd data, such as parlor performance (milking unit attachment time, milk flow rates, etc.) and feed delivery. It is important for the dairy

Downloaded from Vet-eBooks.com

veterinarian to be involved actively with the purpose and function of data collection systems. The veterinarian should review and critically assess the validity of data generated from both manual and automated data collection systems. Knowledge of the accuracy of data collection is useful, and veterinarians should feel comfortable challenging unusual results. For example, when deviations from daily milk yield are used to identify cows for examination, the accuracy of cow identification by the automated identification systems should be known. Unless the farmer is convinced that the data have been collected accurately, analysis based on the results will always be suspect.

Data analysis is the basis of dairy health and performance management programs, but the veterinarian should be judicious in presentation of reports to the dairy producer. The herd evaluation system should be designed to reflect the shared performance goals of the dairy and to detect deviations from performance targets. Computer-generated data are often used for analysis of performance areas. Ideally, the following cycle occurs:

1. The farmer and veterinarian set performance targets based on industry goals, the herd situation, and the resources of the dairy. In most herds, performance targets should be defined for milk yield, reproductive performance, milk quality, replacement management, cow removal, and animal health. Additional specific performance targets such as financial performance may be included on some herds.

2. A system of assessing key indicators for the performance targets should be defined. The monitoring system should specify the indices used, the animals included, and the time interval for reassessing progress made toward reaching each target. When data is available, it is probably useful to review some data (such as daily milk weights or dry matter intakes) more frequently than once a month, depending on the schedule of routine herd visits. Time should be dedicated specifically to review of data. Veterinarians who have remote access to data may wish to generate and review reports before visiting the herd, but it is important that both the producer and veterinarian have similar expectations regarding the importance of herd performance monitoring. Specific details on each area of performance are described within the appropriate chapter of this book, but a summary of some typical performance indicators routinely generated by computers is included here:

a. Milk production. Milk yield per cow per day on either a daily or monthly basis is usually used as the primary indicator of herd productivity. Most computer programs further define milk yield by parity and stage of lactation, and most can generate individual cow and group lactation curves. Lactation curves are useful to visual performance, but they should not be overinterpreted. Differences in the number of animals contributing to points of the lactation curve and innate variation can contribute to erroneous interpretation of the results. Peak milk yield occurs for most cows at 40 to 70 days after calving. Assessing peak milk yield allows assessment of dry cow and fresh cow management. A prediction of total lactation yield can be made by multiplying peak yield (in lb) by 220. For example a cow producing 100 lb of milk at peak would be expected to produce 22,000 lb throughout her lactation. Milk yield data are most useful when they are current and reflect specific management changes. Milk per cow per day responds rapidly to on-farm conditions such as feed changes or environmental extremes. It is generally useful to also monitor long-term trends in milk yield through the use of RHAs. RHAs carry tremendous momentum and should not be relied on to assess current conditions, but they can indicate past performance and long-term trends. Adjusted milk yields such as adjusted corrected milk, 150-day milk, or management level milk are also useful to remove biases introduced by changes in herd composition or stage of lactation. Milk components should also be monitored, since they are an important part of overall productivity and can reflect dietary changes.

b. Reproductive performance. In general, key current indicators of fertility include the calving-to-conception interval, the interval from calving to first service, conception rate, pregnancy rate (defined as the conception rate times the percent of eligible animals bred within a defined time period), heat detection, and reproductive cull rate. These values are often assessed by parity. While averages have been the traditional method of assessing these values, the use of flexible computer programs has increased the number of consultants who are reviewing and setting goals based on the distribution of values. The most effective herd monitor is one that rapidly reflects a breakdown in the system. The need to wait for 21 to 35 days after breeding for expression of estrus or confirmation of pregnancy creates a lag period between action and analysis for most reproductive statistics. Some reproductive statistics, such as days to first service calculated for animals receiving a first service in a defined time interval, are rapid reflections of herd status. Veterinarians who introduce programmed breeding systems relying on injections of gonadotropin-releasing hormone and prostaglandin (described in Chapter 7) should critically evaluate the success of these programs on a regular basis through the use of appropriate monitors such as pregnancy rate.

c. Milk quality. The BTSCC is a key indicator of milk quality and should be reported frequently to ensure that subclinical mastitis outbreaks are detected in a timely fashion. The dairy practitioner should recognize that BTSCC does not reflect the incidence or prevalence of intramammary infection within the herd; therefore a summary of individual cow SCC values by stage of lactation and parity is necessary. It is well known that individual cow SCC values are not distributed normally, so the use of linear scores should be encouraged. Computer reports that indicate the new rate of subclinical infections are useful for detection of developing problems. Many reports include a summary of the rate of clinical mastitis. The veterinarian should be cautious in using this data without validating its accuracy, since many farms do not record all detected mastitis.

d. Replacement management. Diarrhea and respiratory disease are the most significant diseases of calves and should be monitored continually. A consistent mechanism for entry of disease and death events is often lacking for youngstock. Calves are generally housed in separate facilities or removed to dedicated calf-rearing businesses. The use of remote data entry can be helpful to overcome some of these issues. Age and weight at breeding and conception are useful summary data for monitoring programs but require dedication to the system of data entry. The age at first calving is often included in monitoring programs but is simply a long-overdue reflection of the success or failure of past efforts.

e. Cow removal. The herd veterinarian should frequently assess both the rate and reasons for cow removal. Cows are often culled for multiple reasons, and the on-farm computer may not accurately reflect underlying causes. For example, a cow may be listed as culled for low production, but in reality the low production may be a consequence of an extended calving interval because of infertility. The rate of adult cow mortality should also be monitored, since a high cow mortality rate is the effect of inadequate disease detection systems.

f. Animal health. Rates of the most common preventable diseases of dairy cows (milk fever, DA, ketosis, dystocia, retained placenta, lameness, metritis, and abortion) can be summarized easily with computerized herd programs. The veterinarian should advise the farmer about case definitions and appropriate at-risk populations to include in the statis-

Downloaded From Vet-eBooks.com

tics. The definition of the at-risk population used to monitor these diseases is critical to ensure that the statistic sensitively detects changes in the incidence of disease.

g. Special reports. The veterinarian may generate a more detailed report specific to an identified problem. For example, a summary report looking for risk factors for clinical mastitis or DAs may be appropriate to generate if herd indices indicated unacceptable performance in these areas. Additional reports summarizing breeding performance or annual trends may be generated periodically.

3. The producer and the veterinarian agree on defined actions. Actions should be justified based on the herd status and goals. Actions are generally diagnostic, preventive, or treatment oriented. Computers are often used to generate the action lists. Typical activities could include: generation of lists of animals for routine herd fertility exams, examination for illness, selection of cows to obtain milk samples for culture, animals to vaccinate, animals to consider culling, animals to breed, animals to receive BCS, or animals requiring treatments. At this point the cycle repeats when the results of the actions are entered into the computer program.

COMPONENTS OF A DAIRY HEALTH AND PRODUCTION MANAGEMENT PROGRAM

There is considerable variation in the structure of dairy health and production management programs. Numerous dairy practices offer comprehensive health and production management programs that are successful and sustainable. Other practices struggle to define and provide programs that extend beyond routine technical services offered on a monthly basis. In most instances modern health and production management programs have slowly evolved from "herd-health" programs that were focused on rectal palpation. Many informal discussions about diverse management issues occurred over the backs of cows during these early programs, but these programs generally lacked explicit goals and veterinary compensation because management advice was often captured indirectly through the sale of pharmaceutical products. While some programs are still offered in this fashion today, the most successful health management programs offer comprehensive services across a spectrum of dairy herd management (Fig. 6-6).

Regularly Scheduled Farm Visits

The basic structure of the health management program includes scheduled herd visits by the dairy veterinarian. The frequency of scheduled visits is variable and somewhat dependent on herd size. In herds of less than 100 cows, one or two cows calve every week and a single scheduled monthly visit is probably appropriate. These herds may have more unscheduled visits for examination of sick cows compared with herds that are visited more regularly. Larger herds that are calving cows on a daily basis warrant more frequent visits, and weekly scheduled visits are not uncommon for herds of more than 200 cows. A developing trend on extremely large dairy farms (more than 2000 cows) is the employment of a staff veterinarian to oversee and direct day-to-day issues regarding health and performance. The frequency of scheduled herd visits for grass-based seasonal dairy operations varies depending on the stage of lactation of the herd. More frequent visits are necessary in early lactation and during the breeding period of these herds.

Activities at Scheduled Visits

Activities at herd visits fall into four general categories (Fig. 6-6). The foundation of successful health management programs is excellence in provision of *individual animal health care and emergency services.* The remaining activities are grouped as *scheduled technical activities, scheduled analytic and training activities* and the provision of *quality control programs.* The frequency of individual activities will vary, but a schedule defining the minimum suggested frequency is shown in Table 6-9.

TABLE 6-9

*Suggested Frequency of Scheduled Herd Activities for Health and Production Management Programs**

Frequency of Activity	Activity
Weekly or biweekly	Individual animal care and treatment
	Fertility examinations
	Body condition scoring
	Collect diagnostic samples (California Mastitis Test results; milk samples, calf serum, etc.)
Monthly	Dry matter intake
	Feed bunk scoring
	Pasture walks
	Total mixed ration analysis
	Targeted performance reviews
Quarterly	Protocol development and review
	Training sessions
	Consultation with other farm advisors
Semiannually	Parlor observations
	Teat scoring
	Review of financial analysis
Annually	Strategic planning and goal setting
	Milking systems analysis during milking (should be much more frequent for larger dairy farms)

*This schedule is representative of a schedule for a middle- to large-sized dairy and should be amended for individual farm conditions.

Downloaded from Vet-eBooks.com

Individual Health Care and Emergency Services

The provision of traditional veterinary skills involving examination and treatment of animals is an important activity during scheduled visits to the dairy. A frequent schedule of herd visits allows the practitioner to examine cows early in the course of disease when the likelihood of successful treatment is higher. Routine visits also allow the veterinarian to monitor the outcome of treatments and modify treatment protocols as needed. Ideally, the monitoring program includes a system to detect cows that are not performing as expected. Special emphasis should be directed toward the highest-risk cows, including frequent observation of animals during the periparturient period. On small dairy farms, the farm owner is often familiar with individual cows and observes behavioral changes, such as reduced milk yield, anorexia, or lethargy. As farm size increases, it becomes less likely that individual cow behavioral changes will be noticed. In these herds computer-generated lists may be used to select cows for examination. The computer may flag cows that reduce activity (when pedometers are used) or exhibit large drops in daily milk yield. On many large dairy farms an animal handler is assigned to work directly with the group of animals that have recently calved. Some farms have adopted a system that includes routine daily monitoring of body temperature and rumen activity of cows during the first 7 days after calving. Animals that fall outside of normal limits are treated according to predefined criteria or detained for examination by the herd veterinarian. All treatments administered to dairy cows should be recorded in treatment logs (either computerized or handwritten) to assure adherence to proper meat and milk withholding periods.

The frequency of unscheduled visits for emergency medical services usually diminishes on herds that have adopted a health and production management program. In many instances the herd veterinarian trains the producer or animal handler to administer a standard treatment for common diseases. On large dairy farms many animal handlers become proficient in routine activities such as intravenous treatments or simple obstetrical procedures. On these farms the veterinarian should develop a system for staff training and evaluation.

Scheduled, Traditional, Technical Activities

Routine reproductive examinations continue to consume a considerable amount of the veterinarian's time during scheduled herd visits. Attaining reproductive success is an essential determinant of herd productivity. Reproductive programs are fully described in Chapter 7, but it is useful to be reminded that the end point of fertility examinations should be to generate data that can be used to determine the success or failure of breeding programs. The implementation, success, and cost-effectiveness of scheduled breeding programs should be reviewed frequently. It is also common to monitor the effect of the nutritional program by recording BCSs for selected animals. BCSs drop rapidly after calving, reach a nadir by 50 to 80 days after calving, and gradually increase throughout the rest of the lactation (Ruegg and Milton, 1995). BCSs are a good indicator of how the delivered diet meets the energy needs of the cows. While the process of body condition scoring focuses attention on the nutritional adequacy of the diet, a mechanism of summarizing BCS for groups of animals is necessary for full use of the data.

On smaller farms, it is often customary for the veterinarian to perform routine individual animal treatments (such as intravenous injections), prophylactic activities (such as vaccinations) and some technical tasks (such as dehorning calves) during scheduled herd visits. It is appropriate for the veterinarian to perform these tasks because the farm staff may not do the tasks often enough to become technically proficient. On many larger farms these tasks may be performed on a daily basis and animal handlers may become quite competent.

Quality Control Programs

Programs that involve activities directed toward "quality control" are an additional subset of scheduled technical activities. "Quality control" refers to activities that ensure consistency in carrying out key management processes. Vital management areas for most herds include nutritional management, milking management, and youngstock programs. Some farms may also develop quality control processes for environment and housing and farm-specific management of breeding bulls.

Nutritional Management

Advising farms about nutrition is a key activity for dairy cattle practitioners. Feed costs constitute approximately 60% of the total cost of producing milk, and even minor improvements in feeding efficiency can be profitable (Ferguson et al, 1987). Some dairy practitioners function as the nutritional specialists for the dairy farms they serve. They may collect feed samples for nutrient analysis, formulate rations, and advise the farmer regarding crop and harvesting conditions. These veterinarians often devote a considerable amount of their professional time to nutritional management. Chapter 11 describes nutritional management in great detail.

It is common for farms to employ a professional nutritionist or to use a nutritionist employed by a feed company or local cooperative. These professional nutritionists generally formulate the rations and submit feed samples for nutrient analysis. On these herds the veterinarian can have an important role in ensuring that the diet described on paper is adequately formulated and delivered to the cows. Routine scheduled activities such as measuring the dry matter of forages, hand mixing a TMR for one cow and comparing it with the machine-mixed TMR ("TMR test mix"), and scoring the feed bunk to assess feed sorting and dry matter intake are important procedures that help to ensure the successful delivery of a nutritional program. Assessing pasture conditions by periodic inspection of pasture is an important component of managing the nutritional program of herds that use management-intensive grazing. These quality control activities should be conducted routinely as part of the health and production management program.

Milking Management

Achievement of a consistent milking routine is the key to quality milk and is a goal of most farmers. However, many farms have not explicitly described the milking process for their personnel. Less than 20% of Wisconsin farms participating in milk quality teams had written milking routines before beginning the project (Ruegg, 2000). There is tremendous variability in milking routine reported by farmers. In a nonrandom survey of 338 Wisconsin dairy producers, four milking routines accounted for 63% of all routines used but the remaining 117 herds reported using an additional 23 milking routines. In some instances milking staff on the same farm use different milking processes. Milking management should be a standard element of quality control programs. Tasks such as observation of the

Downloaded from Vet-eBooks.com

milking routine and scoring the condition of teats should be performed at least quarterly. The milking system should be analyzed during milking on a scheduled basis depending on milking frequency and herd size. All herds should have key indicators of have their milking system assessed at least annually.

Mastitis control programs are most successful when the practitioner knows the type of mastitis pathogens that are prevalent on the dairy. A scheduled system of routine screening for mastitis pathogens can be implemented as part of the milking management program. The veterinarian can teach farm personnel how to perform the California Mastitis Test (CMT) as part of a surveillance program. Animals routinely screened may include cows at dry off, fresh cows and heifers, and newly purchased cows. Milk samples can be collected and submitted for culture from quarters that show positive reactions to the CMT.

Youngstock Management

Newborn calves and replacement heifers are often housed separately from the lactating cows and may not be observed routinely by the herd veterinarian. In some cases, the veterinarian only interacts with youngstock when a health crisis develops. As described in Chapter 9, the management and delivery of colostrum is a critical control point for calf health. It is relatively simple to implement a routine surveillance system that assesses the adequacy of colostral absorption. As part of scheduled herd visits the veterinarian can collect and test blood samples from selected calves for either immunoglobulin or serum protein levels. On small herds it may be cost effective to routinely test all calves less than 10 days of age at the visit, whereas larger herds may elect to test a random sample of younger calves.

The most visible manifestation of replacement management is the growth rate. Growth rates reflect both nutritional management and the adequacy of disease control and should be monitored to ensure that animals reach the appropriate weight for breeding by 13 to 15 months of age. Measuring the height and weight of heifers is a labor-intensive task that can be delegated to farm personnel on large dairy farms, but the herd veterinarian should review the data routinely. On small farms the veterinarian may measure animals when they are restrained for immunizations or other prophylactic activities.

Environmental Management

Dairy cattle housing is presented in Chapter 12. The environment of dairy cattle can have considerable influence on health and productivity. Some veterinarians recognize this issue and routinely schedule "walk-abouts" through the housing areas to assess factors related to animal comfort and hygiene. Udder cleanliness, hoof and hock lesions, and respiratory disease are often determined by housing conditions. Herd walk-abouts should include areas that are often ignored, such as dry cow and heifer housing.

Breeding Bull Management

Although most dairy farms use AI, many also use bulls to breed animals that have not conceived through the use of routine AI programs. Some farms use bulls to breed the majority of their herd. In many instances these bulls have not been screened for fertility even by simple tests such as scrotal circumference. The management of breeding bulls in dairy herds that use them should be a part of the routine technical activities of the veterinarian. The dairy practitioner should offer breeding soundness examinations, routinely observe the bulls for lameness, and discuss management issues such as the ratio of open cows to breeding bulls, bull rotation, and rest schedules.

Scheduled Analytic and Training Activities

The delivery of scheduled or unscheduled technical activities will not be effective unless there is a system that captures the results of the activities and allows for analysis and ongoing revision. The structure of the health and production management program must include time for the farmer and the herd veterinarian to analyze and discuss herd management issues. In herds that are dependent on hired personnel to implement designated tasks, time must be scheduled to effectively train the personnel that are ultimately responsible for delivery of the programs. There are at least four broad areas that can be included in herd visits: performance reviews, protocol development and review, training activities, and consultation with other farm advisors.

Performance Reviews

It is useful for the herd manager and veterinarian to review herd performance on a regular basis. Performance reviews should be respected as a part of the health and production management program and should not be performed after a tiring session of reproductive exams or surgical procedures have been completed. Time for performance reviews should be realistically allocated, and the farm staff should gather the data needed for the discussion beforehand. The discussion should be based on a comparison of selected herd performance indicators against the herd performance targets. Each discussion should end with the generation of an action list that states who is responsible for implementation. A time period and method of evaluation should also be stated for each action item. Actions and relevant decisions should be documented to aid in communication and future discussions. It is important to realistically assess the farm capabilities. Performance reviews should be a positive experience that allows the producer to define and reach herd goals. When performance is lacking in a number of areas (such as reproductive performance or milk yield), prioritizing activities based on the expected return is useful (Fig. 6-11). Interventions should be targeted toward the areas that are feasible and will show the highest return to the farm. A comprehensive session of strategic planning should be scheduled at least annually. This session should review the performance of the past year and set performance goals for the upcoming year.

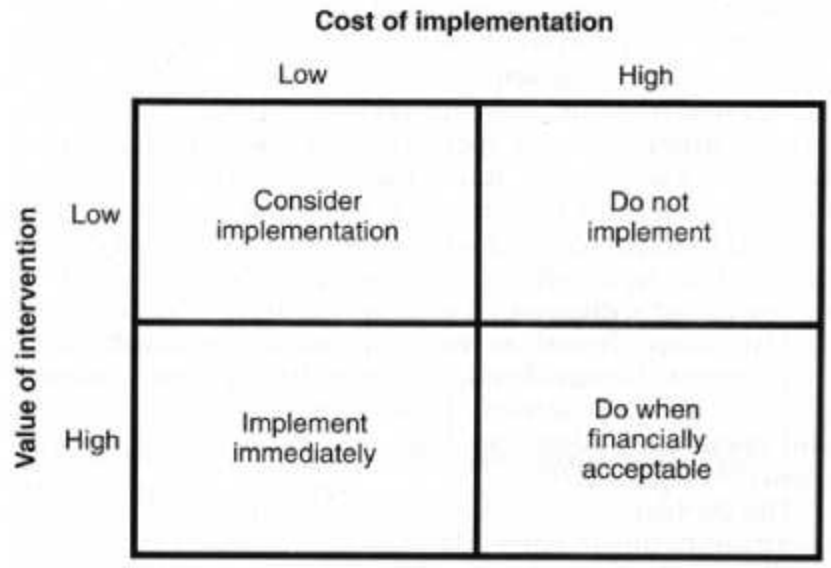

FIG. 6-11 Prioritization of health management decisions.

Downloaded from Vet-eBooks.com

As part of the health management program, some veterinarians become involved in financial management of the dairy operation. The veterinarian often becomes interested in financial management when he or she wants to evaluate the expected financial impact of proposed changes in management. The initial step in economic assessment should be to define the producers' goals and objectives (Hady and Lloyd, 1993). Partial budgeting is a tool that can be applied to project changes in profitability resulting from proposed management changes (Lloyd and Hady, 1994). A partial budget is a static assessment of the net expected change in profitability based on adoption of a management change. It is simple to construct based on farm data. The first step is to add estimated *increased revenue* resulting from a management change to estimates of *decreased expenses* assignable to the management change. The sum of *decreased revenues* and *increased expenses* expected to occur based on adopting the change is then subtracted, leaving the net expected change in profitability. Partial budgets should be calculated routinely as part of the decision-making process on the dairy.

Some veterinarians move beyond partial budgets to true financial management. Cash flow analysis has been recommended as a tool for veterinarians to use to help producers identify management opportunities, establish capital expenditure priorities, and to project the future viability of the dairy (Ferry, 1994). Cash flow analysis is a listing of all annual expenses compared with income. The development of inexpensive accounting software has simplified these analyses.

Protocol Development and Review

On an increasing number of farms, the production of quality milk and the maintenance of animal well-being depends on continuous effort by non-family employees. The development of SOPs is one method that an increasing number of farms are using to ensure that agreed-on processes are implemented. SOPs are commonly developed to define the optimum milking routine on a farm. A typical SOP describes the premilking cow preparation, unit attachment routine, and method for postmilking teat disinfection. An increasing number of mid- and large-sized dairy farms also define disease surveillance systems for fresh cows. The fresh cow SOP may include daily observation and a brief physical of each cow for the first 5 to 7 days after calving. Farm staff generally carry out these activities. It is well within the skill set of most dairy veterinarians to take an active role in the development of these processes and to help ensure that staff is adequately trained to carry out their assigned roles.

Treatment protocols are used to define standard treatments for common diseases on dairy farms. Treatment protocols are advocated when multiple people have responsibility for administering antibiotic treatments to dairy cattle or when extralabel drug use (ELDU) is prescribed. ELDU is any use of a drug that is not specifically mentioned on the product label, such as the following: administration of intramammary mastitis treatments at 8-hour intervals when the product label prescribes 12-hour intervals; administration of 30 ml of an agent when the dosage listed on the label is 15 ml; or use of a product labeled for the treatment of footrot or respiratory disease to treat any other condition. Treatment protocols provide a mechanism for increased communication about treatment plans between the veterinarian and client and allow the farm to partially fulfill requirements for legal ELDU.

The avoidance of residues in food products is a major responsibility of the dairy practitioner. Increased scrutiny regarding antimicrobial use in food producing animals has arisen because of concern about the development of antimicrobial resistance in foodborne pathogens. Veterinarians and producers use antimicrobial agents to treat many infectious diseases of dairy cattle; these agents are justified to protect the well being of the animals. Treatment of mastitis is the most common reason for the use of antibiotics on dairy farms (Allison, 1985). The use of lactating and dry cow intramammary antibiotics and the mistakes regarding withholding periods of milk are the most frequently cited reasons for antibiotic residues (Booth and Harding, 1986; McEwen et al, 1991). Although the level of detected antibiotic residues in meat and milk products is extremely low, antibiotic residues in bulk milk and carcasses occasionally occur. In the United States contamination of bulk milk is rare because of an effective surveillance system based on rapid testing for selected antimicrobial agents of every load of raw milk. Milk that is contaminated with antibiotics is discarded, and the producer is fined.

The requirements for ELDU have been defined by U.S. regulatory officials under the Animal Medicinal Drug Use Clarification Act (or AMDUCA):

- For food animals, ELDU is not permitted if a drug exists that is labeled for the food animal species and contains the needed ingredient, is in the proper dosage form, is labeled for the indication, and is clinically effective.
- ELDU is permitted only by or under the supervision of a veterinarian.
- ELDU is allowed only for FDA-approved animal and human drugs.
- ELDU is permitted for therapeutic purposes only when an animal's health is suffering or threatened. ELDU is not permitted for production drugs (e.g., growth promotion).
- ELDU in feed is prohibited.
- ELDU is permitted for preventive purposes when an animal's health is threatened.
- ELDU is not permitted if it results in a violative food residue, or any residue that may present a risk to public health.
- ELDU requires scientifically based drug withdrawal times to ensure food safety.
- The record and labeling requirements must be met.
- The FDA prohibits specific ELDU. For example, the following drugs are prohibited for extralabel use in food animals: chloramphenicol, clenbuterol, diethylstilbestrol, dimetridazole, ipronidazole, other nitroimidazoles, furazolidone (except for approved topical use), nitrofurazone (except for approved topical use), sulfonamide drugs in lactating dairy cows (except approved use of sulfadimethoxine, sulfabromomethazine, and sufaethoxypyridazine), fluoroquinolones, and glycopeptides (e.g., vancomycin).

The American Association of Bovine Practitioners (AABP) has responded to societal and regulatory concerns about the use of antimicrobial agents by adopting the following recommendations for the prudent and judicious use of antimicrobial agents in dairy cattle (Prudent drug use, 2000):

1. The veterinarian should accept responsibility for helping clients design management, immunization, housing, and nutritional programs that will reduce the incidence of disease and the need for antimicrobials.

2. The use of antimicrobials only within the confines of a valid veterinarian-client-patient relationship (VCPR), for both dispensing and the issuance of prescriptions, has been recommended by the AABP. A valid VCPR exists when all of the following conditions have been met:

   a. The veterinarian has assumed the responsibility for making clinical judgments regarding the health of the animal(s) and the need for medical treatment, and the client has agreed to follow the veterinarian's instructions.

   b. The veterinarian has sufficient knowledge of the animal(s) to initiate at least a general or preliminary diagnosis

Downloaded from Vet-e-Books.com

of the medical condition of the animal(s). This means that the veterinarian has recently seen and is personally acquainted with the keeping and care of the animal(s) by virtue of an examination of the animal(s) or by medically appropriate and timely visits to the premises where the animals(s) are kept.

c. The veterinarian is readily available for follow-up evaluation, or has arranged for emergency coverage, in the event of adverse reactions or failure of the treatment regimen.

3. Veterinarians should properly select and use antimicrobial drugs. Veterinarians should participate in continuing education programs that include therapeutics and emergence and/or development of antimicrobial resistance.

4. The veterinarian should have strong clinical evidence of the identity of the pathogen causing the disease, based on clinical signs, history, necropsy examination, laboratory data, and past experience before making a recommendation for antimicrobial use.

5. Antimicrobials should be used at a dosage and duration appropriate for the condition treated.

6. Product choices and regimens should be based on available laboratory and label (including package insert) information, additional data in the literature, and consideration of the pharmacokinetics, spectrum, and pharmacodynamics of the drug.

7. Antimicrobials should be used with specific clinical outcome(s) in mind, such as fever reduction, return of mastitis milk to normal, elimination or reduction of shedding, contagion, and recurrence of disease.

8. Periodically monitor herd pathogen susceptibility and therapeutic response, especially for routine therapy such as dry cow intramammary antibiotics, to detect changes in microbial susceptibility and to evaluate antimicrobial selections.

9. Use products that have the narrowest spectrum of activity and known efficacy in vivo against the pathogen causing the disease problem.

10. Antimicrobials should be used at a dosage appropriate for the condition treated and for as short a period of time as reasonable. Therapy should be discontinued when it is apparent that the immune system can manage the disease, reduce pathogen shedding, and minimize recurrence of clinical disease or development of the carrier state.

11. When possible, antimicrobials of lesser importance in human medicine should be chosen before choosing a newer generation animal antimicrobial that may be in the same class as a human antimicrobial that may be used as the primary or sole treatment for a human infection. An antimicrobial for which emergence of resistance is expected to be in an advanced stage, should also not be chosen.

12. Antimicrobials labeled for use for treating the condition diagnosed should be used whenever possible.

13. Combination antimicrobial therapy should be discouraged unless there is information to show increase in efficacy or suppression of resistance development for the target organism. Compounding of antimicrobial formulations should be avoided.

14. When appropriate, local therapy (e.g., intramammary, intrauterine, topical) is preferred over systemic therapy.

15. Treatment of chronic cases or those with a poor chance of recovery should be avoided.

16. Prophylactic or metaphylactic use of antimicrobials should be based on a group, source, or production unit evaluation; rather than being utilized as standard practice.

17. Veterinarians should endeavor to ensure proper on-farm drug use. Drug integrity should be protected through proper handling, storage, and observation of the expiration date.

18. Prescription or dispensed drug quantities should be appropriate to the production unit size and expected need so that stockpiling of antimicrobials on the farm is avoided.

19. The veterinarian should train farm personnel who use antimicrobials on indications, dosages, withdrawal times, route of administration, injection site precautions, storage, handling, record keeping, and accurate diagnosis of common diseases.

20. Veterinarians are encouraged to provide written, updated protocols for diagnosis and treatment to clients whenever possible. Those protocols should describe conditions and provide instructions for antimicrobial use at a farm or unit when a veterinarian is unavailable.

Health and production management programs are central to the concept of judicious and prudent antimicrobial use on dairy farms. The development of treatment protocols and SOPs are recommended to meet the criteria for establishing effective therapeutic programs.

Training

The development of treatment protocols and SOPs requires strategies to ensure that employees understand the importance of following written procedures. Most small to mid-sized dairy farms have relatively few employees, and implementation is likely if the farm owner agrees with a process. Larger dairies depend on the continuous performance of hired staff that may have limited experience or conflicting opinions about the necessity to follow an SOP. One role of the veterinarian is to ensure that animal handlers and milking staff are adequately trained so that they can carry out agreed-on procedures. Training is a continuous function. There is a need to train new employees and a need to retrain long-term employees when procedures are changed. Training sessions that are prepared and delivered well can help raise the consciousness of the staff regarding the importance of following procedures.

Consultation with Other Advisors

On many farms the veterinarian should reserve time to consult with other advisors regarding farm performance. In many instances the nutritionist can be a vital ally. Critical farm advisors may also include financial consultants, extension agents, technical service veterinarians and dairy plant field staff. In the worst of circumstances, the farmer receives conflicting advice from various sources and elects to do nothing. In the best of circumstances, farm advisors meet and communicate frequently and unite around farm goals.

Investigations of Health and Production Problems

Even on the best managed farms, unexpected health and production problems arise. Surveillance programs incorporated in health and production management programs should detect problems early before considerable financial damage has occurred. Systems of investigating herd outbreaks have been described (Ruegg, 1993). Epidemiological concepts of disease investigation are useful to identify risk factors and to stimulate corrective action. Quantitative skills useful in herd investigation are described in Chapter 2.

Reasons for Failure of Health and Production Medicine Programs

Not all health and production management programs are successful. The maintenance and growth of a dairy health management program requires the continued motivation

Downloaded From Vet-eBooks.com

and interest of both the farmer and the veterinarian. It also requires continual communication and a willingness to be flexible and responsive to changes in farm conditions. Some causes of failure of programs include the following:

- Mismatching of producer expectations with veterinary skills and motivation or vice versa (see Fig. 6-10). Programs can fail because of either unrealized producer expectations or unrealized veterinary expectations. In either case it is likely that the unsatisfied party will seek out a better match for their needs.
- Inability of the veterinarian to arrive at the farm at scheduled times for nonemergency services. This may be due to a practice schedule that places more priority on provision of emergency services than on consultative services.
- Inadequate communication between the veterinarian and the producer.
- Overwhelming the farmer with recommendations.
- Poor implementation of recommendations by either the veterinarian or farm staff.
- Failure to analyze results and modify practices. This often creates a vicious cycle of diminished interest in data recording, leading to diminished ability to assess performance.
- Inappropriate fee structure for veterinarian. Unless the veterinarian can be compensated properly for time spent on consultative activities, the priority of consultative activities will always be less than the priority of revenue-generating activities.

IMPLEMENTATION AND FINANCIAL ASPECTS OF DAIRY HEALTH MANAGEMENT PROGRAMS

Many veterinarians recognize the income potential of health and production management programs. In surveys by the American Veterinary Medical Association, greater than two thirds of food animal veterinarians believed that herd health management services represent the area of greatest long-term potential for practice revenue growth (Wise, 1987). In spite of this recognition the complete potential of health and production management programs remains unrealized for many practices (Nordlund, 1998; Wassell, 1995). A paradigm for the development of health and production medicine programs has been proposed for practitioners (Nordlund, 1998):

1. Acquire the appropriate skill set including knowledge of dairy record and monitoring systems, disease management including statistical and epidemiological analysis techniques, and an understanding of dairy finance including cost of production determinations and partial budgeting. Attend continuing education programs to accelerate the learning curve.
2. Let clients know what is being offered by using brochures and business cards that describe those services. Do not market pet grooming and 24-hour-a-day emergency services on the same card.
3. Arrange clinic schedules so that each interested veterinarian gets designated time to develop management assistance services. Identify days or weeks where those veterinarians are excluded from sick cow calls and emergency services.
4. Start herd visits with an overview of herd performance, not by wearing an examination sleeve into the barn. Take a few minutes to review or monitor the herd records and performance, make notes or update a graph, then go back to the vehicle for the sleeve and reproductive examination kit.
5. Work with the herd manager to define herd management goals.
6. Use veterinary technicians in the delivery of dairy services. Many dairy services can be facilitated by a technician, including data recording or entry; sample collection including milk, urine, blood, fecal and feedstuffs; and preparation and assistance with procedures.

A survey of veterinary practitioners in the United Kingdom reported that 78% of veterinarians believed that herd health programs would be financially beneficial to a practice (Wassell, 1995). This survey clearly identified "farmer motivation" as the veterinarians' main perception of why some herd health programs failed. This survey then assessed farm clients to determine if differences exist between farms that use routine veterinary services versus emergency-call-only services. Differences in farm size, herd size, seasonality of calving, education, progressiveness, and level of communication were noted. The successful operation of a health and production management program depends on the following features of the veterinary practice (Esslemont, 1995):

- Commitment: agreement and support among practice members should be sought before initiation of a program
- Self-appraisal: review the level of knowledge and skills of the veterinarians offering the program. Recognize when to refer a problem or seek expert advice when limitations exist
- Market research: identify and target clients who are most likely to succeed and start by offering the program to a limited number of clients
- Farm appraisal: use a method for assessing farm's losses and targeting problem areas
- Selling skills to get the herd started: retrospective data should be collected to generate a history of performance
- Setting up a pricing system
- Practice meetings: newsletter production as well as training and interpretation of reports can help generate enthusiasm among clients
- Financial analysis

Compensation for the Veterinarian

Veterinary compensation derived from health and production medicine programs includes both the intangible benefit of contributing to the success of the dairy and the tangible benefit of enhancing personal income. The decision to offer or expand consultative services means that virtually all practices have to reach a decision on how to charge for professional time. Traditionally, veterinary practices subsidized time spent consulting with fees from other services such as emergency visits or high margins on items (such as pharmaceuticals) that were dispensed. The purchasing power of larger dairy farms and the proliferation of pharmaceutical suppliers has limited income from drug sales. The most common methods of charging producers for professional veterinary services are to charge by procedure, time, or contract (Gardner, 1989). Additional charges are usually assessed for visiting the farm (mileage or a standard fee) and dispensing of animal health supplies. Some practices monitor the marginal return above drug cost to assess the relative profitability of various services.

Some practices continue to bill clients based on procedures performed during the herd visit. This system is quite visible to the client and is generally readily accepted because of the tangible results. Examples include reproductive examinations, foot trimming, collection of milk samples, and examination of individual cow problems. There are two major disadvantages of using this method. The client has no financial incentive to be prepared for the visit or to pro-

Downloaded From Vet-eBooks.com

vide for adequate restraint or labor. With this method, adequately charge for time spent on consultation is extremely difficult. The client may not perceive time spent discussing management issues as a billable service. The veterinarian may feel compelled to rapidly complete tasks that generate income and to minimize the time spent developing non-income-generating health management programs. This system has a long history within traditional bounds of the veterinary-client relationship but is generally limited in its applicability to effective health and production management programs.

Most professional service providers charge hourly fees for time spent completing professional tasks. This method of charging is gradually becoming the standard for many dairy practices. Using this system, the veterinarian generally charges a call fee to visit the farm and then adds an hourly fee for time spent on health management work. This system is based on assigning value to professional knowledge and skills delivered over units of time. There may be large discrepancies in hourly fee structures between veterinarians depending on the marketability of their skills and existing local competition. Hourly fees generally range from $45 to about $150. This system is advantageous in that it allows the veterinarian to get paid for actual work done on the farm, which may include diagnostic skills such as palpation, review of records, interpretation of laboratory results, ration analysis, on-farm data entry, and discussions of herd problems with the producer or other consultants. The use of hourly fees to charge for these services is generally readily accepted by the client, but in many instances veterinarians find it somewhat challenging to charge for off-farm services such as record analysis or telephone consultations. Charging by the hour also encourages most producers to attempt to be organized when the veterinarian reaches the farm. This allows for more efficient use of both the veterinarian's and producer's time.

Some practices have defined services that are provided on a scheduled basis and charge a set fee to deliver those services during a specific period (generally an annual basis). These contract services may be based on identification of herd specific goals but most commonly are based on charging a set fee per animal. In most instances contracts for annual health management programs do not include veterinary fees and expenses for emergency veterinary service nor costs of veterinary supplies and drugs. The use of contracts may be advantageous to both the producer and veterinarian in that it allows both parties to project their expenses (or income) in return for specified services. If the amount of work exceeds expectations, this system may be disadvantageous to the practitioner.

Profitability of Health and Production Management Programs

The cost-effectiveness of producer investments in effective health and production medicine programs has been demonstrated repeatedly. It is almost intuitive that programs that reduce losses in productivity because of disease will be beneficial for the dairy producer. Traditional programs that have focused on improvements in reproductive efficiency and milk quality have been known to be effective for over 30 years (Barfoot et al, 1971; Blood et al, 1978; Ellis and James, 1979). One study assessed the long-term performance of herds that were enrolled in herd health management programs for a 2-year period (Hogeveen et al, 1992). This case-control study compared the financial performance of herds enrolled in the program to financial performance of herds that received traditional veterinary services. Financial outcomes were studied during the course of the 2-year program and then reassessed 10 years after the program was completed. The study documented considerable returns during the course of the study, but the positive effect diminished after the program was discontinued.

Partial financial returns from targeted interventions have been documented. One study estimated the impact of free-stall housing on BTSCC values in California dairy herds (Lehenbauer et al, 1998). This study concluded that the BTSCC of herds using free-stall housing was 34,000 cells/ml less than herds that used dry-lot housing during winter conditions. They estimated the improved milk quality resulted in a seasonal benefit of $10.25/cow. Over a 20-year planning horizon, improvements in milk quality alone would account for approximately 36% of the initial building investment.

It is also wise for the veterinary practitioner to be aware of financial limitation that may impact the success of health management programs. Improvements in herd performance may not have much impact on financial performance of the farm family if debt payments consume a considerable amount of farm operating capital.

DISEASE OCCURRENCE RELATIVE TO AGE GROUP AND LACTATION CYCLE

Both the prevention and occurrence of diseases of dairy cattle are linked to age and production cycle. It is therefore logical to assign preventive practices based on the critical high-risk periods for disease. The periparturient period and early lactation are the highest risk periods for most diseases of lactating cows. Many subclinical diseases such as ketosis or subclinical acidosis are related to metabolic and dietary changes that occur during this period. Other syndromes such as subclinical mastitis caused by contagious pathogens and lameness are documented more frequently during middle to late lactation. Diseases that occur later in lactation are often related to longer exposure to contagious organisms or repetitive stresses such as failing to provide adequate cushioning in stall beds. The highest-risk period for youngstock is during the preweaned period. Animals of this age are extremely susceptible to respiratory and enteric pathogens, especially when housed in group conditions. Specific disease control strategies are fully outlined in the appropriate chapters of this text.

Most sporadic clinical diseases have a relatively short duration and have a minimum impact on productivity unless a large proportion of the herd is affected. The long-term impact of subclinical disease is more likely to adversely affect overall herd performance.

Pregnant cow or heifer (during dry period for cow).

1. Select quarters for culture by examining somatic cell count (SCC) or California mastitis test of quarter milk samples 1 month or less before drying off
2. Use appropriate dry cow therapy for mastitis control
3. Vaccinate pregnant dam with *E. coli* J-5 vaccine for coliforms mastitis control and booster as recommended by product label; consider the use of other farm-specific vaccines such as enterotoxigenic K99+ *E. coli*, rotavirus, coronavirus, and sometimes *Salmonella* sp.
4. Perform body condition score (BCS) at dry off and adjust diet as recommended
5. Control cation-anion balance of diet to minimize milk fever; feed low potassium diet
6. Check dietary levels of vitamin E and selenium; supplement animals as needed
7. Trim hooves
8. Dock tails using rubber rings if necessary and allowed
9. Ensure that calving area is clean and dry and is not used for housing sick cows

Downloaded from Vet-e-Books.com

Periparturient cow (1 week before and immediately after calving). Observe the cows daily for the following:
1. Udder edema
2. Dystocia, retained fetal membranes, and metritis
3. Parturient paresis and downer cow syndrome
4. Reductions in appetite or rapid changes in BCS
5. Displacement of the abomasum
6. Remove udder hair by trimming or singeing

Early lactating cow (fresh cow; calving to 1 month afterward). Observe the cows daily for the following:
1. Clinical or subclinical ketosis; use appropriate screening tests
2. Lameness
3. Hypomagnesemia
4. Postparturient hemoglobinuria
5. Displacement of the abomasum
6. Cecal dilatation
7. Estrus
8. SCC and clinical mastitis

Middle and late lactating cow (after first month of lactation). Observe the cows daily for the following:
1. Delayed onset of estrus, repeat breeder
2. Pregnancy diagnosis
3. SCC and clinical mastitis
4. Teat lesions such as hyperkeratosis or ulceration
5. Deviations in milk yield related to disease or nutritional program
6. Butterfat and protein tests
7. BCS
8. Trim hooves in mid-late lactation

Newborn calf from birth to weaning.
1. Drovide necessary obstetric assistance
2. Dip navel of calf
3. Supplement with selenium or vitamin E if necessary
4. Assess level of immunoglobulin in colostrum
5. Ensure adequate intake of colostrum by hand-feeding 4 L colostrums
6. Identify calf with ear tag or tattoo
7. Examine for evidence of congenital defects
8. House in individual pen until weaned
9. Feed milk from cows known to be free of Johne's disease and bovine leukemia, or feed milk replacer until weaning
10. Offer hay and calf starter at 2 weeks of age; wean when eating 1 kg of dry feed
11. Ensure adequate vitamin D intake
12. Observe for major problems: acute diarrhea caused by *E. coli*, rotavirus, coronavirus, *Cryptosporidia* sp., and others; omphalophlebitis, infectious arthritis

Calf from weaning to 6 months of age.
1. Provide adequate diet and housing to achieve optimum growth rate and prevent specific vitamin and mineral deficiencies
2. Vaccinate for infectious bovine rhinotracheitis, enzootic pneumonia, bovine virus diarrhea, leptospirosis, clostridial diseases, and salmonellosis
3. Institute ringworm control and control of internal and external parasites
4. Avoid garbage dumps (lead poisoning)
5. Weigh or tape calf monthly to measure if optimum growth achieved
6. Observe for major problems: enzootic pneumonia of calves, infectious enteritis

Heifer from 6 months to 15 months of age.
1. Remove supernumerary teats
2. Provide adequate diet to ensure optimal growth and prevent specific mineral and vitamin deficiencies
3. Ensure adequate housing and stocking density to control infectious diseases such as coccidiosis and intestinal parasites
4. Observe for diseases that are likely to occur, including bovine virus diarrhea, coccidiosis, pneumonia, ostertagiasis and other parasites, papular stomatitis, calf diphtheria (necrotic stomatitis), ringworm, clostridial diseases, and hemophilus meningoencephalitis

DISEASES OF DAIRY CATTLE NOT NECESSARILY RELATED TO THE PRODUCTION CYCLE

Diseases Controllable by Vaccination. These include leptospirosis, clostridial diseases, anthrax, brucellosis (where legislation permits), infectious bovine rhinotracheitis, infectious keratoconjunctivitis, hemophilus meningoencephalitis, and rabies.

Diseases Controllable by Nutritional Management or Supplementation. These include copper deficiency, vitamin E and selenium deficiencies, polioencephalomalacia, calcium, phosphorus, and vitamin D deficiencies, several other mineral deficiencies (e.g., salt, magnesium, zinc), simple indigestion, rumen overload, ruminal tympany, traumatic reticuloperitonitis and allied syndromes, rumen acidosis and laminitis, low milkfat, fat cow syndrome, and primary acetonemia.

Diseases Controllable by Test and Slaughter. These include leukosis, brucellosis, tuberculosis, Johne's disease and BSE.

Diseases Controllable by Medication. These include coccidiosis, intestinal helminthiasis, fascioliasis, external parasites (lice, chorioptic mange), anaplasmosis, ringworm, and hairy heel warts.

Sporadic Diseases Not Warranting Specific Preventive Techniques. These include listeriosis, contagious bovine pyelonephritis, hemophilus meningoencephalitis, actinobacillosis, actinomycosis, bovine papular stomatitis, bovine malignant catarrh, and spondylosis in dairy bulls.

Diseases Controllable by Usual Hygienic Precautions and Improved Animal Husbandry. These include footrot (foot baths), lameness from diseases of the feet other than footrot and hairy heel warts, pneumonic pasteurellosis, winter dysentery, salmonellosis, pseudocowpox, bovine ulcerative mammillitis, ringworm, *Dermatophilus* infection (mycotic dermatitis), and diseases caused by chemical agents (lead, arsenic, fluorine, molybdenum, sodium chloride, hydrocyanic acid, nitrate, insecticides, urea, mycotoxins, dicumarol).

Diseases Controllable by Prevention of Introduction of Infection. These include foot-and-mouth disease, bluetongue, brucellosis, anaplasmosis, tuberculosis, Johne's disease, leptospirosis, and salmonellosis.

Diseases Controllable by Genetic Surveillance. Certain congenital defects in newborn calves can be recognized clinically and pedigree analyses carried out to identify and remove carrier animals.

CHAPTER 7

Managing Reproductive Efficiency in Dairy Herds

PETER W. FARIN and BARRETT D. SLENNING

Because the cow, like other mammals, produces milk only after giving birth, reproductive management of a dairy herd is central to a dairy farm's overall success in producing milk. The general goal of dairy farms is for cows to produce a maximum amount of milk per day of life at a minimum of feed costs. To do so, cows should calve at regular intervals and therefore must be bred and become pregnant within a given period after calving. If conception is delayed, reproductive inefficiency can lead to milk production inefficiency. Indeed, in the 1950s and 1960s, reproductive services were among the first programs offered by veterinarians. Along with udder health, activities related to reproduction have long formed the foundation services for which the dairy industry finds veterinary intervention useful. As a result, over the past few decades regularly scheduled herd checks have become the most common reason for a veterinary visit to most dairy farms. These visits present an opportunity for in-depth discussions about the herd's reproductive performance and areas of management that affect reproduction and the farm's income. Thus the herd veterinarian must become conversant in several disciplines and expert in several fundamental aspects affecting reproductive efficiency in a typical dairy herd.

This chapter discusses current approaches to the exciting and challenging area of managing reproduction in dairy cattle on the farm. It addresses the needs of the recent graduate veterinarian who is faced with establishing a new herd reproductive program and provides recent information on dairy cattle reproduction to those veterinarians currently engaged in practice. This chapter begins with a discussion of recent trends in reproductive performance of dairy cows. Next, the different reproductive strategies found on dairy farms are discussed, including year-round versus seasonal calving farms and artificial insemination (AI) versus bull breeding programs. Then, diagnostic methods for on-farm reproductive programs, ways to enhance reproduction of the herd and the individual cow, and different strategies for investigating reproductive inefficiency are addressed. Readers who may want more information on specific reproductive problems and diseases of dairy cows are strongly encouraged to consult the relevant chapters in the text by Youngquist (1997a). The next sections of this chapter discuss the different reproductive indexes and approaches for monitoring reproductive efficiency on dairy farms. The chapter closes with a general discussion of the financial considerations affected by reproductive inefficiency.

TRENDS IN REPRODUCTIVE PERFORMANCE AND MANAGEMENT

Little Improvement in Average Performance Over Time

In general, the current level of reproductive performance in dairy herds is well below the published optima. Across the industry, the average days open is 120 to 140 days (calving interval of 400 to 420 days), and the average conception rate is 45% to 50%. In a Canadian study, the reproductive efficiency of artificially bred Holstein cows was as follows: mean services per conception, 1.97; percentage conception to first service, 47%; days from calving to first service, 88; and days from calving to conception, 121 (Tong et al, 1979). In this study the reproductive efficiency was highest in small herds with 35 or fewer cows, and producers who managed their labor efficiently for the production of milk also managed their herd well for reproductive performance. The level of reproductive performance in dairy herds in the United States is also below optimum (Spalding et al, 1975); the calving interval for dairy cows averages at least 13 months in most areas and longer in many states (Hawk, 1979). Data from nearly 5000 Dairy Herd Improvement Association (DHIA) herds in the southeastern United States in 1986 revealed only 43% estrus detection efficiency, 86 days to first breeding, 46% successful inseminations, and minimum average days open of 133 days (calving interval of 413 days; Fetrow et al, 1988). Despite efforts by veterinarians to provide routine reproductive service to dairies, these averages have proven remarkably resistant to change over the past several decades.

Researchers following long-term trends in dairy herd reproductive indexes have recently published troubling findings regarding industry average performance. Silvia (1998) studied the records of 70 Kentucky dairy farms over a 20-year period and reported that the average services per

Downloaded from Vet-eBooks.com

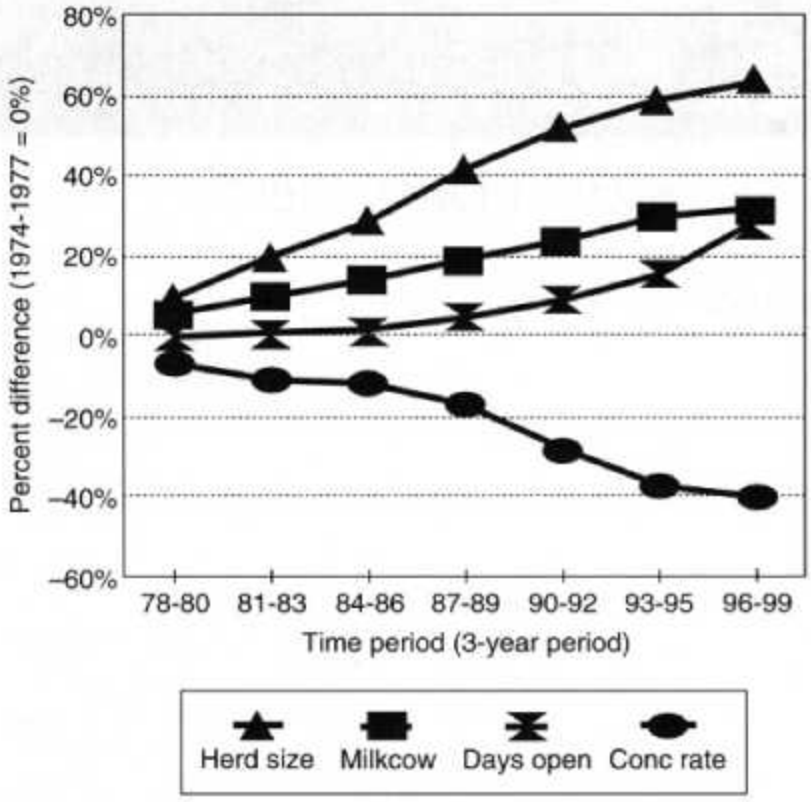

FIG. 7-1 Trends in herd characteristics and reproductive success over 25 years for 338 Southeastern U.S. dairy herds. Values are relative to the situation in the 1974-1977 period. Herd size and production have increased over time, however, reproductive indexes have degraded. (Adapted from Washburn SP, Brown CH, McDaniel BT, et al. In Pritchard DE, editor: Proceedings of the conference on Managing Reproduction in Southeastern Dairy Herds, Salisbury, NC, February 23-24, 2000.)

pregnancy had degraded by 1.29 (2.91 versus 1.62), causing nearly an 80% decrease in performance ([2.91 − 1.62]/1.62 = 0.80) and an estimated conception rate decrease of approximately 56%. Silvia also reported that, over the same period, average days open had increased by nearly 1.3 standard estrus intervals (27 days).

Washburn et al (2000) summarized Dairy Records Management Services data from eight U.S. Southeastern states, comprising the period of 1974 through 1999, for 316 Holstein herds, 17 Jersey herds, and 5 herds of other dairy breeds. The outcomes are shown in Fig. 7-1. Over the period evaluated, and across all breeds followed, herd size increased an average of 64% (from 112 in 1974 to 184 in 1999) and per cow milk production increased by 31% (from approximately 6600 kg in 1974 to 8600 kg by 1999). During the same time, however, average days open increased on average by 27% (from 127 days in 1974 to 161 days in 1999), and typical overall conception rates fell by 41% (from 54% conception rate in 1974 to 32% by 1999). Although the magnitude of effect appears somewhat different in this second study, the larger data set confirms the major trend identified by Silvia (1998): reproductive indexes are degrading on modern dairies.

There are likely several reasons for the loss in reproductive performance. The herds studied by Washburn et al (2000) are from the southern United States and hence may be sensitive to heat stress, and that sensitivity may be greater with increased production and/or herd size (Farin et al, 1994). As has been suggested in numerous studies, there is also a negative relationship between production and fertility, although the practitioner needs to discern between *individual animals* or *herds* when discussing this topic. For instance, in a herd-level situation, the data presented in the next subsection suggests that higher-producing herds perform at least as well reproductively as, if not better than, lower-producing herds. Similarly, a study of over 15,000 cows in 26 New York herds identified milk production as playing a minor role in reproductive outcome (Eicker et al, 1996). However, on an individual animal basis, higher production individuals within a herd are often at risk of lowered reproductive performance. Furthermore, cows selected for high milk production show different characteristics in follicular and endocrine functions that could lead to decreased reproductive efficiency (Nebel and McGilliard, 1993).

Washburn et al (2000) suggest that besides any genetic correlations between milk production and reproduction, the way in which genetic records for bulls are established may actually be rewarding those pedigrees with decreased fertility; the later a cow rebreeds (within reason), the higher milk production indexes she will have in most of the standardized systems. Thus producers may have been selecting inadvertently family lines that breed later, making the job of maintaining high reproductive performance more difficult. Again, the cause of the industry's degrading performance in reproduction is likely multi-factorial: genetics, nutrition, facilities, reproductive practices and technologies, and financial factors have probably played a role. The important point is that whatever the reason for this decline in reproductive performance over time, it appears to be real, and it will make careful management of reproduction even more important in the future.

The decline in reproductive performance forces everyone in the profession and industry to reconsider what we are doing and why. If, after a few decades of reproductive services and production medicine, reproduction is degrading on the average dairy farm, practitioners need to look closely at their role in this diminution. Perhaps the industry has encouraged evaluation of indexes that are actually inappropriate for long-term performance improvement. It is possible that this apparent loss of performance is causing an actual overall improvement in dairy herd stability and efficiency; prior goals based on maintaining short lactations and calving intervals may no longer be appropriate. However, even if this "rose-colored glasses" view of the data were correct, it is still troublesome that the industry's efforts to accomplish a different result are seemingly ineffective. Perhaps producers focus on short-horizon, individual-based decisions that paradoxically work to damage herd-level outcomes. They might be encouraging activities and practices that, while meeting the needs of individual animals or individual animal-classes, is limiting the performance of the herd; breeding that "good" cow yet another time may perpetuate genetic and management factors within the population that, over time, harms the population. Other possibilities exist. However, practitioners must be aware of the problem and must be willing to look in a new light at the entire system surrounding dairy cow reproduction, including their efforts and goals.

Regional and National Baseline Data

U.S. Department of Agriculture, National Animal Health Monitoring System Data

In 1996 the U.S. Department of Agriculture's National Animal Health Monitoring System (USDA/NAHMS) assessed multiple factors in dairy herd health and productivity by surveying over 2500 producers from the top 20 dairy-producing states (approximately 83% of U.S. milk cows). The data were sorted by breed, herd size, and production. The following discussion pertains to the information extracted for dairy herds completely comprised of Holsteins, as summarized in Table 7-1.

Several trends can be identified from Table 7-1. First, it appears that as herd size increases, so does production, on-

BVD, Bovine viral diarrhea; *Hemoph*, hemophilus; *IBR*, infectious bovine rhinotracheitis; *Lepto*, leptospirosis.

Data are from the 1996 U.S. Department of Agriculture National Animal Health Monitoring System Dairy '96 report, *Management practices associated with high-producing U.S. dairy herds*. Data are reported according to the highest-producing 25% of participants *(High)* and lowest-producing 25% of participants *(Low)* within each of four herd-size categories.

*Indicates the difference observed between "High" and "Low" quartile producers is statistically significant ($P \leq .05$). Statistical significance not reported for the interquartile differences; however, average production for the herd size categories suggests the small herds had lower production, the largest herds had the highest production, and each was significantly different from the two middle herd-size categories.

farm computer ownership, use of prostaglandin (PGF)-based reproductive programs, and consideration of break-even milk production in culling decisions. The use of pasture-based feeding appears to decrease as herd size increases. It is also apparent that, within herd size categories, the highest quartile producers are statistically more apt to use nearly all of the practices shown in Table 7-1 than are their lowest quartile peers, until the individual vaccinations in use are examined. This is especially true for herds with fewer than 200 cows; in these herds the top quartile producers had adopted each listed practice to a significantly higher degree ($P \leq .05$) than had the lowest quartile producers. The exception is in the pasture use index, wherein the relationship was the reverse: across herd sizes, a significantly higher proportion of lowest quartile producers use pasture than do their highest quartile peers.

Once herd size exceeds 200 cows, the picture is not as clear. For instance, it appears that, in the largest herds, there may be a trend of decreasing use of DHIA records systems. This is likely due to the very large herds being able to amortize the costs of custom-reporting systems with their own on-farm systems (note that the lowest quartile producers in the "500+ Cows" category reported a higher level of on-farm computer use than did even the highest quartile producers in the categories of less than 200 cows). The picture is similar regarding veterinary involvement in reproductive consultation. There is a significant difference in utilization between the low-quartile and high-quartile producers when herd sizes are less than 200 cows (with the highest-quartile producers more apt to use veterinarians for reproductive consultation), but not so in the larger herds. In this index, there is little apparent difference across herd size categories in the utilization rates of the high-quartile producers. The picture for vaccination use also shows an interesting herd-size effect. Apparently, once herd size reaches a certain point, it becomes standard practice across quartiles to use the reproductive vaccines identified, though paradoxically it seems that a trend exists whereby the highest quartiles use these vaccines at a *lower rate* than do their lowest-quartile peers. The reasons for this finding are not clear.

Dairy Herd Improvement—Provo Regional and Production-Based Data

One of the DHIA's records processing center, DHI-Provo, had approximately 10% of the U.S. herds and 19% of the U.S. cows enrolled in its varied test plans, as of January 1999 (Wiggans, 1999). The center publishes regional data on its

*For U.S. dairy herds subscribing to the Dairy Herd Improvement—Provo dairy records processing center for 1997. Significant associations are found between rolling herd average milk production *(RHA)* and the indexes of days in milk *(DIM)* at first breeding, days open, % detected heats, and average age at calving (all show $P \leq .05$). Data adapted from DHI Computing Service, DHI-Provo. Available at http://www.dhiprovo.com/vetzone (accessed October 23, 2000).

†Categories of relative herd-average milk production.

‡Extrapolated from same source (Holstein Report 160: Percent of Detected Heats), which does not list regional data.

Internet site that is adapted and summarized in Table 7-2. The table addresses several baseline and reproductive data points on both a regional basis and by relative milk production. No information is given as to the statistical significance of any of the apparent differences. However, it appears that the eastern region of the United States tends to have lower milk production, increased days in milk, increased days in milk at first breeding, more days open, increased calving interval, older average age at calving, and a higher culling rate than the other two regions listed.

In addition to the information just given, the trends in milk production suggest that days in milk at first breeding decrease as rolling herd average milk production goes up (decreasing approximately 3 days for each 500-kg increase in rolling herd average; $P = .05$). Furthermore, there is a concomitantly strong association between rolling herd average and days open (decreasing approximately 1.5 days for every 500-kg increase in rolling herd average; $P = .04$), according to the DHI-Provo data in Table 7-2. Percent of heats detected displays a similar statistically significant association with rolling herd average (a 500-kg increase in rolling herd average is associated with just over a 1% increase in percent heats detected; $P = .03$). Age of the herd also appears to be associated significantly with rolling herd average ($P = .02$), although here it is a negative association. Although it appears that services per conception for pregnant cows decreases as rolling herd average decreases, it is not statistically significant using the DHI-Provo data ($P = .12$). The same is true for the percent pregnant at first service ($P = .08$). Finally, no linear association appears to exist between rolling herd average production and culling levels ($P = .91$).

The conclusion from the DHI-Provo data is that higher production on a herd level is associated with decreased days in milk at first breeding, days open, average age at calving, and increased percent of detected heats. Based on these data it is not possible to determine whether the increased milk production drives the reproductive performance data or whether the reproductive trends are driving milk production. It simply may be that quality dairy management is able to achieve both high milk production and good reproductive performance simultaneously. Finally, the DHI-Provo data also suggest that a veterinarian might expect to see regional differences in both production and reproductive performance.

National Databases and Future Reproductive Performance

The USDA/NAHMS data allow practitioners to make several predictions about the clientele now and in the future. If we assume that the index on pasturing cattle captures, to a

Downloaded from Vet-e-Books.com

major degree, a representative sample of seasonal breeding herds in the United States, then veterinary intervention in these herds faces several difficulties. These herds tend to be small and low producing, and therefore are less likely to adopt advanced practices in records systems, endocrine management of reproduction, vaccination programs, and use of veterinarians in consultative positions.

The USDA/NAHMS data suggest that the initiation of high-end consultative, production medicine-based, reproductive programs generally will be less apt to be adopted or to succeed on smaller and lower-producing farms. Unfortunately, as with many factors of dairy management, these farms are also the farms that often most need such services. This situation has been a factor in the industry throughout history. The marketing quandary this places before dairy veterinarians, therefore, is not likely to go away for a long time.

The USDA/NAHMS data imply that larger herds are more apt to adopt reproductive technologies and are more likely to intensively manage their cows. This also means that such farms may be more likely to recognize the value of preventive work and veterinary consultation (except, apparently, when vaccination programs are considered). Here, it seems that larger, higher-producing herds are showing a trend of less vaccination use. Perhaps these farms cannot make these programs "pencil out." Perhaps these managers feel they can depend on better overall cow health and biosecurity rather than on vaccination. Either way, this indicates that a major tool of the production medicine veterinarian is losing its appeal in the large, high-producing herd. If this is true, and the direction of the industry is toward the larger, higher-producing herds, it promises to make life a bit more difficult for those veterinarians unaccustomed to justifying their recommendations on other than a strict biological basis.

The DHI-Provo data complement the USDA-NAHMS data, because they suggest that increased milk production and reproductive performance go hand in hand. Biologically, it makes sense that poor reproductive performance tends to decrease average milk production per cow. It also seems a reasonable assumption that those managers who are adept at managing cows for high production are also likely to be able to successfully manage a reproductive program. It is tempting to assume that this relationship between increased production and improved reproduction is accomplished by the similar trend in increased veterinary input witnessed in the USDA-NAHMS data. But that is only speculation.

The reader needs to be aware that no segment of the dairy industry is a monolith; there will be high quality dairies, and there will also be poor managers in each of the identified subgroups. Never assume that because a farm is relatively small, or relatively low producing, that the management is proportionately below average. The practitioner need only walk onto a small, low-producing, seasonal grass-fed dairy that is also achieving four times the net income per unit milk than its confinement-reared neighbors to recognize this is true. Likewise, being big and high producing does not guarantee high-quality management. As the twist on the old saying goes, ". . . The race may not always go to the swift, but it is the best way to bet. . . ." So, while the previous comments are perhaps overly broad in their scope, they bring out issues of which veterinarians and the dairy industry need be aware. We need to recognize that these general trends exist.

REPRODUCTIVE DISORDERS AND CULLING

Reproduction is the primary reason given for why cows are culled in modern dairies (Bascom and Young, 1998), accounting for 20% of all primary culling reasons, and approximately 10% each for all secondary and tertiary culling reasons. Bascom and Young (1998) also found that reproduction became a more important culling factor as herd production rose. It should be noted that it is unlikely that all of these cows culled for reproductive reasons were truly infertile.

Reproductive culling is actually an amalgamation of culling because of several disorders (infectious, metabolic, and traumatic), each of which negatively impact reproductive efficiency (Gröhn et al, 1998). In addition, it has been long recognized that the differing reproductive problems are interrelated. For instance, one study followed 2850 Holsteins from 33 New York herds and looked at reproductive diseases and culling (Erb et al, 1985). In this study cows experiencing dystocia were also nearly three to four times more likely to suffer retained fetal membranes, metritis, and culling; they also averaged over 7 days longer to first service than did cows not experiencing dystocia. Cystic ovarian disease, in this study, was associated with an over-16-day delay in first service. Overall risk of culling was increased by reproductive disorders by a factor of 2 to nearly 4. But the culling picture is often not so cut and dry. In a study of Swedish cows (Emanuelson and Oltenacu, 1998), researchers found that animals suffering from some disorders may have actually been "protected" from culling, depending on the herd's overall level of milk production; cows with apparent anestrus are nearly 20% less likely to be culled in herds at the lower quartile of production, whereas apparent anestrus is essentially a nonfactor in culling for herds in the highest quartile of production. (The relevant results are illustrated in Fig. 7-2.) It is likely that dairies are willing to "put up" with poor reproductive performance if milk production is high. This makes the control of reproductive disorders much more complicated.

To add to the importance of controlling reproductive disorders on dairies, Peeler et al (1994) found that several reproductive disorders showed a relatively high risk of recurrence for nearly 1500 pairs of successive lactations in Great Britain. Hence reproductive failure is the most common cause of culling, and most reproductive disorders are risk factors for other reproductive problems and for other health problems. Once a cow experiences one type of difficulty, assuming she is not culled, she is at higher risk of the same problem in the next lactation.

SEASONAL AND NONSEASONAL DAIRY PRODUCTION

Different Goals, Different Drives

Perhaps the most common example of a seasonal producing dairy is an intensively grazed, grass-fed farm. These systems, once the only means of producing milk worldwide (and still the system of choice in areas such as New Zealand), began to fall into disuse across parts of Europe, the Americas, and the industrialized sections of Asia and Africa, from the 1930s up until fairly recently. The ability to manage grass and cows has improved, however, and along with changes in the economics of dairy production, these improved abilities have created a new interest in this type of production.

In seasonal herds cows must calve at the time of year best suited to the needs of the particular herd to meet milk quotas or when supplies of feed are at their most plentiful and best able to supply the nutrient demands of lactation and pregnancy. As a result, they may have as little as 6 to 8 weeks to breed the entire herd successfully to match it to the desired calving season. Cows that do not meet this goal are usually at increased risk of culling. In some situations, rather than cull the cow, the producer may opt to actively induce abortion in a cow with PGF or a glucocorticoid-PGF protocol to force her to "calve" at the optimal time of year. Neither option is good. Forced culling of cows can play havoc with genetic improvement and puts extreme stress on a

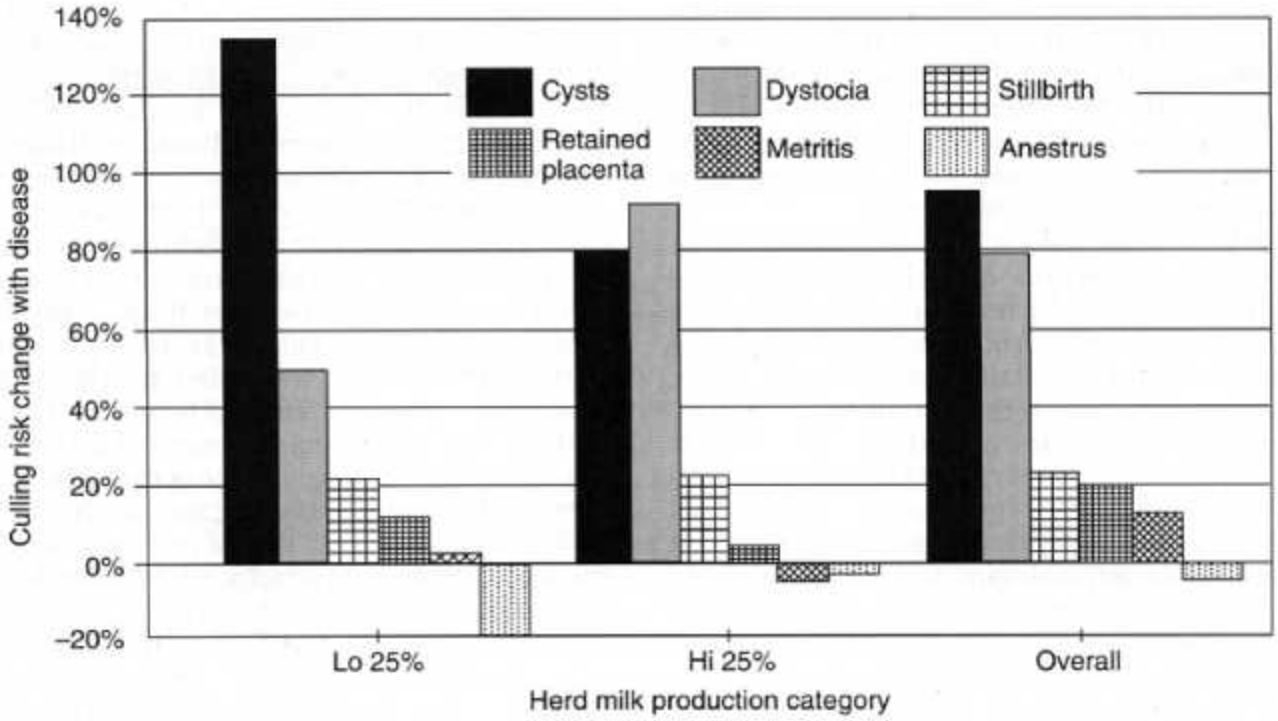

FIG. 7-2 Effect of reproductive disease on culling risk for Swedish dairy cows, based on the lowest quartile of herds by milk production *(Lo 25%)*, the highest quartile *(Hi 25%)*, and overall levels of milk production *(Overall)*. Total number of herds = 1090; total number of cows = 33,748. (Adapted from Emanuelson U, Oltenacu PA: *J Dairy Sci* 81:2376-2382, 1998.)

herd's youngstock program. Induced abortion of cows also stresses the youngstock program and leads to concerns of animal welfare, because often the premature calves are born alive or calves may be euthanized at birth. Again, neither option is acceptable as a long-term reproductive strategy. Hence, it becomes essential for a seasonal herd to achieve its optimal breeding window, which translates into a 12-month calving interval.

The most common type of dairy in North America is not a seasonal grass-fed dairy but a nonseasonal confinement-reared dairy. In such a dairy, feeds in the form of a mixed ration are brought to the cows. Throughout the year feeds are stored on farm, making the dairy relatively indifferent to the growing season. As a result, most such herds practice year-round calving. The practitioner must understand, however, that because of market actions, many of these farms will have times of the year when calvings are more concentrated than at others. For instance, throughout the eastern part of the United States, milk pricing is such that dairies are "rewarded" for producing milk in the autumn. The "reward" may be higher prices, or it may take the form of setting the basis for total amount of milk the dairy may sell at other parts of the year at a given price. Either way, the farmers are prodded to produce in the fall. The important difference between this type of seasonality and that of the grass-fed dairies is that, should a cow miss getting bred in time to calve in the autumn, the cow is not necessarily at greater risk of being culled. The dairy simply suffers an opportunity cost of the postponed calving; the dairy foregoes some added income by missing the best calving time.

There are other drawbacks for a year-round calving herd when cows are not bred on time. Cows' daily milk production decreases as the time from parturition passes (increasing days in milk). The producer has two options for a cow with delayed conception: either dry off the cow and allow a long dry period, or continue to milk the cow with reduced daily milk production. Neither option results in as much average milk per day as would have been possible if the cow had conceived at a proper time postpartum. In nonseasonal herds, the fundamental economic purpose of a reproductive program is to minimize the variation in lactation lengths and keep them at an appropriate length without prolonging the dry period. Other economically important objectives of reproductive programs are reduced culling because of reproductive inefficiency, reduced need for treatment of reproductive disease, increased genetic selection opportunities, and earlier first calving in heifers.

Different Strategies, Different Optima

It should be apparent that one of the main differences in reproductive strategies between seasonal and nonseasonal farms is that the former *must* achieve a 12-month calving interval to survive, whereas the nonseasonal herd has more leeway in determination of an optimum calving interval. Although a calving interval of 12 months has been associated with yielding the optimum amount of milk and number of calves over the lifetime of the cow in a nonseasonal dairy (de Kruif and Brand, 1978), it is likely that, for high-producing herds, the optimum interval is longer than 12 months.

Part of the difficulty in interpreting most research on calving intervals is that the economic return of individual systems is confounded by the abilities of individual dairy managers and by the reproductive goal the dairy is attempting to achieve. For decades, extension agents, dairy science professors, consultants, and veterinarians have been telling producers that a 12-month calving interval is optimal (Wells and Burton, 1981; O'Conner, 1993). Dairies that reach this goal most consistently are usually the dairies with the best managers. Furthermore, these "best reproductive managers" are likely also better at other aspects of running a dairy, such as cost control and finances. Hence, it is not surprising when a study finds that the farms reaching a 12-month calving interval are also the highest profit farms—indicating that efficient reproduction is usually a good proxy measure for an overall well-run dairy. However, most studies cannot show whether those same farms would have done even better economically had they opted for a longer or shorter calving interval. Another confounder to most calving interval studies is that herds that achieve a long calving interval were

Downloaded From Vet-eBooks.com

likely attempting to reach a 12-month interval. Hence, they will have experienced most of the expenses involved in making the 12-month calving interval—with another 2 months' worth of estrus detection labor, hormonal manipulation, and semen—yet will have generated the lowered average income from the longer interval. Therefore the researchers prove not that a *planned* 14-month calving interval is worse than a 12-month interval, but that a farm that misses its goal by 60 days does worse than a farm that does not miss its goal. Again, this is not surprising. Finally, survey-type research, of necessity, treats many inputs as constants across levels of production and herd size. This means that feed and feed costs, for example, are assigned as constants per unit of milk produced, in essence making milk production immune to economies of scale or increases in efficiencies. Since both of these are primary goals of growth and increased production, these types of studies will inappropriately discount such management practices.

Some researchers have attempted to get around the limitations just mentioned, either through whole-farm clinical trials or through computer modeling and simulation. As an example of the former study type, Holman et al (1984) established programs to achieve different lengths of monthly calving intervals in Israeli dairies, thereby avoiding the second of the above confounders to most calving interval research. They found that a 13-month calving interval developed higher income per cow than did a 12-month interval. Furthermore they found that, if planned, incomes per cow did not significantly decrease until beyond a 15-month calving interval. As an example of the latter study type, Slenning (1986) demonstrated that in the typical large herd situation in California, optimum calving intervals lengthened with increased lactational production. He further demonstrated that significant losses were associated with calving intervals that were shorter than optimal, but that losses for calving intervals up to a few months longer than optimal were relatively small. The conclusion here was that if a producer were to minimize risk, the appropriate strategy would be to avoid *shortened* intervals, not lengthened intervals. But perhaps the most important lessons from these two studies (and similar work) is that optimal calving intervals are dairy specific and that there are no surefire goals applicable across the board in nonseasonal herds.

BREEDING PROGRAMS: ARTIFICIAL INSEMINATION AND BULL BREEDING

Since the inception of the AI industry in the late 1930s, bull breeding of dairy cows has decreased. The reasons for this trend are many, but they can be mostly explained by a few salient points. First, in most parts of the world AI offers a producer the best genetic improvement possible. Bulls that enter commercial bull studs for AI use are derived from the very top, and most heavily researched, genetics in the individual breeds. In contrast, bulls purchased locally or raised internally on a farm cannot usually compete genetically with those offered by bull studs. Second, the use of bulls in a dairy's reproductive program requires different facilities than one that does not use bulls. For instance, bulls should be rotated for reasons of libido and body condition. Hence a dairy should have pens for bulls that are not breeding currently. In addition, because of their size and aggressiveness, bulls usually require more stout fencing than do cows. Third, AI largely eliminates the transmission of venereal diseases; indeed, it is the recommended treatment modality for many sexually transmitted diseases. Furthermore, bulls, because of their size, can injure older or smaller cows. Hence there are human and cow health concerns with bulls. Fourth, the capabilities of the average dairy farmer have increased over the past decades. Most dairies now have at least one member of the management team with a college degree, and some dairies have management-level personnel with a Master's level of training. In addition, some clients' management include Ph.Ds and lawyers. Such highly trained individuals can make good use of the technical aspects and data-intense methods needed to maximize the value of AI protocols. Finally, on-farm safety is a growing issue on dairies with bulls. As herds become ever larger, and more and more of the work force is hired help, a farm's liability in the case of worker safety and bulls becomes an increasing concern. Future insurance costs may make bull breeding a financially unsound strategy because of risk.

Strengths and Weaknesses of Different Breeding Systems

The vast majority of commercial dairies operate their reproductive program as (1) an exclusively AI system, (2) exclusively bull-bred system, or (3) an AI-bull hybrid system. We will briefly look at the strengths and weaknesses of each system.

Artificial Insemination–Exclusive Herds

For dairies that opt to breed cows solely through artificial means, the advantages are primarily gained through genetic gain and from not having bulls on site. These dairies' potential for genetic improvement is maximized. In addition, commercially available bulls are evaluated for a variety of their daughters' characteristics, from conformation through milk production and milk quality as well as lifespan, economic returns, and disease status. Thus producers can weigh the type of genetic progress to fit the current needs of their herd. This allows mating to be chosen for individual cows—mating that improves on the cow's weaknesses and takes advantage of her strengths. Furthermore, dairies that do not use bulls tend to have lower needs and costs for facilities and fencing in terms of construction and maintenance. In addition, herds using only AI for breeding avoid the costs and dangers of bulls, whether those are measured in terms of disease transmission in the herd or of worker health and safety.

AI is not problem free. First and foremost, AI depends on humans to determine when a cow is receptive (estrus detection) and to deliver live semen to the cow during the short period during which the cow can conceive (breeding technique and timing). Numerous authors have identified estrus detection as the weakest link in dairies' reproductive programs, a link that may explain the majority of economic losses from reproductive failures. In addition, estrus detection can be tedious and time consuming; it is often easy for people to rationalize why some other task(s) should take precedence in their workday. Furthermore, individuals who have the knowledge and skills to properly and consistently perform the tasks involved in AI tend to command some of the highest salaries within the industry. Finally, a growing concern in the AI industry is the resulting genetic concentration that occurs within dairy breeds. It is not uncommon, for instance, for the most widely used bulls in a breed to be related; some are half brothers. Such concentration brings with it a potential loss of genetic diversity and the amplification of genetic afflictions. In fact, the industry already has seen certain genetic problems (bovine leukocyte adhesion deficit, for example) appear over the past few decades. While the industry is actively monitoring for such diseases and establishes tests for the same as soon as one is identified, AI increases the potential for such abnormalities to become widespread in the dairy cow.

Exclusively Bull-Bred Herds

The advantages for bull breeding primarily relate to the bulls' ability to accurately detect cows in estrus better than any human-based system and to deposit semen at the most appropriate time in a cow's estrous cycle. Bulls happily work weekends, nights, and holidays; they do not ask for vacations or pay raises. In short, they are usually enthusiastic workers that need little to no training or guidance in performing their jobs.

Bull-bred herds have particular problems. Bulls will not record the breedings they accomplished; it is left to the human managers to do this. This requires monitoring estrus behavior, just as with AI herds. In fact, many of the other published difficulties with bull-breeding strategies are not the fault of the bulls, per se, but the fault of lack of management. For instance, some dairies place bulls in the milking herd or in with their breeding-age heifers and then ignore them for weeks or months. This assumption that the bull is able to perform is the likely cause of more reproductive disasters in bull-bred herds than any other factor.

Actual bull-based, as opposed to management-based problems, are plentiful. First, bulls can spread venereal disease such as campylobacteriosis and trichomoniasis. In addition, bulls display varying levels of libido; therefore some bulls are simply less aggressive in breeding than others. Even those bulls with high libido can have feet or leg problems that limit their serving capacity or ability to correctly identify, mount, and breed a cow. Bulls that have injuries to the reproductive tract, especially injuries to the testicles and scrotum, can have lowered semen quality, either short term or long term. Hence a producer may see the bull-breeding cows but may not be aware that semen quality is too low for acceptable levels of conception to occur. Furthermore, bulls usually gain excess body weight on a typical milk-cow ration. Heavy bulls tend to be less active reproductively. As a result, the manager who assumes all is well in a bull-bred herd can easily suffer months of poor performance until the problem is recognized. By then it may be too late for many of the herd's cows to be saved.

As previously mentioned, the typical dairy bull's size and temperament also requires the dairy to experience increased housing and facility expenses as well as increased health and safety concerns. Why dairy bulls seem to be more dangerous than beef bulls is likely due to a combination of factors. However, dairy bulls are creatures that command respect and constant vigilance from the people who work around them.

One bull-breeding system that has become less common on dairy farms is the "hand-mating" system. In such a system, a dairy's management performs estrus detection, as would be normal for an AI herd. However, when a cow is identified as being in estrus, she is moved to a bull pen (typically a small pen in which a single bull lives). The cow is observed to be bred and is then returned to the herd. The advantages of this system are that bull weight and libido can be monitored more effectively, safety of personnel is improved, and facility expenses are usually decreased. The disadvantages, however, are that the system requires intensive estrus detection on the part of management and suffers from lower genetic performance of all bull-based systems. Thus a hand-mating system combines the worst of both systems.

Artificial Insemination/Bull-Breeding Hybrid Systems

Large dairy herds often use a hybrid system comprised of both AI and bull breeding. Cows are usually exposed to AI-based breeding during early lactation, and then they are brought to a "clean-up bull" pen. For instance, a herd might set a limit for days in milk or number of AI breedings for cows, beyond which the animal goes to a milking string in which the clean-up bull resides. The protocol might be that every cow is moved to the clean-up bull pen after being bred three times by AI or after she passes 100 days in milk, whichever comes first. These hybrid breeding systems take advantage of the positive qualities of both AI and bull breeding. Every cow gets a chance to be bred to an AI bull, thereby maximizing the genetic potential of her offspring. In addition, those cows not conceiving to AI are also submitted to the clean-up bull's intensive estrus detection and breeding capability, thereby maximizing their chances of becoming pregnant in a timely fashion. As a result, such herds enjoy the advantages of both systems. In addition, they do not hamper the bulls' ability to detect estrus and to breed on time, as do the "hand-mating" systems.

Unfortunately, a hybrid AI/clean-up bull system carries most of the disadvantages of either individual system. Dairies using the hybrid breeding system have increased expenses in highly trained labor for AI, plus in facilities and maintenance for the bulls. In addition, the herd may suffer from poor estrus detection when cows are in early (and likely optimal breeding window) lactation; they could also suffer from poor breeding performance resulting from a mismanaged bull. There also appears to be a threshold herd size to allow a combined, or hybrid, system to be successful. It is our experience that herds smaller than 350 milking cows will often not be able to group cows effectively enough to make a hybrid system worthwhile.

REPRODUCTIVE EXAMINATION OF COWS

Accurate and easy-to-follow reproductive records are critical to a sound reproductive program. There are several types of record-keeping systems for reproductive data of individual cows ranging from cow cards to computer-based recording programs. Reproductive indexes and strategies for analysis and monitoring of herd-level reproductive data are discussed later in this chapter. The following section presents an overview of on-farm physical exam and laboratory methods for evaluating reproductive system. Palpation of the reproductive tract per rectum remains the most common on-farm technique for assessment of reproduction in cows. In addition to palpation, we discuss the use of ultrasonography and other diagnostic methods, such as progesterone assays, that can provide additional information for the practitioner.

Regular Herd Evaluations

Reproductive performance of the herd can be evaluated monthly, biweekly, or even more frequently in large herds. To achieve optimum herd reproductive performance, it is necessary to obtain optimum performance from each cow. Usually, this requires that each cow calve as close as possible to every 12 to 13 months, beginning at 24 months old. Achievement of that objective depends on breeding cows to conceive by an average of 85 to 120 days after calving. Three important points of procedure are involved:

1. The routine, systematic evaluation of the herd's reproductive status and attention to management activities that impact on reproduction.
2. The concentration of reproductive management activity during the postparturient period and up to 3 months later.
3. Regular physical examination of the cow's reproductive tract.

The achievement of an acceptable calving-to-conception interval (e.g., 85 to 120 days) necessitates concentrated management activity during the first 90 days after calving. In gen-

Downloaded from Vet-eBooks.com

eral, early postpartum breeding in dairy cows results in more calves and higher milk yield per day of herd life. However, early-bred cows usually require more inseminations per conception. Breeding normally can begin at about 45 days postpartum with an acceptable rate of reproductive performance, and, with current management practices, a desirable calving interval can be achieved by shortening the interval to first insemination to about 50 to 60 days postpartum. Each day of delay beyond the optimum calving-to-conception interval of 85 to 120 days often reduces the farmer's profit margin (Olds et al, 1979). Each dairy farm, and often groups of cows within a dairy, has a different optimum calving-to-conception interval. The practitioner is encouraged to determine the optimum interval from calving to conception for the dairies that he or she may service.

Reproductive Examination by Palpation

Good palpation skills are an invaluable aid to the practitioner who is initiating a new reproductive health program or maintaining an existing program for a dairy. Emphasis is on the examination of cows for pregnancy, cows that are not detected in estrus by a certain time after calving, cows that experienced calving difficulty or other postpartum problems, and cows that fail to conceive following multiple inseminations. Palpation per rectum of the reproductive tract for monitoring normal uterine involution and ovarian activity is usually done one or more times before the initiation of breeding (Mortimer et al, 1997). Palpation at approximately 35 days or more after insemination is commonly used to diagnose pregnancy in cows and heifers (Youngquist, 1997b). Cows should be examined again to confirm pregnancy status one or more times before the expected dry-off date. Detecting pregnant and open cows and identifying normal and abnormal changes of the uterus and ovaries provide important information for making clinical and management decisions.

Ultrasonography

Ultrasonography is a valuable aid for early diagnosis of pregnancy, determination of fetal sex, and accurate identification of uterine and ovarian structures. The potential economic benefits of including ultrasound as a routine procedure in reproductive programs should be evaluated for each individual herd. We anticipate that the use of ultrasound units on dairy farms will continue to increase as the cost of ultrasound units decreases and the units become more adapted for use under a variety of herd conditions. A good quality portable ultrasound unit with a 5.0-MHz probe works well for general reproductive examinations of the uterus and ovaries of cows and heifers. A more detailed examination of ovarian structures may be achieved with the use of a 7.5-MHz probe.

Several conditions of the uterus and ovaries may be assessed with the aid of an ultrasound unit. The developing bovine conceptus can be detected using real-time ultrasonography by at least 19 and 24 days of gestation (Curran et al, 1986); however, diagnosis of pregnancy by ultrasound in large groups of cattle under farm conditions can usually be accomplished in large groups of dairy cows after Day 25 or 26 of gestation. The fluid-filled uterus of the early pregnant cow appears mostly black or anechoic. Because of normal fetal loss, cows diagnosed pregnant at this early stage of gestation should be examined again after Day 60 of gestation to confirm pregnancy. Phenotypic sex of the fetus can be determined through the use of an ultrasound to visualize the location of the genital tubercle, which is the presumptive clitoris or penis (Curran and Ginther, 1991). Fetal sex determination may be performed at approximately 55 to 100 days of gestation, with Days 60 to 80 of gestation being our preference. Ultrasonography may also be used to determine the number of fetuses *in utero* as well as the viability of the developing fetus based on fetal movement and heart beat. Early identification of fetal gender and viability provides the producer with additional information for making decisions about selection and selling of dairy animals. Ovarian follicular waves and corpus luteum (CL) development associated with the normal estrous cycle (Pierson and Ginther, 1988) as well as ovarian cysts may be detected using ultrasonography (Edmondson et al, 1986; Farin et al, 1992). In addition, pathological conditions of the uterus such as pyometra may be visualized with ultrasonography (Fissore et al, 1986).

Other Diagnostic Tests

Progesterone Assays

The most commonly used on-farm assay for progesterone is an enzyme-linked immunosorbent assay (ELISA) for progesterone concentration in milk. In addition, several diagnostic laboratories provide services for determining concentrations of progesterone as well as other reproductive hormones in serum or plasma samples of cows using a radioimmunoassay (RIA). Progesterone is secreted from the CL on the ovary of the cow during the luteal phase of the estrous cycle and during pregnancy. In nonpregnant cows, progesterone concentration in milk is low on the day of estrus (Day 0), gradually increases to about Day 7 of the estrous cycle, remains elevated during the luteal phase, and then decreases following CL lysis on about Day 18 after estrus. In pregnant cows progesterone concentrations remain elevated. Thus concentrations of progesterone in samples of milk, serum, or plasma taken at about 20 to 22 days after breeding are low in nonpregnant cows and elevated in pregnant cows. Most cows with low progesterone concentrations approximately 20 to 22 days after AI are not pregnant. Cows with low progesterone may be coming into estrus, may be in standing estrus, may be going out of estrus, may have a follicular ovarian cyst, or are anestrus. In contrast, cows with high progesterone at 20 to 22 days after breeding are assumed to be pregnant. Accuracy of diagnosing a cow as pregnant based on a high progesterone is approximately 75% (Zaied et al, 1979). Cows assumed to be pregnant early based on a high progesterone should always be confirmed pregnant by palpation or ultrasonography later in gestation, because other conditions such as AI of cows not in heat, inaccurate breeding records, early embryonic death, pyometra, and cystic ovaries can result in cows being diagnosed pregnant erroneously.

Milk progesterone assay is the most effective on-farm method to assess the accuracy of estrus detection (Nebel et al, 1987). Although a low progesterone level does not guarantee that the cow is in estrus or that insemination was performed correctly (and correctly timed relative to estrus and ovulation), a high progesterone level does indicate that the cow was *not* in estrus. We have found milk progesterone assays to be helpful when working up herds with low pregnancy rates and a suspected estrus detection problem. The dairy producer may collect and freeze milk samples from each cow at the time of breeding. After a suitable number of samples have been collected, they can be assayed for progesterone concentration. Results of progesterone assays allow the practitioner to determine the percentage of cows inseminated that were *not* in estrus (as indicated by a *high* progesterone concentration). The insemination of cows not in estrus can be a serious problem on both large and small dairy farms (Reimers et al, 1985; Slenning and Farver, 1990). In a study of dairy farms in the northeastern United States, Reimers et al (1985) found that 5% to as high as 60% of

Downloaded From Vet-e-Books.com

cows among herds were inseminated and not in heat based on high concentrations of milk progesterone. *The practitioner should be alerted to a potential estrus detection problem when more than 5% of cows that are called in heat and inseminated also have high progesterone in milk.* These assays may also be used to determine the percentage of heifers with high progesterone that may be responsive to PGF treatment for estrus synchronization, and for differentiating between luteal (high progesterone) and follicular (low progesterone) ovarian cysts in cows (Sprecher et al, 1988).

Cytogenetic Testing

Cytogenetic evaluation of individual animals is needed to confirm parentage or to provide the practitioner with additional diagnostic information for specific conditions such as freemartinism (Buoen et al, 1981). These tests can be performed by diagnostic laboratories on bovine lymphocytes or on tissue such as a skin biopsy.

Vaginoscopy

A clear plastic vaginal speculum allows for rapid examination of the vaginal vault for assessing trauma to the cervix and vagina following calving and for visualizing the external os of the cervix for detection of normal discharges (e.g., lochial discharges found early postpartum, or clear mucus discharges of estrus) and abnormal discharges (e.g., purulent endometritis).

Uterine Culture and Biopsy

Samples of uterine fluid for aerobic and anaerobic bacteriological evaluation may be indicated in cows with severe or chronic uterine infections. Sterile infusion pipettes that are guarded from contamination while passing them through the vaginal vault can be used to obtain fluid from the uterus or cervix of cows (Mortimer et al, 1997).

Biopsy of the endometrium of the cow has been used to provide histological evidence in the diagnosis of endometritis. However, biopsy of the endometrium may result in decreased reproductive performance of cows (Etherington et al, 1988); thus it is not recommended as a routine herd procedure.

Recovery of Embryos

Superovulation treatment followed by AI and uterine lavage (flush) may be used to recover embryos or oocytes from cows suspected of having problems associated with the uterine tubes or ovulation. Recovery of embryos or oocytes by uterine flush with a phosphate-buffered saline solution on Day 7 or 8 after insemination can help confirm ovulation and patency of the uterine tubes (Bowen et al, 1978).

ENHANCING REPRODUCTIVE EFFICIENCY

The goal of reproduction on a dairy farm is to produce a calf, thereby inducing a new lactation. Accomplishment of this goal depends on production of viable oocytes, delivery of these oocytes to the oviduct for fertilization, availability of viable spermatozoa in the the oviduct, transportation of the fertilized ovum to the uterus, successful signaling of maternal recognition of pregnancy, development of the placenta, physiological maintenance of the pregnancy, and successful parturition. Indeed, there are many physiological and pathological causes of reproductive failure in dairy cows. Fertilization failure and early embryonic mortality are major contributors to reproductive failure in cattle (Zavy, 1994). Factors that decrease fertilization rates include production of poor quality or aged oocytes, use of semen from low-fertility bulls, and poor timing of insemination relative to days postpartum or ovulation. In cows with no disease problem the rate of embryonic mortality is relatively stable although subject to decrease by poorly timed insemination or by such factors as high environmental temperature, use of semen from low-fertility bulls, and insemination of pregnant cows. Fertilization rate almost certainly can be improved, to a marked degree in some dairy herds, by inseminating only cows in estrus, correcting errors in semen handling, improving the timing of insemination relative to first observed standing estrus, and inseminating cows with semen from bulls of proven fertility.

Additional factors that are critical to high reproductive efficiency include management efforts to reduce nutritional and lactational stress in early lactation. The maintenance of appropriate energy balance and nutrient intake reduces the incidence of fatty liver, fat cow syndrome, and ketosis. Positive steps should also be taken to prevent the introduction of brucellosis, *Campylobacter* sp., leptospirosis, trichomoniasis, and other infectious causes of infertility as well as selection against bulls, and possibly cow families, that have a high incidence of dystocia. Culling policy also has an important effect on reproductive efficiency. For example, if all cows that do not exactly match reproductive targets are immediately culled, the apparent reproductive efficiency of the herd at any one time is considerably enhanced. The numbers may look good, but the total effect on the herd's economy may be disastrous because of the young average age of the herd and the almost certain result of a lowering of the herd's milk yield and increased costs for replacement heifers. Alternatively, if the culling policy is directed solely at improving cow milk production, there may be a tendency to keep old or infertile cows because of their genetic worth.

As discussed earlier in this chapter, milk production of cows has increased and reproductive performance of cows has declined during the past 20 years as evidenced by increased days open and decreased conception rates. Problems related to breeding management (e.g., elective postponement of rebreeding and low estrus detection rate) and the negative influences of high milk production and heat stress may be responsible for this decline in reproductive efficiency. This suboptimal level of reproductive performance in many dairy herds is matched by the paradox that, in some herds, substantially higher levels of performance are achieved. Dairy farms with successful reproductive programs incorporate excellent cow nutrition, a committed management team, effective estrus detection programs, strategic use of estrus synchronization protocols, attention to breeding techniques, and routine reproductive examination and treatment of problem cows. In general, efforts to improve reproductive performance of cows on individual farms have been shown to be profitable (Galton et al, 1977).

Postpartum Uterine Infections

Postpartum infection of the uterus has long been considered an important cause of bovine infertility (Erb et al, 1981a,b). Dystocia, twinning, and retained fetal membranes increase the risk of a cow developing postpartum uterine infections. Management efforts should be directed toward prevention of uterine infections by providing cows with adequate nutrition, maintaining sanitation in the calving area, and reducing the incidence of dystocia. Cows with certain types of uterine infection, such as cows with pyometra, usually respond very well to treatment with PGF alone. However, cows with other infections of the uterus such as severe metritis

Downloaded From Vet-eBooks.com

and chronic endometritis often require additional antibiotic therapy (Youngquist and Shore, 1997).

Postparturient Metabolic Diseases

Milk fever, ketosis, and other metabolic diseases may adversely affect reproductive performance of cows. These diseases may affect the oocyte by altering normal follicular development contributing to defective follicles that are recruited for ovulation during the optimum breeding interval. For example, acetonemia is reported to have prolonged the calving-to-conception interval of affected cows by 51 days and increased the services per conception rate by 0.73 services (Nenadovic et al, 1979).

Early Postpartum Estrous Cycles

Practices to encourage early postpartum estrous cycles and breeding after calving help to reduce the intercalving interval but often at the expense of lower conception rates. However, this practice does not appear to have any apparent deleterious effect on long-term fertility (Williamson, 1980). The simple monitoring of reproductive status, especially postpartum estrous cycles, does not encourage greater reproductive efficiency of itself (Munro et al, 1982). There must be intervention by the producer and the veterinarian so that the recognition of an impending problem is countered by preventive actions. In particular, adjusting the ration to provide an adequate dry matter intake and a nutritional level to meet the needs of early lactation and conception is a common strategy. Cows should be fed during the dry period and early lactation to minimize the negative energy balance that is detrimental to the return of cyclicity. The feeding program should avoid excessive weight gain in dry cows but should be a high-energy density ration after calving. The relationship between fertility and roughage, rather than concentrates, has been demonstrated (Bogin et al, 1982). High-quality forages should be fed to, and attention paid to the neutral detergent fiber (NDF) and dry matter intake of, cows in the first several weeks' postpartum.

There is convincing evidence that the fertility of cows is significantly affected by their energy and health status 2 to 3 months before the estrous cycle of breeding. Cows in significant negative energy balance sustain damage to the developing population of follicles that are recruited for ovulation 2 to 3 months later. This contention is supported by several observations. Cows in hot climates have reduced fertility for up to 2 months after high temperatures have passed (Faust et al, 1988). Early postpartum clinical disorders can affect fertility 60 to 80 days later, despite the fact that the primary disorder has long since healed (Oltenacu et al, 1983). Negative energy balance in the first 9 days postpartum reduces progesterone levels of cows during the luteal phase of their second and third postpartum estrous cycles (Villa-Godoy et al, 1988). Cows that lose a significant amount of weight (more than 0.5 body score points, 5-point scale) in early postpartum have extended days to each ovulation and have significantly reduced conception rates for at least the first three services (Britt, 1991). This difference is not simply a function of milk production. The difference in reproductive performance was seen even though the groups that did not lose as much weight on average gave the same amount of milk as the group that lost weight. In another study, cows that lost 1 body score point had a first-service conception rate of only 17% compared with conception rates over 50% for cows that lost less than 1 body score point (Butler and Smith, 1989).

Another nutritional aspect that appears to influence reproductive function is the amount and character of the protein in the cow's ration at the time of insemination. Cows fed high levels of rumen-degradable protein have been shown to have reduced reproductive efficiency (Ferguson and Chalupa, 1989). Similarly, heavy feeding during the dry and peripartum periods alter follicular development and decrease reproductive performance. Nutritional deficiencies that lead to the loss of body condition, as well as deficiencies of copper, cobalt, iodine, iron, and selenium, may also reduce reproductive efficiency indirectly (see Chapter 11).

The most favored biological treatment to restore estrus cycling after parturition is the maintenance of good condition during the dry period, at calving, and during early lactation. Efforts have also been made, however, to modulate the return to fertile estrus by the use of hormone therapy in the early postpartum cow. Variable results have been observed when PGF or gonadotropin-releasing hormone (GnRH) was used in dairy cows during the postpartum period, as measured by the impact on subsequent fertility and days open (Etherington, 1984; Etherington et al, 1988; Oxender, 1991). In regards to the effect of administration of these hormones on subsequent uterine infection, the use of GnRH during the postpartum period may increase the incidence of pyometra (Etherington, 1984). However, the use of PGF during the postpartum period may decrease the occurrence of pyometra (Etherington et al, 1988).

Detection of Estrus

Inaccurate estrus detection can lead to incorrect timing of insemination and insemination of cows that are not in estrus. Ideally, cows should be inseminated about 12 hours after first observed estrus (AM/PM Rule). The detection of behavioral estrus in cows must be a planned activity on the farm; just like milking is a planned activity. Observation of the herd for 30 minutes in the morning before and after milking, at midday, and late in the evening allows the accurate detection of estrus, but few producers take the time to do the task properly. In herds in which cows have access to pasture or exercise lots, tail chalk, pedometer, and heat mount detectors as well as the use of cows treated with testosterone (androgenized cows) are possible alternatives. Although each method is successful and preferred in a particular environment (Fulkerson et al, 1983), tail chalk or tail paint is preferred in most cases because of low cost and ease of application. A thick layer of chalk is applied to the hair and skin over the dorsal spines of the sacral and first coccygeal vertebrae. The chalk is rubbed off when a cow stands in response to being mounted by other cows. Surgical preparation of bulls to be used as heat detectors on dairies has serious disadvantages, including vaginal entry of cows and the possible introduction of venereal disease.

Progesterone concentrations of milk or serum may be used to monitor estrus detection accuracy (see "Progesterone Assays" section for details). Inaccurate estrus detection can appear as decreased conception or pregnancy rates and should be considered before focusing on areas such as inseminator error, semen quality, or cow infertility.

Another approach for evaluating estrus detection accuracy is to examine the intervals between one estrus event and the next. If estrus detection is accurate, the interestrus interval should be either 18 to 24 days or 38 to 45 days, and at least 60% of second estrus events should be in these intervals (Weaver and Goodger, 1987a,b). If the interval is not, the presumption is that at least one of the two cycles was detected incorrectly. However, *interestrus intervals are of little value in herds in which prostaglandins are used regularly to synchronize estrus.* This measurement is also confounded by extended estrous cycle length associated with early embryonic death. In addition, for estrus events two cycles from the first,

Downloaded from Vet-e-Books.com

the variability of the timing of the second cycle is such that it can be difficult to be confident which estrus is within the appropriate window of time.

Inseminator Efficiency

The person doing the AI can have an important effect on herd fertility. Poor technique in storage or in thawing straws of semen as well as failure to deposit the semen in the uterine body can reduce fertility. The veterinarian should work to assess and monitor the effectiveness of the farm's inseminators by observation and analysis of breeding results. In small dairy herds, the practitioner must be careful not to overinterpret the results of a limited number of breedings.

Examination of the Reproductive System and Records

Regular visits by a veterinarian to examine cows for evidence of pregnancy and to uncover reasons for nonpregnancy are the basis for reproductive herd health programs. These visits also provide an ideal opportunity to review reproductive records of cows and discuss targets for the farm's reproductive and breeding program. The frequency of herd visits depends on herd size, season, and the specific goals of the farm's reproductive program. Farm visits are often conducted monthly or biweekly on small- to medium-size dairies and weekly on large dairy farms.

Control of Reproductive Diseases

Control measures for infectious diseases causing reproductive failure in dairy cows vary depending on the prevalence of the disease and the specific location of the dairy farm. Infection and abortion caused by bovine brucellosis has decreased in many parts of the world. In contrast, leptospirosis is still a serious cause of bovine abortion in many areas and is controlled by vaccination two or more times with a multivalent bacterin and by reduction of exposure of cows to potentially contaminated materials on the farm such as polluted water or aborted fetuses. Infection with *Campylobacter fetus* ssp. *venerealis* (formerly *Vibrio fetus*) in dairy cattle is controlled by AI. Where natural breeding is practiced, vaccination of the bull before the breeding period may be an effective method to control the spread of this venereal disease. Trichomoniasis is rarely seen in dairies and is effectively controlled by the use of AI. Bovine abortions caused by herpesvirus or infectious bovine rhinotracheitis (IBR) are controlled by vaccination. Abortions caused by bovine virus diarrhea (BVD) are also controlled by vaccination as well as by detecting and eliminating contact with infected animals (Barr and Anderson, 1993).

Estrus Synchronization Programs

Failure to detect estrus and inaccurate estrus detection are the major reasons for poor reproductive performance on many dairies. Low estrus detection rates have stimulated an increased interest among producers in effective programs for synchronization of estrus and ovulation in cows. Improvements in reproductive performance of groups of cows in heat at one time can be attributed to an increased opportunity to detect cows in standing heat or to inseminate groups of cows at a fixed-time regardless of standing heat. These programs also concentrate labor efforts in the breeding program. Ideally, estrus synchronization protocols should control the function of the CL, the development of ovarian follicles, and the ovulation of follicles with viable oocytes. A variety of different synchronization protocols have been used successfully in dairy cows, and new protocols are developed continually to improve rates of synchronization of estrus and ovulation as well as rates of conception following AI. This section discusses commonly used synchronization programs for cows and heifers (for review, see Whisnant et al, 2000).

Essential prerequisites for a successful estrus synchronization program are excellent cow and heifer management including identification (readable ear tags) as well as maintenance of records of all animals to be synchronized, detected in estrus, and inseminated. Success of synchronization programs in dairy cattle may be measured by rates of estrus detection, conception, and pregnancy.

Synchronization programs use special terms to describe outcomes. Estrus detection rate refers to the percentage of cows detected in standing heat among those cows eligible to be detected in heat. *Conception rate* represents the percentage of cows that became pregnant among those cows actually inseminated. *Pregnancy rate* refers to the percentage of all eligible cows that are diagnosed pregnant during one estrous cycle or synchronized breeding period. Thus pregnancy rate is influenced by heat detection efficiency and by both conception rate and estrus detection rate. Conception rate and pregnancy rate are synonymous for protocols that use fixed-time insemination of all cows or heifers.

Prostaglandin and Analogs

Protocols incorporating prostaglandin $F_{2\alpha}$ (PGF) or its analogs are commonly used in cows and heifers to induce a synchronized estrus by shortening the length of the estrous cycle. Recall that a functional CL is necessary for PGF to be an effective synchronization treatment because PGF acts by causing lysis of the CL. A standard protocol is to administer two injections of PGF 14 days apart. This 14-day treatment protocol is easy for producers and practitioners to schedule. Cows responding to treatment will exhibit standing heat 1 to 5 days after the second injection of PGF, and they can be inseminated at the usual time relative to standing heat or at a fixed time after the second injection of PGF. Although different intervals between injections of PGF may be used to synchronize estrus, subsequent cycle length and pregnancy rate may be influenced by the interval between injections of PGF. For example, pregnancy rates were greater for cows receiving PGF injections 14 days apart compared with those that received injections only 11 days apart (Folman et al 1990).

Timed insemination following PGF injection has been attempted; however, in most studies conception rates have been consistently lower than insemination after detection of treatment with PGF (Stevenson et al, 1987; Archbald et al 1992). For example, Stevenson et al (1987) found a 23% conception rate after a single AI at 80 hours after PGF treatment compared with 54% for AI at 12 hours after detected estrus. In that study the use of two inseminations at 72 and 96 hours after treatment with PGF produced conception rates of 30%. It is likely that lower fertility following timed insemination can be attributed to differences in follicular wave development at the time of CL regression, causing varying times to estrus and ovulation (Thatcher et al, 1996).

Results of economic models of estrus control on dairy farms have shown that the practice of using prostaglandins on dairies is usually profitable (Fetrow and Blanchard 1987). However, this is not likely true when these programs are based primarily on detection of the CL before administration of PGF (Ferry, 1992). This is likely due to the limited accuracy of palpation alone for identifying CL (Kelton, 1991). Several researchers have attempted to identify cows that should respond to PGF based on elevated progesterone

Downloaded From Vet-e-Books.com

concentrations in milk. Stevenson and Pursley (1994) compared PGF treatment of cows with high milk progesterone concentrations to cows submitted for insemination based on detection of standing estrus. The use of milk progesterone tests decreased days to first AI, calving intervals, and cost per pregnancy; however, the cost was greater than weekly injections of PGF to all noninseminated animals. In another study, Kristula et al (1992) found that weekly PGF injections followed by standard estrus detection decreased days to first insemination and increased pregnancy rate by 30% over the first 90 days postpartum compared with PGF treatment of cows identified as having a CL by palpation *per rectum*. In addition, the costs per pregnancy were also less for the weekly PGF injection program.

Heifers that have attained the appropriate age and weight for their breed to begin normal estrous cycles may also be synchronized using PGF at a 10- to 12-day interval.

Gonadotropin-Releasing Hormone and Prostaglandins

Protocols for synchronization of estrus as well as control of follicular waves and ovulation have now become an integral part of reproductive management programs for lactating cows on many dairies. These protocols are based on the findings that treatment of cows with GnRH or an analog could induce ovulation or luteinization of dominant follicles (Twagiramungu et al, 1995). The addition of a second injection of GnRH after PGF has allowed for the use of timed insemination (insemination following hormone treatment without estrus detection) in lactating cows (Pursley et al, 1995; Stevenson et al, 1996). A commonly used protocol in lactating cows consists of GnRH (100 μg), followed 7 days later by PGF (25 mg Lutalyse), then 48 hours later by a second injection of GnRH, then AI of all cows 16 hours later (Ovsynch protocol). Cows between days 5 and 12 of the estrous cycle respond best to the Ovsynch protocol. This protocol is effective in lactating cows but not in heifers, perhaps because of differences in follicle waves between cows and heifers (Pursley et al, 1997a,b).

Because fixed-time insemination protocols do not involve estrus detection, they offer significant advantages to dairy producers. However, to be efficacious, conception rates for these programs should be similar to those seen for AI after estrus detection. In a recent review, Whisnant et al (2000) compared the results of seven different studies in which cows were given either a standard 14-day PGF treatment and AI after detected estrus or an Ovsynch with fixed time insemination. Conception rates, although variable, tended to be slightly less with Ovsynch; however, pregnancy rates were generally higher with Ovsynch than after PGF treatment, with estrus detection rates often being the determining factor. Across the seven studies, conception rates ranged from 22% to 47% for the PGF treatment and from 27% to 47% for Ovsynch. Pregnancy rates ranged from 11% to 30% for PGF treatment and from 27% to 47% for Ovsynch. For example, Pursley et al (1997a,b) compared the Ovsynch protocol with regular PGF injections followed by estrus detection. Pregnancy was diagnosed using ultrasonography at 32 to 38 days after insemination. Animals found not pregnant were started again on the same protocol used previously. First service pregnancy rates were similar for both groups of cows (37% for Ovsynch and 39% for PGF treatment), but days to first service and days open were decreased for the Ovsynch protocol. Pregnancy rates by 60 and 100 days were greater for cows that received Ovsynch (Pursley et al, 1997b). Britt and Gaska (1998) evaluated the Ovsynch method and two injections of PGF 14 days apart, and found no differences between the two treatment groups in conception rates, but pregnancy rates were increased and services per conception decreased in the Ovsynch group. Based on costs of a $1 (U.S.) per day cost for days open and $10 for labor, the Ovsynch program was significantly less expensive than the PGF method (Britt and Gaska, 1998). The cost of the Ovsynch protocol may be lowered by using half the dose of GnRH (50 μg) without adversely effecting pregnancy rates (Fricke et al, 1998).

About 60% or more of cows will not conceive the first time with these protocols and must be dealt with subsequently. It appears that pregnancy diagnosis with ultrasonography may be an effective method for early identification and retreatment of these open cows. In one study, Moreira et al (1997) examined resynchronization of cows that have gone through the Ovsynch protocol. Cows in that study were given GnRH on Day 20 after AI and examined for pregnancy using ultrasound on Day 27 after AI. Open cows were given PGF at this time and were inseminated after estrus or given GnRH 48 hours later and bred 16 hours after GnRH. Pregnancy rate after the ultrasound examination for the resynchronized cows was 33%, which was similar to pregnancy rates after the first insemination.

Progesterone and Analogs

Progesterone or its analogs can be used to synchronize estrus in cows. Although this method has not yet been approved for use in lactating dairy cows in the United States, research on its use has been conducted and is approved in other countries. Two devices have been developed for cattle: a progesterone-releasing intravaginal device (PRID) and a controlled internal drug-releasing (CIDR) device. The CIDR contains progesterone in a silastic elastomer and a capsule containing estradiol benzoate, and the PRID consists of progesterone in a silicone elastomer coil with estradiol benzoate in a gelatin capsule. The degree of synchrony increases with the length of time the CIDR is in the cow, but pregnancy rates decrease with increased length of progesterone treatment (Macmillan and Peterson, 1993). Prostaglandins or estradiol may be used after the removal of a progesterone-releasing device (Xu et al, 1997).

Embryo Transfer and Related Biotechnologies

Embryo Transfer

The dairy industry has used AI extensively to improve herd genetics by exploiting intensive selection applied to sires and dams of AI bulls. Dairy producers are also the primary users of embryo transfer (ET). ET allows for the production of more offspring from a cow in a shorter period, effectively decreasing the generation interval. In addition, frozen embryos may be transported nationally or internationally and may be used in the control of transmission of certain diseases (Stringfellow and Seidel, 1998). The scope of ET has expanded tremendously in the past 10 years. Today conventional ET may also be linked to other reproductive biotechnologies such as embryo sexing, semen sexing, oocyte collection, and in vitro embryo production (IVP) as well as the more recent applications to transgenesis, cloning, and marker-assisted selection for specific disease resistance and production traits (Bishop et al, 1995).

Animal-breeding models of the impact of superovulation and conventional embryo transfer (Multiple Ovulation and Embryo Transfer [MOET]) of superior dams have shown that these breeding systems were of value for developing elite populations of dairy cattle for progeny testing (Nicholas and Smith, 1983). Further acceleration of genetic gains may be possible by including links to other biotechnologies, such as IVP, in these breeding systems (Dekkers, 1992). However,

Downloaded from Vet-eBooks.com

the potential economic benefits of using ET vary between producers but should be most evident when based on the sale of calves resulting from ET (Everett, 1984).

Superovulation treatment of the embryo donor cow as well as AI, embryo collection, and transfer are typically performed on the farm or at an ET facility. Briefly, multiple ovulations are commonly induced in donor cows and heifers by administration of follicle-stimulating hormone (FSH) during the midluteal phase of the estrous cycle and PGF or an analog at the end of FSH treatment to induce estrus. Donors are then artificially inseminated based on standing estrus, and embryos are collected nonsurgically by uterine lavage (flush) on Day 6, 7, or 8 after estrus. Total number of embryos recovered per donor is variable; however, most donor cows will average four to six transferable-quality morulae or blastocysts per flush (Hahn, 1992; Hasler et al, 1983). Variation is present both within and between donors in superovulatory response to FSH treatment, total number of embryos recovered, and the proportion of transferable quality embryos. Variability in number of recovered embryos has been attributed to environmental effects such as farm (Hahn, 1992).

Recovered embryos are either transferred nonsurgically into recipients on Day 7 (±1 day) of their estrous cycle or frozen and stored in liquid nitrogen for future transfer with good results (Hasler et al, 1987). Recent developments in cryopreservation techniques have led to successful freezing of embryos in ethylene glycol, the rapid thaw of embryos in a warm water bath, and the transfer of embryos directly into recipients (called "direct transfer" [DT]). Embryos intended for DT are packaged and frozen in yellow straws. It is important for practitioners to follow the guidelines established by the International Embryo Transfer Society when collecting and processing embryos for commercial purposes (Stringfellow and Seidel, 1998).

In vitro Production of Embryos

IVP refers to the use of laboratory systems to produce embryos. This process usually includes retrieval of oocytes from the ovaries of a cow, in vitro maturation of oocytes, in vitro fertilization, and in vitro culture of presumptive zygotes to the blastocyst stage of embryo development. Birth of the first calf resulting from the transfer of an embryo that had undergone in vitro fertilization and culture was reported by Brackett et al in 1982. Embryos are now routinely produced in laboratories worldwide through the use of a variety of culture systems. Applications of IVP in cattle include production of embryos from either nonpregnant or pregnant cows for transfer into recipient heifers; genetic salvage of donor cows, production of embryos from cows that respond poorly to superovulation treatment, or cows with acquired blockage of the uterine tubes. Furthermore, IVP may be used in the production of potential AI sires, production of half-sib embryos using semen from different sires, and production of embryos for transgenesis, cloning, and related research. Producers often alternate between IVP and conventional ET in an attempt to increase embryo production from donor cows. IVP services are available to dairy producers at several embryo transfer facilities and universities.

Briefly, oocytes may be harvested from ovarian follicles using ultrasound-guided transvaginal oocyte retrieval (TVOR). Oocyte retrieval may be repeated frequently either on the farm or at an ET facility until the desired number of oocytes are obtained. The yield of transferable quality embryos after IVP varies from about 25% to 35% or greater. Acceptable pregnancy rates can be achieved after transfer of IVP embryos; however, these rates are usually lower than those seen after transfer of embryos from conventional superovulation and ET (Hasler et al, 1995). Calves resulting from the transfer of embryos produced in vitro may have increased birth weight and placental problems such as an increased incidence of hydrallantois (called "Large Offspring Syndrome") (Hasler et al, 1995; van Wagtendonk-de Leeuw et al, 2000). Thus recipients carrying pregnancies from the transfer of IVP embryos may require obstetrical assistance at the time of parturition.

Sexed Sperm and Sexed Embryos

Successful use of sexed spermatozoa has been demonstrated in a variety of species, including the bovine (Seidel and Johnson, 1999). Sex ratios of approximately 90% heifer or bull calves are possible after insemination of heifers with sexed sperm (Seidel et al, 1999). The use of sexed sperm may allow dairy producers to target part of their breeding programs for production of replacement heifers, or perhaps production of bull calves for potential AI sires. Sexed sperm cells may also be used in IVP systems to produce embryos of a predetermined sex for transfer. Spermatozoa are sexed based on differences in their X-Y DNA content. Recent improvements in high-speed sorting of spermatozoa indicate that sexed semen will likely become available for commercial on farm use in the near future.

In contrast to the potential future use of sexed sperm, the transfer of embryos of a predetermined sex has already been used by dairy producers for several years. The method for sexing embryos involves biopsy of the embryo mass and determining genetic sex using rapid PCR techniques. A simplified method of embryo biopsy and sex determination allows embryos to be sexed before ET on the farm (Bredbacka et al, 1995).

Transgenesis and Nuclear Transfer

In the future, nuclear transfer and transgenics may influence the dairy industry and the dairy producers' breeding program. Transgenic biotechnology is used to make animals with a gene or genes that are not their own. In contrast, cloning by nuclear transfer allows for the production of a series of genetically identical individuals. The potential economic returns for producing transgenic dairy animals for pharmaceutical and food purposes have fueled research efforts in these areas. Potential future applications of transgenics and nuclear transfer in dairy cattle include modifying genes for important production traits such as the polled trait, heat resistance, and disease resistance; enhancing the nutrient value of milk; changing milk components for more efficient processing and digestion of dairy products; and producing biopharmaceutical products such as clotting factors, anticoagulants, and blood replacement products (Bishop et al, 1995; Wall, 1996).

INVESTIGATING REPRODUCTIVE INEFFICIENCY

General Procedure

An investigation of decreased reproductive inefficiency in dairy cows includes a clear definition of the problem, examination of the cases, and formulation of a plan of action. A guide for conducting an examination of a herd for a reproductive problem is shown in Table 7-3. In addition, different causes of reproductive failure are shown in Table 7-4, and the common causes of abortion in dairy cows are outlined in Table 7-5. The relative importance of each of these causes varies widely from farm to farm and even from time to time on any one farm. An accurate diagnosis of reproductive failure is, to a large extent, dependent on how much importance

Downloaded From Vet-eBooks.com

TABLE 7-3

General Approach to Reproductive Problems on a Dairy Farm

Action	Information Source/Comments
Describe the problem	Records analysis and history; animals affected (individuals, group, or herd; parity; days in milk; etc.)
Prevalence	Season of year; specific location on farm (e.g., calving lot, milking lot, pasture)
Pattern	Category of problem: "cow fertility," "bull fertility," "breeding management," or "environment"
Cost to farm	See text and Tables 7-4 and 7-5
Investigate cases	Physical examinations
	Evaluate breeding management and cow management
	Diagnostic tests as needed
	See text and Tables 7-4 and 7-5
Formulate a plan of action	Treatment of cases/herd; changes in cow management, breeding practices, or facilities as indicated
Intervention	Follow-up exams/diagnostic tests
Prevention	Change plan of action as indicated
Monitor response	See text sections "Reproductive Parameters for Measuring Success" and "Monitoring Reproductive Performance" and Tables 7-4 and 7-5

the producer and veterinarian place on the reproductive program of the farm. This section presents a summary of the more common causes of reproductive failure in dairy cattle.

In herds on a computerized herd health program, a decline in reproductive performance becomes obvious early if the responsible veterinarian is paying close attention to the reproductive indexes produced at monthly intervals by the program. In other herds the problem is often much further advanced at the time it is recognized. It is a great advantage in these herds (if they have sufficiently good data) to begin the investigation by analyzing their records. Thoughtful examination of the records can often narrow the likely problem area. This can make the on-farm part of the investigation much faster and more effective. Indeed, the practitioner challenged with solving a reproductive problem will appreciate that these problems are often closely linked to one another. For example, cows with twins are more likely to suffer dystocia and have retained fetal membranes. In addition, cows with metabolic disorders such as ketosis as well as dystocia and retained placenta have increased risk of developing metritis (Correa et al, 1993). In general, reproductive problems in dairy cattle are often noninfectious, temporary conditions. However, *the practitioner should always rule out infectious causes first when investigating cases of abortion.*

The workup of reproductive inefficiency should begin with a systematic analysis of available records on the affected group of animals within the herd. This allows the clinician to determine the prevalence and pattern of the problem as well as the relative cost of the problem to the farm. The more cows available for analysis of pregnancy data, the better the estimates of herd fertility. Reproductive inefficiency often affects cows in a particular lot or parity such as a nutrition problem, or it may be scattered throughout the herd and associated with a point-source such as a poor semen handling or insemination by a particular AI technician. Alternatively, reproductive problems can appear as one or more nonpregnant individual animals that an owner has a keen interest in getting bred.

Specific on-farm investigations are different depending on the major problem area(s). However, by gaining a broad view of the farm's problems through records analysis, problem areas that have not come to the farmer's attention are not overlooked. For example, a herd that is having a problem with anestrous cows often also has a problem of repeat breeders or early postpartum disease. Regardless of the problem, it is usually productive to obtain a general history about breeding practices, artificial or natural breeding, timing of breeding, techniques used, method of estrus detection, status of nutrition and BCSs, disease control programs, and introduction of new animals. At the point at which individual cow information is needed, the use of a combination of each cow's reproductive record for the past year and the findings on physical examination of the genital tract makes it possible to define the cow's reproductive status. It is much easier to do this if the breeding history of the herd has been submitted beforehand, the cows' records evaluated, and a comprehensive list of cows to examine has been produced. This indicates those cows that need examination and outlines their immediate past histories and the reasons for selecting them for examination.

Overall reproductive performance (days open, abortion rate, culling rate, disease rates) should be examined. If excess days open is the major problem, then the next step is to break the days open into potential sources. Assuming an acceptable voluntary wait period and no excess pregnancy wastage, excess days open can be attributed to poor conception, poor estrus detection, or both (see the "Tools to Expand the Value of Standard DHIA-Based Reproductive Indexes" section later in this chapter). Conception problems can be further segmented by looking at conception rates for various subgroups of cows (e.g., all cows, pregnant cows, heifers). If conception rates in pregnant cows are high, attention can be directed at estrus detection accuracy, insemination and semen quality, and problems affecting the herd as a whole, such as malnutrition or high environmental temperatures. If conception rates in pregnant cows are acceptable, then causes affecting specific subgroups of cows can be addressed (e.g., postpartum disease, infectious disease in younger animals).

Estrus detection problems usually lead the investigation directly to the farm to consider management and labor, housing, nutrition, and foot and leg problems. If estrus detection accuracy problems are suspected, the dairy producer can be asked to collect milk from cows at breeding to determine milk progesterone levels. In contrast, abortion problems require both on-farm and laboratory investigations, as do most

Downloaded From Vet-eBooks.com

TABLE 7-4

Diagnosis of Problems Associated with Reduced Fertility in Dairy Cattle

Category of Fertility Problem	Relative Frequency of Occurrence	Method of Diagnosis/Comments
COW FERTILITY		
Early embryonic death	High	Early pregnancy diagnosis using ultrasonography; interestrus intervals >18-24 days often difficult to determine in herds using estrus synchronization programs
Abortion	Varies	See Table 7-5 for differentials and methods of diagnosis
Dystocia	Varies	History; vaginal-vulvar lacerations; check age at calving, herd goal: <10%
Other accidents of gestation	Low	Reproductive examination, history; examples: hydropsical conditions of placenta or fetus, fetal mummification, fetal maceration
Uterine infection	Varies	Reproductive examination, bacterial culture; includes metritis, pyometra, and endometritis; often a sequela to dystocia or retained fetal membranes; herd goal: <10%
Vulvitis and vaginitis	Varies	Reproductive examination, vaginoscopy, microbial culture; infectious conditions include granular vulvitis, and infectious pustular vulvovaginitis
Urovagina; pneumovagina	Low	Reproductive examination; sequela to dystocia, obstetrics, trauma, or poor perineal conformation
Inflammation and adhesions of cervix, oviducts, ovaries	Varies	Reproductive examination; recovery of embryos to check oviduct patency; sequela to dystocia, trauma, or uterine infection; common conditions include: cervicitis, salpingitis, and occasionally ovaritis
Ovarian cysts	Varies	Reproductive examination; most cows with ovarian cysts are anestrus; herd goal: <10%
True anestrus	Low	Reproductive examination; ration analysis
Metabolic disease	Varies	Physical examination, urine or serum biochemistry, ration analysis
Freemartinism	High	Heifers born co-twin to a bull; physical examination and/or cytogenetic testing of suspected heifer
Segmental aplasia	Rare	Reproductive exam, necropsy; examples: white heifer disease, uterus unicornis; congenital/heritable
Ovarian hypoplasia	Rare	
Ovarian tumors	Rare	History, palpation/ultrasonography; histopathology for definitive diagnosis; granulosa cell tumor is most common
BULL FERTILITY		
Poor semen quality	Varies	Rule out problems with estrus detection, semen handling/AI technique first; check liquid nitrogen tank, individual straws for semen quality, contact AI center, use high fertility AI sire; breeding soundness examination of herd bull
Poor libido and/or serving capacity	Low	Observe herd bull service cows; aggressive behavior may interfere with mating activity
Reproductive diseases of herd bulls	Varies	Campylobacteriosis and trichomoniasis; encourage the use of AI
Developmental abnormalities of bulls	Low	Examples include central fusion of chromosomes and chimerism
Sire influence on size of calf	High	Check calving ease scores of AI sires in herds with increased dystocia
BREEDING MANAGEMENT		
Poor estrus detection	High	Palpation/ultrasonography or records indicate an increased percentage of nonpregnant cows; open cows with a corpus luteum on the ovaries should also have elevated milk progesterone levels (cycling); use milk progesterone at time of insemination to detect cows *not* in estrus at breeding; records analysis may reveal interestrus intervals >18-24 days; consider using estrus detection aids and estrus synchronization programs
Poor semen handling; AI technique	High	Check timing of AI relative to standing heat, placement of semen, temperature of semen thaw bath, level of liquid nitrogen in semen tank; consider an on-farm AI training session
ENVIRONMENT		
Heat stress	High	High ambient temperature is antagonistic to embryonic survival, and detection of cows in estrus
Inadequate facilities/ housing/footing	High	Poor footing; cows are more difficult to detect in estrus; high percentage of lame cows
Improperly balanced ration	Moderate	Ration analysis; body condition score
Toxic agents/ poisonous plants	Low-moderate	Consider high levels of nitrates (>0.20% of dry matter), zearalenone and other mycotoxins

AI, Artificial insemination.

TABLE 7-5

Diagnosis of Bovine Infectious Abortion Diseases

Disease	Clinical Signs	Age at Abortion/ Fetal Loss	Fetal/Placenta Gross Lesions	Diagnostic Tests Available*	Test Samples*
VIRAL					
Infectious bovine rhinotracheitis	Abortion storm possible. No signs in aborting cows. Any form of clinical disease may be seen in herd on initial exposure.	Any gestational age; most in second half of gestation.	Fetus: none, autolyzed Placenta: possible edema.	Viral isolation . Fluorescent antibody. Immunohistochemistry. Histopathology.	Organ pool Kidney, lung, liver, adrenal, spleen, placenta. Same. Same.
				Abortion Dx requires infection + pathology	
Bovine virus diarrhea virus	Usually no clinical signs; however, any form of clinical disease possible.	Abortions usually in first 4 months. Live calves infected in utero may have cleared virus and be normal or have anomalies or persistent viral infections.	Abortions: none; possible mummies. Calves: None or deformities (cerebellar hypoplasia, hydrocephalus, ocular deformities, alopecia, thymic hypoplasia).	Viral isolation. Fluorescent antibody. Immunohistochemistry. Fetal antibody titer. Gross pathology. Histopathology.	Kidney, lung, spleen. Kidney, lung, spleen. Kidney, lung, spleen. Pleural fluid serum. Congenital deformities. Major organs, brain, eye (presumptive w/o detection).
BACTERIAL					
Leptospirosis	Infertility, abortions. Abortion storms possible. No signs in aborting cows. Acute fatal disease in young: icterus, hemoglobinuria. Agalactia, mastitis possible.	Abortion at any gestational age; placenta retained.	Fetus usually autolyzed with no gross lesions.	Fluorescent antibody. Serology. Bacterial isolation.	Kidney. Maternal pleural fluid: possibly specific titer. Difficult/impractical: kidney, urine, aqueous, humor, fetal fluids.
Campylobacter fetus ss. *venerealis*	Bull breeding operation. Infertility/early embryonic death. Some cows with metritis, sporadic abortions.	Abortions primarily between 4-7 months gestation.	Fetuses fresh, autolyzed or mummified. Possibly fibrinous pleuritis, peritonitis, pericarditis. Placenta thickened with surface exudate.	Bacterial isolation. Dark field microscopy. Histopathology.	Preputial smegma, vaginal secretions, placenta, fetal abomasal fluid, lung. Fetal abomasal fluid. Presumptive diagnosis: placenta, lung, liver.
				Limited value: Fluorescent antibody. Vaginal mucous agglutination.	Preputial/vaginal fluids. Vaginal secretion.
Brucellosis	No signs other than abortion.	Abortions in third trimester. Placenta retained.	Placenta thickened with surface exudate. Cotyledons mottled. Fetuses are usually fresh. Fetal bronchopneumonia.	Bacterial isolation. Serology.	Placenta, fetal abomasal fluid, lung. Uterus, milk, maternal lymph nodes. Maternal serum: see text. Fetal pleural fluid: possibly specific titer. Milk ring test.

TABLE 7-5

Diagnosis of Bovine Infectious Abortion Diseases—cont'd

Disease	Clinical Signs	Age at Abortion/ Fetal Loss	Fetal/Placenta Gross Lesions	Diagnostic Tests Available*	Test Samples*
BACTERIAL (cont'd)					
Brucellosis				Histopathology.	Supportive: placenta, major organs.
Opportunistic bacteria	Usually no signs. Sporadic abortions. Possible abortion storms with *Salmonella* and *Listeria*.	Abortions at any stage, but most in last half of gestation.	Primarily placentitis and broncho-pneumonia. *Salmonella* and *Listeria*: fetus autolyzed.	Bacterial isolation. Histopathology.	Placenta, fetal abomasal fluid, lung, liver. Supports bacterial infection: placenta, major organs.
PARASITIC					
Trichomoniasis	Similar to *C. fetus ss. venerealis*. Primarily infertility, rare abortions.	Abortions primarily in the first 5 months of gestation.	Fetuses are autolyzed with no gross lesions. Placenta possibly edematous.	Protozoal isolation. Direct wet mount examination. Histopathology.	Preputial smegma, cervical mucus. Preputial smegma, cervical mucus. Placenta, fetal lung.
Neospora sp.	Abortion storms possible. No clinical signs in cows.	Abortions at any stage; most occur between 5-7 months gestation.	Fetuses are autolyzed with no gross lesions.	Histopathology. Immunohisto-chemistry.	Presumptive diagnosis: major organs, brain, muscle. Brain, primarily.
MISCELLANEOUS DISEASES					
Mycotic	Sporadic abortions. No clinical signs in cows.	Abortion usually in third trimester. Placenta may be retained.	Fetuses are usually fresh. Possibly focal dermatitis. Marked placentitis with leathery scarred foci. Possible fetal broncho-pneumonia.	Fungal isolation. KOH wet mount. Histopathology.	Placental or fetal lesions, fetal abomasal fluid. Skin lesions. Placenta, fetal skin, lung.
Epizootic bovine abortion	Abortion storms possible. Abortion in heifers and new cows. Limited to Southwest (tick vector). No clinical signs in cows.	Abortion usually in third trimester. Occasionally live, weak calves.	Fetuses are fresh. Enlarged lymph nodes, liver, spleen. Possible fibrin in body cavities, petechia in thymus.	Histopathology.	Major organs, thymus, lymph node, brain.

cases of excess clinical reproductive disease. Excess culling for reproductive reasons is usually best approached by first examining the individual records of cows culled for reproduction to determine the underlying problems in those cows.

Once the prevalence, pattern, and estimated cost of the problem are determined, individual cows or heifers should be examined with particular attention to the reproductive system and collection of appropriate samples for additional diagnostic testing. The practitioner then should outline and follow a plan of action for intervention, which should include the steps needed to resolve and prevent the problem in the future. Finally, the practitioner needs to devise a plan to monitor the problem and make additional changes in the plan as needed (Table 7-3).

Common Problems

The step of passing from classifying the type of infertility to the specific cause requires some knowledge of the relative frequency of the common causes. This ensures that, when an investigation is undertaken to determine the cause, the most likely one is not left until the end of the investigation before it is considered. The most common causes of reproductive inefficiency are, in order of descending frequency:

1. Inadequate estrus detection. As herds have increased in size and labor input per cow has been reduced, the management of details often declines. Detection of estrus is the most sensitive activity in breeding management, and failure to do so leads to cows not being bred. This commonly causes an erroneous snap diagnosis of "anestrus." The diagnostic exercise required is not a laboratory one, although whether a cow has been in estrus or not can be inferred from blood or milk levels of progesterone. A careful clinical examination of the ovaries of so-called anestrous cows is required to demonstrate whether they are, in fact, cycling. As a subset of this group, a careful watch for a high proportion of nonpregnant cows among those presented for pregnancy diagnosis is also useful.

2. Breeding cows at the wrong time. The insemination of cows not in estrus, or cows that are pregnant, is one of the

Downloaded From Vet-e-Books.com

disadvantages of an artificial breeding program. The timing of insemination relative to ovulation is also important. Cows should be inseminated approximately 12 hours after first observed standing estrus (the AM/PM rule). Herds suspected of inseminating cows at the wrong time should be investigated using results of milk progesterone assays, breeding records analysis, and palpation of the reproductive tract.

3. Nutritional stress. Inadequate nutrition, mostly by way of an insufficient supply of energy, is a common cause of reproductive inefficiency. This may be due to an absolute shortage of feed or a shortage relative to a high milk yield. The cow's change in body condition in early lactation and milk yield are both good indicators of the cow's nutritional status. In addition, dry matter intake and feeding program evaluation are the next step, including forage analysis.

4. Infectious agents. Infectious diseases causing embryonic and fetal loss are summarized in Table 7-5. These are the diseases that lend themselves to diagnosis by laboratory examination of the entire aborted fetus and placenta as well as additional diagnostic tests. Although the infectious agents usually account for few of the infertility problems in dairy cattle and are specifically isolated in only 23% to 46% of the abortions in fetuses submitted to diagnostic laboratories, they are still a significant cause of loss in certain individual herds (Barr and Anderson, 1993).

Laboratory Investigations

Feed Analysis

A complete analysis of the feed for energy, fiber, protein, and minerals provides the best indication of overall nutritional adequacy in the herd. This needs to be accompanied by an accurate estimate of total daily feed intake per cow. The reader is referred to Chapter 11 for information on ration analysis and interpretation.

Milk Urea Nitrogen

Milk urea nitrogen (MUN) is a measure of protein nutrition that can potentially impact reproduction in dairy cows. Research beginning in the early 1990s has indicated that excess protein in the diet of lactating dairy cows is associated with both increased costs of feeding and depressions in cow fertility (Elrod et al, 1993) as well as with excess environmental nitrogen accumulation (Jonker et al, 1998). The decreased fertility in the Elrod study was associated with a lowered uterine pH, which was itself correlated with increases in ration degradable intake protein. In a recent review, Butler (1998) suggests that a urea value of 19 mg/dl in serum is associated with changes in uterine physiology based on increased secretion of PGF after exposure of endometrial cells in vitro to elevated urea concentrations. This response could plausibly explain the observations of decreased plasma progesterone and lowered fertility in cows fed excessive amounts of protein.

Milk samples for urea evaluation are normally taken during a given dairy's regular milking times. Assuming no major changes in the ration, the resulting values for most dairies vary primarily with regards to when the milk sampling occurs relative to feeding. Ferguson (1999) reported an approximate 2 mg/dl difference in MUN determinations between milkings, when feeding occurred between those milkings (mean prefeeding milking, 12.3 mg/dl; mean postfeeding milking, 14.4 mg/dl). However, the range of individual samples for each milking were largely unaffected (prefeeding milking, 7.6 to 20.6 mg/dl; postfeeding milking, 8.2 to 20.1 mg/dl) by timing relative to feeding. DHIA values for MUN are composites of samples taken on test day, therefore they include both milkings for a twice-a-day milking dairy. Such a sampling modality should show less variability resulting from feeding protocols than would an individual-level sampling strategy.

MUN samples are best evaluated as means of small groups because individual animal samples are too variable and bulk tank samples are too crude for an average analysis. The number of animals required for credible analysis is not set in stone, however a common recommendation for the minimum number of animals required is to sample at least eight animals per group of interest (fresh cows, high producers, heifers, etc.), or at least 10% of each group of interest, whichever is greater. However, other authors recommend higher numbers for accuracy: a minimum of 25 animals per group (Jonker et al, 1998), or even all cows in the herd or group (Hopkins, 2000). For small herds it may be most feasible to sample the entire herd and run stratified analyses on the data. To establish consistency over time (thereby allowing development of a herd- or group-level comparison baseline), samples should be taken from the same milking each time and have the same laboratory analyze those samples each time. In addition, cows should be visibly healthy and eating and should have moderate-to-low levels for SCCs.

Given the inherent biological variability in determination of MUN concentrations, it is not surprising that the recommendations for target levels are also somewhat variable. However, most authors agree that averages between 10 and 14 mg/dl should be considered normal (Ferguson, 1999). Ninety-five percent of individual animal samples likely vary between ±4 mg/dl (Grant et al, 1996) to ±6 mg/dl (Ferguson, 1999) beyond the group's mean value. Access to a minimum 2- or 3-month historical baseline for the group in question is essential in the evaluation of any single test's results. Interpretation of MUN tests is based on protein:energy nutrition. Elevated levels (≥16 mg/dl) are often indicative of excess dietary protein, deficiencies in rumen-available fermentable carbohydrate, or improper combinations or ratios of protein to fermentable carbohydrate. Low levels of MUN (<10 mg/dl) are often indicative of deficient levels of ration protein, inappropriate ratios of degradable to nondegradable protein, or excess rumen-available fermentable carbohydrate. It is imperative, however, that any MUN interpretation *not* be completed in a vacuum; it is one aspect of an overall nutritional workup for a herd and, as such, should be used in combination with evaluations of the ration, the ration's components, and the feeding practices on a farm.

Metabolic Profile Tests

Determination of blood urea nitrogen (BUN), serum copper, glutathione peroxidase for selenium deficiency, serum calcium, and phosphorus levels can provide a guide to the cow's nutritional status with respect to each of these dietary ingredients. With the exception of selenium status and perhaps BUN, metabolic profiling has been largely unrewarding as a diagnostic technique because the animal's basic homeostatic mechanisms try to hold blood parameters at normal, even in the face of severe nutritional imbalance.

Tissue Samples

Analysis of liver and other body tissues for minerals such as copper may be indicated in grass-fed dairy cattle.

Fetuses and Placentas

For abortion investigations, submission of samples to diagnostic laboratories should include entire aborted fetuses and their placentas as well as other appropriate samples (Table 7-5).

Downloaded from Vet-eBooks.com

Semen Evaluation

If estrus detection accuracy and insemination timing and technique is acceptable, an unexpected decrease in conception rate should prompt a laboratory evaluation of the semen.

Genital Fluids and Discharges

Samples of fluids from the uterus, cervix, or vagina of the cow or the prepuce of the bull may be taken for microbiological culture and identification (Barr and Anderson, 1993). Careful sampling and/or special transport media are necessary when certain genital infections such as mycoplasmosis, trichomoniasis, or campylobacteriosis are suspected. In addition, samples of uterine fluid from cows suspected of having infection of the uterine tubes should be submitted for isolation of both aerobic and anaerobic bacteria.

Abattoir Specimens

When possible the evaluation of the reproductive tracts of cows culled for infertility may provide the practitioner with additional information.

Corrective Action and Monitoring of the Results

Having made a definitive diagnosis, the next steps are to introduce corrective measures and monitor the effects. Corrective actions may include improvement in the surveillance of estrus detection, the use of estrus detection aids, improvement in the feeding program, the specific treatment of cows, and training in proper insemination technique. Before implementing the new change, some consideration should be given to whether the program is less costly than the problem, and value of the program should be weighted by its probability of success. The specific nature of the corrective action should be documented for future reference, and the results should be monitored and recorded. Failure to achieve the desired results may necessitate a reinvestigation of the problem in greater depth.

REPRODUCTIVE PARAMETERS FOR MEASURING SUCCESS

General Comments on Reproductive Indexes

Anyone looking at any of a number of typical dairy records systems will immediately realize that the industry measures "reproduction" in many ways. Whenever such a situation occurs, the industry is trying to say three important things. First, the thing being measured is considered so important that they are willing to expend a great deal of time and effort to measure it sufficiently. Second, no single index is obviously capable of yielding the complete picture, hence, they evaluate several different ways to capture it. Finally, it is a complicated thing; each index must be giving a slightly different perspective on the amorphous thing. Reproduction in modern dairies fits this purpose nicely: it is vitally important and can be quite complex to grasp. So reproduction is viewed in a number of ways.

In most cases the economically motivated objectives for a reproductive program are not the parameters most closely discussed as veterinarians monitor the efficiency of reproduction on dairies. This is largely because most veterinarians do not have access to sufficient data to make economic estimates. Instead, veterinarians tend to focus on the more direct biological outcomes of the reproductive process. Reproductive outcomes such as days from calving to conception (days open), conception rates, measures of estrus detection efficiency, and disease and abortion rates are of primary importance in the analysis of dairy reproductive programs. Many of these indexes are strongly correlated with total herd profitability; however, be aware that veterinarians are following proxies for herd financial performance, not the performance itself.

Specific Indexes Common to Most DHIA-Based Records Systems

Some of the more common indexes reported by major records systems, and followed by those wishing to monitor herd-level reproductive performance, are listed in this section. The following section describes some of the techniques the consultant can use to garner more information from these indexes.

Average Days Open

Average days open (or days in milk to conception) is commonly seen as the "bottom line" measure of the efficiency of a dairy herd reproductive program. It represents the average interval from calving to conception in a herd. This measure is significantly confounded by culling policy and the policy by which cows are included in the calculations (Fetrow et al. 1990). As veterinarians have become more adept at records analysis, they have begun to examine not only the average days open but also the distribution of days open. It is possible to have a generally acceptable average days open but with significant number of cows at costly extremes of that average (Ferry, 1992).

For instance, Fig. 7-3 demonstrates a cumulative sum graph of "days in milk at conception (days open)" for two hypothetical dairy herds. The figure reported by DHIA is the average "days open." The two herds are only 2 days apart in this index (i.e., Herd A = 112, Herd B = 114); hence, it would be normal to think neither herd was doing exceptionally better than the other. However, if the practitioner evaluates not the average performance but determines what proportion of each herd achieves our goal range for *days open*, a different story emerges. Assume the management for both herds was targeting a 12.5- to 13.5-month calving interval. That translates to a desired range for *days in milk at conception* of approximately 95 to 125. Note in Fig. 7-3 how 68% of Herd A met the targeted range, but only 39% of Herd B did so. In addition, the practitioner can immediately see that Herd B has problems with animals having too short a "days open" (i.e., 26% of the herd has a "days open" <95) as well as too long a "days open" (approximately 35% appear to have an extended breeding period). For Herd A, less than 12% are being bred too early, and approximately 20% are conceiving late. Although Herd A is doing better than Herd B overall, both herds may have trouble with some late conceiving cows. again, the practitioner would not be able to discover this by looking only at averages.

Average days open is usually a highly skewed number (see Chapter 2 for discussion of skewed data), which makes the use of averages questionable. For example, a current herd with which one of the authors is working has a reported *average days open* of 140. However, the distribution of days open is such that a few very high count cows are responsible for the average figure being higher than that of 60% of the cows. The median days open, representing the lower 50% of the herd, is 123. Hence, half the cows have days open of 17 days or *more* below the mean, and 6 of 10 cows have less than the mean of days open. This is demonstrated in Fig. 7-4.

In many reporting schemes, the actual data being reported are more correctly called *minimum average days open* because cows bred too recently to be examined for pregnancy diagnosis are assumed by the system to be pregnant. Therefore the figures reported will usually be optimistic. The

Downloaded from Vet-eBooks.com

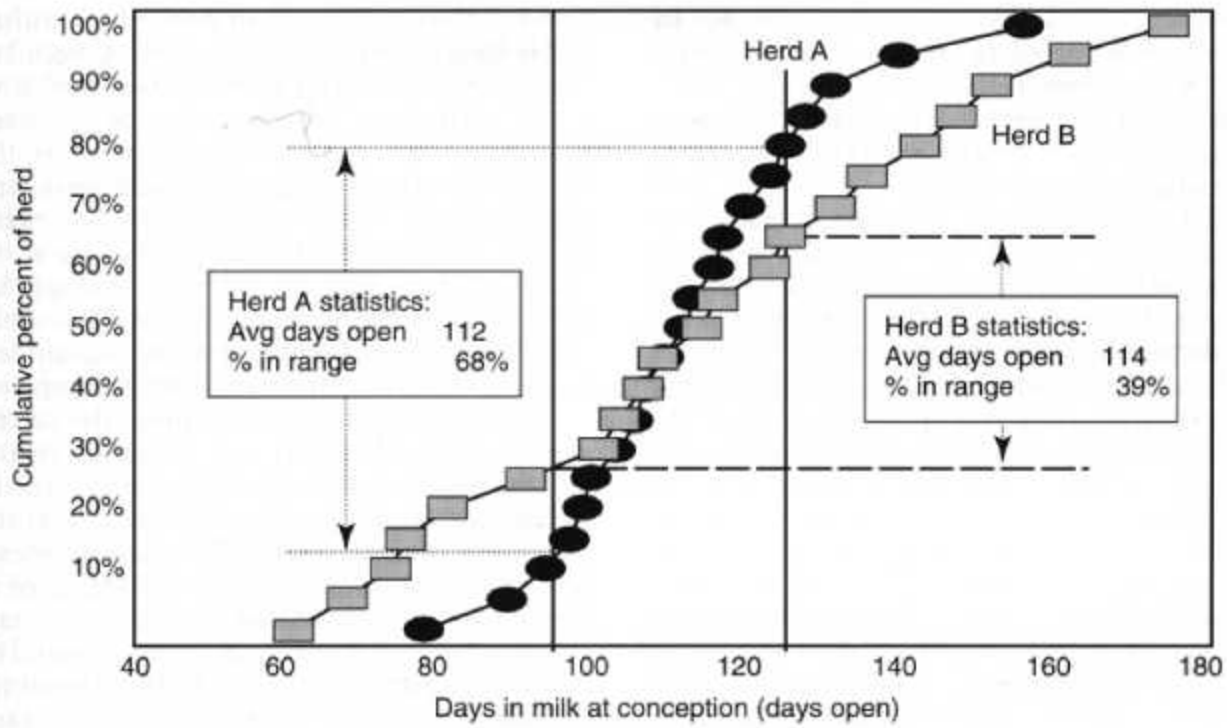

FIG. 7-3 Demonstration of effect of variation in "Days Open" for two hypothetical herds using a cumulative sum graph. Note the two herds have approximately the same value for "Days in Milk at Conception (Days Open)." However, Herd A has over two thirds of its cows in the desired range, and Herd B has only 39% of its cows in the desired range. The average values for "Days Open" would lead the practitioner to believe both herds were on target, when they are not.

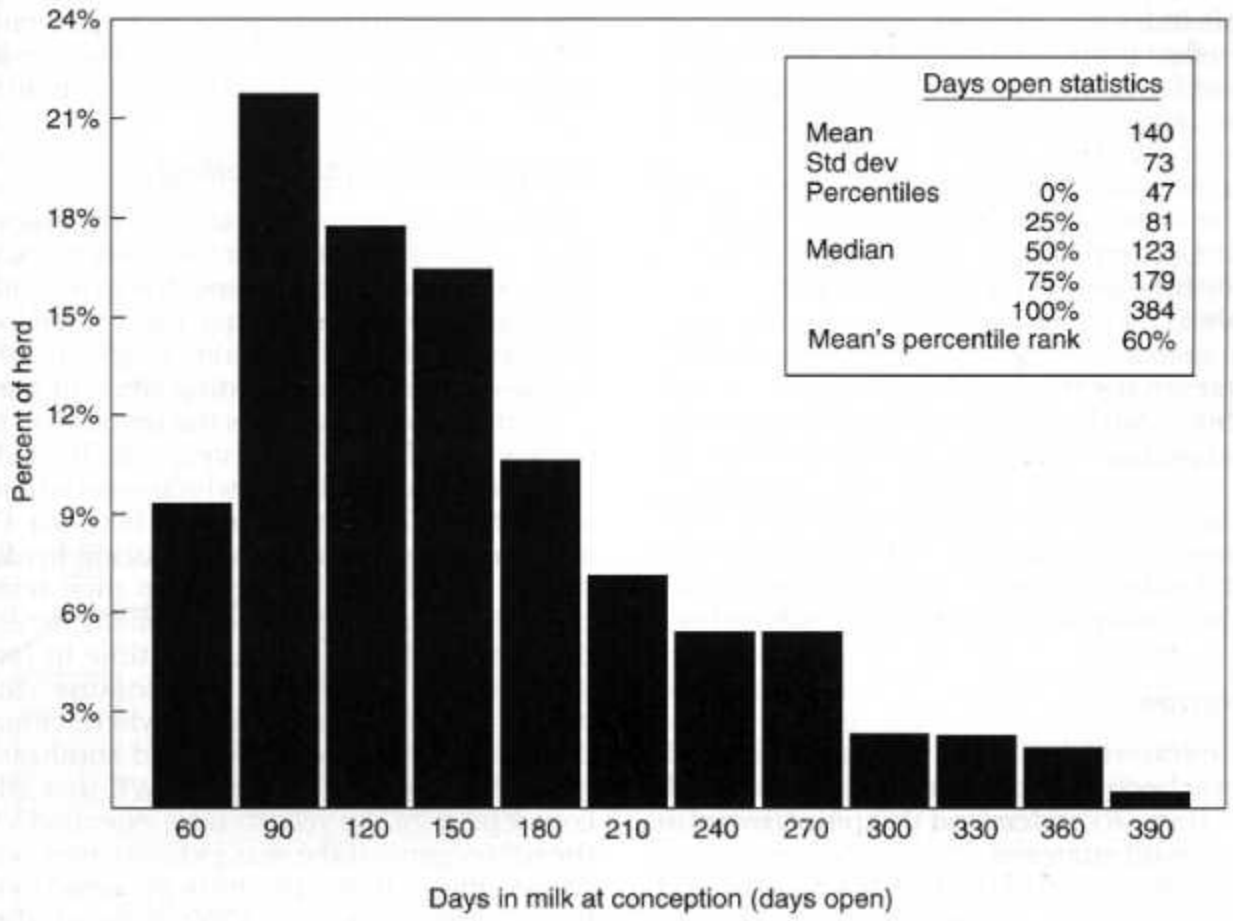

FIG. 7-4 Distribution of days open for an actual 250-cow Holstein dairy in North Carolina. The data are highly right skewed, such that the mean is nearly one estrous cycle greater than the median. Sixty percent of the herd actually has days open that are less than the calculated mean. Hence the usual index followed—*average days open*—is a pessimistic view of reproduction efficiency.

only situations veterinarians will commonly face in which this index *will not* be optimistic is in bull-bred herds that do not record heats. In such instances, the only time a cow enters the database is after she is diagnosed pregnant, and a date of conception is back-calculated for her. It should also be noted that a recurring problem with many measures of reproductive performance is also evidenced in *average days open*. In many records systems a cow must be bred to enter into the calculation. As an example of this problem, if a person owned 10 cows and only bred one of them, that single animal's statistics would enter the calculation. If that animal became pregnant on its 90th day after calving, the

Downloaded from Vet-eBooks.com

herd's reported *minimum average days open* would be 90. In other words, this index is completely blind to what is going on in unbred animals. However, if the record system allows unbred cows to submit their current days in milk value to the calculation, then the index will still be optimistic, but it will be impacted by nonbred cows.

The DHI-Provo data from Table 7-2 displays averages for this index in the range of 145 to 155 days. Note this is much longer than most references will recommend. Hence, our recommendations are biologically impractical, the published averages are skewed by a low proportion of high-days-open cows, or producers have found that achieving our recommendations is not cost effective. It is likely that the second reason predominates; however, all three reasons likely apply.

Calving Interval

The measurement of the calving interval—that is, the period from one calving to another—is too historical to be of real value in the regular assessment of reproductive performance in continuous calving herds. To obtain a mean figure for the herd, all cows must calve twice so that the calving index includes events that, for some cows, could be 1.5 to 2 years in the past. Thus cows that are reproductive failures— those cows that fail to be bred, conceive, and carry a calf to term—are not included in this index. In addition, in many recording systems, a cow contributes her value to the herd summary as soon as she calves, and it remains until she calves again. In others, this index is calculated based on breedings and may therefore reflect more current practices on the farm. Either way, the figure for calving interval is often heavily affected by past events and can have little to do with what is currently going on in the dairy. Thus average days open is the preferred general measure of overall fertility for current practices. The reader is referred to the previous "Different Strategies, Different Optima" section for a discussion of the difficulties in establishing goals for calving intervals.

The data in Table 7-2 suggest average dairy performance for calving interval is in the range of 13.7 to 14.1 months. Again, this is higher than the standard 12-month, or 12.5- to 13.5-month, recommendation commonly found in the literature. Likely, the reported values for calving interval are skewed upward by a few extended lactation cows. However, it should be noted that not all clients will reach the recommended calving interval. It is important to remember that to get an average of 13.7 to 14.1 months, some herds were lower and some were higher. Likely, some herds were *much* higher.

Days in Milk, Average

At first glance this index, which is simply the average length of time the cows have been milking, has nothing to do with reproduction, but it does. To understand this point, we must digress and discuss dry-off strategies.

The reasons most cows are dried off are because either (1) the cows are within 60 days or so from calving and are dried off to give the cows a chance to involute and prepare for a new lactation, or (2) the cows' milk income no longer covers the cost of milking them, so they are turned dry to await another lactation. It is evident that reproduction plays the major role in both decisions; if a cow is bred at an appropriate time and has not suffered untoward diseases or traumas, she should be turned dry for the former reason—because she is within 2 months of calving again. Hence, a herd that has abnormally high *days in milk* indexes is also very likely to be suffering from poor reproduction.

Be aware that the index just mentioned is not without its problems. Because *days in milk* is an average over all cows, it also has the problem of all averages. For instance, for the two herds designated in Fig. 7-3, Herd A would show an "average days in milk" of 198 days, while Herd B would show 198 days, assuming the calvings were equally distributed throughout the year. Remember, however, that Herd A would be considered the much better managed herd once the distribution of *days in milk at conception* was examined. Therefore *average days in milk* also misses the effects of distribution. In addition, this measure can be altered quickly through selective culling, calvings, or drying off. As a result, it is most helpful to follow this index over time. Any sudden jumps one way or another may be due to culling, calvings, or mass dryoffs.

All lactating cows contribute to the calculation of *average days in milk*. A cow is still included in this measurement whether she is bred or not. Hence, *average days in milk* is one index that *is not* blind to nonbred cows. It can provide the analyst with a measure that encompasses all cows in the herd. Furthermore, by taking advantage of what is normally considered a weakness of averages, it is very sensitive to extreme values. As a result, as cows calve and enter the herd, or if cows are allowed to stretch their lactation to well beyond normal, or if groups of cows are culled or sent to the dry lot, *average days in milk* will rapidly change, allowing an analyst to identify periods when such events are taking place. All of these events are important to remember because they can also impact interpretations of milk production and other measures of reproduction.

Table 7-2 suggests an average performance for *average days in milk* of just under 205 days. As with the previous indexes, this is beyond the commonly suggested range of 150 to 180 days by one or two estrous cycles. The previously mentioned potential reasons for this discrepancy hold here as well.

Days in Milk, First Breeding

Also known as *days to first service*, this index is simply the average postpartum time for the cows to be bred for the first time. Some researchers consider it one of the most important factors in determining the overall performance of a dairy's reproductive program (Ferguson, 1995). It is affected by the choices made regarding when to start breeding cows.

In most records systems the term *option period* or *voluntary waiting period* (VWP) is listed, which signifies the postpartum time, in days, during which cows will not be bred. Typically, the VWP of most farms is between 45 and 55 days in milk; however, many high-producing herds, and herds aiming for 365-day milk records on their registered cows, will opt for higher VWPs. However, many herds choose to breed their first calf heifers at a later time in lactation than they might their cows, which will confuse what VWP actually means. Furthermore, in areas where climate affects reproduction (e.g., the southwest and southeast United States), many herds use a "variable" VWP that allows cows in the cooler parts of the year to have extended VWPs and cows in the hotter parts of the year to have shortened VWPs. Another confounder is that intensively managed herds may combine this seasonal variance in VWP with consideration of an individual cow's milk production, such that higher-producing cows may be given extended VWPs relative to their lower-producing peers. Finally, most DHIA processing centers default to a 60-day VWP if the dairy does not enter one in their record system. Hence, although records systems happily report a set VWP for a farm, the consultant must be aware that the listed figure may only apply to a certain proportion of the herd throughout the year, if at all.

Days in milk, first breeding is often interpreted as a strong measure of estrus detection capability in a herd. To do this, of course, one needs to know when the herd "wanted" a given cow to be bred, relative to what the *days in milk, first*

Downloaded From Vet-eBooks.com

breeding indicates. If a herd is aiming for a 12-month calving interval—meaning *days in milk at conception* will be targeted in the 85 to 90 days range—then *days in milk, first breeding* by necessity will need to occur in the average cow before the period of 85 to 90 days in milk. Again, more in-depth use of this variable is discussed in the following section.

In bull-bred herds, *days in milk, first breeding* is primarily a historical index. It is historical because the only data going into it, in most bull-bred herds, are the calculated days in milk at conception—data that are discovered only at pregnancy examination. Thus the index loses most of its ability to describe estrus detection intensiveness and therefore its primary value in bull-bred herds.

The data from DHI-Provo, shown in Table 7-2, indicate that *days in milk, first breeding* for most dairies fall in the range of 79 to 95 days. This range is approximately one to nearly two estrous cycles longer than the commonly recommended value of 60 days, so some of the previous reasons why the typical farm is not reaching the recommendations will hold. Furthermore, if these herds were not targeting a 12-month calving interval, such a difference would be expected. However, should the individual cow's *days in milk, first breeding* be right skewed, a published range such as that in Table 7-2 could be misleading.

Estrus Detection Rate

Also known as *percent heats bred* or *percent heats detected*, this parameter measures the *intensity* of estrus detection but not the *accuracy* of estrus detection. The former assesses whether it is being done at all or at a reasonable level; the latter determines whether it is being accomplished precisely. It is possible to have high apparent estrus detection intensity and poor reproductive results. The insemination of cows not in estrus can be a serious problem on small as well as large dairy farms (Reimers et al, 1985; Slenning and Farver, 1990). Obviously, these cows do not conceive when bred.

The relationship between estrus detection intensity-accuracy and overall reproductive performance is worth consideration at this point, because it is often not considered (Fig. 7-5). Assume that someone is hired to breed cows who knows nothing about estrus detection. To get some cows bred, this person opts to bring in every cow every day and breeds them all. Of course this will not be a very effective strategy; the majority of cows will not be in estrus at the time of breeding, so conception rates will be essentially nil. However, the records will indicate that estrus detection would be very high. In terms of clinical test efficiencies, such a strategy would show a 100% sensitivity and no specificity; there would be no false negatives but many false positives. This coincides with the bar and area section of the left side of Fig. 7-5. Now imagine a second situation in which the person performing estrus detection will only identify those cows that stand to be mounted, have a clear mucus discharge, and are very active, as being in estrus. These cows will likely be highly fertile because they will be identified at the ideal times to be inseminated. Hence, conception rates will be high. However, estrus detection rates will be quite low because few cows display all the signs of estrus at any one time. In terms of test efficiencies, this strategy will have a very high specificity (few false positives) but would have a fairly low sensitivity (many false negatives). This corresponds to the situation at the far right of Fig. 7-5. At either extreme, when estrus detection appears to be very high, or when conception rates appear to be quite high, overall herd performance will suffer. The proper balance between estrus detection intensity and accuracy exists, however, at points in between these two extremes, as shown by the curve in Fig. 7-5.

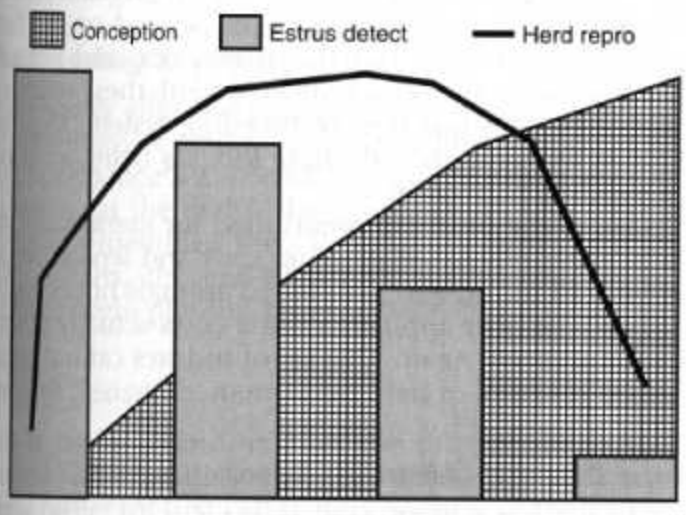

FIG. 7-5 Graphic depiction of the interplay between estrus detection intensity and overall conception rate. When estrus detection rate is extremely high, many cows not truly in estrus will be identified and bred. As a result, conception rates will decline. Conversely, at very low estrus detection rates, only those cows most profoundly showing estrus behaviors will be bred, and these animals will tend to become pregnant. As a result, conception rates will increase. The best overall herd performance will occur when neither measure is at an extreme, as suggested by the "Herd repro" curve.

The commonly used index for estrus detection is *percent heats bred*, which is a comparison of the calculated number of estrus events that a herd should have seen against the actual reported number of events, each over a specified period. Most of these systems assume the involved cows have a 21-day estrous cycle. Thus, all things being equal, one would expect to see approximately 30/21, or 1.4, estrus events per cow per month. From this estimate must be subtracted the succeeding interval in which the reporting date is too early for pregnancy determination. Simply stated, if the herd has three cows in the breeding window and follows them for 1 month, a person would expect to have seen at least four heats (average of 4.3). If the dairy reported two estrus events from the three cows, the *percent heats bred* would calculate to 2/4.3, or 46%. Again, the calculation is not quite this simple, but this example serves to make the point.

Note that the estrus detection rate is one of the few indexes discussed that captures all the cows. It is not blind to nonperforming cows, as are *average days open* and *services per conception*. However, in modern times this index has been proving of decreasing value because it has a "hardwired" assumption of a 21-day cycle for cows. With current trends of increasing use of hormonal manipulation of the cows' estrous cycle, and the concomitant alteration this manipulation causes in the length of the cows' cycles, the 21-day assumption becomes harder to support.

In many dairies, *percent heats bred* can reach above 80% for long periods when management focuses on heifers. In the milking herd, such levels of long-term performance are difficult to maintain for a variety of reasons. It is not uncommon for well-managed herds in either the southeast or the southwest United States to achieve monthly levels of milking herd *percent heats bred* of 80% or higher in the cool parts of late winter and to be capable of only reaching 35% to 40% during the heat of summer. This 50-percentage-point difference seems to hold whether the cool weather maximum is 80% or 60%; the mid-summer drop will be to 30% or 10%. Certainly, in more "cow-friendly" climates, this kind of seasonal impact on estrus detection will not be as severe. However, when working with the milking herd, pushing the system to exceed 70% estrus detection rates (without hormone analysis) is likely to lead to inaccuracy and be counterproductive

Downloaded from Vet-eBooks.com

for most dairies. Even if estrus detection remains accurate, there appear to be diminishing economic returns to improvements at estrus detection beyond 70% (Oltenacu et al, 1981; Rounsaville et al, 1979).

As was the case for *days in milk, first breeding*, the index *percent heats bred* is of little value in bull-bred herds, because most of these farms only record estrus events on which the cows became pregnant. Other heats are often not observed and therefore not recorded.

Table 7-2 suggests that a typical dairy will show a *percent heats bred* at approximately 43% to 52%. As mentioned above, before deciding how well or how poorly a given herd is doing in this regard, a veterinarian should consider the confounding factors such as weather, production, herd age structure, and management goals. For any given farm, this index will show a great deal of variation across time and production.

First Service Conception Rate

This index is considered by many researchers to be one of the best predictors of overall reproductive program success and, along with *days in milk, first breeding*, should be the focus of farm resources ". . . to exert the greatest control on reproductive performance. . . ." (Ferguson, 1995). *First service conception rate*, also called *conception rate to first service*, is calculated by determining the proportion of animals that became pregnant on their first service. It is the result of combining estrus detection accuracy and breeding technique. Thus low values for this index can result from poor estrus detection and/or errors in AI technique; it cannot be considered as a pure measure of either.

Similar to the previous two indexes, *first service conception rate* is of little to no value in a bull-bred herd. In most reporting systems, a bull-bred herd will show this index at 100%. Only one breeding is recorded (the back-calculated date of conception from the estimated stage of pregnancy at the pregnancy examination), so conception rate is apparently perfect. If only this were true.

Data from Table 7-2 indicate most dairies reach a 42% to 54% range of performance regarding *first service conception rates*. This is much lower than the commonly recommended goal of 60% or more from the literature. The possible explanations for such a discrepancy mentioned previously for other indexes are likely valid here.

Services per Conception

This index is often reported in two forms: *services per pregnancy, pregnant cows* and *services per pregnancy, all cows*. The differences are what numerator is used and how the indexes are interpreted. For instance, assume a three-cow dairy herd has cows identified as A, B, and C. Over the period in question, you bred cows A and C once and cow B twice. Cows A and B were later found pregnant to their respective breedings. To calculate *services per pregnancy, all cows*, count the number of services applied to all the cows in the herd ($1 + 1 + 2 = 4$) and divide this sum by the number of cows becoming pregnant to those breedings (2). Thus 4/2, or 2.0, *services per pregnancy, all cows* was yielded. To calculate the value for *services per pregnancy, pregnant cows*, the analyst counts the number of services applied only to cows that became pregnant. In this example the number would be three ($1 + 2$) services applied to cows that became pregnant. Again, divide this figure by the total number of cows becoming pregnant (2) to get *services per pregnancy, pregnant cows*. For this example, *services per pregnancy, pregnant cows* is 3/2, or 1.5.

At times, persons or systems may report conception rates on a "per pregnant cow" or on an "all cow" basis. To convert the previous *services per pregnancy* indexes to conception rate indexes, simply take the inverse of the former. For example, in the previous situation, the *conception rate, all cows* would be 1/2, or 50%, and the *conception rate, pregnant cows* would be 1/1.5, or 67%.

Interpretation of these indexes is fairly straightforward. The "pregnant cow" figures are usually taken as measures of the efficiency of conception when fertile cows are bred. Of course, this definition is somewhat teleological, for our definition of "fertile" is simply the number of cows the herd got pregnant; there are likely many more "fertile" cows in the herd, but we cannot identify them. Be that as it may, it is a rough proxy for the "male" side of the insemination process: semen quality, insemination technique, timing of insemination, and accuracy of estrus detection. The "all cows" measure includes all breedings in the herd, whether the cow ultimately became pregnant or not. Hence, it is usually a better measure of overall herd conception efficiency. If *services per pregnancy* in all cows is significantly larger than *services per pregnancy* in pregnant cows, then there must be problem breeder cows in the herd.

The *services per pregnancy, pregnant cows* and *services per pregnancy, all cows* indexes are confounded in some herds by factors that affect all cows, such as inadequate nutrition, heat stress, and infectious infertility. Depending on climatic conditions and how soon postpartum cows are bred, *services per pregnancy* in pregnant cows could be in the 1.5 to 2.5 range. According to Table 7-2, however, typical performance levels for this index run in the range of 1.9 to 2.4.

The reader might reasonably ask why the ultimate goal for *services per pregnancy* is not 1.0. The reason is fairly simple: for a breeder to achieve near perfection in outcome, the breeder must only work with nearly perfect cows, both behaviorally and physiologically. Thus, to achieve exceptional performance, the breeder must bypass some cows as "not quite there yet." Unfortunately, few cows ever display "perfect" estrus events, so some cows will nearly always be deemed inappropriate for breeding. The end result is that those cows being bred will likely be the most fertile, so the breeder will develop outstanding *services per pregnancy* values, but the herd's overall reproductive performance will be decreased. This is, again, the situation to the far right of Fig. 7-5. Such a dichotomy could occur whenever the value of this index drops below 1.8. So be careful; "better" is not always better.

Because both the *services per pregnancy, pregnant cows* and *services per pregnancy, all cows* indexes depend on the herd's management recording individual services, and since this rarely occurs accurately in a bull-bred herd, these indexes are of little value with this type of breeding system. Most bull-bred herds will end up with these indexes being reported at 1.0, suggesting perfection.

Similar to the problem mentioned for *average days open*, the *services per pregnancy, pregnant cows* and *services per pregnancy, all cows* indexes are "blind" to animals not being bred in the herd—it only applies to those cows actually observed in estrus and bred. Again, this set of indexes cannot be used as a single measure of herd performance.

Various Disease–Abortion Rates

Some sections of this chapter are devoted to specific health-related causes of infertility and pregnancy wastage, and will not be explored here. It is important, however, for a true monitoring system to keep track of such events. It should be noted that most DHIA-based records systems, and many private record services, do not track such data. As a result the effort and motivation to do this largely falls on the consulting veterinarian and herd owner. A veterinarian should not simply assume these data are being collected and analyzed; most often they are not.

Reproductive Practices Specific for Seasonal Herds

Voluntary Waiting Period and Dry-Off Dates

In these herds the VWP often ends on the same date for all cows, irrespective of when any individual cow calved. In a similar way of thinking, dry-off dates for cows are usually set for the same time and are primarily driven by pasture budgets in pasture-based dairies—budgets designed to ensure that the availability and demand for feed are balanced for the remainder of the season. Important aspects of the reproductive practices for a seasonal herd follow.

Planned Start of Mating

This occurs on the day following the end of the herd's VWP. However, many seasonal herds set the *planned start of mating* for 14- to 16-month-old heifers at 14 days earlier than the end of the VWP.

Prebreeding Period

Cows that were bred very late in the season will often be induced to calve if their estimated calving date is less than 40 days before the *planned start of mating*. At approximately 28 days before the *planned start of mating*, all cows will be evaluated for post-parturient reproductive problems such as retained fetal membranes, metritis, and pyometra.

Breeding Season

The breeding season usually runs for 6 to 8 weeks. Mating will often be accomplished using artificial methods for the first 4 to 6 weeks of the breeding season. Bulls are usually brought in for the remaining 4 to 6 weeks of the breeding season. At 21 days into the breeding season, veterinary examinations are usually conducted on all nonbred cows. It is not unusual for the veterinarian to find that most of these cows in grass-fed dairies are in anestrus because of negative energy balance. At 45 to 55 days after the end of the AI part of the breeding season, all cows not seen to return to service are usually scheduled for pregnancy examination. At a similar period after the end of the breeding season, all cows not previously identified as pregnant are usually examined.

Postbreeding Season

In the weeks after the final pregnancy examinations several records-intensive actions are taken. First, the overall breeding performance is assessed. Second, cull cows are identified for culling at the end of lactation. Third, late calving cows are usually identified for scheduling in their induction program. Finally, the end-of-season pasture budget is established to begin planning for the best dry-off times.

Calving Season

This is set for 280 days after the start of the last season's *planned start of mating*. As mentioned above, it may start 2 weeks earlier for first calf heifers because of their earlier start of breeding.

Reproductive Indexes Commonly Used in Seasonal Herds

Seasonal herds often follow the same indexes as mentioned above. However, other data can prove to be of value, oftentimes of more value, in these systems. The primary reason is that seasonal herds need to develop data sources that can be collected and analyzed in only a few weeks—anything longer than this would make the index irrelevant to breeding management.

Calving Rate

This index is calculated as the percent of cows calving during a stated period. In most cases, the period is 14 days. Typical goals for this index are to have 30% to 40% of the herd calving in the first 2 weeks of the *calving season*. For each 2-week period following, the goals are often an additional 30% to 35% of the herd calving for weeks 3 and 4, 20% to 25% for weeks 5 and 6, 10% to 15% for weeks 7 and 8, and 5% for the final period, if needed. This index allows a veterinarian new to a farm to establish how well the past season went.

The values for *calving rate* can be broken down by parity. If older animals were calving late in the season, it is possible pasture quality was an issue. If younger animals were calving late, then pasture quantity may have been an issue.

Premating Heat Rates

This index evaluates the estrus detection capability of the herd management for the 24 days immediately preceding the *planned start of mating*. A typical goal is 80% to 90%. If it is lower than this, the herd will have difficulty achieving a 6-week breeding season. Higher values for *premating heat rates* may suggest that estrus detection is inaccurate, leading to unacceptably low conception rates and extended breeding seasons.

As with *calving rate*, this index can be broken into parity-specific rates. In general, one expects the first calf heifers to have relatively low *premating heat rates*, oftentimes 5% to 10% lower than those of older cows. For third lactation and higher cows, the number should be close to 90%. For animals calving in the 40 days before the *planned start of mating*, the values for *premating heat rates* will be much lower—often only 20% or so. If the values are lower, management should evaluate whether the problem is lack of estrus detection or decreased estrus activity.

Submission Rates

This index represents the quantity of cows bred each week, or each 2-week period, of the *breeding season*. It is usually reported as a cumulative percentage. It is a direct measure of estrus detection efficiency. The values for the weeks 1 through 6 of the breeding season can be reasonably set at 30%, 60%, 90%, 93%, 97%, and 100%. Again, this index can be evaluated on a parity basis or on a basis of whether the cows had calved more than 40 days before the start of breeding or not.

Returns to Estrus Rates

This index can be a valuable measure of estrus detection accuracy. If previous estrus detection was accurate, only 10% to 12% of cows should be found coming back into heat before 17 days. As before, this should only be evaluated in cows in which prostaglandins are not used.

In-Calf Rates

This index is calculated as the percent of cows becoming pregnant during weekly or biweekly segments of the *breeding season*. It is usually reported as a cumulative percentage of the cows available at the start of the season. This index will reflect the same dynamic as that shown for *calving rate*. Therefore reasonable goals for *in-calf rates*—for biweekly evaluation—would be 33%, 65%, 87%, 97%, and 100%.

Tools to Expand the Value of Standard DHIA-Based Reproductive Indexes

Expanding the Possibilities

The previously described reproductive parameters are the bases for most analyses of dairy herd reproduction. A few things can be done with them to bring out more information about what is going on in the herd. The techniques are largely based on farm-specific assumptions and/or other, non-DHIA, data.

Percentage of Possible Estrus Events Detected

Work performed in 1974 suggested that fewer than 5% of dairy cows remain anestrus by 40 days in milk (Britt et al, 1974). It is likely that with the ensuing quarter century's increase in production, this number has increased. Nevertheless, the true proportion of anestrus cows in a well-fed confinement farm should be near this figure. However, in a grass-fed, nonsupplemented dairy, should the weather have delayed pasture production relative to the herd's calving season, anestrus cows by 40 days in milk may be quite common.

As mentioned previously, estrus detection is fundamental to reproductive success and is usually the weak link in any AI-based dairy's reproductive program. Unfortunately, many of the indexes used in current records systems carry with them a large proportion of historical data, which makes them fairly insensitive to changes in the herd's condition or performance. Hence, these reproductive indexes may not respond quickly enough to identify trends in performance. Luckily, there are other means to establish monitoring indexes that better reflect current situations.

Pregnancy Rate at Pregnancy Examination. Perhaps the simplest of the "real-time" measures, this determination of the proportion of cows held for pregnancy examination that were, indeed, pregnant yields a powerful indicator of estrus detection efficiency over the previous month or more. The reason this works is simple: A dairy operator will only hold up cows for pregnancy examination when that producer feels the cow is actually pregnant. Had the operator seen the cow in heat after a breeding, the cow would have been rebred, her pregnancy examination would have been delayed, and she would not have been presented for examination. The process to calculate this index follows:

1. Count the number of cows presented for pregnancy examination. Be certain to exclude, for example, any animals held for standard pregnancy rechecks or pre-dry-off examinations (Value A).
2. Count the number of these cows that were diagnosed pregnant. Include animals declared pregnant but possibly in process of losing the pregnancy. If she conceived to the breeding, she is counted (Value B).
3. Of the cows found nonpregnant, count the number that are apparently anestrus and/or have cystic ovaries. Include severely lame cows. Also take into account animals that, in the past month, had disease events causing sepsis, such as severe mastitis (Value C). The total count of these animals, which represent those cows likely to not have shown signs of estrus associated with normal estrous cycles, is subtracted from the count in Value A (the number of animals submitted for examination). This is done because those cows, because of extenuating circumstances, were abnormal in such a way as to make them not eligible for conceiving, maintaining a pregnancy, *and* displaying normal signs of estrus.
4. Calculate the *pregnancy rate at pregnancy examination* as follows:.

$$\text{Value B} / (\text{Value A} - \text{Value C})$$

Interpretation of the *pregnancy rate at pregnancy examination* index is fairly simple: the higher, the better. Reasonable goals appear to be in the 70% and higher range. Again, this will be strongly affected by season. Our experience has been that a producer may consider late winter/early spring-time performance for this index as unacceptable if it drops below 80%, yet may consider itself as doing well if, by late summer, the same index is in the 50% range. In addition, the length of time from breeding to pregnancy examination will affect the interpretation. For example, suppose the veterinarian usually schedules pregnancy examinations for 45 days or more after insemination, instead of 35 days or more after insemination. Any cycling cow found nonpregnant will likely have had two estrus events since breeding, whereas at the 35-day check the typical cow will have had only one. Hence, cows found open at a 45-day pregnancy examination suggest management missed more than a single estrus event.

Other Ways to Calculate Estrus Detection. In addition, there are other ways to calculate estrus detection, should the reporting system a client uses not give the information. Sometimes the consulting veterinarian may not know how a program calculates a figure and simply wants to check on the data being given. The following indexes can help in both situations.

Percent of Breedable Estrus Events Detected (%BEED). This index of estrus detection focuses on "breedable" estrus events—those heats that occur *after* the end of the herd's option period or VWP. To calculate the percentage the practitioner needs to know the *average days open*, VWP, and either the number of heats per cow detected or the conception rate. It is calculated as follows:

$$\text{Breedable heats} = \{[\text{Avg days open} - (\text{VWP} + 10)]/21\} + 1$$

As an example, if a herd had an *average days open* of 147, a VWP of 55, and a 50% conception rate, this herd's breedable heats would be $\{[147 - (55+10)]/21\} + 1$, or 4.9.

To calculate %BEED, divide the average number of heats observed per cow (this can be assumed to be 1/conception rate, or $1/0.5 = 2$, should the count not be available) by the breedable heats and multiply by 100:

$$\begin{aligned}\%\text{BEED} &= (\text{Heats detected per cow/breedable heats}) \times 100\\ &= (2/4.9) \times 100\\ &= 41\%\end{aligned}$$

CAVEATS. Note that this index assumes the cows follow the standard physiological interestrus interval of 21 days and that the listed VWP is appropriate for all cows. We know that not all cows cycle every 21 days and that dairies treat cows differently regarding VWP. Furthermore, if a herd makes use of prostaglandins to any major degree (remember, the USDA-NAHMS survey in Table 7-1 suggests that perhaps one in five dairies expose at least 50% of their cows to prostaglandins), this will make the 21-day assumption invalid. However, if the dairy's use of prostaglandin is fairly constant over time, this index can be a useful "yardstick" for within-herd comparisons. The practitioner will not be certain the figure derived is accurate, but changes in the figure will very likely signify alterations in the actual process being monitored. However, it will not be advisable to use this index in between-herd comparisons.

The "VWP + 10" segment is a built-in assumption as to when the typical cow will cycle. It assumes most cows will cycle in a 21-day period, and that half of them will cycle in half that period. Hence, the "average" cow should be seen in estrus 10 days after the end of the VWP. On further examination, however, this will not be true in early lactation. This is because most estrus events are clustered in time: first estrus

Downloaded from Vet-eBooks.com

after calving is usually between days 16 and 18, the second estrus occurs something on the order of 16 to 20 days later (between 31 and 37 days after calving), and it is not until the third estrus event that cows establish the more typical 18 to 24 day cycle (i.e., between 49 and 61 days after calving). The fourth estrus, then, would occur between 67 and 85 days in milk.

Therefore, for a VWP of 60 days, the practitioner might expect a few estrus no. 3 cows to be cycling on the day following the end of the VWP but would not expect to see the estrus no. 4 cows to start coming into heat for at least a week. The practitioner should not, therefore, be surprised if, immediately after a 60-day VWP, not many cows are identified as being in heat—the biology says that should be exactly what to expect. However, for a 50-day VWP, he or she should expect to be in the phase of estrus no. 3 where more cows will be identified each day for the first 5 days or so and level out for another 6 to 7 days. Then it should get "quiet" again.

The preceding information is not to say that we need to account for each cow's estrous cycle timing to estimate estrus detection efficiency. The computations would be tedious and likely in error, and the results would not be of much more validity than the broad "VWP + 10" assumption. Just be aware that how well such indexes reflect reality will be a function of the actual level of normal cyclicity in the herd and which VWP the dairy operator has chosen.

Estrus Detection Efficiency Using "Breeding Interval." As with the previous index, this index addresses estrus detection after the first breedable estrus event. To calculate it the analyst must know *average days open*, *services per conception*, and either *days to first service* or VWP. First, the analyst must calculate the breeding interval in either of two ways:

$$\text{Breeding interval} = (\text{Average days open} - \text{days to first service}) / (\text{Services per conception} - 1)$$

$$\text{Breeding interval} = (\text{Average days open} - [\text{VWP} + 10]) / (\text{Services per conception} - 1)$$

The estrus detection efficiency is given simply by taking the ratio of the average estrus length (usually assumed to be 21 days) and the breeding interval:

$$\text{Estrus detection efficiency} = \text{Average interestrus interval} / \text{Breeding interval}$$

For instance, suppose a herd's data were the following: average days open = 147; services/conception = 2.4; days to first service = 86; VWP = 55. The breeding interval, using each means to calculate it, would be the following:

$$\text{Breeding interval} = (147 - 86) / (2.4 - 1) = 44;$$

$$\text{Estrus detection efficiency} = 21/44 = 39\%$$

$$\text{Breeding interval} = (147 - [55 + 10]) / (2.4 - 1) = 59;$$

$$\text{Estrus detection efficiency} = 21/59 = 36\%$$

The estrus detection efficiency has the added advantage of representing the estrus detection performance for different groups within the herd, assuming the analyst can get at subgroup data. For instance, it is easy to imagine working the "breeding interval" type of calculation for both pregnant cows and for all cows. In another situation, the analyst might run the calculations by parity group.

CAVEATS. The second of these two equations uses VWP, which, as mentioned previously, may not be appropriate for all cows. They also use *average days open*, which is likely skewed (Fig. 7-4) and therefore a questionable index.

Estrus Detection Efficiency Using Interestrus Intervals. In this index the assumed normal cycle length of 21 days is divided by the average number of days between consecutive services, or by the published *interestrus interval*. As an example, assume a herd displayed an average interestrus interval of 27 days. Its estrus detection efficiency value, using the interestrus interval, would be as follows:

$$\text{Normal cycle length / Interestrus interval} = 21/29 = 0.72 = 72\%$$

CAVEATS. Although this calculation is, by far, the simplest of the three examples given, it suffers from the same problems mentioned above: it assumes the herd's cows are cycling in a 21-day period. Thus the same arguments presented above hold here. The more variable the natural cycle of the cows, and the more use of prostaglandins by the herd's management, the less valid this index will be. As mentioned at the start of this overall section, whenever the practitioner is offered multiple ways to measure something, he or she is being told three things: (1) it is important, (2) no single measure is sufficient, and (3) the topic is complicated. All three hold true for estrus detection.

Indexes to Help Determine Allocation of Reproductive Inefficiency to Different Management Areas. Often identification of a herd in reproductive trouble is not difficult. The tricky part is deciding what aspects of reproductive management are lacking and, of those, which appear to be the major limiting steps in the process. For most AI herds a good way to start this process is to evaluate whether the losses are primarily due to estrus detection or to problems with conception. They all depend on *average days open*, a figure previously mentioned as suffering from some problems. The "days lost" calculations also assume all cows have a 21-day estrous cycle, which has also been called into question previously. And the estimation of the impact that imperfect heat detection has also assumes the typical cow will be seen in estrus about half an estrous cycle following the end of the VWP. Again, as we discussed above, this is unlikely to occur across the board. But, though they are imperfect, and we should always be cognizant of how differences in our client herds can play havoc with these assumptions, they make for useful and intuitive benchmarking indexes.

Waste Days. This is a simple measure of the total losses resulting from reproductive inefficiency. It is calculated by simply subtracting the herd's goal for days in milk at conception from the herd's *average days open*. For instance, if the herd desired a 12.5-month *calving interval*, then the goal for days open would be 100 ([12.5 × 30.4] − 280 = 100). Should the herd's actual reported *average days open* be 147, then the waste days would be as follows:

$$\text{Waste days} = \textit{Average days open} - \text{Goal days open} = 147 - 100 = 47$$

The waste days for this herd, then, is 47. In and of itself, this makes for a simple measure of reproductive efficiency to follow over time. But more can be done with a little more calculation.

CAVEATS. There are no real problems with the previous calculation beyond the question of whether using an average for *average days open* is appropriate.

Days Lost Because Of Conception Failure. This calculation is intended to give the analyst an idea of the proportional contribution of conception failure to overall days lost resulting from failure on the breeding side of the reproductive process. It assumes that, in a perfect world, a 100% efficiency in breeding is attainable. Therefore any breedings beyond 1.0 indicates a failure. For example, if a herd had an *average days open* of 147 and a *services/pregnancy, pregnant*

Downloaded from Vet-e-Books.com

cows of 2.22, the days lost resulting from failure of conception (DL_C) would be calculated as follows:

$$DL_C = (\textit{Services/pregnancy, pregnant cows} - 1) \times 21$$
$$DL_C = (2.22 - 1) \times 21$$
$$DL_C = 26$$

CAVEATS. The true figure for days lost resulting from conception failure is likely lower, since this index assumes 100% accuracy in estrus detection. That is, it assumes all cows bred were actually in estrus. The analyst knows this is not the case, so he or she is probably "blaming" some of the extra open days inappropriately on conception problems. In addition, as mentioned previously, this index uses a base expectation of a perfect world. Some clients may get tired of always being told they are not perfect; they are also unlikely to be willing to pay you for having a firm grasp of the obvious. We will deal with that soon, but first let us take a look at what we can come up with for days lost resulting from estrus detection errors.

Days Lost Resulting From Estrus Detection Failure. This estimation is aimed at the intensity of estrus detection on a dairy herd. If the above herd also had a VWP of 60, the days lost resulting from estrus detection failure (DL_{ED}) would be derived by the following equation:

$$DL_{ED} = \textit{Average days open} - (VWP + 10) - DL_C$$
$$= 147 - (60 + 10) - 26$$
$$= 51$$

This calculation estimates the time lost resulting from missing heats to be 51 days, or nearly twice that of the loss resulting from conception trouble. Therefore, if the practitioner wanted to help this herd, he or she might want to focus initially in on estrus detection, since it appears to contribute the highest proportion of inefficiency to the herd. Note also that the *average days open* minus the sum of DLED and DLC comes to $147 - (51 + 26) = 70$, which is when the average cow is typically assumed to come into estrus after a VWP of 60 days.

CAVEATS. Again, remember that we said the previous calculation likely overestimated true conception losses. This figure is likely, therefore, an *underestimate* of the true losses resulting from failures in estrus detection. Also, the aspect of the client being held to an impossible standard applies here as well.

Converting "Days Lost . . ." Calculations To Fit With Goals. Remember that the two "days lost . . ." calculations look at losses compared with perfection. A dairy will never be able to live up to them. One way to keep these issues up front with a client, and yet reward the client for reaching a goal, is to compare these figures against the more practical and goal-oriented waste days. The thinking here is that, should a client reach a goal for reproduction, our figures should indicate "zero inefficiency." Such a finding can lend a great deal of motivation to, and build a strong sense of personal satisfaction in, a client. It is explained below.

The process is simple. The consultant first derives the relative percentages of lost days resulting from one aspect of reproductive practices: either conceptions or estrus detection. Then the consultant multiplies this figure against waste days to arrive at the actual loss, relative to a reasonable goal, not relative to an unreasonable expectation of perfection. This figure subtracted from waste days will yield the losses resulting from the other aspect of reproductive practices:

$$\text{Proportion lost days resulting from conception } (PL_C) = DL_C / (DL_C + DL_{ED})$$
$$PL_C = 26 / (26 + 51)$$
$$PL_C = 0.34$$

$$\text{Loss vs goal resulting from conception } (GL_C) = PL_C \times \text{Waste days}$$
$$GL_C = 0.34 \times 47$$
$$GL_C = 16$$

$$\text{Loss vs goal resulting from estrus detection } (GL_{ED}) = \text{Waste days} - GL_C$$
$$GL_{ED} = 47 - 16$$
$$GL_{ED} = 31$$

The relative importance of the loss resulting from problems with estrus detection is still roughly twice that of the loss resulting from conception failure, so we have not given up our ability to identify which of the two seems to contribute most to reproductive inefficiency. Now, however, should the farm reach its goal for *average days open* (100 days), both of the estimated "losses vs goals" calculations will generate values of 0.0, just as they should upon reaching that goal. Pat your client on the back. Buy them a bottle of champagne. Let them be happy. Then set a new tougher goal and start the process all over.

CAVEATS. The problems with the set of calculations presented are the same as for the indexes that went into it. Because the calculation depends on *average days open*—a right-skewed data set—the use of an average can be misleading. The median would be more realistic but is not reported under most records systems.

Measures of Change in Overall Reproductive Performance. A relatively simple means to evaluate whether there are changes in overall reproductive efficiency over the preceding year is approached by creating a comparison of different ways to calculate calving intervals.

Predicted Calving Interval Versus Actual. As mentioned before, the published *calving interval* is largely of historical interest; it yields information on what happened over the past year or more. This is insufficient resolution to be of much value in day-to-day decision making. However, the practitioner can use *calving interval* as part of a process to generate data regarding current operations, specifically whether overall reproductive performance has improved, stagnated, or worsened over the preceding year. This is accomplished by comparing *calving interval* against a calculated *predicted calving interval*. It accomplishes this by indirectly comparing *average days open* to *calving interval*, by transforming *average days open* into the *predicted calving interval*. To do this, simply add the typical cow's gestation length (average = 280 days, range for Holstein = 278 to 282 days) (Youngquist, 1997a) to *average days open*. Divide this by the number of days per month (365/12= 30.4) to get the *predicted calving interval* in months. For example, the *predicted calving interval* for a herd averaging 147 days open would be as follows:

$$\textit{Predicted calving interval} = (\textit{Average days open} + \text{gestation length}) / (\text{Days per month})$$
$$\textit{Predicted calving interval} = (147 + 280)/30.4$$
$$\textit{Predicted calving interval} = 14.0$$

In general, comparison of the *predicted calving interval* with the published *calving interval* will give an analyst insight into progress on the farm. If overall reproductive performance is improving, then the *calving interval* should exceed the *predicted calving interval*; if performance is decreasing, the opposite will occur.

CAVEATS. Culling can impact *predicted calving interval* calculations. The concerns mentioned for *average days open* or *calving interval* also apply to this index.

MONITORING REPRODUCTIVE PERFORMANCE

Changing General Role of the Veterinarian

From Commodity to Investment

For most of the twentieth century veterinarians responded to their clients' requests for assistance after the client had identified a problem. Most commonly this problem dealt with an individual animal. So, then, did the veterinarian's response. The costs of the problem had to be balanced with the costs of the solution, for veterinarians' activities were in the role of loss minimization. The natural criterion for clients to use in choosing a veterinarian, then, was cost. As a result, many veterinarians concentrated on having the lowest charges they could; their time and effort was a commodity, and all commodities' markets are determined by price. In the 1960s and 1970s, however, a different model emerged for food animal practice: the scheduled services model. At the start these services were primarily focused on reproduction and udder health. Because the veterinarian's activities were aimed at groups of cows, as opposed to strictly focusing on individual animals, the costs of those interventions could be amortized over the group. This lessened the cost pressure somewhat. But at this stage, however, veterinarians were still largely in the role of responding to problems identified by the client; veterinarians were still loss minimizers. By the 1980s, however, production medicine came into its own. Two major differences exist between production medicine and previous practice modalities. First, the veterinarian should be at least as involved in monitoring the herd as the client. Second, the veterinarian acts on herd-level trends by dampening negative trends and promoting positive trends. For production medicine, inputs are affecting numerous animals, and because they largely work through long-term programs, the effect is also long term. The veterinarian is no longer a "loss minimizer" but an "investment" in widely affecting long-term results. This is rarely seen in purest action as in dairy reproduction.

Basic Objectives for Either Seasonal or Nonseasonal Herds

The basic objective of most programs is an average days open of 85 to 120 days (calving interval of 12 to 13 months), although the preceding parts of this chapter should cause the reader to only accept this goal after evaluating what is best for any individual dairy. How this is achieved biologically is the same, irrespective of the breeding plan used in the herd. The breeding plan may be year round with some cows calving every month, as is the case in most North American dairies, or with seasonal or block mating, which is more common in European dairies. In these cases, mating may be concentrated in one part of the year or in two mating periods to catch the flush of pasture growth or to have maximum milk available when incentive prices operate.

The measurement of reproductive efficiency is performed differently for the two management systems. In seasonal or block-mated herds the emphasis in management is on concentrating the mating, and therefore the calving, into as short a season as possible. This may be as short as 6 weeks. It is not possible in these circumstances to watch trends, correct management, and observe results. Everything happens too quickly. In these herds it can be worthwhile to make weekly visits and be on the watch for early warnings, but trends do not really become evident over such short time spans. Therefore the farmer's activity is concentrated into the breeding period with a view to getting as many cows pregnant as possible, using the veterinarian in the periods immediately before and at the end of the breeding period to intervene if estrus or breeding rates are too low or to attempt to concentrate unbred cows into a tight group if the breeding period is too extended.

In a herd bred year round, the veterinarian can observe performance from month to month and recognize trends early, which enables him or her to recommend changes in management and environment and then observe the effects of the changes over the next month or two. The essence of veterinary reproductive services in these herds is a repetitive cycle of monitoring (use of records, observations, and palpation) and intervention.

There is, in addition, a need for veterinary participation in routine herd level evaluation, reproductive examinations and pregnancy confirmation, and laboratory investigations. Veterinarians also have a role to play in preventing loss by abortion, infectious infertility, and dystocia. Their participation in this sort of work generates data that are invaluable in measuring performance and supplying back-up data that may be critical when making a causative diagnosis.

Example of Reproductive Evaluation Using Commercial Dairy Records Analysis Software

Introduction to the Example Herd

The example herd is a 120- to 130-cow dairy in southeastern North Carolina that has been having problems in a number of areas, one of which is reproduction. The herd has been in its current site for decades. It is bred by AI and is a confinement-reared dairy. We will look at some of the records normally available, as well as some software that allows for customized investigations. Finally, we will calculate some of the indexes listed in the previous sections of this chapter.

Dairy Herd Improvement Data

Fig. 7-6 displays the commonly reported reproductive data by DHIA. In Fig. 7-6 it has been excerpted using the PC-DART records software (PCDART 7.0, Dairy Records Management Systems), as PCDART's *Standard Report 801* – Herd Summary – Reproduction. It lists, in order, sections relating to summarizing events of the current breeding herd and the total herd, as well as summaries by service sire, on abortions (evidently not reported by this herd), a dry cow profile, and a 12-month summary. A few items to note from this report:

Reproductive summary of current breeding herd. The first column of the first section of Fig. 7-6 indicates the total breeding herd is 22 animals, equally divided between first lactation, second lactation, and third-plus lactation cows. With only 7 or 8 animals per subgroup, be careful not to consider differences of 10% to 15% as being important; a difference of 1 in 7 is over 14%. Similarly, there are only 18 animals in the *Bred But Not Diagnosed Pregnant* ("Bred But Not Diag. Preg.") group. However, the suggestion from this table is that *days to first service* seems to increase with parity; the older cows are being bred first nearly one estrous cycle period after the first lactation animals. Of course, always be skeptical of such trends when they are established with only two to four animals in each group.

Reproductive summary of total herd. The second section of Fig. 7-6 suggests that 16% of all first services occur *before* the end of the VWP. This suggests the herd management is not using its records effectively; rigorous use of records would prevent such early breedings. In addition, nearly one fourth of the herd is first bred after 100 days in milk, meaning they are at least 40 days beyond the VWP (VWP is shown at upper left of the report). This section does not support the

FIG. 7-6 Example of a reproductive summary report from a computer-based records system (PC-DART), which is, itself, an excerpt from the Dairy Herd Improvement Association Herd Summary Report (Report 202). It indicates this example herd has severe reproductive problems, as identified in the text. *VWP*, Voluntary waiting period.

parity-based increase in *days to first service* ("Days Open at 1st Service") suggested in the previous section; here, each parity group has extended time to first breeding. *Services per Pregnancy, Pregnant Cows, ("Services per Pregnancy, Preg. Cows")* in the next set of columns, is elevated for all parity groups, but especially so for first lactation animals. The same is true for the "Services per Pregnancy, All Cows." The projected calving intervals and days open show extremely extended periods. Here it appears that older cows are actually doing better, relatively speaking. The last set of columns addresses *interestrus intervals*. The majority of these intervals are in the 36+-day categories. This suggests either poor estrus detection and/or early embryonic loss.

Dry cow profile. Nearly 90% of the dry periods are in the 40- to 70-day category. Approximately 6% of the dry periods are longer than 70 days. However, the average dry period is 57 days, so it does not appear that those beyond 70 are likely to be much longer than recommended. There is no suggestion, therefore, that this herd is drying off cows that took too long to be bred, and therefore, have elongated dry periods.

Yearly reproductive summary. This herd appears to have an estrus detection problem; its monthly average for *percent heats observed* ("% Heats Obs.") is 37, with a best figure of 48 and a worst of 9. This herd shows that estrus detection is at its best, relatively speaking, in the cooler months of winter and spring, which is typical for the southeast. Note, also, that the "success rate" or *conception rate* for those breedings is quite low (avg = 25; range = 0 to −43). As mentioned previously, it cannot now be determined whether this poor conception rate is due to breeding technique or estrus detection inaccuracy. However, the veterinarian should be

concerned with both estrus detection and conception on this dairy.

Evaluation of Fig. 7-6 suggests the herd has extremely long *days open* and *calving interval* as well as extended *days to first service*. In addition, *services per conception* for either all cows or pregnant cows is overly high. The *interestrus interval* data given in the "Service or Heat Interval" section identifies the point that intervals are two or more estrous cycles. Finally, *Days Dry* (or "Dry Days") is not extended, however, the data for *Percent Heats Observed* and *Pregnancy Success* indicate both heat detection and conception could be problems.

Current Test-Day Analysis Program, Herd Summary Pages/Yearly Reproductive Summary Information

This is a report generated by another program in the PC-DART package, CTAP (Current Test-Day Analysis Program), and is displayed in Fig. 7-7. It largely repeats the data from Fig. 7-6, except that it also, as an option, lists the standard deviations (SDs) for several of the indexes. This allows the veterinarian to determine if the use of averages for these indexes is appropriate. The *services per conception, pregnant cows* ("Servs/conception [preg cows]") index shows a standard deviation that is over half the magnitude of the average. This means that a 2 SD distance below any of these figures will go into negative values. This cannot happen in real life, so the only explanation is that these data are highly skewed. Thus the use of averages for *services per conception* is not appropriate. The *Days to First Service* ("Days to first serv [breed herd]") data barely pass the 2 SD test. It appears, then, that these indexes may be nominally distributed normally, at least sufficiently so that averages are credible measures of central tendency. The new data presented by CTAP are the *Average Previous Calving Interval* ("Avg previous calving interval"). It easily passes the 2 SD test. It suggests that calving intervals, by parity group, were poor last year, suggesting that reproduction could be a long-term problem.

Spreadsheet Calculator

Fig. 7-8 is a spreadsheet that calculates reproductive rates and ratios that expand the value of information from the DHIA-based indexes, as defined earlier in the chapter. It makes the calculations for each of the three standard parity groups, as well as on a herd basis. Each of the four "Estrus Detection Measures" suggest estrus detection is only in the upper 20% to upper 30% range. Relative to a goal of 70% to 80%, this is exceptionally poor performance. The "Days Lost Due to Inefficiencies" measures suggest first lactation animals have twice the amount of *waste days* as do the other parity groups, which are themselves losing 50 to 90 days. It appears that 24% to 37% (average, 29%) of those *waste days* is due to conception failure. Hence, estrus detection inefficiency is responsible for two to three times that proportion of *waste days*, with first lactation animals appearing to suffer the worst estrus detection. Finally, it seems that there may be some evidence that things are actually getting better, although only marginally so. Such a result could simply be due to culling effects.

Summary of Findings

The DHIA, CTAP, and spreadsheet analyses all point to severe problems with estrus detection on this herd. Conception rates are also a concern, however, they likely only contribute 25% to 33% as much inefficiency (and, hence, costs or losses) as do estrus detection errors. The worst overall performance appears to be in the first lactation animals.

Further investigations would be warranted. Certainly, the analyst should look at nutrition and body condition to determine if there are contributing difficulties here. In addition, because of the first lactation involvement, the analyst should be interested in determining if facilities are limiting or if the youngstock program is producing poor heifers. With conception rates in question, a review of breeding procedures and techniques is also necessary.

The example provided should not be taken as exhaustive; it is meant only to give the reader a few suggestions in how

to interpret and synthesize the information from standard dairy records systems.

FINANCIAL IMPLICATIONS OF REPRODUCTIVE INEFFICIENCY

Concerns and Caveats

The process of estimating the cost of reproductive inefficiency is confounded by many issues (Britt, 1985). Earlier in this chapter we discussed the difficulties in interpreting many of the standard measures of reproduction. Since our measures of financial implications for reproductive performance depend on these indexes, it makes sense that economic estimates of the bottom line impact of a dairy's reproductive successes and failures should also be viewed with a somewhat skeptical eye. For instance, several indexes *(days open, days in milk, days to first breeding)* are skewed so that looking at mean values will be misleading—yet veterinarians often talk about the "cost of an extra open day" without regard to its distribution within a herd. Other indexes predominantly represent historical data (for example, *calving interval*) that may or may not be applicable to today's decisions and may be strongly affected by culling and replacement policies—yet veterinarians often compare calving intervals at one time across herds, and within a single herd across time, without

Downloaded From Vet-eBooks.com

considering how it can be confounded. Finally, with differing goals between farms, changeable business structures across dairies, and varied pricing strategies between regions, there are no hard and fast rules in applying economic theory to dairy farm reproductive performance.

Even given the above caveats, some things can be stated. The financial implications of reproductive inefficiency will be based on the biological outcomes of the system, and those outcomes can be described. For instance, in herds that calve year round, the major loss when cows are slow to conceive is lost milk production because the cow spends more time at the end of lactation or as a dry cow. The cost of the lost milk depends on both the price of the milk and the cost to produce it, which vary over time and season and are different for cows at varying levels of production. There is a clear association between poor reproductive performance *(extended days open)* and lowered milk production (Fetrow et al, 1988) when measured as an average per day. The association is probably not entirely causal; managers who do poorly at reproductive management likely do poorly in other management aspects as well. There are other reports, however, that specifically relate selection for high production with increased health care requirements, including reproduction (Gilmore and McDaniel, 1977; Shanks et al, 1981; Young et al, 1985), and with a concomitant potential genetic selection for extended lactation length (Silvia, 1998; Washburn et al, 2000). In seasonally calving herds, small delays in conception may mean that the cow will be culled, so loss per extra day open is an abruptly discontinuous function. Reproductive inefficiency reduces the number of calves born, increases the cost of semen and labor expended, may increase the cost of veterinary service and therapy, and slows genetic progress. As mentioned previously, any consideration of the costs of reproductive inefficiency quickly becomes connected with culling policy and its costs. If cows are culled to improve average reproductive performance, those costs should be assessed properly as reproductive costs, even though often they are not considered.

One last factor that impacts the ability to distill out the financial outcomes of reproductive efficiency is that most of the basic methods of financial analysis, such as partial budgets (see Chapter 2), ignore risk. Although it makes sense that the quicker a cow is bred back, the higher a proportion of her upcoming lactation will be spent in the higher producing early stages. She will also be more quickly facing one of the riskiest periods in her life: the peripartum period. Hence, shortening of the lactation intervals also increases the proportion of a cow's lifetime that she is most at risk of disease and injury, not to mention that it also increases the proportion of her life spent as a nonproducing dry cow. Other risks factor into the decisions that determine a cow's overall reproductive success or failure. In the warm climate areas of the world, seasonal heat stress often changes the risk perception, and therefore the decision process, of breeding a cow. For example, the risk of lowered production based on season of calving in the southeastern United States may well overwhelm any general concerns about lactation length (Farin et al, 1994). Failure to consider the risks inherent in reproductive management leaves out important information that molds the decision to breed or to not breed a cow.

As discussed in Chapter 2, our inability to know everything, and our being forced to address uncertain situations, does not excuse us from helping our clients make decisions. Similarly, even though we understand that the measures we use are less than perfect and that many studies will not include every important facet of a problem, we can still make use of the literature in exploring the financial implications of reproductive inefficiency in modern dairies. We simply need to be careful in how we interpret them.

Reproductive Performance and Finances

Some studies have used retrospective data or surveys to investigate the association between reproductive performance and finances (Olds et al, 1979; Jansen et al, 1987; Lemrick et al, 1987). Estimates in the United States for the cost of a day open past some target level (85 to 100 days) have varied: $0.78 (Speicher and Meadows, 1967), $1.00 (Britt and Gaska, 1998), $1.22 (Lemrick et al, 1987), and $2.03 (Lineweaver, 1975, assuming a target of 85 days). There are many problems with all of these estimates. Each estimate includes differing parameters. For example, some include the value of calves, some subtract feed costs, and some factor in culling costs. The exact nature of the herds used to derive these estimates are hard to extrapolate to a specific existing herd, as are the market prices of cattle or milk. Inflation and the time value of money (see Chapter 2) should be factored in, but specific multipliers are impossible to determine or apply to the various aspects of the analysis. Extrapolation to other countries' management systems and economies is probably too dangerous to attempt.

Perhaps the best way to use these types of studies is to estimate the biological effects and leave it to the user to apply the financial evaluation. For example, in a study in the southeastern United States, it was found that an added day open reduced net milk production 4.5 kg in heifers and 8.6 kg in older cows (Olds et al, 1979). Thus at $0.25/kg milk, the loss in milk income per added day open would be $2.15 for older cows.

Spreadsheet/Modeling Estimates

Spreadsheet approaches to estimating the costs of reproductive inefficiencies have been developed (Goodger et al, 1988; Slenning, 1986). Spreadsheets may have varying degrees of complexity, from assigning a cost per day open to calculating income over feed costs for various stages of lactation and the value of lost calves to the complex accounting of financial flows relating to the dairy's reproductive program. Some may include culling costs and costs of therapy, extra labor, and semen. Some deal with all factors as if they were certain, whereas others allow for uncertainty and encourage "what if" investigation.

Spreadsheets have the advantage of allowing ad hoc evaluations using a particular farm's data. They have a potential disadvantage when the analyst allows the number crunching to get ahead of the logic in the spreadsheet. For instance, in reproductive analyses, certain costs such as feed and labor are often allocated on an average per-unit-milk-produced basis, when in reality these inputs show changing ratio input relationships as production increases. In other words, feed efficiency is not fixed—it tends to improve with increased production (see Chapter 2 for review). A system that ignores this point will inappropriately "penalize" higher production with a poor estimate of efficiency.

The most sophisticated approaches to calculating the costs of reproductive inefficiency are simulation modeling and expert systems, which are mathematical systems that project the biological and financial flows on the dairy that result from specified starting conditions of both farm and cow status and management policy (Marsh et al, 1987; Houben, 1995; Plaizier et al, 1997). Other expert systems may focus less on the financial impacts and serve more as diagnostic systems (Levins and Varner, 1987). Although far more robust than other approaches, these models are often difficult to use or are not available for use by the practicing veterinarian.

Financially Reasonable Goal for Reproduction

None of the programs for estimating the costs of reproductive inefficiency is complete, universally applicable, or fully validated. None has gained wide acceptance or practical

Downloaded From Vet-eBooks.com

field use. Veterinarians should accept that all such models are just that, models. Simple, easily understood models that achieve the right order of magnitude may be more useful than complex, inaccessible models that are more accurate and less understandable. In general, what is important is a fairly focused sense of magnitude of loss, so that management can compare the magnitude of the costs of intervention with the costs of the problem.

Considering what is known regarding the costs of reproductive inefficiency, the following conclusions for herds that calve year round seem supportable. Having cows conceive very early after calving (less than 50 days) is at least as costly as having delayed conception. The optimum *days open* is probably between 85 and 120 days for most herds. Herds with excellent reproductive management can afford a stricter policy on culling for production and for failure to conceive by a specific date. Poorly managed herds should be more lenient in their culling policies; extensive culling to achieve acceptable herd statistics for reproductive performance is likely to be more expensive than the extended *days open*.

CHAPTER 8

Culling and Genetic Improvement Programs for Dairy Herds

BRIAN RADKE and GEORGE SHOOK

Potential Role of Culling and Genetic Improvmeent Programs in Herd Health

Dairy producers and veterinarians have intensified their efforts in nutritional management, udder health, reproductive performance, and replacement heifer rearing to improve herd performance and production efficiency. However, there appears to be less recognition of the potential for herd improvement using two other important dairy herd strategies: culling and genetic improvement.

Organizations involved in dairy cattle breeding, such as artificial insemination (AI) centers, animal geneticists, and breed organization centers, have invested heavily and have made significant strides in genetic improvement (Leitch, 1991). Approximately a 1.5% annual rate of improvement in productivity has been attributed strictly to improved genetic potential. On the other hand, there is little doubt that there could be greater implementation and use of these genetic gains.

Traditionally, veterinarians have not become involved in the culling and genetic improvement strategies, even in herds with comprehensive health management programs. Some veterinarians have become familiar with the prominent sires and cow families in particular breeds. This knowledge is useful for client relations and for developing producer confidence. Extension of this knowledge into meaningful definitions of goals for genetic improvement and effective herd culling strategies, however, has been extremely rare.

This chapter consists of two major sections. The first section presents information on culling in dairy herds. The inseparability of a herd's culling strategy and replacement strategy is emphasized. Methods of developing a prospective culling and replacement strategy based on economic merit are described. In the second section, the basic principles of genetic evaluation and improvement programs are presented. Proposed methods by which veterinarians can incorporate genetic improvement into health management programs are also outlined.

CULLING AND REPLACEMENT STRATEGIES FOR DAIRY HERDS

Culling describes the removal of a cow from a herd because of sale, slaughter, or death. An obvious, but often overlooked, issue in culling is that for a given herd size, the number of replacements determines the number of cows culled. That is, if herd size remains constant, an animal in the herd must be culled for every heifer that enters. The increasing of cow longevity is receiving increased attention in the dairy industry. But longevity cannot be increased without decreasing the number of cows culled, which reduces the requisite number of replacements necessitating the sale (or reduced purchases) of replacement heifers. These points highlight the interdependent nature of a herd's culling strategy and replacement strategy. The commercial availability of sexed semen, with its ability to catapult annual culling and replacement rates well above 80%, will highlight the interdependency. This interdependency is more fundamental than merely relating animal flows into and out of a herd. Culling and replacement decisions are inseparable because, by definition, they involve the comparison of the animal currently in the herd with a potential replacement. Because of their inseparability, the two strategies should be considered a single strategy—the herd culling and replacement strategy.

This section deals with the complex issue of culling and replacement in dairy herds. An economic rather than a biological approach to culling and replacements is used. That is, the cow is not generally culled because she is no longer able to produce or is not profitable, but because a replacement is expected to be more profitable. While profit maximization does not drive every decision, economics usually plays some role in decision making. If nothing else, the profit foregone by not making the most profitable decision is usually of interest to the decision maker. Although the emphasis is on economics, biological factors are important too. Disease is an important factor in animal profitability, and animal welfare concerns may become increasingly important in dairy cow culling and replacement programs. Although the emphasis is on profit maximization, the strategies can be modified easily to maximize other objectives. For example, if the herd objective is to maximize milk production or genetic improvement instead of maximizing herd profit, the principles of animal replacement can be applied to these alternative objectives.

The complexity of the herd culling and replacement strategy is contributed to by its high level of integration with a number of other areas of dairy enterprise management. For example, the culling and replacement policies have direct implications for udder health, disease control and treatment, reproductive management, and replacement heifer programs. Opportunities exist to increase herd profit through an improved culling and replacement strategy. Such a strategy is easy to implement and adapt—the greatest obstacle may be in altering the industry's assumptions and beliefs about culling practices.

The purpose of this section is to provide the information necessary to develop culling and replacement strategies that can be implemented and are profitable. First, the principles of culling and replacement decisions are reviewed and considered. Although it is not possible to directly apply these

Downloaded from Vet-e-Books.com

principles to actual decision making, an understanding of the principles is necessary in customizing a herd's culling and replacement strategy. With the aid of computer models, these principles have been used to produce two tools, culling guidelines and a range of target culling rates, which are useful in developing culling strategy. Each tool is considered in turn, including discussion of the various measures of culling. The target range of culling rates does not aid in identifying which cows to cull, therefore the reasons and risk factors for culling and how to interpret this information is presented. The decision about how many cows will be culled dictates the number of replacements required. If there are more replacement heifers than required, a method of heifer selection is required. Then the risk and return from culling and replacement strategies is considered, followed by material on customizing the strategy for a particular herd. This section concludes with the implications of culling and replacement strategies for herd health programs and methods of estimating the culling component of the cost of disease.

PRINCIPLES OF A DAIRY HERD CULLING AND REPLACEMENT STRATEGY

In principle, the herd culling and replacement strategy for a dairy herd consists of the following two steps: (1) identify which cows to cull and which replacements will enter the herd to maximize herd profit, and (2) determine when to actually sell the cows that have been identified for culling. The decision in the second step is relatively straightforward and simple—a cow identified for culling is culled when either limitations in herd resources forces her sale or she is no longer profitable. Examples of limitations in herd resources include an excess of cows for the herd's human or physical resources (e.g., number of stalls, milking parlor capacity) or, in the case of herds operating under a supply managed system, an excess of milk for the herd's quota holdings. A cow designated for culling is no longer profitable when her milk revenue is less than her variable cost of milk production.

A potential role for the veterinarian in the second step of when to sell the cull cows is to incorporate animal welfare concerns into the decision process. That is, consideration of the animal's welfare may lead to her sale earlier or later than would otherwise occur if her welfare was overlooked. In addition, the veterinarian can advise producers about the marketing channel (e.g., livestock auction, direct shipment to slaughter facility, emergency on-farm slaughter, euthanasia) most appropriate given the animal's clinical state.

In contrast to the relative simplicity of assessing when to sell the cows designated for culling, a method of making the more important decisions of step one is not as obvious. Fortunately, standard capital budgeting replacement models provide the principle of how to assess and compare animals' profitability. The *general decision rule* in capital budgeting, customized to culling, is to replace the current asset (i.e., cow) with a replacement (i.e., heifer) if the heifer's expected profit per lactation, averaged over her life, is greater than the expected profit from the cow's next lactation and is greater than the expected average (time-valued) profits from the cow's subsequent lactations. Thus *the replacement decision rule is to replace a cow with a heifer if the heifer is expected to be more profitable.* As explained below, it is not possible to apply this decision rule in making actual cow replacement decisions. However, a good understanding of the principles of cow replacement decisions and the decision rule is important in customizing a herd's culling and replacement strategy.

The decision rule is difficult to apply directly to cows and the potential replacement heifers because of the extraordinary predictive power required. Application requires predicting the future profits of the animals. Furthermore, to properly incorporate the process of genetic improvement, these predictions are required for all potential future herd replacements. To predict an animal's future profit requires predicting her biological performance such as future milk production, which, at a minimum, requires predicting her future reproductive performance. While onerous, these biological predictions are possible through the use of statistical techniques, such as survival analysis. However, it is important to appreciate that predicting a potential replacement heifer's expected profit per lactation, averaged over her life, also requires predicting the length of her life or when she will be culled. Thus, by applying the decision rule above, she will be culled when the expected profit from her next lactation is less than her potential replacement's expected profit per lactation (again averaged over the potential replacement's life). In other words, to know the current replacement heifer's expected average profit per lactation requires knowing the culling decision of all her potential replacements. In addition, presumably, if the culling decisions of potential future replacements were known, then the culling decision of the current cow and replacement heifer would also be known and this exercise would be unnecessary. Thus step one is complicated. The folly of trying to circumvent this complicated, but necessary, approach by using simple cow versus heifer comparisons in making culling decisions has been examined (Radke and Lloyd, 2000).

Solution techniques for the complex, capital budgeting replacement issues just mentioned are available and have been applied to the issue of culling and replacement strategies to maximize producer profit. These models are intended to test the impact of various culling decision strategies on the profitability of a dairy enterprise. Briefly, the two broad categories of computer-based solution techniques are simulation (Allaire and Cunningham, 1980; Allaire, 1981; Congleton, 1988; Marsh et al, 1987; Dijkhuizen and Stelwagen, 1988) and optimization models (Rogers et al, 1988a; Dijkhuizen et al, 1985; Van Arendonk and Dijkhuizen, 1985; Bauer et al, 1993). Both techniques require simulating the animals and management of a dairy herd for decades. The models simulate the biological performance of the animals, including their milk production, health events, and reproductive performance. The management decisions simulated include breeding and culling decisions for each animal. The economic performance of the animals is also included. The simulation models can be used to compare different culling strategies. But the conclusions drawn from the comparisons should be tempered with the realization that the best strategy is only relative to those considered. That is, alternative strategies may exist that are superior to those considered. In contrast the optimization technique leads to the optimum culling policy (i.e., the culling policy that maximizes herd profit) for the conditions modeled. The optimization models generally use numeric stochastic dynamic programming to apply the capital budgeting decision rule to each animal and all potential replacements of the herd for decades. The models included moderate values of estrus detection and conception rates, and culled cows were sold for meat (not dairy) purposes. In addition, sensitivity analysis is used to investigate variations in the input assumptions on the economic outcome.

The complex computer optimization models have been recommended to develop culling policies specific to a given situation rather than applying general guidelines (McCullough and DeLorenzo, 1996). This recommendation was based on the finding that simultaneously varying a number of the model inputs resulted in meaningful changes to the optimal policies. The lack of availability of the models and expertise required to customize and operate the models limits the practicality of the recommendation. In addition, the

Downloaded from Vet-eBooks.com

data collection and analysis required to fully customize a model for a specific herd could be quite burdensome. Similar to other areas of herd management, culling recommendations that are herd or animal specific are not currently feasible. However, these models have led to two tools, culling guidelines and a range of target culling rates, which are useful in developing a culling strategy. Each of these are presented including consideration of the various measures of culling. The discerning reader will recognize that despite the earlier discussion of the necessity of simultaneously comparing the cow and the replacement, the emphasis will be first on cow culling, followed by consideration of replacement heifer selection. In order to implement a culling and replacement strategy, it is necessary to disengage into a culling strategy followed by a replacement selection strategy. However, despite appearances, the interdependency is maintained because, in generating the two tools, the computer models simultaneously considered the cows and the replacements.

CULLING GUIDELINES

Insemination guidelines are available for Dutch and U.S. dairy herds (Tables 8-1 and 8-2). A simplified guideline for dairy herds has also been produced (Table 8-3). These guidelines indicate the minimum level of milk production to start and continue breeding individual cows. Cows not inseminated are designated for culling. The level of milk production is relative to the herd average production and is expressed on an age-corrected basis. Thus, for example, production level comparisons would be based on mature equivalents or breed class averages for the United States and Canada, respectively. Cows at the minimum level of milk production are expected to be equally profitable as the average replacement heifer. Cows at greater than the minimum production level are expected to be more profitable than the average replacement. The Dutch Dairy Herd Improvement Association (DHIA) has made insemination guidelines available to producers to aid their individual cow insemination and replacement decisions (Dohoo and Dijkhuizen, 1993).

The guidelines suggest that some low-producing animals should never be bred, whereas only moderate levels of

TABLE 8-1

*For dairy conditions in the Netherlands, this table shows the effect of increasing parity, and increasing days open on the minimum production level (as a percentage of the herd average) required to economically justify breeding a cow. For example, a third-lactation cow at 125 days in milk needs to have only 90% of the herd average milk production to warrant breeding. On the other hand, a seventh-lactation cow at 205 days open should not be bred at less than 105% of herd average.

Note that higher milk production is needed to offset delayed insemination because of lower profit associated with prolonged calving intervals. With increasing age, higher production is needed to counteract the increased risk of culling and ensure the cow is profitable relative to the genetically improved replacement heifer.

TABLE 8-3

Guidelines for Breeding Cows According to Productive Capacity

Production (Percent of Herd Average)	Breeding Strategy
Less than 80	Do not breed
80 to 90	Cease breeding at 160 days
Greater than 90	Cease breeding at 240 days

production are required to economically justify continued insemination. For example, under Dutch conditions, it is profitable to breed a first lactation animal in her seventh month of lactation if her age-corrected milk production is at least 92% of the herd average (Table 8-1). Premature cessation of breeding this animal, causing her culling and replacement, leads to decreased profit. Also, it may be economically justifiable to persist in breeding cows much later into lactation than is often considered feasible in North America (Dohoo and Dijkhuizen, 1993). These guidelines suggest North American producers have made some premature culling decisions leading to the unnecessary culling of some animals. This led to decreased herd profit because of higher than optimum culling rates.

The simplified guidelines presented in Table 8-3 have been compared with insemination policies of a fixed cutoff point (e.g., no breeding 160 days after calving) that ignored the cows' production. These comparisons were conducted with variable reproductive performance and evaluated under U.S. (Marsh et al, 1987) and Dutch conditions (Dijkhuizen and Stelwagen, 1988). Generally, the simplified guidelines presented in Table 8-3 provide greater economic returns than the more restrictive fixed cutoff point policies.

TARGET CULLING RATE RANGE

Only some of the literature on optimum culling rates provided insemination guidelines. In contrast, it was routine for each study to report some measure of the culling rate that maximized producer profit. The simulation studies would also commonly compare optimum and nonoptimum culling rates and their effects on the economic and biological performance of the herd. There is a general consensus that culling rates of 20% to 30% maximize producer profit under the economic and production conditions commonly found throughout a number of dairy-producing countries (Radke and Lloyd, 2000). An exception is the culling rate in the range of 40%, which is considered optimum in the southern United States because of the effects of heat stress on production and reproduction (DeLorenzo et al, 1992). In the absence of heat stress, the optimum culling rate in the United States is 25% (Rogers et al, 1988a).

It is surprisingly difficult to apply these target culling rates to individual farms for two reasons. First, varying measures of culling are reported in the dairy industry, and although these measures are related, it is not necessarily easy or even possible to convert one measure to another. The second, and likely more important, reason is the lack of standard definitions for these rates, which is a problem exasperated by the failure of many authors to report their method of calculation. As a result, a great onus is placed on the reader of the culling rate literature to ensure apples are not being compared to oranges, as frequently happens.

Calculating Culling and Herd Turnover Rates

There are two common methods of calculating the culling rate. These calculations are limited to animals that have calved at least once. The method adopted here is that *culling rate equals the number of animals culled per year divided by the average herd size*. Although the average herd size for a year can be calculated by averaging the cow inventory at the beginning and end of the year, the use of more frequent measures of herd size is preferred because of fluctuations in herd size. For example, calculating the average by including the herd size in each of the 12 months is more accurate than considering only the size at the beginning and end of the year. Another common method of calculating the rate at which cows leave the herd is dividing the number of animals culled per year by the total number of animals that were ever in the herd in that year. In other words, the denominator of the second calculation, which we call the *herd turnover rate*, is the sum of the average herd size and the number of cows culled. The first method is adopted, not only for its intuitive appeal, but also because it is more epidemiologically accurate. The epidemiological definition of culling rate is the number of animals culled per unit of animal time at risk. Therefore the denominator used in the calculation should reflect the number of animal years the animals were at risk of being culled. The herd turnover approach of using all the cows that were in the herd at any time in the year overestimates this animal time at risk because the culled cows and their replacements were in the herd only part of the year. The herd turnover approach counts a cow and her replacement as each being at risk for the entire year, whereas the culling rate calculation recognizes that, between the two animals, there was only a single year of cow risk for culling.

For example, consider a dairy herd that over the course of a year averages 100 cows and culls 40 cows. Using the above definitions the culling rate is 40% (40/100) and the turnover rate is 28.6% (40/[100 + 40]). Using the above calculations, a 40% culling rate is equivalent to a herd turnover rate of 28.6%.

The literature occasionally refers to culling risk instead of culling rate (i.e., a culling risk of 24%). Technically the culling rate is not a rate because the animals' time at risk has not been calculated with sufficient accuracy. (The calculation of animals' time at risk in terms of days rather than months or years would help alleviate this concern.) *Risk* (i.e., culling risk or, alternatively, culling risk rate) is the term used when the measurement of time at risk is relatively crude. However, because the term culling rate is so entrenched in the culling vernacular, we will continue to use it rather than the preferable terms of culling risk or culling risk rate.

Much more important than the method of calculating the culling rate is ensuring that rates being compared have been consistently calculated. For example, in a survey of 50 dairy herds in England, an average total annual culling rate of 23.8% was reported (Esslemont and Kossaibati, 1997). It appears the average culling rate is well within the target range. However, the reasons for culling 6336 animals were collected from the records of 26,644 animals that calved. This implies the 6336 culled animals are included in the 26,644 animals. Thus with the above definitions, the average culling rate is 31.2% (6336/[26,644 − 6336]) and the herd turnover rate is 23.8% (6336/26,644).

Care is required in comparing the culling rate of herds undergoing expansion with the literature's optimum culling rates, which are for herds of constant size. The mere act of expansion can lead to a lower culling rate than if the herd had maintained a constant size. For example, suppose a 100-cow herd expanded internally to 110 cows in 1 year, and during this year the herd had a 37% culling rate. To achieve a 37% culling rate the herd must have sold 39 cows (0.37 × [{100 + 110}/2]). Thus 39 heifers must have entered the herd just to maintain an average herd size of 105 cows. In addition, 10 more heifers must have entered the herd to permit the internal expansion from 100 to 110 cows. The herd of 100 cows must have actually calved 49 heifers. If the herd had not expanded, its culling rate would have been 49%. Similarly, the veterinarian would expect that once the herd stops internal expansion, the culling rate should return to 49%.

Finally, extra care must be taken in the assessment of culling rates averaged across herds. These averages represent the mean of a distribution of individual herd culling rates. In the example from England, at first glance the average 31.2% culling rate in the herds may not appear problematic

Downloaded From Vet-e-Books.com

because the rate is just slightly higher than the maximum of the target range of culling rates. But the distribution of individual herd culling rates is likely symmetrical (i.e., equal number of herds with culling rates above and below the mean culling rate), and thus over half the herds in the study have culling rates higher than the optimum range. This assessment of culling rates is much different than that at first glance.

The culling rate is the preferred measure for monitoring culling in dairy herds. It is easily understood, easy to calculate with commonly available dairy herd records, easy to compare with the literature, and, relative to some of the other measures that are presented below, stable.

Survey of Culling Rates

Average dairy industry culling rates from the last decade for various geographical areas are listed in Table 8-4. This table should be interpreted as a broad picture of the culling practices of the dairy industry as represented by a number of dairy-producing regions of the world. Care must be taken in interpreting the results from any single study and comparing them with others because the methodologies vary greatly. For example, the Australian study was based on only eight herds, so caution is required in extrapolating this result to a larger population. (In contrast, the other studies had a minimum of 50 herds.) In addition, the time frames of the studies ranged from a single year to over a decade. For example, the Canadian study revealed that the annual industry average culling rate ranged from 35% to 38% in the span of 5 years and resulted in the 5-year average of 36% reported in Table 8-4 (Durr et al, 1997a). The study discusses reasons for yearly fluctuations in industry average culling rates. Another difference among the studies was the culling reasons considered. For example, in contrast to the other studies, cows sold for dairy purposes (i.e., exported, sold for dairy purposes or rented) were excluded from the Quebec study (Durr et al, 1997a).

As a broad view of the culling practices of some major dairying regions of the globe, Table 8-4 presents a surprisingly consistent picture. The average culling rates range from 26% in Australia to 36% in areas of North America. The average culling rates of the majority of regions have culling rates above the target range. This suggests dairy producers in a number of areas may be able to profit from altering their current culling and replacement strategies in favor of a lower culling and replacement rate. Application of the earlier warning about interpreting industry average culling rates illustrates the diversity of current culling practices. For example, individual herd culling rates of one study ranged from 13.5% to 49.0%, with an average of 31.5% (Esslemont and Kossaibati, 1997). Similarly, another study with an average culling rate of 28.4%, had an interquartile range of 12% to 54% (Whitaker et al, 2000). These broad ranges around the averages suggest every region has producers with culling rates greatly exceeding the target range of culling rates and therefore the opportunity to increase profit by reducing their rates.

Culling rate is a crude measure of the culling practices of a herd because it is an average for the entire herd. For example, two herds with the same average culling rate can have different age distributions because of differences in the marginal culling rates for each lactation or age of cow. In addition, presumably, the different age distributions will translate into varying profitability. *Herd composition* based on age or parity is occasionally used in the dairy industry (Table 8-5). There are no published suggested herd compositions to maximize herd profit, and if there were, they would likely be difficult to replicate. Although there are no suggested age distributions, the culling guidelines imply 15% to 20% of first-lactation cows should be culled (Dohoo and Dijkhuizen, 1993). The percentage of the herd as first calf heifers can be a useful quick method of gauging the culling rate.

Percentage of First Lactation Animals in the Herd and Culling Rate

Great care must be exercised when using the percentage of first lactation animals in a herd to evaluate the culling rate. This measure of culling can vary widely over time because of

TABLE 8-4

Survey of Dairy Herd Culling Rates

Authors	Geographical Area	Average Culling Rate
Jones et al (1995)	New York, USA	36.0%
Esslemont and Kossaibati (1997)	England	31.2%*
Durr et al (1997a)	Quebec, Canada	36.0%†
Seegers et al (1998b)	Western France	32.3%
Stevenson and Lean (1998a)	New South Wales, Australia	26%
Whitaker et al (2000)	Southern England	28.4%‡

changing population dynamics in the heifer and cow populations. For example, unequal distribution of heifer calvings over time, changes in the number of first lactation animals culled, and changes in herd size can all markedly affect the monthly percentage of first lactation animals in the herd. Many DHIAs routinely report the percentage of the herd that is first lactation animals. Because of the potentially wide variation, use of this measure from a single point in time is not appropriate; thus the measure can be misleading. Rather, consideration of the herd's percentage of first lactation animals over some period (e.g., the last 12 months) is a more appropriate measure of the culling rate.

The usefulness of the percentage of first lactation animals in the herd as a measure of the culling rate arises from the vast majority (if not all) of replacements being first-calf heifers. Therefore the percentage of first-calf heifers in the herd, corrected for the calving interval, provides a minimum estimate of the number of animals culled from the herd in the last year. For example, in reporting the average culling rate of Quebec Holstein herds, Durr et al (1997a) stated that, on average, the herds consisted of 33.4% first parity animals. If a herd had maintained a constant size, at least 33.4% of the herd must have been culled in order for the herd to consist of 33.4% first calf heifers. But care is needed in assessing the time span over which this culling has occurred. The average calving interval for these first lactation animals is 12.9 months (390 days) (Durr et al, 1997a). After calving, a first-calf heifer on average remains a first-calf heifer for 12.9 months. Thus culling 33.4% of the herd occurred over the last 12.9 months or 1.07 years, and the annual culling rate for the herd is at least 31.2% (33.4%/1.07). This is the minimum herd culling rate because the first-calf heifers that were culled have not been included in this rate. To understand this, consider a herd that has 33.4% first-calf heifers. If one of the first-calf heifers is culled and replaced with another first-calf heifer, neither the number of animals in the herd nor the number of first-calf heifers has changed. Although a first-calf heifer was culled, the herd still consists of 33.4% first-calf heifers. The actual culling rate can be estimated by dividing the minimum culling rate by 1 minus the (marginal) culling rate of first-calf heifers. From the Durr (1997a) study, roughly 25% of the Quebec first-calf heifers were culled, so an estimate of the herd culling rate is 41.6% (31.2%/[1 − 0.2]). Notice this estimate is greater than the actual average culling rate of 36% reported in Table 8-4. The inaccuracy of the rate based on the percentage of first-calf heifers is due to the variable population dynamics warned of earlier. The percentage of first-calf heifers is perhaps most useful as a quick method of confirming a herd's reported culling rate. For example, if Durr et al (1997a) had reported a herd culling rate of 24% and the herd consisted of 33.4% first-calf heifers, an inconsistency is immediately apparent and further investigation of the culling rate is warranted. A common reason for the percentage of first lactation animals consistently exceeding the herd's reported culling rate by a large amount is the reported culling rate is actually the herd turnover rate.

Length of Cow's Life and Culling Rate

Several culling measures use the length of the average cow's life in a dairy herd. Longevity considers the cow's age at culling. Productive life or herdlife is the length of time from first calving to culling. Thus productive life or herdlife is equal to longevity less the average age at first calving. These measures are variably expressed in the units of months, years, or lactations.

If productive life or herdlife is expressed in years, the culling rate is equal to 1 divided by the herdlife (Durr et al, 1997a). For example, in the Quebec study the overall productive life was 33.1 months for owner sampler herds and 32.97 months for official herds, and the respective culling rates per year were 36.22% and 36.40% (Durr et al, 1997a). If productive life or herdlife has the units of lactations, the analyst must, before calculating the culling rate, convert the units to years through multiplication with the average calving interval measured in years.

Similar to culling rate, herdlife is an average for the herd. Therefore the previous comments about culling rates—such as two herds with the same culling rates, having different age distributions and thus profitability—are just as applicable to herdlife as a culling measure. Measures of longevity are frequently reported monthly by dairy herd improvement associations. Similar to the measure of percentage of first lactation animals in the herd, longevity measures will vary from month to month, although the variation is not as extreme.

CULLING REASONS

A target culling rate assists in the determination of how many cows should be culled but not which cows should be culled. A large literature base describes dairy cattle culling practices, especially the reasons and risk factors for culling. But caution is required in interpreting this literature for a few reasons. A consistent system is lacking for assigning the reasons dairy cows are culled. General agreement does not exist about which reasons should be considered (Table 8-6). Misclassification also occurs because a culled cow typically can be attributed to only a single reason. For example, cows that are poor producers because of chronic subclinical mastitis might be classified as a low production cull or a mastitis cull. A low producer that has not conceived after one or two inseminations may be classified as a reproductive cull (because the producer is less willing to invest time, semen, and effort on a low-producing cow) or as a low-production cull. Another common example of unclear classification of culling reason involves cows with significant lameness. Such cows often have an increased risk of developing mastitis, reduced chance of being observed in standing estrus, reduced feed intake leading to lower milk production, and poor body condition. In fact, the cause of the lameness may have originally been improper provision of fiber in the cow's diet. When this cow is culled, should the reason for culling be attributed to low production, reproduction, mastitis, foot and leg problem, or a miscellaneous reason?

Furthermore, the literature describes industry practices for better or worse, so care is required when this information is used to make recommendations. For example, reproduction is generally one of the more commonly cited reasons for culling. Based on this finding, recommendations are frequently made to focus effort on reproductive management to reduce this culling. But because reproductive performance is a critical and challenging control point in cow profitability, its commonness as a culling reason is *expected*—it would be surprising if reproduction were *not* a common reason. If the producer is interested in profit, these interventions in reproductive management should be undertaken only if they are profitable. Reproduction is a critical element in cow profitability, so some interventions will be profitable, but there is a level of reproductive performance at which the returns from further improvement are insufficient to cover the associated costs. Perhaps the recommendation's concentration on reproductive management is misguided; maybe the problem is not the reproductive management but the decision to cull these animals. As described in the "Culling Guidelines" section, it appears that the decision to stop breeding animals and cull them (likely as reproductive culls) routinely occurs earlier than is economically optimal and leads to decreased

herd profit. Then the high reproductive culling rate (and the effect of reproduction on the risk of being culled) might simply be a reflection of the culling criteria for the industry. The reproductive culling rate could be reduced simply by continuing to breed these animals longer, as suggested by the culling guides. This would reduce the reproductive culling without any intervention in reproductive management.

Reasons and risks for culling, and therefore the literature analyzing this industry data, are highly predicated on culling decision making. That is, the literature on culling reasons or risks of culling reflect what is observed (i.e., the factors that farmers consider when they make their culling decisions). This literature does not necessarily indicate the optimum way of culling cows (Rajala-Schultz and Gröhn, 1999a). However, the optimum culling rate literature suggests this decision making could be improved. It is unclear whether the relationships and conclusions in the current literature would still be applicable if the decision-making criteria changed.

The suggestion that culling decisions could be improved does not imply that producers are not correctly identifying which cows to cull. Rather it may be a reflection of the higher than optimum culling rate. As explained earlier, in the assessment of which cows to cull, ideally only those cows that are less profitable than a replacement heifer would be culled. This method leads to the correct culling decisions for each cow and, as a result, produces the optimum culling rate. But the comparison of each replacement with each cow is difficult and would be cumbersome in making the tactical day-to-day decisions of which cows to cull. Instead, in the absence of guidelines to aid their culling decisions, producers have likely first decided on a culling rate. (High culling rates may reflect the producer's subconscious decision to calve all heifers or the producer's decision being made in the mistaken belief that the increased genetic progress and milk production leads to greater herd profit). Thus, faced with the desired culling rate, the producer knows how many cows need to be culled and then decides which cows to cull. Good managers likely have an intuitive ability to correctly rank the cows in terms of their profitability. Then starting with the least-profitable cows, they continue to cull cows until the number of culls dictated by the culling rate is reached. This suggests the decisions about which cows to cull are correct given the culling rate. In other words, prematurely stopping breeding and culling cows for reproductive reasons may be the result of an excessive culling rate, not problems with identifying which cows to cull. In order for the culling rate to be higher than optimum, some wrong culling decisions must have been made. This suggests that if an optimum culling rate were the target, the mistake of prematurely culling these animals may not be made.

The criteria dairy producers use to make decisions about culling cows are related to the farmers' motivations and goals and to their production system and social status (Beaudeau et al, 1996). Culling criteria differ between farmers, and they are sociologically structured. Culling practices are parts of farming styles. Culling decisions are completely embedded in the whole farming process. Different groups of

Downloaded from Vet-e-Books.com

farmers demonstrate different ways of thinking and deciding regarding culling. In comparing risk factors for culling in dairy herds, the risk of culling for clinically identifiable conditions such as reproductive failure and udder abnormalities can differ significantly between farms (Stevenson and Lean, 1998b).

Although significant advances in dairy herd management have been made in recent years through the development of computerized record systems for animal health and production, little progress has occurred at the farm level in making better culling decisions (Lehenbauer and Oltjen, 1998). Record systems have improved the quality and quantity of data that are available for review in making culling choices, but minimal change has occurred in the way these data are analyzed to determine which cows are to be culled from the herd. Many producers start with a list of cows producing less than some specified daily amount of milk based on the most recent test day information (Lehenbauer and Oltjen, 1998). This minimum level may or may not be related to a calculated minimum value for "break-even" daily milk production of the herd. Usually the stage of lactation, reproductive status, and age of the cow are examined next. Low-producing cows that are pregnant and approaching a stage of pregnancy that would provide a reasonably normal length of the dry period are often retained in the herd. Further consideration is typically given to some measure of genetic worth or contribution to herd value, such as pedigree information, percentage of herd mature equivalent production, or ranking of the particular cow in a listing of estimated relative producing ability. In addition, individual cow attributes are often considered, such as the chronic disease or conformational defects. Finally, the decision maker often gives careful thought to current dairy herd dynamics over both the short term and the long term. Consideration would typically include significant variations that would occur during the next several months in the number of dry cows and pregnant heifers expected to calve as well as any long-term goals for herd expansion or contraction. To some extent these herd-level factors often determine the actual number of cows to be culled at any given time. Most importantly, nearly all the analysis occurs by a rather ad hoc and informal process that usually incorporates heuristic methods (trial-and-error discovery) by the decision maker for reaching conclusions about which cows to cull. This process has also been described as nonprogrammed, depicting variable and unpredictable results being obtained at different times under similar conditions.

Factors Affecting Culling

Survival Analysis: The Effect of Diseases on the Risk of Culling

Most epidemiological studies of the relationship between diseases and culling have used standardized regression techniques such as logistic regression and discriminant analysis. These techniques provide a measure of culling risk. That is, they assess the degree to which various factors (e.g., disease) affect whether or not an animal was culled in a certain period. These studies tended to ignore when, in the lactation, disease and culling occurred (Beaudeau et al, 1995). Survival analysis is a more sophisticated statistical technique that assesses the effect of these risk factors on longevity. The *length of productive life,* defined as the number of days between the date of first calving and date of culling or death, is the commonly used measure of dairy cattle longevity. A common problem in analyzing longevity measures is the presence of incomplete (also known as censored) records because some cows have not been culled by the end of the study period. That is, a cow's longevity is not known until she has been culled from the herd. For those cows still in the herd at the end of the study, a censored measure of their longevity is the number of days between the date of first calving and the end of the study. This is termed *censored longevity data* because it only indicates the minimum true longevity. The cows with censored longevities could have been culled days, weeks, months, or years after the end of the study, but in any case their true longevities were greater than their censored longevities. To exclude these censored records from the analysis or to treat them as exact would bias the results. Survival analysis can correctly incorporate all the longevity data, including the censored data, into the analysis. The great advantage of survival analysis (with time-dependent covariates) in researching culling risks is its ability to incorporate the chronology of events into the analysis (Gröhn et al, 1998). For example, the stage of lactation when a disease occurs is included. Then the effect of the disease on the subsequent risk of being culled at various future stages of the lactation can be explored.

Using survival analysis with time-dependent covariates, researchers examined the effects of seven diseases on culling in 14 Holstein cow herds in New York state calving over a 1-year period and followed for an additional 9 months (Gröhn et al, 1998). The modifying influence of milk yield and conception status on the relationship between disease and culling was examined. The interactions between these factors and stage of lactation were taken into account. The seven diseases considered (and their incidence) were milk fever (0.9%), retained placenta (9.5%), displaced abomasum (5.3%), ketosis (5.0%), metritis (4.2%), ovarian cysts (10.6%), and mastitis (14.5%). Older cows were at a much higher risk of being culled. Calving season had no effect on culling. Higher milk yield was protective for culling. Once a cow had conceived again, her risk of culling dropped sharply. Cows that did not conceive had a significantly higher risk of culling than those that did. Mastitis was an important risk factor throughout lactation, but metritis was not. Milk fever, retained placenta, displaced abomasum, and ketosis raised the risk of culling at certain stages of lactation. Failure to consider the milk yield and conception status of the cows would have led to overestimation of the importance of these diseases on culling risk. The results indicate that dairy farmers consider many factors, including diseases, milk yield, conception status, parity, and stage of lactation, when deciding whether and when to cull a cow.

The total effect of 15 diseases on time of culling were studied in 39,727 Finnish Ayrshire cows that calved over a 1-year period and were followed until the next calving or culling (Rajala-Schultz and Gröhn, 1999a). The diseases studied were: dystocia, milk fever, retained placenta, displacement of the abomasum, metritis, nonparturient paresis, ketosis, rumen disorders, acute mastitis, hypomagnesemia, lameness, traumatic reticuloperitonitis, anestrus, ovarian cysts, and teat injuries. Parity had a significant effect on culling, the risk of culling being four times higher for a cow in her sixth or higher parity than for a first-parity cow. The effects of diseases varied according to when the diseases occurred and when culling occurred. Mastitis, teat injuries, and lameness had a significant effect on culling throughout the whole lactation. Anestrus and ovarian cysts had protective effects against culling at the time they were diagnosed. In general, diseases affected culling decisions mostly at the time of their occurrence. The exceptions were mastitis, teat injuries, and lameness, whose effects extended throughout the entire lactation, and milk fever, dystocia, and metritis, which also had an effect on culling decisions at the end of lactation. The results indicate that diseases have a significant influence in culling of dairy cows, and the effects of those diseases vary depending on both the time of

Downloaded From Vet-e-Books.com

disease occurrence and the stage of lactation when culling occurred.

The reproductive status of the cow was also important in the culling decisions of the Finnish cows. The knowledge about a cow's pregnancy status had a different effect on culling depending on the stage of lactation; the earlier the farmer knew that a cow was pregnant, the lower was the risk of culling (Rajala-Schultz and Gröhn, 1999b). When the number of inseminations was accounted for, the effect of pregnancy status decreased, distinguishing between cows that failed to conceive and cows that were never even inseminated. If a cow had been inseminated more than once, there was a protective effect against culling, which indicated that the farmer was willing to invest the time and effort to get certain cows pregnant in order to keep them. Pregnant cows are less likely to be culled, and high producers have a lower risk of being culled than low producers (Rajala-Schultz and Gröhn, 1999c).

A study on the effect of disease on length of productive life of Holstein cows in 47 herds in France assessed by survival analysis found the probability of a cow being culled increased in early and late lactation in older cows, in low-producing cows, and in cows with poor reproductive performance (Beaudeau et al, 1995). Udder disorders and reproductive disorders, mainly through poor reproductive performance, appeared to be the major health events influencing length of productive life. Mastitis before the peak of lactation or during the dry period increased the risk (relative culling rate in first lactation of 1.3 and 4.0, respectively). Teat injuries and nontraumatic udder diseases had a major influence on longevity. Cows with late metritis or early abortion had poor survival. Generally, the influence of health disorders was lower than the contribution of reproductive performances and score for milk production for changing the length of productive life of cows. Economic considerations are thus key criteria in culling decisions by the producer, whose objective is mainly to minimize losses from longer calving interval and lower milk production.

Age

Dairy cows have differing risks of being culled, depending on their age. Reports from Ontario (Dohoo and Martin, 1984b) and Ohio (Allaire et al, 1977) found the same age-related risks for culling, with some differences at earlier parities. In Ontario, cows were at highest risk of being culled between 3 and 4 years and after 7 years of age. A significant peak in the risk of culling occurred 300 to 400 days after first calving. In other words, the end of first lactation represented a significant culling decision point. In Australian dairy herds the risk of culling increased with increased parity (Stevenson and Lean, 1998a). This was accounted for specifically by increased risk of culling for calving disorders, reproductive tract lesions, and disorders of the udder. Risk of culling for failure to conceive remained constant throughout productive life. In Ohio the risk of a cow being culled increased more steadily with age than in Ontario. However, the risk in cows more than 7 years of age was equivalent in both regions. The annual culling rates according to age, for both studies, are shown in Table 8-7.

The reasons for culling change according to age. The most important reason for culling of first-calf heifers is reproductive failure. In a 5-year survey of culling in Holstein dairy herds in France, cows culled for infertility were younger and culled later in lactation (Seegers et al, 1998b). The relative importance of reproductive performance in culling decisions decreases as cows grow older. However, there is no absolute decrease in culling because of reproductive failure. The relative reduction in the importance of reproductive performance results from an increase of overall culling rate in older cows and an increase in the other reasons for culling (Allaire et al, 1977). The rate of culling for mastitis, other disease, and injury increases with age (Seegers et al, 1998b). Culling for low production is highest after the second lactation. This supports the observation that producers are reluctant to cull first-calf heifers for poor production, preferring instead to "give them a second chance" to produce better in second lactation.

Level of Production

Not surprisingly, low-producing cows are more likely than high-producing cows to be culled. Dairy cows have an additional 2.3 months of total herd life and 0.15 additional lactations in the herd for each 1000 lb (450 kg) of first-lactation milk production above the herd average (White and Nichols, 1965). The risk of culling increases significantly for

cows with negative deviations from herd average fat-corrected milk production. For example, 29% of cows that achieve less than 90% of herd average production are removed from the herd, whereas only 17.4% of cows that produce in excess of 110% of herd average production are culled (White and Nichols, 1965). These data suggest that poor producers are almost twice as likely to be culled as good producers.

The reasons for culling and variation in culling rate for 4923 dairy herds served by the regional DHIA Center at Raleigh, North Carolina have been reported (Fetrow, 1988). The overall pattern of culling is similar, regardless of the average milk production level in the herd. However, some differences exist between high- and low-producing herds in the reported reasons for culling cows. High-producing herds sell a larger percentage of animals for dairy replacement purposes than low-producing herds, whereas low-producing herds report more cows culled for poor production. This difference likely reflects the high-producing herds' ability to sell their culls as replacements for lower-producing herds. High-producing herds report more cows culled for mastitis and low-producing herds have a higher death rate (Fetrow, 1988). As with any observational study, it must be emphasized that these observations are associations and do not imply a cause-effect relationship.

Disease

Disease as a risk factor for culling was considered in the survival analysis section earlier. Disease is commonly reported as a reason for the removal of a cow. However, reporting disease as a final cause for culling may be biased because often producers only consider the final disease event before culling. A disease may have a more fundamental role as a predisposing factor of the listed reason for culling. For example, chronic lameness may be the primary reason for a cow's poor reproductive performance, but the cow is likely to be reported as a reproductive cull. The literature on the associations between health disorders and culling of dairy cows has been reviewed. Certain diseases increase the risk of culling regardless of the production system being used (Beaudeau et al, 1993).

It is important to consider the effect of the presence or absence of a disease in the cow's lactational history as a risk of her being culled. A prospective epidemiological investigation in Canada evaluated the association of common disease events with culling and stage of lactation (Dohoo and Martin, 1984a). Several common diseases of dairy cows increase the likelihood of culling during the first 150 days of lactation. In this study the effects of age and farm of origin were controlled in the analysis. The relative risk of being culled was calculated for each disease condition.

The relative risk assigns a value to the increased likelihood that a cow that has experienced a particular disease is to be culled when compared with a cow that has had no disease. A more detailed explanation of relative risk and examples of this calculation are presented in Chapter 2. The relative risk for culling with some disease events is high (Table 8-8). Mastitis requiring systemic therapy increased the likelihood that a cow would be culled in the first 150 days of lactation by approximately ninetyfold. Cows that were recumbent with milk fever, even with successful response to therapy, had a twenty-nine-fold increased risk of being culled. Cows with teat injuries, foot or leg problems, and respiratory disease also had an increased risk of being culled. An elevated somatic cell count (SCC) was the only condition associated with an increased risk of culling after 150 days of lactation (Dohoo and Martin, 1984b). The association of a high SCC with late-

TABLE 8-8

Relative Risk of Being Culled After Common Predisposing Disease Factors

Disease Factors	Relative Risk*
Mastitis requiring systemic therapy	90
Mastitis requiring only local therapy	4
Milk fever with cow down	29
Disease of feet or legs	31
Teat injury	35
Respiratory disease	9

From Dohoo IR, Martin SW: *Prev Vet Med* 2:771-784, 1984.
*Relative risk is the increased odds that a cow with the disease condition will be culled in the first 150 days of lactation compared to a cow with no disease.

lactation culling was significant, even with the effects of age and level of milk production excluded. The culling of cows with mastitis is likely to reduce the risk of further infection in the herd. However, the costs of such action, in terms of reduced milk production and increased replacement costs, are generally thought to outweigh the benefits but not in all circumstances (Stott and Kennedy, 1993). Under conditions in the United Kingdom it is economically viable to cull certain cows because of mastitis for a variety of reasons. On the other hand, because milk yield does not decline with age in the later lactations, culling such cows may not be economical.

Examination of the relationship between diseases during two consecutive lactations and culling indicates the udder health and reproductive disease from both previous and current lactations can be primary health-related criterion involved in culling decisions (Beaudeau et al, 1994a). However, in general, culling appears to be related primarily to short-term effects than to consideration of the entire disease history of the cow.

The relationships between diseases of dairy cows and culling also depends on whether the cows were culled during early or late lactation has been investigated for Holstein cows in French herds (Beaudeau et al, 1994b). Nontraumatic udder disorders, teat injuries, milk fever, and the occurrence of both ketosis and assistance at calving were significantly associated with an increased risk of being culled early (odds ratio ranging from 1.6 to 10.3). Early and late abortion, late metritis, poor reproductive performance, retained placenta, nontraumatic udder disease within 45 days postpartum, and mastitis occurring in the first 3 months of the lactation were positively associated with a late culling (odds ratio ranging from 1.2 to 6.6). Cows with lower breeding value for milk and higher parities were high risk groups for culling. A lower level of milk production and occurrence of both reproductive disease and poor reproductive performance were risk factors for late culling.

The effects of parity, stage of lactation, and culling reason on the commercial carcass weight of French Holstein cows have been examined (Seegers et al, 1998a). In primiparous cows the effect of age at first calving led to differences for carcass weight. Locomotor disorders, accidents, and health disorders other than reproductive and udder disorders were associated with lower carcass weights. Infertility as a culling

Downloaded From Vet-e-Books.com

reason was associated with highest carcass weights, and large variations between farms were noted.

Body Conformation

No reported studies have prospectively evaluated the effect of body conformation or type classification scores on the risk of culling. Conformation is occasionally listed, though, as a reason for removal of cows from the herd (Westell et al, 1982). However, the appraisal of dairy type does not appear to be significantly associated with an increased risk of culling (Van Vleck and Norman, 1972). Conformation traits evaluated before 4 years of age were not effective in predicting the time or reason for a cow being culled.

Categories of Culling Reasons

Frequently the reasons for cow culling are assigned into categories. The apparent purpose of this categorization is to aid culling decision making and to target management interventions. The assignment of dairy cow culling into the categories of *voluntary* and *involuntary* is firmly entrenched in the literature. The appropriateness and usefulness of these categories have been questioned (Dohoo and Dijkhuizen, 1993; Radke and Lloyd, 2000). In contrast, there is strong support for emphasizing the economic nature of the culling decisions (Dijkhuizen et al, 1986; Marsh et al, 1987; Dijkhuizen and Stelwagen, 1988; Jones et al, 1995; Radke and Lloyd, 2000). An alternative system of categorizing culling reasons, *economic* and *biological* culls, are reviewed next, followed by a review of the traditional voluntary and involuntary system of categorization.

Economic and Biological Cull Categories

Essentially, all living animals culled from dairy herds are removed for economic reasons, but the disposal of diseased cows is typically considered to be forced replacement. However, in most of these cases the decision to remove an individual animal is based on economics (Dijkhuizen et al, 1986). The cow is not culled because she is no longer able to produce but because a replacement cow is expected to yield higher and more efficiently and therefore to be more profitable. Even though this culling decision involves an economic analysis that is performed subjectively, it is still an economically based decision.

Economic Culls. Many examples of economic culling can be described that would have previously been categorized as involuntary removals. A repeat breeder cow is culled as a reproductive failure on the assumption that continued attempts to achieve pregnancy will lead to an extended time in late lactation or in the dry period. Even though many of these cows may eventually conceive, the extended calving interval lowers their profitability sufficiently that a point is reached at which it is more profitable to replace them. A cow with a persistently high SCC because of subclinical mastitis can be a productive member of the herd and may even be successfully cured by dry cow therapy. However, this cow may be culled to avoid the direct cost from her mastitis and to remove her as a source of infection for the rest of the herd. Similarly, a thin cow with chronic lameness resulting from diseases of the feet may respond to repeated foot trimming and supplementary nutrition to improve body condition. However, this cow is judged to be an economic drain on the herd and is commonly culled. Even yearling or first-calf heifers sold as dairy replacements are usually sold with the expectation that their sale can net more profit than if they were retained as productive animals in the herd. Low producers are culled to make space for more profitable animals. Each of these examples represents an economic culling decision.

Biological Culls. These are defined as cows that are incapable of any reasonable level of production, so the producer has no sensible choice but to cull the animal. Examples of cows in this category include those with leg fractures or ruptured cruciate ligaments, lymphosarcoma, or a federally reportable disease such as brucellosis, as well as those that have died. In general these events are rare in dairy herds. This does not imply that none of these conditions can be treated medically or surgically. However, these are situations in which an individual animal is destined for removal from the herd unless there is major medical intervention. In these cases, decision analysis can be used to evaluate the economics of the therapy (Dohoo and Dijkhuizen, 1993). Since the decision to cull or treat the cow depends on economics, it is somewhat difficult to distinguish biological culls from economic culls.

Perhaps an appropriate category modification would be to change the biological category to a welfare category. An economic versus a welfare categorization in the dairy industry highlights society's concern over animal welfare. Such a categorization explicitly recognizes that an otherwise profitable cow is culled because it is in the best interest of the animal's welfare. However, it is difficult to think of a situation in which the animal would not have some underlying pathological condition (e.g., lameness) causing the decreased welfare. Thus, aside from increased awareness in the industry of welfare issues, it is unclear whether much would be gained over simply recognizing the culling as being due to the underlying condition (e.g., lameness).

Another situation that occasionally occurs in dairy herds is culling for emotional reasons. In such situations the producer may severely dislike the disposition of an individual cow or a recently-calved heifer may have an excitable temperament (Fetrow, 1988). However, these situations are rare and can be considered as biological reasons.

Voluntary and Involuntary Cull Categories

The voluntary and involuntary culling paradigm is a large source of confusion in the culling literature. It involves grouping commonly reported culling reasons into voluntary or involuntary categories. Table 8-6 presents some commonly cited reasons for culling according to voluntary or involuntary categories. The term "voluntary cull" has been used to define those animals that leave a dairy farm either because of low production in the absence of a known disease problem, or because the herd has an excess of animals and elects to sell individuals as replacements for other dairy herds. Involuntary culls have been loosely defined as those cows that leave the herd against the wishes of the producer. Within this definition, it is presumed that if the major problem, cause, or event had been avoided, then the cow would have had sufficient productive merit to have remained in the herd. Voluntary culling is generally regarded as desirable and involuntary as undesirable. The generally held perception is that voluntary culls are made for profitability reasons, whereas involuntary culls are financial detriments to the herd. There are a number of concerns with the voluntary versus involuntary categorization.

Miscategorization of Cows. The classification problems discussed previously in assessing the reasons cows are culled are compounded when those reasons are assigned to a voluntary or involuntary category. For example, as mentioned in the culling reasons section, cows with low production resulting from subclinical mastitis may be classified as low-production culls or mastitis culls. Cows classified as the former would be included in the voluntary culling category,

Downloaded from Vet-eBooks.com

whereas those assigned to the mastitis reason would be considered involuntary culls. Similarly, the other examples discussed in the culling reasons section (i.e., the low producer that has not conceived after one or two inseminations, and the significantly lame cow) could be included in the voluntary or involuntary category depending on which culling reason the cow was assigned.

Effect on Culling and Replacement Strategies. The categorization of animals as involuntary culls may hamper critical consideration of the culling and replacement strategies (Radke and Lloyd, 2000). Sometimes categorization as involuntary culls is incorrectly interpreted as the producer having no choice in the decision and therefore unable to change the decision (e.g., from Durr et al [1997b]), "Involuntary culling occurs when a cow has to be culled irrespective of her performance relative to that of her herdmates. . ."). Producers have a choice in all their culling decisions except for those animals that die or are strictly incapable of ever conceiving. For example, to prevent the culling of the cows whose breeding was prematurely ceased, a producer need only change his decision and not cull the cow. If producers and their advisors continue to believe they have no choice in many of their culling decisions, their opportunity to change these decisions and therefore their culling rates is severely limited.

Relationship with Profitability. The intent of the voluntary and involuntary categorization appears to be to increase profit. Unfortunately, this intent is somewhat misguided because it is not clear that the involuntary culls are necessarily detrimental to herd profit or that the voluntary culls increase herd profit. For example, the cows whose breeding was prematurely ceased and subsequently culled were still sufficiently profitable to have remained in the herd longer. These culled cows may have been included in the involuntary category of reproductive culls or in the voluntary category because of low production; in either case, these cows were profitable when culled, and changing the culling decision represents an opportunity to increase herd profit. Therefore, despite being classified as involuntary culls, these cows were still sufficiently profitable (relative to a replacement) such that they should have remained in the herd. Cows categorized as involuntary culls are not necessarily detrimental to herd profitability. If these cows were included as voluntary culls because of low production, then changing the decision on these cows represents a profit opportunity. Thus voluntary culls do not necessarily increase herd profit. Some simulation studies on the profitability of culling rates indicate that excessive voluntary culling can reduce producer profit (Allaire, 1981; Allaire and Cunningham, 1980). In addition, the poor milk production of the voluntary culls without clinical disease may also present a profit opportunity. For example, the poor production may have resulted from poor sire selection or inadequate heifer management. Simply put, the absence of clinical disease in a low-production cow does not preclude the possibility that the cow had the potential to be more profitable. In contrast, the economic perspective is to maximize the profit of all cows and to cull the least profitable. In economic terms, clinical disease is only a single, albeit important, management factor that can affect animals' profitability. In calling for improved herd husbandry to reduce culling rates because of involuntary reasons, the profitability of such interventions must be considered and not simply assumed.

Involuntary Culling and the Optimum Culling Literature. Ironically, much of the confusion over voluntary and involuntary culls appears to have originated from the culling rate simulation and optimization models. In the models a distinction was made between the culling for low production and failure to conceive and the culling for all other reasons. The culling decision based on low production and failure to conceive was typically made by the models based on comparing the profitability of the cow with that of her potential replacement. These were termed *voluntary culls*. The lost milk production and financial cost of cows culled for all other reasons were also included in the models. However, the model did not decide whether to cull these animals; the proportion of cows culled for all other reasons was assumed to be known and was an input to the model. These culling decisions not made by the model were termed *involuntary culls*. Involuntary culling included culling for mastitis, other health disorders, milking speed, temperament, pendulous udders, other husbandry related problems, and death. Involuntary culls included 2% infertile cows, which were cows that were inseminated but failed to conceive by the eighth month of lactation (Rogers et al, 1988a).

The percentage of involuntary culling was varied, and the level of involuntary culling was found to have a large impact on herd profit and on the optimum herd culling rate (Rogers et al, 1988b). (A decrease in the level of involuntary culling was somewhat compensated by an increase in the level of voluntary culling. For example, if 16.5% of the herd were involuntary culls, and the profit maximizing voluntary culling rate was 8.6%, then the total culling rate was 25.1%. However, if the involuntary rate was 13.6%, the most profitable voluntary rate was 9.8% for a total of 23.4%.) The focus on increased herd profit from reduced involuntary culls has been inaccurately extrapolated to the dairy industry on two accounts. First, the definitions of involuntary culls vary between the models and the industry. Failure to conceive—one of the most commonly considered reasons for involuntary culling in the dairy industry—is considered a voluntary cull in the optimization models. Second, the models' results have been misinterpreted. The models' focus on involuntary culling precludes considering improved reproductive performance as a method to improve profitability. This was undoubtfully the intent of the studies. More likely, the models were meant to highlight the large negative financial impact of the increased culling that is associated with decreased cow profitability, regardless of cause.

Retrospectively, the differing approaches toward reproductive culls also raise issues about the method of inclusion of involuntary culling in the models. The objective of the models was to determine the culling decisions that maximized producer profit. Presumably, the approach of not having the model decide whether to cull the involuntary culls, with their decreased profitability, resulted from the belief that these cows were so unprofitable relative to a heifer that the model would simply cull them all. Therefore, if the results of the decision were already known, there was little need to have the model reproduce this decision. However, it is noteworthy that conventional wisdom has included reproductive culls as involuntary culls (Table 8-6). This would imply that failure to conceive sufficiently impairs a cow's profitability to such a degree that there is little question about whether she should be culled. The culling models did not take this approach and, as described earlier in the culling guides, found that it is profitable to continue to breed cows longer than it commonly considered profitable. Thus it appears conventional wisdom on the unprofitability of involuntary reproductive culls is inaccurate. A natural extension of this is to wonder whether the assumptions about the relative unprofitability of other involuntary culling reasons are also misguided, and whether it would have been preferable for the culling models to have assessed the profitability of all culling decisions, especially those that are commonly considered involuntary. One of the optimization models was expanded to include the deci-

Downloaded From Vet-eBooks.com

sion of whether to cull cows with mastitis under Dutch conditions (Houben et al, 1994). Although the mastitis lowered the cows' profitability, in most cases the optimum decision was to treat rather than replace the cow. With a mastitis incidence of 9.7 clinical cases per 10,000 cow days, the model found 12.7% of the animals culled had mastitis. This is reasonably comparable with 8% of Dutch cows being culled for mastitis, given the inaccuracy of assigning culling reasons.

In summary, to increase herd profit, producers should concentrate on increasing the profitability of their cows. In terms of culling, the best culling decisions have been made if the least profitable cows are culled, regardless of the reasons. It is not clear how the classification of culls into a voluntary versus involuntary category aids the process of assessing their profitability. It is possible that, because of confusion and inconsistent definitions, the categorization has hindered the industry's efforts to make the best culling decisions.

Relationship with Genetic Progress. Involuntary culls are generally assumed to be detrimental to the herd's genetic progress. Simulation studies found that different cow culling systems have little effect on a herd's rate of genetic improvement, with sire selection playing a much more important role (Allaire, 1981; Pearson and Freeman, 1973; Korver and Renkema, 1979). This is consistent with the discussion in the genetics section of this chapter where it is reported that less than 10% of genetic improvement is due to cow culling and selection of herd replacements.

Reasons for Voluntary and Involuntary Culling. Even with the difficulties, it is useful to review the reported reasons for culling dairy cows. The results of several articles have been compiled in Table 8-6 (Fetrow, 1988). These results represent studies from several different regions in North America performed from 1962 to 1986. It is noteworthy that none of the reports used exactly the same culling reasons or categorized the reasons the same way. Construction of this table necessitated merging some of the categories into the "Disease" or "Miscellaneous" group. The results shown are proportions of culled animals attributed to each culling reason. They do not represent the percentage of the herd culled per year.

The average of the studies just mentioned suggests that approximately 40% of the animals culled from dairy herds leave for voluntary reasons and 60% are involuntarily removed. In other words, if 30% of a herd is culled during an average year, then approximately 12% is removed voluntarily and 18% involuntarily. However, there is considerable variation around these averages. Several studies of culling in dairy cattle have shown voluntary culling rates ranging from 49% (Westell et al, 1982) to 26.5% in a large Ohio study (Allaire et al, 1977). These differences may reflect large variations in the potential for export and local sales between these two geographic regions.

A survey of 340 dairy herds in England over a 1-year period found an average culling rate of 28.4%, with 7.2% resulting from infertility, 4.6% from mastitis, 2.2% from lameness, 2.6% from poor milk yield, 4.7% from age, and 7.1% from miscellaneous causes, including death (Whitaker et al, 2000). Infertility, mastitis, and lameness were responsible for half of the culling, with infertility being the most important factor. The average size of the herds was 133 cows, ranging from 33 to 432, with an average milk yield per cow per year of 6620 kg, ranging from 4000 to 9200 kg. The average annual rate of assisted calvings was 8.7%, injury 0.9%, digestive tract disease 1.3%, ketosis 0.4%, hypomagnesemia 0.7%, hypocalcemia 5.3%, mastitis 36.6%, and lameness 23.7%.

In a survey of 50 Holstein-Friesian dairy herds with an average of 178 cows over a 3-year period, the average total culling rate was 31.2%. Of the disposals, 54% were culled by the end of their fourth lactation. Infertility was the most common reason for culling (36.5%), followed by management policy (11.5%), mastitis (10.1%), BSE (7.4%), and lameness (5.6%). The most common causes of death were mastitis (8.9%) and BSE (11.5%), but 46% died for unknown reasons (Esslemont and Kossaibati, 1997). The culling rate ranged from 13.4% to 49.0%, which indicates a substantial difference between achieved and potential herd performance. Voluntary culling accounted for 11.3% of the disposals, and involuntary culling accounted for 88.7%.

Almost 60% of all cows in the average Quebec herd were either in first or second lactation, which means a very young population of cows. Over the period of time there was a decrease in culling for low production, from 16% in 1981 to 4.5% in 1994, and an increase in some of the major involuntary culling reasons, from 23% in 1981 to 32% in 1994, because of reproductive failure, mastitis, and lameness (Durr et al, 1997b). Another important result was that differences in overall culling between official and owner sampler herds were mostly due to sales and not due to voluntary and involuntary culling reasons. Dairy producers have been culling more intensively for low production in first (rather than later) parities, but a decrease in voluntary culling was observed in all parities. Culling rate increased with parity number for all major involuntary reasons, as opposed to sales, in which proportion of cows culled decreased with parity number.

The major reason for involuntary culling in dairy herds is reproductive failure. On average, 23% of all culls were removed for infertility (Table 8-6). Mastitis and udder health problems represent the next largest culling reason, resulting in 15% of all culls. Mastitis and reproduction accounted for more than half of all involuntary culling. Other categories with a significant percentage of the total culls are disease and injury (10.4%), death (3.3%), foot and leg problems (1.8%), and temperament (0.2%). A further 7.3% were attributed to miscellaneous reasons. Within each category, there is considerable variation among the studies reported. This variation is especially prominent for the reported death rates. Some reports do not include a death rate, and those that do vary from 0.6% to 11.8%. The more recent studies reported substantially higher rates of death as a cause of exit from the herd. For example, in a study of 32 commercial herds in Ontario, 7.9% of all culls were a result of death (Dohoo and Martin, 1984b). The 1986 DHIA records from the southeastern region of the United States reported an 11.8% death rate in cows removed from dairy herds. It is suspected that death rates in the earlier studies were underreported.

In a survey of why farmers cull dairy cows, reproductive failure was the primary reason, milk yield was second, and mastitis was third (Bascom and Young, 1998). Culling was lower for mastitis and milk yield, but higher for abortion and reproduction, in high-yielding Holstein herds than in low-yielding Holstein herds. Culling for mastitis and milk yield was lower in high-yielding Holstein herds than in non-Holstein herds. In a selection of Australian dairy herds, high milk yield in the first lactation was a risk factor for culling resulting from udder disorders. This suggests that managers of high-producing herds should pay particular attention to mastitis control and should select for sound udder conformation to reduce the effect of this type of involuntary loss (Stevenson and Lean, 1998b). Shorter calving intervals were also associated with an increased risk of culling for udder

Downloaded from Vet-eBooks.com

disorders and low milk production. This association may have been influenced by late abortions, creating a shortened calving interval and a greater tendency for farmers to cull these cows (Stevenson and Lean, 1998b).

In a historical cohort study on Dutch dairy farms, the risk of culling was higher for cows that had a caesarean section than for control cows (Barkema et al, 1992). Infection of cows with *Neospora caninum* is a significant cause of premature culling in dairy herds (Thurmond and Hietala, 1996).

METHODS OF REPLACEMENT HEIFER SELECTION

Following an insemination guide or targeting a given culling rate will determine the number of replacement heifers required. However, this determination may be somewhat difficult when the insemination guide is used, since it is not obvious exactly how many cows will be culled. Dairy herds with good reproductive performance and efficient heifer-raising programs can have enough young stock to replace over 40% of the cow herd annually. There is evidence that the majority of U.S. dairy producers raise and calve a large majority of their heifers (Heinrichs et al, 1994; Radke et al, 2000). This high replacement rate is consistent with the dairy industry's high culling rates previously noted and indicates the need for a method of heifer selection.

Surprisingly, there is little literature on methods of heifer selection. Lifetime profit corrected for the opportunity cost of postponed replacement is the correct method of ranking animals for profitability (Van Arendonk, 1991). This measure of an animal's lifetime profit explicitly recognizes that, in retaining the animal in the herd, the average potential replacement's profit is foregone. First-lactation milk production is moderately correlated with this measure of lifetime profit (Weigel et al, 1995) and therefore is a suitable objective for heifer selection. Surprisingly, there is little literature on methods of predicting heifers' subsequent first-lactation milk production. Genetic estimates of heifers' production abilities explain less than 7% of the within-herd variation in first lactation, mature equivalent milk production (Radke, 1998). On a small group of heifers, the heifers' genetic estimates for milk production explained only 3% of the variation in first-lactation milk production. The addition of the heifers' serum β-lactoglobulin levels explained 21% of the variation in first-lactation milk production (Mao and Bremel, 1995). However, analysis of this serum protein is not widely available, its production is limited to late gestation, and its biological relationship with milk production is unclear. Although genetics do not explain a lot of the within herd variation in first-lactation milk production, they are somewhat able to correctly rank animals, within herd, on subsequent production. Because the ability to rank animals on milk production is more important than the ability to predict actual milk production when selecting heifers to meet a target culling rate, genetics are useful in heifer selection. (Notice that comparing the profitability of all cows and heifers would require predicting the actual profit, and associated milk production, of each animal.)

Computer optimization and simulation programs have been used to generate heifer selection rules that maximize producer profit. Three scenarios were used that varied the percentage of heifers kept and looked at whether the raising of heifers resulted in a profit or loss (Radke et al, 1999; Radke, 1998). The study considered the period between the heifers' births and first calvings. Genetic estimates of the heifers' producing abilities were updated throughout this period. A complicated heifer selection rule that used each heifer's parents' predicted transmitting ability for milk, fat, and protein and their associated reliabilities was only slightly more profitable than heifer selection based on estimated breeding value of milk. However, use of the more complicated rule was not warranted, since the minimal increase in profit was not sufficient to compensate for the added complexity of gathering the necessary data and employing the more complicated rule.

With the information just described, heifer selection is a relatively simple matter. Based on the desired culling rate among the cows, the number of excess heifers is known. Heifers expected to calve within a given period should be separated into cohorts for selection purposes. An enterprise budget is used to determine the age at which it is most profitable, or least costly, to sell the excess heifers. Based on the genetic estimate of milk production ability for that period, the heifers that serve as cohorts for selection purposes are then ranked, with the lowest-ranking requisite number of heifers being sold.

The heifer enterprise budget should be divided preferably into periods that coincide with the release of new updated genetic estimates. Care must be taken in creation of the enterprise budget to only consider costs that would change in response to raising fewer heifers. For example, consider a farm that currently has heifer facilities. If, in response to raising fewer heifers, the profitability of the remaining heifers will not increase (because of less overcrowding, for instance), or if no other animals will take the place of the sold heifers, the facility cost cannot be assigned to any other animals and will be incurred regardless of whether the heifers are sold or not. As a result, in this case, the cost of the facilities should not be included in the cost to raise a heifer.

Basing heifer selection on genetics increased U.S. producer profit by over $20/heifer versus random heifer selection, which represents a 3% to 5% increase in farm profit. This $20 increase in profit accrues over the heifer's lifetime. The study also revealed that heifer selection based on genetic estimates captured only about 25% of the profit available if the animals could be ranked correctly on their subsequent milk production and profitability. This highlights the need for future research on methods of heifer selection. Evidence exists that U.S. producers are not using genetics in their heifer selection decisions (Radke et al, 2000).

RISK AND RETURN OF OPTIMUM CULLING AND REPLACEMENT STRATEGIES

Simulation models revealed that using an optimum culling rate increased herd profit from 2% to 40% (Radke and Lloyd, 2000). The large range in increased profit was due to an arbitrary culling method being compared with an optimum culling strategy for a given level of herd management. Thus the increase in profit is a function of how "good" the arbitrary method of culling was. Returns in the lower end of this range (e.g., 5%) seem quite plausible. In addition, heifer selection will increase profit another 3% to 5%. In summary, potentially, the strategy of an optimum culling rate and heifer selection strategy could be quite profitable to dairy producers.

Although calving fewer heifers and therefore having fewer animals available entails some risk in terms of the ability to respond to unforeseen circumstances (e.g., low production of the selected animals), heifer selection and lower culling rates also have favorable risk attributes. First, selection with sale of the excess heifers offers an immediate large source of cash flow from their sale revenue. Second, this management strategy is favorable in terms of its short- and long-term reversibility. In the short term, if a

Downloaded From Vet-eBooks.com

producer decides too many heifers have been sold and wants more heifers than are available, more can be bought or perhaps the sold heifers can be repurchased. However, purchase of animals may present a biosecurity risk to the herd. Longer term, if heifer selection is practiced and a producer is dissatisfied with the results, the former practice of calving all future heifers can be reintroduced. Health management, by providing a consistent environment that permits the expression of genetic potential, plays a critical role in minimizing the risk from heifer selection and lowered culling rates. Finally, modifying the culling and replacement strategy is favorable from a risk perspective because it does not involve large irreversible capital investments. Instead, a producer need only change his culling decision criteria and possibly modify other areas of herd management.

CUSTOMIZING OPTIMUM CULLING AND REPLACEMENT STRATEGIES

Herd Objectives

The objective of the simulation and optimization models is to maximize herd profit, but the models also provide information useful for herds with other objectives. For example, to maximize herd milk production the models suggest the herd culling rate should be approximately 35% (Allaire, 1981; Allaire and Cunningham, 1980) for North American herds. One study found that a 26% culling rate maximized milk revenue compared with the 23% rate that maximized the profit of Dutch herds (Van Arendonk, 1987). In addition, culling rates higher than the economically optimum range may slightly improve herd genetic progress. It is noteworthy that the range of culling rates common in North American herds is similar to the culling rates that maximize milk production. It is possible that the higher-than-economically-optimum culling rates in North American herds result from herd managers targeting maximum milk production as a proxy for maximum herd profit. The decision rule of comparing the cow and the replacement heifer can be modified to achieve any objective. If the objective is to maximize milk production rather than profit, the cow should be replaced if the average milk production of the heifer is greater than the cow's production in the next lactation. Similarly, if maximum genetic progress is the objective instead of maximum profit, the cow should be replaced if the heifer is genetically superior.

The results just mentioned indicate that decreasing the culling rate into the economically optimum 20% to 30% range slightly decreases herd milk production and genetic progress. The decrease in milk production is only a few percentage points because the drop in milk production resulting from selection from among fewer animals is partially compensated by having more cows in the later higher-producing lactations. At higher culling rates the cost of attaining higher milk production and genetic improvement is greater than their value, causing a decrease in profit. With all else being equal, higher-producing cows are generally more profitable. For a given culling rate, the highest-producing animals are desirable, but the strategy of higher milk production at any cost is not economically wise.

Customizing Individual Herd Culling Rates

As with any area of herd management, culling and replacement strategies need to be customized for each herd and adapted as circumstances change. An understanding of the principles of cow replacement decisions, and in particular the replacement decision rule, is powerful in customizing and adapting herd culling strategies. For example, the culling optimization and simulation models reveal that the optimum culling strategies are not sensitive to changes in the level of herd milk production, feed cost or milk price. Yet the optimum strategies do vary with reproductive performance of the herd and with changes in the price of a replacement animal relative to the price of a cull cow. These effects are all understandable, and in fact predictable, based on the principles and decision rules discussed earlier. The decision rule, which determines the optimum culling strategy, compares the profit of the potential replacement and the cow. Therefore any factors that affect the profitability of both the heifer and the cow have a minimum impact on the optimum culling strategy. Changing levels of herd milk production, feed costs, and milk price apply to both the cow and heifer and affect the profitability of each. Because these factors apply to each, however, the profitability of the cow relative to the heifer remains unchanged, and as a result the optimum culling strategy does not need to be customized or adapted as these factors change.

In customizing culling strategies for a given herd or adapting the strategy for a given herd over time, consideration is required of only those factors that affect the profitability of the cow or heifer, not both. There are three common factors that disparately affect the profitability of the cow relative to the replacement heifer: decreased cow milk production (extended calving intervals is a specific and important example), the price of a replacement heifer relative to the cull cow, and expansion of the herd.

Decreased Cow Milk Production

Profit from animal production is largely a function of continued high milk production. In addition to the animal's level of milk production, reproductive performance is also important to prevent the animal from spending an excessive amount of time in late lactation or the dry period. The profit-maximizing culling rate will be higher in herds with impaired levels of milk production or reproductive performance among the cows. For example, in the southern United States, a culling rate in the 40% range maximizes herd profit because of the deleterious effects of heat stress on the cows. The potential replacement's first-lactation milk production and profit are relatively unaffected by the heat stress. However, the deleterious effects of the heat stress on first-lactation reproductive performance and energy balance decrease milk production and profit in subsequent lactations. This factor is not limited only to herds that experience heat stress but is applicable to any herds in which the profit of the cows is decreased relative to the heifers, regardless of cause. If the cows have severely impaired milk production or reproduction because of health or management problems, a culling and replacement rate higher than the target range is preferable. Because of the decreased cow profitability, these herds will have decreased profit; freshening more heifers will help mitigate some of the loss. However, the underlying reasons for impaired cow performance should be investigated, since correcting these increases cow and herd profitability. As the cow profitability relative to the heifers returns to a more typical level, the profit-maximizing culling rate will decrease into the target range.

Extended Calving Intervals. One of the most common applications of the principle of maintaining cow production and profitability is management of cows with extended calving intervals (i.e., extended lactations or dry periods). Lowering the culling rate decreases reproductive culls, and as the culling guidelines clearly illustrate, breeding will continue for extended periods. This increased time

Downloaded from Vet-eBooks.com

to conception causes extended periods until the next lactation. Producers must be able to manage these cows so the production in the following lactation is not impaired. If the productive ability of these animals cannot be maintained, a higher culling rate is indicated. Alternatively, producers could consider the cost of altering their management practices (e.g., altering feeding management) to maintain the next lactation health and milk production of the animals with extended calving intervals.

Replacement Heifer Price Relative to Cull Cow

The second-common factor that requires adapting the culling and replacement rates is the price of a replacement heifer relative to the cull cow. Table 8-9, from one of the optimization models, provides an example of this factor's effect. As the price difference between a replacement and the cull cow increases from $450 to $650, the optimum culling rate decreased from 28% to 24%. Although the example is for the United States, the same principle is applicable even if a heifer is normally worth less than the cow. As the price of the replacement rises relative to the price of a cull cow, the optimum culling rate decreases, and vice versa. A pedagogical device useful for intuitively understanding the situation in which the heifer normally is priced higher than the cull cow is to consider the price difference as the cost of identifying poor-producing first-lactation animals. If a producer can calve a replacement, determine that she is a poor producer (and therefore of relatively low profitability), and then sell her for the same price as she would have sold for as a springing heifer, the producer has in essence paid nothing to identify this replacement as a low producer. In fact, the producer has a net profit from the animal's calf and milk production prior to her being sold. In this situation, it is most profitable to freshen all heifers (i.e., have the maximum biologically possible culling rate). This situation is potentially plausible for superior performing herds that are able to sell their culls for use as dairy animals in lesser herds. In contrast, most U.S. commercial herds will sell their culls for beef price and realize losses on the order of magnitude included in Table 8-9 for each first-lactation animal culled. In truth, the optimization models take the price difference (whether positive or negative) into account when developing the optimum culling rate. Therefore, regardless of whether the price difference between a replacement and cull is normally positive or negative, the optimum culling rate decreases if the price of a replacement rises relative to the cull's price.

TABLE 8-9

Effect of Cull Cow and Heifer Values on Optimum U.S. Culling Rates

Replacement heifer value minus cull cow value	Optimum culling rate
$450	28%
$550	25%
$650	24%

From Rogers GW, Van Arendonk JAM, McDaniel BT: *J Dairy Sci* 71:3453-3462, 1988.

This occurs because the price rise decreases the replacement's profit compared with that of the cow. Thus, even under Dutch conditions, for example, in which the price of a replacement is lower than a cull cow, the profit-maximizing culling rate will decrease as the relative price of the replacement rises (Van Arendonk, 1985; Van Arendonk and Dijkhuizen, 1985).

The culling literature indicates that the economic benefits of the increased rate of genetic improvement and increased milk production from higher selection pressure are simply not sufficient to compensate for the large losses described above. The target culling rate range is appropriate for a wide range of relative prices between replacement and culls, as illustrated by Table 8-9. Everything else being the same, the greater the price of the replacements relative to cull cows, the lower the profit-maximizing culling rate. This concept can also be used to adapt the culling rate to short-term price changes. For example, if the farmer were presented with the opportunity to sell replacements at an increased price, it would be economically rational to sell more of the heifers and thereby lower the culling rate.

Expansion of Herd

In herds undergoing expansion, the optimum culling rate is lower than the optimum rate if the herd maintained a constant herd size, because not all of the replacements are replacing or being compared with cows. By definition, the herd must have excess capacity to expand, permitting the replacements to enter the herd without necessitating the culling of a cow. In any herd with excess capacity the first priority should be to use the available capacity. As long as excess capacity exists, an animal should only be culled if it is not covering at least its variable costs and making some contribution to fixed costs. Depending on the degree of herd expansion and the number of available replacement heifers, the culling rate could be low. Only if the number of replacements is greater than that required to fill the herd to capacity and replace the animals that are not covering their variable costs should consideration be given to replacing cows (which are profitable) with heifers (which are expected to be more profitable). A method to assess the annual number of replacement heifers required to maximize herd profit during expansion is as follows:

1. The decision about how many cows to cull centers on comparing the profit of the potential replacement with that of the cow. This comparison is appropriate for the portion of the herd that currently exists.
2. Using the target culling rate for a herd of constant size and the number of animals currently in the herd, the number of heifers required to replace cows in the herd is known.
3. The desired level of herd expansion dictates the number of additional replacements required. If desired, allowances can also be made for the anticipated level of culling among these additional replacements during the year (i.e., the culling guides suggest 15% to 20% of first parity animals should be culled).

To permit herd expansion the number of replacement heifers entering the herd will be greater than the number of animals culled. When the culling rate is calculated for the expanding herd, it will be lower than the rate targeted for a herd of constant size.

Selecting and Implementing a Herd's Target Culling Rate

Assessment of the target culling rate for a herd should begin with determining the current culling and replacement strat-

Downloaded From Vet-eBooks.com

egy, including the culling rate, the rationale for the rate, and the method of selecting cows for culling and heifers for replacements. The information in this chapter can aid assessment of the current culling practices and replacement strategy and whether any modifications are required in any part of this strategy. In general, if possible, it is advisable to slowly implement any management change to give management sufficient time to respond to the changes and assess the results. This approach is applicable to altering the culling and replacement strategy of a herd. For example, if a herd with a 35% culling rate has target of 25%, in the next year it could aim for a rate of 32%. To achieve a rate of 32% would require the sale of approximately 10% of the heifers that would otherwise have calved and entered the herd.

In order to achieve a lower culling rate, the cow culling decisions must also be changed. For example, if the herd targeting a 32% culling rate next year averages 150 cows, it will need to cull only 48 cows instead of 53. Unless proactive steps are taken to alter the herd's cow culling decisions, it could easily end up culling roughly 53 cows again. A "monthly culling budget" will assist in effecting a lower culling rate and ensuring the target culling rate is achieved. For example, to achieve the 32% culling rate, on average the herd would designate four cows a month for culling. In terms of implementation of a target culling rate, when these cows actually leave the herd is not of particular interest; rather, the focus is on the decision of how many cows have been designated for culling. Obviously, the average number of cows designated for culling per month is just that—an average to which the farmer does not strictly adhere. The number in any month may be lesser or greater. The cumulative number of cows designated for culling in that year can also be tracked and compared with the target. The monthly culling budget, and the number of cows designated for culling year-to-date, integrate the herd's target culling rate into individual cow culling decisions. That is, the individual cow culling decisions are made with the goal of achieving the desired culling rate, rather than the culling rate merely being the end result of individual cow culling decisions.

HERD HEALTH IMPLICATIONS OF CULLING AND REPLACEMENT STRATEGIES

Modification of the culling and replacement strategy of a dairy herd has herd health implications. A reduction in the culling rate will allow problem cows that otherwise would have been culled to remain in the herd and require health care and management. One definition of herd health is the provision of an environment that permits the animals to express their genetic potential for production and profit. Such an environment is important for herd profitability.

Monitoring the reasons cows are culled helps to identify health management problems that may be impairing the profitability of the herd and the culling and replacement practices. If the least profitable cows have been culled, then the correct culling decisions have been made, regardless of the reason the cows were culled. Monitoring and evaluating the reasons the cows were culled can be useful in identifying management areas with the potential for biological improvement. The profitability of the potential interventions should then be assessed. The classification of culls as voluntary and involuntary is not helpful in identifying profitable interventions. At a minimum, the reasons each cow is culled should be recorded. These could include the reproductive status, production level, and any other germane information, such as disease status, at the time the animal was identified for culling.

CULLING COMPONENT OF THE COST OF DISEASE

Diseases often cause decreased productivity and profitability of an animal. If the decrease is sufficiently large, the animal is culled because a replacement heifer is expected to be more profitable. In assessing the cost effectiveness of preventing or decreasing the severity of the disease, the veterinarian must calculate the cost of the culling component of the disease. This cost has commonly been calculated as the price difference between the cost of a replacement heifer and the salvage value, if any, of the culled animal. This price difference method assumes that the animal, before the disease, was equally valuable as a replacement heifer, but it fails to recognize that the replacement may be superior or inferior. The cost of the culling component has been suggested as the difference in the value of the animal with and without the disease (Radke and Lloyd, 2000). To determine the value of the animal before the disease, her market value as represented by the price she would receive in a herd dispersal sale could be used.

In the absence of knowledge of the animal's market value, an alternative approach is to estimate both the number of lactations the animal would have remained in the herd if she had not been affected by disease and the profit associated with each lactation. If financial statements are available, the profit a cow will generate in a year can be estimated by dividing the total annual dairy enterprise profit by the average number of cows (Dohoo and Dijkhuizen, 1993). The profit of each lactation can also be gauged crudely by using the price of a replacement, which represents her expected future discounted cash flows from each lactation and her salvage value. If the average life of a replacement is three lactations, then she has a cash flow from each of three lactations and her salvage value. Ignoring the discounting of the cash flows to represent the time value of money, her price is the sum of the cash flows from three lactations and her salvage value. For example, if the average replacement price is $2000 and the average salvage value is $500, then the profit from her lactations is $1500 (i.e., $2000 − $500). If the average animal has three lactations, then on average there is $500 ($1500/3 lactations) profit per lactation. With this crude method, the cost of culling the cow in the current lactation due to the disease, whereas otherwise she would likely have been culled in the next lactation, is $500. In contrast, the price difference approach of subtracting the cost of the diseased cow's salvage value, if any, from the price of a replacement heifer would have resulted in an estimated cost of $1500 ($2000 – $500). It is difficult to understand how culling a cow one lactation earlier resulted in a loss of $1500. Notice also that if the analyst thought the animal would have remained in the herd for an additional two lactations, the profit-per-lactation method would suggest that the cost of prematurely culling her was $1000. In contrast, the price difference approach would have resulted in a cost of $1500. So although the cow's expected future number of lactations varied from one to two, by using the price difference method, the cost of her premature culling did not vary. The profit-per-lactation method is crude but can serve as a basis of initiating discussion with the producer on the culling component of the cost of disease.

GENETIC IMPROVEMENT PROGRAMS FOR DAIRY HERDS

Genetic improvement is an area of herd management that traditionally has not been within the scope of veterinary practice. The consulting practitioner must first give attention to immediate problems in herd management and demonstrate to the client a quick improvement in herd performance; these are accomplished by changes in management and herd environment. This section shows that genetics contributes substantially to the long-term improvement of herd performance. Therefore the practitioner and client who envision a long-term consulting relationship must not overlook the long-term consequences of a herd's genetic improvement program. Certainly, a comprehensive assessment of a herd's current and future opportunities for improvement must include an assessment of genetic improvement policies and practices.

The second half of this chapter outlines the role of genetics in animal performance and herd improvement for production and health traits. A survey of the tools and methods for genetic improvement of dairy herds leads into approaches for assessing the herd's genetic status and planning the herd's genetic future. Attention is given to methods for improvement of yield traits that are well developed and for which many herd managers have some awareness. A special feature is the description of genetic improvement methods for health and reproductive traits. Although these systems are still undergoing development, producers have limited awareness of useful tools that currently exist for health and fertility traits. This material will enable the practitioner to become conversant in the language, concepts, and methods of genetic improvement.

TRENDS IN HERD IMPROVEMENT

Genetic improvement of milk production in dairy cattle is one of the great success stories in the history of agricultural science. Although the science of animal genetics began in the 1920s, successful practice of genetic improvement in dairy cattle began in the 1960s (Van Tassell and Van Vleck, 1991). During the 1960s, all of the modern tools needed for genetic improvement became available and were put into practice. These included AI, frozen semen, computer systems, centralized databases, and statistical techniques. These tools and methods have undergone continuous refinement. Today's systems for genetic improvement are well honed and highly sophisticated. These systems involve close cooperation among producers, production recording associations, AI organizations, breed associations, and government agencies.

Genetics has proved to be a powerful strategy for improving productive efficiency of dairy cattle. Fig. 8-1 shows the gains in U.S. Holstein breed average milk yield, breeding value, and environmental value by cows' year of birth; results are compared against a 1957 base (Animal Improvement Programs Laboratory, 2000b). From 1960 to 1995, 305-day milk yield per cow increased from 13,783 to 23,346 lb—a gain of more than 9500 lb in 35 years! The gains in breed average are due to gains in genetics, or breeding value, and gains in environmental value, i.e., feeding, management, and health care. The rate of improvement has accelerated: During the 1960s the breed average increased at a rate of about 140 lb per year; during the 1990s, annual gains increased to more than 500 lb per year. Genetic improvement before 1960 was slight by today's standards, but rapid improvements were being made in feeding and management at that time. By 1977 the total improvement after 1957 in breed average milk production was due equally to genetics and management. Since the late 1960s annual improvements

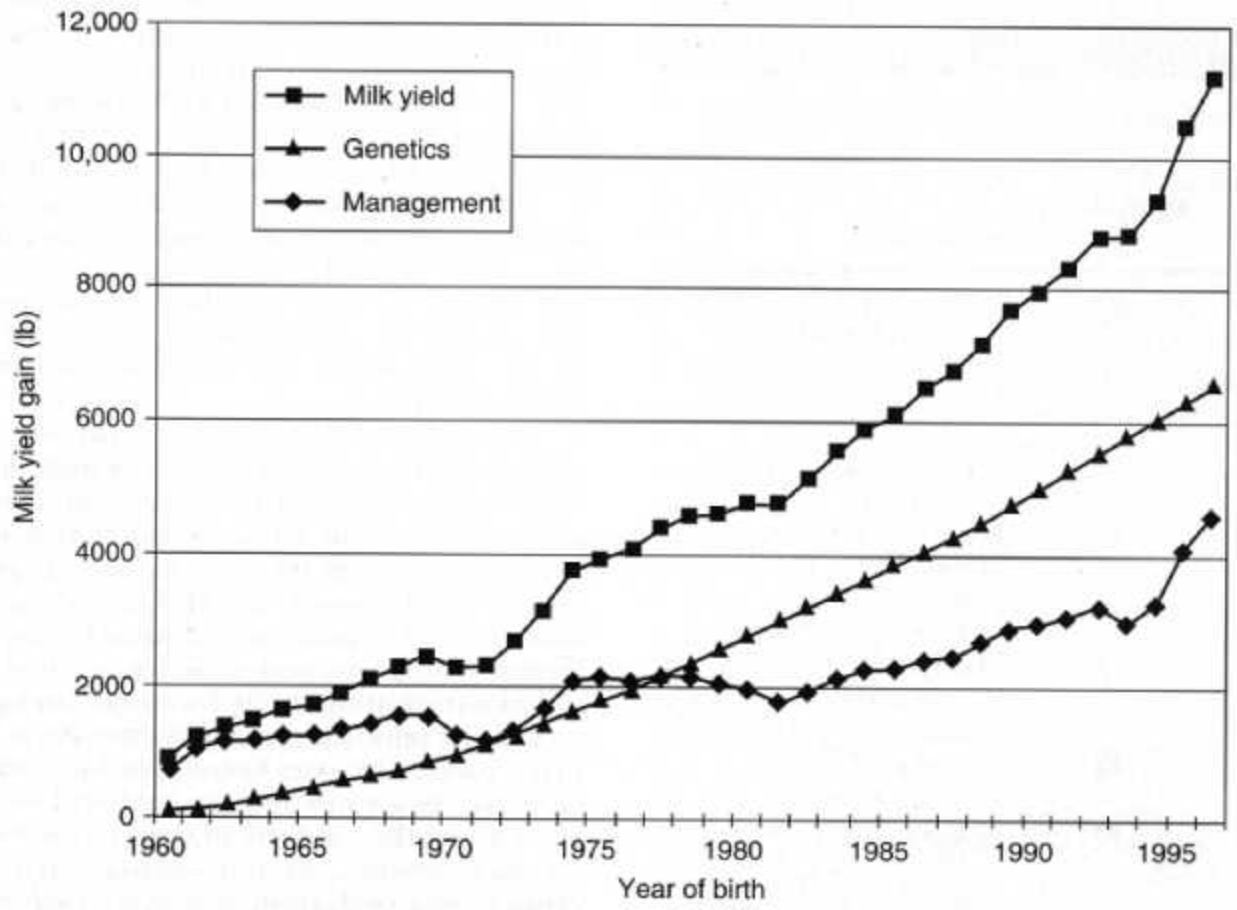

FIG. 8-1 Genetic, management, and phenotypic trends for milk yield in U.S. Holsteins. (Data from Animal Improvement Programs Laboratory, 2000. Available at http://aipl.arsusda.gov/main/data.html#gtrend [accessed March 5, 2001].)

Downloaded from Vet-eBooks.com

resulting from genetics have been greater than those from feeding and management. Throughout these years about 60% of the gain in breed average was due to genetics; the remaining 40% was due to management.

ROLE OF GENETICS IN INDIVIDUAL ANIMAL PERFORMANCE

Geneticists use *heritability* to express the degree of genetic influence on differences among cows in measures of performance. In statistical terms, heritability is the square of the correlation between breeding value and phenotypic value; also, heritability is the regression of breeding value on phenotypic value (i.e., the portion of difference between animals' phenotypic values that is due, on average, to the difference in their breeding values). Heritabilities for the yield traits are around 30%. This means that, on average, 30% of the difference in yield between any two cows taken at random is due to genetics. The rest of the difference is due to "environment," a category that includes feeding, management, health care, and many other known and unknown factors. Typical heritability estimates for several traits are listed in Table 8-10. Heritabilities are high for body size and the percentages of fat and protein. This implies that genetics has a relatively large influence and that environment has a small influence on these traits. Conversely, reproductive and health traits have low heritabilities, indicating that environmental factors contribute largely to the differences among animals and genetic differences are relatively small. For example, clean housing and sanitary milking practices are major environmental contributors to differences among cows for mastitis and somatic cell score (SCS), which are traits with low heritabilities.

TABLE 8-10

Heritability Estimates for Selected Traits in Dairy Cattle

Trait	Heritability (%)	Reference
Milk yield	30	Van Tassell et al, 1999
Fat yield	30	Van Tassell et al, 1999
Protein yield	30	Van Tassell et al, 1999

Calfhood pneumonia	10	Muggli-Cockett et al, 1992
Paratuberculosis susceptibility	6	Koets et al, 2000

ROLE OF GENETICS IN HERD IMPROVEMENT

The large contribution of genetics to improvement of a population is shown in Fig. 8-1. Similar results can be expected in individual herds, although some will experience larger gains than others. Herds with a poor genetic background can obtain relatively rapid herd improvement through genetics. Herds with top genetics also will continue to improve by choosing bulls with high genetic merit, but their rate of improvement will be less dramatic.

Improvements in feeding, management, and health care can produce a desirable response in as little as a few days to as much as several months. Genetic gains are more gradual. Genetic decisions made today will not begin to impact the milking herd until 3 years from now, and the full impact will take 4 or 5 years. For this reason, it is important for herd consultants to focus first on problems that can produce a quick return. However, the long term must not be ignored, or else the client cannot remain economically competitive. Mistakes in feeding and management can be corrected in the short term; mistakes in genetics will exist for the lifetime of the animals. Therefore it is imperative to be consistent in implementing good genetic decisions.

The array of management remedies for solving dairy herd problems is extensive; the array of genetic tools is more limited. Genetic programs are well developed for improving milk yield, milk composition, and type characteristics. Genetic tools for improving reproduction and health traits are only beginning to emerge. Fortunately, a large amount of research is in progress toward the goal of developing genetic approaches to improving disease resistance and reproductive performance. These tools will continue to emerge and be enhanced over the next decade. This chapter focuses on currently available genetic technologies.

Differences among herds, like differences among cows, are due to both genetic and environmental factors. It has been estimated that 20% to 30% of the differences in milk yields among herds is due to genetics. Feeding, management, and health care should be seen as the major cause of differences in herd performance. Herds with the highest levels of performance are likely superior because of both high levels of genetics and high levels of management. Herds with low or moderate levels of performance may be limited in either genetics, management, or a combination of both. Evaluation of each herd's sire selection policies and management practices will reveal opportunities for improvement in both genetics and management. In spite of the fact that most of the difference among herd averages is due to feeding, management, and health care, more than 60% of herd improvement over the long term is due to genetics (Fig. 8-1).

Although 50% of the genes are derived from each the sires and dams of animals, over 90% of the genetic improvement in dairy herds is due to sire selection. Less than 10% of genetic improvement is due to cow culling and to selection of herd replacements from better cows (Van Tassell and Van Vleck, 1991; Dekkers, 1992). Genetic improvement on the dam side of the pedigree is limited by the fact that selection intensity and selection accuracy are low. Accuracy of predicted transmitting ability for cows is about 75% of the accuracy of sire selection. Selection intensity is limited by the fact that reproductive rates in cows are low—about one offspring per year. As a consequence, herd replacements must come from about the top 90% of cows in the herd. Sire selection, on the other hand, is more accurate than cow selection because genetic evaluation of sires is based on the performance of large numbers of their progeny. Furthermore, selection of AI sires is far more intense than cow selection because of the

Downloaded From Vet-eBooks.com

great reproductive capacity of bulls. In the first phase of selection, young sires are produced from the top 1% or 2% of cows in the breed mated to the top 2% to 4% of proven AI bulls. In the second phase, bulls are progeny tested with as few as 50 to 75 daughters in the United States to as many as 200 daughters in some European countries. Only the top 10% of these are put into active AI service after progeny testing. Because of the importance of sire selection to genetic improvement, this chapter will focus primarily on the many facets of sire selection for commercial herds.

TOOLS FOR GENETIC IMPROVEMENT

Information on which to base genetic selection decisions is well developed in many countries, including the developing countries. Although procedures and nomenclature are similar among the countries, many differences exist among countries in the data used for computing genetic evaluations, methods of data analysis, scale of measurement, and genetic base. The policies and practices of 31 countries that participate in Interbull were recently summarized (Interbull, 2000b). The procedures described here will be for those in North America.

Predicted Transmitting Ability

In the United States and some other countries, predicted transmitting ability (PTA) is the measure of an animal's genetic value. In its simplest form, PTA is a measure for ranking individual bulls and cows based on genetic merit. In general, PTAs are expressed in the same units of measure as the performance records from which the PTAs were derived, such as pounds or kilograms for the yield traits, percent for milk composition, and points for SCS or type traits. The practitioner needs only to list bulls in rank order of PTA to identify the best and worst for genetic improvement.

PTA, however, is much more than a number for ranking animals: It is a prediction of the differences in performance (e.g. milk yield) expected in future daughters of the bulls or cows. Most meaningful is the comparison between the PTAs of two animals. If PTA for one bull is 2000 lb milk and the PTA of a competing bull is 1200 lb, future daughters of the higher bull are expected to produce 800 lb more milk per lactation than daughters of the lower bull. This difference is expected to be the same in herds with low or high levels of performance. Comparing animals in this manner is a less abstract way to think about PTA.

Estimated Breeding Value

In Canada and many other countries, genetic evaluations are expressed as estimated breeding value (EBV) rather than predicted transmitting ability. The words "estimated" and "predicted" are synonymous, and no distinction should be inferred from those terms. Breeding value and transmitting ability are closely related concepts, but they are not synonymous. Breeding value expresses the effect of an animal's genes on the animal's own performance; transmitting ability expresses the effect of an animal's genes on the performance of its progeny. Genes and chromosomes in an individual occur in pairs: Breeding value measures the total effect of all pairs of genes and chromosomes on the animal's own performance. The sperm cells and egg cells that parents transmit to their progeny contain only one member of each gene or chromosome pair: Transmitting ability measures the average value of the genes in an average sperm cell or egg cell or the value of half of an individual's chromosomes. This equation can be expressed by the following:

$$\text{Breeding value} = \text{Transmitting ability} \times 2. \quad [1]$$

EBV and PTA are both measures of genetic merit and may be used in similar ways to select genetically improved sires and dams.

Comparing the EBVs of two animals measures the extent to which genetics causes a difference in performance of the two animals. Consider, for example, two cows with respective EBVs of 2600 lb and 1000 lb. Genes of the cow with the higher EBV are predicted to confer an advantage of 1600 lb to the performance of the higher cow compared with genes inherited by lower EBV cow. Because of environmental differences, the actual performance of the lower EBV cow may be higher than the performance of the higher EBV cow. Nevertheless, all the performance and pedigree information available provide a best estimate of the genetic differences between animals. With Equation 1, progeny of the cow with the higher EBV are expected to produce 800 lb (0.5×1600) more than the progeny of the lower EBV cow.

Genetic Base

Many definitions of genetic base are used; these differ from country to country and from trait to trait within a country. Users are cautioned to be especially aware of the frequency and timing of changes in genetic base in their country. A brief description of genetic bases in member countries is available (Interbull, 2000b).

The PTAs and EBVs are measured against a genetic base. Genetic base is an arbitrary reference point for comparison of genetic evaluations. EBVs and PTAs are relative measures, not absolute values. An analogy is the Celsius temperature scale for which the freezing point of water is a reference point. Whereas the freezing point of water is a constant reference point for temperature measures, genetic bases are defined in a variety of ways depending on the trait and country. In the United States, the genetic base is updated at 5-year intervals and remains fixed for each 5-year period. For example, from 1995 to 1999, the genetic base was the average PTA of cows born in 1990; this average for the yield traits is set to zero. From 2000 to 2004, the genetic base will be established as the average of cows born in 1995. Because bulls are more highly selected and fewer in number than cows, the PTAs of bulls are not used in setting the base. In Canada and many other countries, the genetic base is updated each year.

For many traits, the base population average for PTA or EBV is set to 0 (i.e., the average PTA or EBV of cows born in a certain year is set to 0 and evaluations for all animals are expressed as a difference from 0). As a result, genetic evaluations may have positive or negative values. If a cow's PTA for milk is 2000 lb, her daughters are expected to produce 2000 lb more milk than the daughters of an average cow born in the base year. In the United States, the genetic base for SCS is set to the breed average SCS for cows born in the base year; in this case, PTAs are always positive and resemble daughter averages.

It is important for users of PTA or EBV to be aware of the changes in genetic base and the consequence of those changes. Genetic improvement is quite rapid for some traits, like milk yield, and quite slow for other traits, like SCS. For traits undergoing rapid genetic improvement, updating the genetic base can cause a substantial reduction in the PTAs reported for individual animals. Updating the base does not change the ranking of animals, because all cows and bulls are measured against the same genetic base and the same amount of base change applies to all animals. In the Canadian scheme with annual updating of the base, a bull's EBV decreases a small amount each year. In the United States'

Downloaded From Vet-eBooks.com

system with 5-year updates, a bull's PTA is expected to be rather stable within each base period, but the PTA drops substantially when base changes do occur.

Reliability of Predicted Transmitting Ability or Estimated Breeding Value

Genetics and environment together cause differences in animal performance. The PTA measures the genetic merit; it is a prediction of average performance of future progeny. The PTA or EBV is calculated by sophisticated statistical techniques applied to the performance records of an animal (if any exist) and all known relatives; records of close relatives are weighted more heavily than records of distant relatives. Although performance records are used to predict genetic merit, environmental effects make performance records an imperfect predictor of genetic merit. Heritability measures how closely performance is related to genetic merit.

How closely does the *predicted* transmitting ability approximate an animal's *true* transmitting ability? True transmitting ability cannot be measured; PTA is inferred from the animal's own performance and the performance of all known relatives. New performance records are added to the data base and PTAs are updated at regular intervals two or four times per year in many countries. As new information is incorporated into the evaluation, PTA more closely approximates the true transmitting ability. How stable are these PTAs over time as new information is added? Measuring accuracy or stability over time of PTA is the role of *reliability*. When reliability is low, PTA may change dramatically as new records are included in the evaluation, because a prediction based on relatively few lactations is less accurate. As reliability approaches the upper limit of 99%, the PTA is based on such a large number of records that only small changes in PTA are likely to occur; the PTA is virtually equal to the animal's true genetic value. In statistical terms, reliability is the square of the correlation between PTA and true transmitting ability.

Reliability depends on heritability and on the number of records used in computing the PTA. Records on the animal itself and close relatives contribute more to reliability than records on distant relatives. As more lactations, daughters, and pedigree information are added to the data files, the reliability of an animal's PTA increases. Traits with low heritability require more performance records to reach a given level of reliability than traits with high heritability. Or for a given number of records, reliability will be lower for traits with low heritability, unless the number of records is extremely large; in this case reliability for all traits reaches 99%.

Reliabilities for cow PTAs are generally below 60% because living cows usually have few, if any, daughters. Reliabilities for bulls vary with the bull's stage of life. For young bulls with only pedigree information, reliability is typically 30% to 40%. Bulls with an initial AI proof involving 40 to 70 daughters have reliability of 75% to 85%. Reliabilities for older sires often reach the limit of 99% because they may have hundreds or thousands of daughters.

Reliability may be the most misunderstood and most widely misused quantity in genetic evaluation. Some have interpreted reliability as a measure of the fertility of a bull's semen. A common misuse of reliability is to select bulls on a combination of PTA and reliability (e.g., PTA times reliability). In effect, this process favors some bulls with high reliability and moderate genetic merit in preference to bulls with highest genetic merit and intermediate reliability. Daughters of bulls with higher PTA will perform better, on average, regardless of reliability. Whether reliability is high or low, the PTA is calculated so that a bull's future PTAs are equally likely to increase or decrease as new performance information becomes available. Some producers make decisions as though low-reliability bulls were more likely to decrease than to increase as new information becomes available. Rather, the increases or decreases in future PTAs will vary more widely for low-reliability than high-reliability bulls. For example, with reliability at 90%, chances are two out of three that a bull's PTA will stay within 240 lb milk above or below his current PTA. With reliability at 70% chances are two out of three that a bull's PTA will stay within 400 lb milk above or below his current PTA.

It is not widely known among producers and others that reliability is built into the calculation of PTA; this lack of information is one cause for the misuse of reliability. For bulls, PTA is essentially a weighted average of daughter deviation and parent average (PA). Consider the simplified case of two hypothetical bulls shown in Table 8-11. These bulls have equal amounts of pedigree data and the PA for both bulls is 0, equal to the genetic base. Also assume that the daughters of both bulls average 2500 lb of milk above their contemporaries (daughter deviation). The bulls differ only in the number of daughters. When the number of daughters is large, the daughter deviation is weighted heavily, PA has little weight, the PTA is only slightly less than daughter deviation, and reliability approaches 100%. Conversely for the bull with few daughters, daughter deviation receives less weight, PA is more heavily weighted, the PTA is substantially less than daughter deviation, and reliability is lower. In summary, the genetic evaluation procedures "discount" the daughter deviation for the number of daughters, so it is not necessary—indeed it is improper—to further discount the PTA for low reliability.

How to Use Reliability

How should reliability enter the sire selection process? First, it should be considered only in the final stages of sire selection. The initial screening of bulls should be based on PTA or EBV, the measure of genetic merit. For two bulls with similar PTAs, the practitioner might choose to use the bull with higher reliability. After the decision of which bulls to buy based on PTA, reliability is considered; the practitioner should purchase larger amounts of semen for bulls with high reliability and smaller amounts for low-reliability bulls. Since a bull's reliability increases over time, additional units of semen may be purchased if his PTA values remain competitive with other selected bulls.

Bulls with high reliability (e.g., above 80%) may be used extensively because their PTAs are not likely to change in future evaluations. Individual young, unproven bulls and proven bulls with low reliability should be used sparingly because their PTAs may change as new daughters are added to the evaluation. It may seem paradoxical, but several un-

TABLE 8-11

Effect of the Number of Daughters on Predicted Transmitting Ability (PTA) and Reliability When Daughter Deviation and Parent Average Are Equal for Two Bulls

	No. of Daughters	Daughter Deviation	PTA	Reliability of PTA (%)
Bull A	600	2500	2450	98
Bull B	30	2500	1600	75

Downloaded From Vet-eBooks.com

proven or low-reliability bulls with high average PTA may be used to breed a large portion of a herd. Although PTAs of individual bulls in the group may increase or decrease with new information, the average PTA of the group should change little. In effect, the average PTA of a group of bulls has a high reliability even though the reliabilities are low for individual bulls in the group. It is for this reason that a herd's participation in AI young sire sampling programs subjects the herd to very little risk for genetic merit.

TRAITS WITH GENETIC EVALUATIONS

Genetic evaluations are published for milk yield, yields and percentages of fat and protein, SCS, herd life, and some 15 conformation or type traits. Evaluations of bulls are commonly published for calving difficulty and sire nonreturn rate. In some countries, additional disease and functional traits such as milking speed and temperament are also published; these are described elsewhere (Banos, 1996; Ruane et al, 1997).

The percentile distributions for many of the traits just described are shown in Table 8-12. These distributions were based on 623 Holstein bulls actively marketed by the United States AI industry in August 1999. The genetic base for these PTAs was cows born in 1990; because of genetic gain, the PTA levels for the yield traits are high in relation to a contemporary cow population. A future change in genetic base will substantially reduce these levels for the yield traits. Rather, little change would be expected for the nonyield traits because genetic gain is limited. Distributions such as these can serve as benchmarks for measuring the quality of sire selection decisions on farms.

Variation among bulls shows the opportunity to create genetic improvement. Variability among bulls is indicated in Table 8-12 by the 90th percentile range, the difference between the 5th and 95th percentiles. The differences between percentile levels is stable over time and between genetic base changes. Variation within the top and bottom 5% of bulls is not reflected in the 90th percentile range; a large amount of variation does exist within these extremes. In fact, the difference between the best and worst individual bulls is more than twice the 90th percentile range for each trait.

Milk, Fat, and Protein Yield

Milk, fat, and protein yields are recorded through officially recognized production recording systems such as Dairy Herd Improvement (DHI). The basic record is test day yield recorded monthly or at less-frequent intervals; traditionally these test day yields are accumulated to a 305-day total that is analyzed by the genetic evaluation system. Some testing plans allow reduced frequency of fat and protein measurement. Many countries have implemented or are moving toward a "test day model" in which the individual test day yields are analyzed; this enables a more precise adjustment for environmental factors (Jamrozik et al, 1997; Wiggans and Goddard, 1997). Adjustments to the observed yields are applied to remove effects of age and season of calving, parity, days in milk, times milked per day, and days open. Typically records are standardized to mature age, twice daily milking, 305 days in milk, and 100 days open (Norman et al, 1995).

Large differences exist among bulls in genetic merit for the yield traits (Table 8-12). These traits are highly correlated; bulls high for one trait will often be high for the other two traits as well. Sire selection decisions should be based primarily on PTAs for these traits because they determine the revenue production of the dairy enterprise. In most countries an index is published that combines these three traits with weights that represent their local economic values.

Fat and Protein Percent

Genetic evaluations for the component percentages may be accomplished by direct analysis of the recorded percentages, or they may be obtained indirectly. In the United States these PTAs are computed indirectly from the PTAs for the yield traits. Equation 2 illustrates this calculation for protein percent:

$$\text{PTA P\%} = \frac{(\text{PTA P} + \text{BA P})}{(\text{PTA M} + \text{BA M})} - \frac{\text{BA P}}{\text{BA M}} \qquad [2]$$

where *BA* represents breed average, *P* represents protein yield, and *M* represents milk yield. In effect, the formula calculates a bull's daughter average for protein percent from the PTAs for milk and protein yield, then subtracts the breed average protein percent.

TABLE 8-12

Percentile Distributions for Predicted Transmitting Abilities (PTAs) for Selected Traits of Active Artificial Insemination Holstein Bulls in the United States

	Percentile*					
Trait	95	75	50	25	5	90th Percentile Range
Milk (lb)	2508	1965	1643	1319	559	1949
Fat (lb)	86	63	51	37	15	71
Protein (lb)	78	64	54	43	25	53
Fat (%)	0.14	0.02	−0.05	−0.1	−0.21	0.35
Protein (%)	0.08	0.04	0.01	−0.02	−0.07	0.15

*Percentage of bulls with PTAs below the values shown in the body of the table.

Downloaded from Vet-eBooks.com

A moderately negative correlation exists for the component percentages with milk yield; bulls with high PTAs for component percentages tend to be below average for PTA milk. Only a slight correlation exists between the PTAs for a component yield and percentage of that component.

An important question in sire selection is whether selection should be based on the component percentages or component yields. In most markets, higher revenues are generated by daughters of bulls selected for the component yields. The initial selection criteria should include the component yields. Component percentages may be considered as a secondary selection criterion among bulls that have high component yields. A common fault among producers is placing too much emphasis on the component percentages. The best decisions will be made by selecting bulls that rank high for an index of milk and component yields; especially an index that represents local milk prices.

Somatic Cell Score

Somatic cell count (SCC) is a commonly used indicator of mastitis. Results from many studies confirm that SCS is the most suitable single trait for the indirect reduction of the incidence of mastitis through selection (Mrode and Swanson, 1996). In many production recording programs, SCC is tested in bucket milk of individual cows each month. The SCCs are converted to scores, as illustrated in Table 8-13; each doubling of SCC is associated with a 1-point increase in SCS (Shook, 1993). The scores are averaged over a complete lactation. The lactation averages are adjusted for lactation length and age and season of calving (Schutz et al, 1995); the adjusted SCS values are used in genetic analysis (Shook and Schutz, 1994). Cows that are free of mammary gland infection maintain low SCS throughout lactation; cows with severe, chronic mammary infection have the highest lactation average SCS. Research has shown that mammary gland infection is the major cause of increased SCC; in the absence of infection, factors such as stage of lactation, age, and season have little effect on SCC (Harmon, 1994). A moderate elevation in SCC was once considered necessary to prevent infection; currently it is understood that moderate and high levels of SCC are due to subclinical infection and, therefore, are undesirable.

SCSs are preferred over SCCs for genetic evaluation because they have: (1) higher heritability (Ali and Shook, 1980; Monardes et al, 1983; Mrode and Swanson, 1996), (2) better discrimination between infected and noninfected cows (Berning and Shook, 1992), (3) linear relationship with milk yield loss (Raubertas and Shook, 1982), (4) normal frequency distribution, and (5) uniform standard deviations among animals within sire or herd (Ali and Shook, 1980). These findings are summarized in more detail elsewhere (Shook, 1982; Shook, 1993).

TABLE 8-13

Correspondence Between Somatic Cell Count (SCC) (cells/ml) and Somatic Cell Score (SCS) for Selected Values of SCS

SCC	50	71	100	141	200	283	400	566	800
SCS	2.0	2.5	3.0	3.5	4.0	4.5	5.0	5.5	6.0

Shook GE: *Vet Clin North Am Food Anim Pract* 9:563-581, 1993.

Research has shown that sire evaluations computed only in herds with low average SCS are virtually identical to sire evaluations computed only in herds with high average SCS. Furthermore it was shown that heritability of SCS is similar in herds with low or high average SCS (Banos and Shook, 1990). Therefore SCS records from all herds are used in computing PTA SCS, and the recommendations for application of genetic evaluations for SCS are the same for herds at all levels of SCS.

Genetic correlation measures the tendency for PTAs or EBVs of two traits to vary together. Genetic correlation estimates between milk yield and clinical mastitis vary around 0.3, indicating a weak tendency for increased genetic susceptibility to mastitis as genetic improvement for yield takes place. Therefore it is important to include a measure of mastitis in sire selection programs. Estimates of the genetic correlation between SCS and clinical mastitis vary around 0.7; this implies that cows and bulls with high PTA SCS have greater genetic resistance to clinical mastitis (Mrode and Swanson, 1996; Shook, 1993). Because low SCS indicates the absence of mastitis, sire selection should favor bulls with low PTA SCS.

The frequency distribution of PTA SCS for U.S. Holstein bulls in active AI service is shown in Fig. 8-2 (Animal Improvement Programs Laboratory, 1999b); the bars show the percentage of bulls that fall into each category of PTA SCS. The PTA SCS of AI bulls ranges from 2.7 to 3.7, a difference of 1 point. In the same herd environment, daughters of the highest bulls will have geometric average cell counts that are double those of daughters of the lowest bulls. For example, in a herd in which geometric average of daughters of the lowest bulls is 150 cells/ml, daughters of the highest bulls are expected to average 300 cells/ml (150×2). In general, a difference of x units in PTA SCS for two bulls means that average SCC for daughters of the higher bull is expected to be 2 raised to the power x times the average SCC for daughters of the lower bull. For example, if the difference, x, between PTA SCS for two bulls is 0.8, the SCC for daughters of the higher bull is expected to be $2^{0.8} = 1.74$ times the SCC for daughters of the lower bull in the same herd environment. This relationship between SCC and PTA for SCS applies in herds at all levels of SCS (Banos and Shook, 1990). It should be noted that in the United States the genetic base for PTA SCS is set to breed average SCS rather than 0, as is done for other traits.

The 90th percentile range of PTA SCS is 0.46 points for active AI bulls (Table 8-12). This rather narrow range is due to the low heritability of 10% for SCS (Table 8-10) and, in

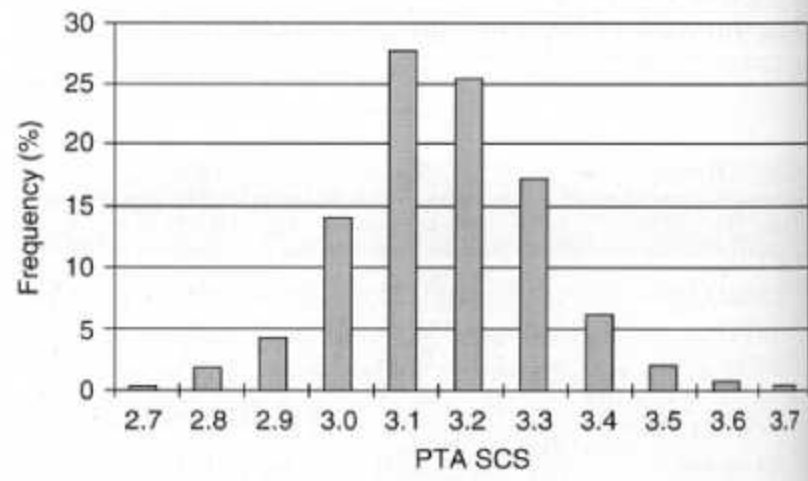

FIG. 8-2 Frequency distribution of predicted transmitting ability for somatic cell score *(PTA SCS)* for active artificial insemination Holstein bulls in the United States. (Data compiled from Animal Improvement Programs Laboratory: Genetic evaluation results, 1999. Available at http://aipl.arsusda.gov/main/data.html [accessed March 6, 2001].)

Downloaded from Vet-e-Books.com

some cases, limited numbers of daughters with SCS records. Also, this narrow range means there is limited opportunity for substantial genetic improvement of SCS. The great majority of bulls are within an acceptable range of PTA for SCS. The greatest concern is the 5% to 10 % of bulls with highest PTA SCS; these should be avoided unless they are truly outstanding for other more important traits.

Managers of herds with low average SCS may believe that sire differences in PTA SCS are of no concern in their situation. Research has shown that the genetic differences among bulls' daughters are similar in herds with both high and low average SCS (Banos and Shook, 1990). This means that herds with low average SCS will realize the same genetic improvement from selection against SCS as herds with high average SCS. Also, it means that sire selection recommendations should be the same for all herds regardless of herd average SCS. Sire selection against SCS should not be seen as a substitute for clean housing, good milking practices, and other methods of mastitis prevention. Daughters of bulls with low PTA SCS are as responsive to environmental conditions as daughters of bulls with high PTA SCS.

Herd Life

Herd life measures overall ability of the cow to stay in the herd. Long herd life is desirable because the cost of rearing a heifer to milking age is divided among more units of production, reducing the rearing cost per unit of production. Cows that are free of disease, with good reproductive performance and high milk production, have longer herd life. The phenotypic correlation of milk production with total herd life is 0.4; genetic correlation is 0.2 (Short and Lawlor, 1992). Studies have found herd life extended by 0.11 to 0.16 months per one percentile increase in cow's rank within the herd for milk yield (Boldman et al, 1992; Short and Lawlor, 1992); in other words, the difference in herd life between cows with the highest and lowest milk yields within a herd is 11 to 16 months. In some countries, total herd life is adjusted for yield, so it measures more directly the effects of health, reproduction, and other management factors on cow survival. Herd life adjusted for milk yield is often called functional herd life. It remains controversial whether genetic evaluations should be based on total or functional herd life.

Genetic evaluations in the United States are called PTA productive life (PL) and are based on total herd life, specifically the number of months in lactation from first calving until 7 years of age. A cow is credited with up to 10 months of herd life per lactation, and months are accumulated over all lactations. A cow's actual herd life is recorded when she is culled or reaches 84 months of age (VanRaden and Klaaskate, 1993). Average herd life for U.S. Holsteins is 25 months. Until actual herd life is known, it is predicted on the basis of age at first calving, total months in milk, and months in the current lactation. These predictions begin at 3 years of age. Early age at first calving and short calving intervals that result from good reproductive performance contribute to increased herd life. Daughters of sires with high PTA PL have these desirable characteristics.

For sire evaluation, PTA PL is based on pedigree data, actual and predicted PL of daughters, and the bull's PTAs for linear type traits. PTAs for udder conformation and foot and leg traits have been shown to improve the accuracy of PTA PL, especially when only predicted herd life is available for the majority of daughters or when daughter numbers are small. The frequency distribution for PTA PL for active AI Holstein sires in the United States is shown in Fig. 8-3. The 90th percentile range for PTA PL is 3 months (Table 8-12), whereas the full range is 6 months. This means that daughters of the highest bulls will have, on average, about 6 months more PL than daughters of the lowest bulls. As with PTA SCS, this narrow range of PTA PL is due to the low heritability of 8% (Table 8-10); this also indicates the somewhat limited opportunity for substantial genetic improvement of PL.

Calving Difficulty

Difficult calving, or dystocia, causes increased calf and cow mortality, higher veterinary costs, decreased milk production and a decline in reproductive performance (Dematawewa and Berger, 1997). Greater calving difficulty occurs with first parity parturitions, bull calves, and larger calf birth weights. Sire evaluations for calving difficulty are published

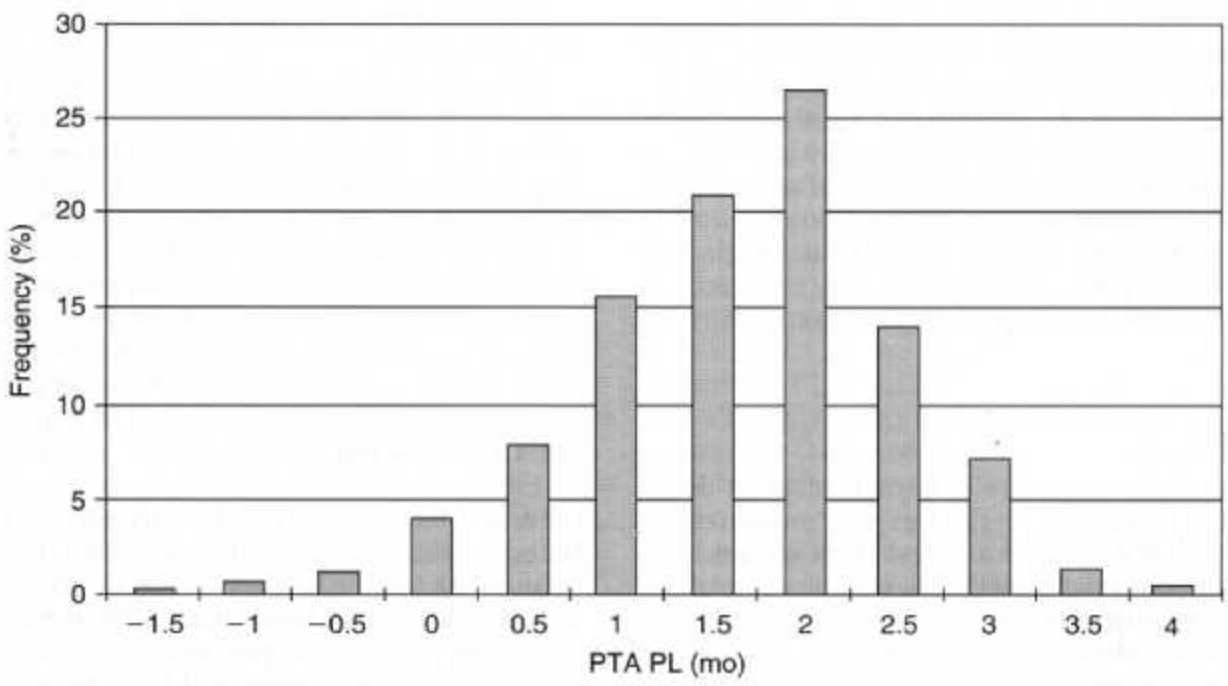

FIG. 8-3 Frequency distribution of predicted transmitting ability for productive life *(PTA PL)* for active artificial insemination Holstein bulls in the United States. FIG. 8-4 Frequency distribution of calving difficulty evaluations for active artificial insemination Holstein bulls in the United States. (Data compiled from National Association of Animal Breeders: Active AI sire list, August 1999. Available at http://www.naab-css.org/db [accessed March 6, 2001].)

in many countries. Calving difficulty is influenced by the sire of the calf and by the sire of the cow. Some countries publish calving difficulty evaluations for both sire of calf and sire of cow.

Calving difficulty, as evaluated in the United States, is measured as the percentage of difficult births in heifers (Berger, 1994). Results are published only for sire of calf effects, although plans are in progress to develop sire of cow evaluations. Calving difficulty is scored on the farm and only for Holsteins. Fig. 8-4 shows the frequency distribution of calving difficulty evaluations of bulls; the bars show the percentage of bulls that fall into each category of calving difficulty. Sire summaries for calving difficulty range from a low of 6% to a high of 16% and average 10% (National Association of Animal Breeders, 1999). Evaluations are available for more than 80% of active AI Holstein bulls. Calving difficulty evaluations are not PTAs because they do not predict daughter performance. They measure the birth difficulty of calves sired by the bull rather than the genetic merit of the bull.

To reduce calving difficulty in the herd, yearling heifers should be mated to bulls with calving difficulty scores that are at or below the average of 10%. Up to 40% of semen purchased should be from bulls with low calving difficulty for use in this manner. Because calving difficulty is much less frequent in multiparous cows, calving difficulty evaluations may be disregarded when selecting bulls to mate with cows in milk.

Nonreturn Rate

Attainment of reproductive success is a major cost in dairy herd management. Heritability estimates for measures of reproductive performance are typically less than 4% and average around 2%. These low heritabilities indicate limited opportunity for genetic improvement; most efforts toward improving reproduction should focus on management. Nevertheless, geneticists are developing data systems and evaluation methods to take advantage of the genetic variation that does exist for this group of economically important traits. Genetic evaluations for measures of both male and female fertility will emerge as the research advances.

Currently, evaluations in the United States are available only for male fertility. These are not genetic evaluations in the sense that they do not predict the reproductive performance of a bull's sons or daughters. Rather they evaluate the fertility of the bull as a service sire. In the United States, estimated relative conception rate (ERCR) is computed for Jersey and Holstein sires. These evaluations are "relative" rather than absolute measures because they contrast the nonreturn rates among bulls within herds and aggregate these contrasts across herds. Data are from first services in commercial herds in the DHI system (Dairy Records Management Systems, 1999). The data are limited by the fact that many producers do not report service sires and breeding dates in their DHI records. Estimates are adjusted for the cows' early lactation energy-corrected-milk production, lactation number, stage of lactation, month of breeding, herd, and year. Only services reported in the most recent 3 years are included in the evaluation.

The frequency distribution for ERCR of active AI Holstein bulls is in Fig. 8-5 (Dairy Records Management Systems, 1999). The nonreturn rates for the best bulls are 11% higher than the worst bulls; 90 percent of bulls fall between −1 and +4. Reliability of ERCR and the number of first services on which the evaluation is based are published with ERCR. Results are published only for bulls with more than 300 first services. Reliabilities range from 48%, with 300 services, to 99% when more than 15,000 services are reported. Because of the limit of 300 services and the relatively rapid turnover of active AI bulls, ERCR results are available for only about one third of active bulls.

ERCR, when it is available, should be used as a secondary criterion for sire selection; primary selection should be based on the yield traits. Research has shown that each point of increase in ERCR has a value of about $2 in reduced reproductive costs in herds with 50% estrus detection rate and 50% conception rate per service (Pecsock et al, 1994). In other words, a producer could afford to pay up to $10 more per unit of semen for bulls with ERCR +3 compared with bulls with ERCR −2 (other factors being equal). Premiums of up to $5 per ERCR point per unit of semen are justified in herds with low (30%) estrus detection rate and low concep-

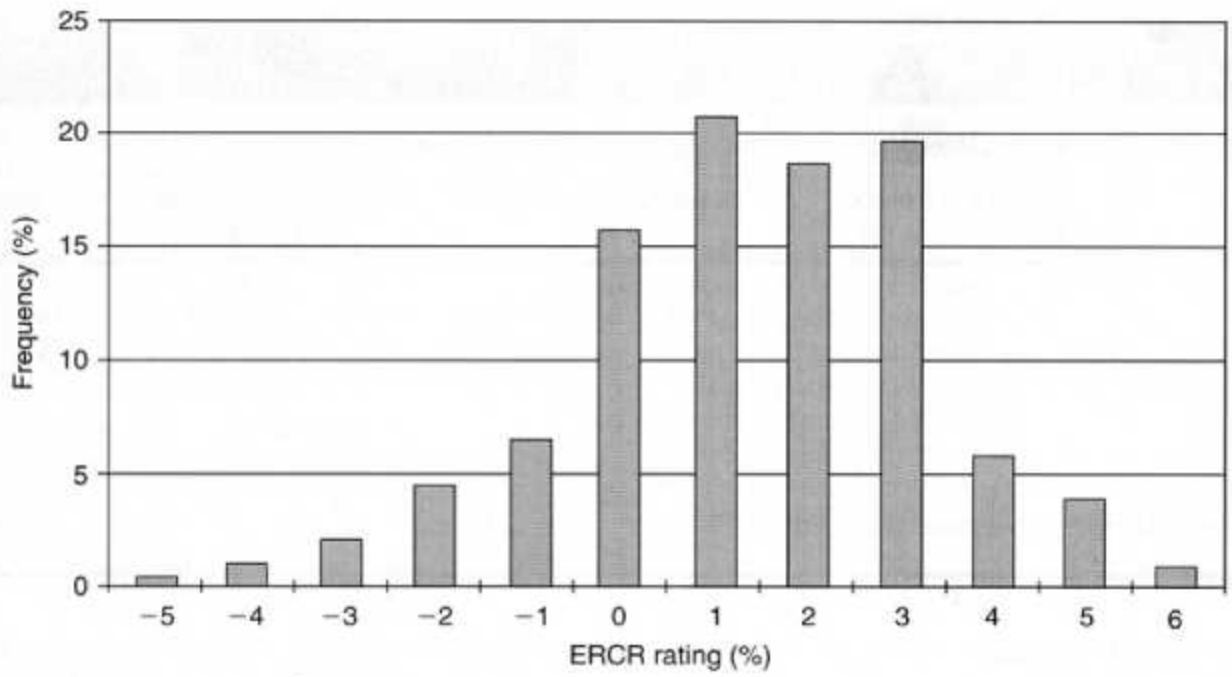

FIG. 8-5 Frequency distribution for estimated relative conception rate *(ERCR)* for active artificial insemination Holstein bulls in the United States. (Data compiled from Dairy Records Management Systems: AI sire fertility summary. Available at http://www.drms.org/sire.htm [accessed April 9, 2000].)

tion rate. The ERCR evaluations are more useful when choosing sires to breed milking cows because conception rates are higher in heifers. Also, bulls with the combination of high ERCR and low semen cost should be chosen to breed cows with poor reproductive performance.

MULTIPLE TRAIT SELECTION

With so many traits to consider when selecting sires, how can producers simplify the process and make profitable decisions? Two screening approaches are popular for reducing the long list of available bulls to a short list for more detailed consideration. These approaches are independent culling levels and selection indexes.

The culling level approach is perhaps the more intuitive one. It involves setting a lower limit for several traits; candidate sires are those that exceed the culling levels for all the traits. For traits such as SCS or calving difficulty for which lower values are more desirable, upper limits rather than lower limits are set. This approach is easily applied in spreadsheets and databases; also, it is used in many of the popular sire selection software applications.

Setting the culling levels is not easily optimized from an economic perspective. The principal disadvantage of the culling level approach is that some bulls outstanding for an economically important trait may be disregarded because they are below the culling limit for a trait of lesser importance. Several cautions should be observed when culling levels are established. These practices avoid some of the most serious problems in use of culling levels:

- Use culling limits for only a few, and only the most important, traits; avoid the temptation to set a culling level for every trait.
- Consider percentile ranges of PTAs, such as those in Table 8-12, as a guide in setting culling limits; without this guide the culling limits are highly arbitrary and may lead to overemphasis on unimportant traits and underemphasis on the most important traits.
- Set higher limits relative to the percentile ranges for the most important traits; use lower relative limits for less important traits.
- Update culling limits each year to stay current with genetic gain and genetic base changes.
- Try several sets of culling limits to find a desirable combination; look at the characteristics of bulls that are eliminated by the culling levels as well as the bulls that exceed the limits.

The selection index approach is preferred as a tool for screening sire lists. Research has shown that when economic values of traits are known, selection index will lead to selection of animals with a higher average economic merit than the culling level approach (Hazel et al, 1994; Hazel and Lush, 1942). Selection indexes combine the PTAs for several traits into a single number; each trait is weighted in proportion to its economic value. Sires are ranked on the index, and the highest ranking sires are chosen. In effect, a culling level can be set for the index alone. It is not necessary—in fact it would be redundant—to simultaneously set culling levels for an index and traits that are included in the index.

Specialists have developed a variety of selection indexes for different purposes. These are widely published for use by producers. Selection indexes are modified from time to time as new traits are introduced into the genetic evaluation system, as new understanding of the economic values of traits is gained, and as economic conditions change. Each country has developed its own selection indexes that correspond to local economic conditions and breed improvement philosophies.

Net merit index, developed and published by the USDA Animal Improvement Programs Laboratory, is widely used by commercial producers in the United States. This index combines PTAs for milk yield, fat yield, protein yield, SCS, and PL. This index is formulated in terms of net dollar income over feed cost per lactation. The formula for net merit (NM in the following equation) is as follows:

$$\begin{aligned} NM = {} & (\$0.022 \times \text{PTA milk}) + (\$0.56 \times \text{PTA fat}) \\ & + (\$1.40 \times \text{PTA protein}) + (\$11.30 \times \text{PTA PL}) \\ & - [\$28.22 \times (\text{PTA SCS} - \text{BA SCS})] \end{aligned} \quad [3]$$

where BA SCS represents breed average SCS, the genetic base for SCS; the genetic base for other traits is 0. The negative economic value for SCS reflects the fact that lower PTAs for SCS are desired. This index is currently undergoing review and revision (VanRaden, 2001).

Downloaded from Vet-eBooks.com

TABLE 8-14

Actual and Relative Economic Weights for Traits in Net Merit Index

Trait	Actual Economic Weight ($/unit)	Standard Deviation of PTA	Economic Value ($/SD)	Relative Economic Weight
Milk yield (lb)	.0217	800	17.36	3.1
Fat yield (lb)	0.56	30	16.80	3.0
Protein yield (lb)	1.40	25	35.00	6.2
Somatic cell score	−28.22	0.2	−5.64	−1.0
Productive life (mo)	11.30	0.9	10.17	1.8

PTA, Predicted transmitting abilities; *SD*, standard deviation.

The traits in net merit differ widely in the amount of genetic variation among animals (Table 8-12). Comparing economic weights in the formula for net merit makes it appear SCS is emphasized more heavily than production or PL; in fact, the opposite is true as illustrated in Table 8-14. Standard deviations for transmitting ability are shown in the third column of Table 8-14. Multiplying the actual economic weights in the index by the standard deviations gives the dollar value per standard deviation for each trait. Dividing the economic value per standard deviation for each trait by the economic value per standard deviation for SCS leads to the relative economic weights for the traits shown in the last column of Table 8-14. The economic weights for PL and SCS are based on limited research. The reader might speculate that these nonyield traits may have more economic importance than the index allows. However, one reason for the strong emphasis on the yield traits is their large standard deviation relative to the standard deviations for PL and SCS. Nature simply offers greater opportunity for improvement of the yield traits.

Another index widely used by registered Holstein breeders in the United States is the Type-Production Index (TPI), a name trademarked by Holstein Association USA. The TPI is formulated with relative rather than actual economic weights. The PTA for each trait is multiplied by a relative economic weight and divided by the standard deviation of PTA. The formula is:

$$\begin{aligned}\text{TPI} = \big(\{[(3 \times \text{PTA Protein}) / 19] + [(1 \times \text{PTA Fat}) / 22.5] \\ + [(1 \times \text{PTA Type}) / 0.7] + [(0.65 \times \text{UDC}) / 0.8] \\ + [(0.35 \times \text{FLC}) / 0.85]\} \times 50\big) + 576\end{aligned} \quad [4]$$

The udder composite (UDC) index combines the PTAs for six udder traits; the feet and legs composite (FLC) index is an index of four feet and leg traits. Both composite indexes weight the component traits in proportion to their correlation with herd life (Holstein Association USA, 1999). The coefficients 50 and 576 in the TPI formula only change the mean and range of index values; they have no influence on the relative weights of the traits. Each breed association publishes its own production and type index. Indexes similar to net merit and TPI are published in other countries.

Clearly, one index is not appropriate for all herds. For most commercial producers the index of choice would likely be net merit. Registered breeders will want to use their breed association's production and type index. A selection index should be chosen that is consistent with the producer's strategy for herd improvement. An appropriate selection index is an excellent tool for screening bull lists, (i.e., to quickly reduce the number of bulls for detailed consideration to a manageable number). Among bulls with high index values those with other desired characteristics such as low calving difficulty, low semen cost, low SCS, desirable type, high protein percent, and absence of genetic defects should be chosen. This approach ensures that the bulls ultimately selected are among the highest available for traits that are most important and places secondary consideration on the secondary traits.

BALANCING GENETIC MERIT AGAINST SEMEN COST

Balancing genetic merit against semen cost is an important economic consideration for herd managers. Investment analysis procedures have been developed and can be applied to this question (Everett, 1975; McGilliard, 1978). Herds with poor conception rate and high calf mortality expend more units of semen per heifer that enters the milking herd; herds in this category will realize a lower return on their semen expenditures, and these herds need to be sensitive to semen costs. Conversely, herds with high levels of reproductive performance that bring a high percentage of heifers born into the milking herd achieve a good return on semen investments; these herds can afford higher semen costs and should be more sensitive to the genetic differences among bulls. Financial health of the dairy enterprise is another important consideration. Herds with cash flow problems or high debt/equity ratios must focus on quick returns to the semen investment as in all other investments. Such herds must be more sensitive to semen costs and less sensitive to genetic values than herds with lower debt loads or cash flow concerns.

Not surprisingly, the decisions just detailed are complicated by the fact that bulls with better genetic merit come at a higher cost; they are in greater demand because of their higher genetic value, and high demand drives up semen prices. Semen prices are rather sensitive to the economic principles of supply and demand. Another complicating factor is that semen prices for the same bull can vary from day to day and area to area. A good buy on a particular bull on a given day may not be a good buy for another time or another herd.

Producers should avoid buying semen strictly on price. The lowest-cost semen from a genetically inferior bull indeed may be overpriced in comparison to somewhat higher-cost semen from a bull with substantially better genetic merit. "Overpriced" here means that the lower-cost bull may provide a lower rate of return on investment than the genetically better bull with higher cost. The converse can be true also; top genetic bulls can be overpriced in comparison with other bulls with substantially lower semen costs and only marginally lower genetic values.

TABLE 8-15

Average Semen Price and Genetic Merit of Top 100 Holstein Bulls Selected on Expected Net Revenue for Three Levels of Herd Management

Management Level	Net Semen Price	PTA Merit Index	PTA Milk Yield	Protein Yield
High	19.96	213	2304	75
Average	19.25	210	2260	74
Low	17.50	201	2159	71

Compiled from Rogers GW: Expected net revenue, 1999. Available at http://www-das.cas.psu.edu/grogers/sire (accessed March 6, 2001).
PTA, Predicted transmitting abilities.

All herds have cows with reproductive problems; in general, these cows should be mated to bulls with lower-cost semen because as a group, these inseminations will produce a lower return per unit of semen. A portion of the semen purchase on any farm should include a certain percentage of low cost semen for use on cows with known reproductive problems.

Although much research has been performed on analysis of semen investment decisions (Blake, 1992; Everett, 1975; McGilliard, 1978; Rogers, 1990; Wilcox et al, 1984), rather limited software is available to support these decisions. Perhaps most prominent is the expected net revenue (ENR$) program, which is accessible through the Internet (Rogers, 1999). The program offers a choice of three selection indexes and two criteria by which to rank bulls; users may specify a culling limit for one trait from a choice of several traits.

The ENR$ computer program computes the expected net revenue from one unit of semen for a bull as a difference from the expected net revenue of a non-AI bull. The calculations consider the bull's semen cost, ERCR, and PTAs for the yield traits, PL, and SCS. The bull's genetic merit is expressed in the performance of his daughters and their descendants. Net revenues from the bull's descendants are projected for several future years and discounted to present value; the discounted net revenues are accumulated over time (Rogers, 1990). Discounting accounts for the fact that a future return on a current investment must be greater than the investment cost to produce a return on the investment. In other words the expectation of a future revenue has less current value than a current revenue of the same amount.

The ENR$ results can be computed for three levels of herd management. Herd management levels depend on the herd's conception rate and success of rearing herd replacements from birth to milking age. Although financial aspects of the enterprise are not factored into the calculations, herd management level can, to a limited extent, be a proxy for financial well-being. Herds with weak financial condition should choose the average or below-average level of herd management, even if reproductive and replacement management are excellent. The program is not designed to handle the combination of low herd management and weak financial condition.

Table 8-15 shows the average semen cost and genetic merit for the 100 highest bulls for ENR$ under three management levels. The higher management option places less emphasis on semen cost and more emphasis on genetic merit in comparison with the lower management levels; as a result the high management option tends to select sires with higher average semen cost and genetic merit. Users in fact may want to use the higher management option to choose bulls for the best cows, the low management level to choose bulls for cows with poor reproductive success, and average management level for the remainder of the herd. Because conception rate in heifers is substantially higher than in cows, a higher management level may be advantageous when selecting bulls to mate with heifers.

The ENR$ is another tool, like the selection indexes, for screening lists of bulls. It uses a selection index as the measure of overall genetic merit. The advantage of methods like ENR$ over a selection index is that they consider semen cost and rank bulls on basis of income over semen cost.

GENETIC DEFECTS

A veterinarian may encounter animals affected by genetic defects in routine practice and be called on to characterize a condition or diagnose a cause. Fortunately, such occurrences are rare; unfortunately, the rarity can leave the veterinarian unprepared for the task. A definitive diagnosis requires detailed analysis for which the cost often exceeds the willingness of a client to pursue a cause. As a result many defects remain undiagnosed or undiscovered. Nicholas et al (2000) have compiled a comprehensive database of references for genetic defects in livestock. Dennis (1993) provides an extensive presentation of genetic and other congenital defects in livestock.

Genetic defects are an important consideration in sire selection and mating. These cause various degrees of morbidity and mortality. Some are lethal in utero or soon after birth; others cause unthriftiness and make the animals useless in an economic enterprise. Most often, the inheritance pattern for genetic defects is autosomal recessive at a single locus. "Autosomal" means that the condition exists on one of the autosomal chromosomes instead of the X or Y chromosomes; as a consequence, inheritance is similar in males and females. "Recessive" means that the defective allele must be present in the homozygous state (i.e., it must exist on both chromosomes to cause the defective phenotype). The normal allele is "dominant" in this inheritance pattern because animals with one normal allele and one defective allele exhibit the normal phenotype; these animals are called "carriers" because they appear phenotypically normal but carry the defective allele. Although some genetic defects do exhibit more complicated inheritance patterns, the focus here is on those with the autosomal recessive pattern. In this section, a few of the defects that attained prominence in recent decades are reviewed.

Some Common Genetic Defects

Bovine leukocyte adhesion deficiency (BLAD) is due to a mutation in the gene that encodes the CD18 cell surface glycoprotein. The mutation causes reduced expression of adhesion molecules on leukocytes and multiple defects in leukocyte function. Neutrophils of affected animals are unable to migrate out of the bloodstream to enter infected tissues and destroy invading pathogens. Consequently, BLAD animals have frequent, recurrent bacterial infections, delayed wound healing, and persistent, extreme neutrophilia. Affected animals grow poorly, and the condition is essentially lethal by 6 months of age. A DNA test can identify carriers of the mutant allele. A survey in 1992 found a carrier frequency of 14% among U.S. Holstein bulls in AI and nearly 6% in Holstein cows. An active screening and culling program has nearly

Downloaded From Vet-e-Books.com

eliminated the defective allele from the AI sire population. The defective allele was traced to Osborndale Ivanhoe, a bull born in 1952 and used extensively in AI (Shuster et al, 1992).

Animals affected with citrullinemia appear normal at birth but become depressed within 24 hours. These animals are unable to eliminate ammonia, and they display neurological symptoms that become progressively worse leading to death within 1 week after birth. This condition is caused by a mutation in the gene that codes the urea cycle enzyme argininosuccinate synthetase. Citrullinemia became prominent in Holsteins in Australia where more than 10% of cattle were carriers. The mutation was traced to a bull, Gray View Criscross, bred in the United States. This bull was never widely used in his home country, and the condition never reached a serious prevalence outside of Australia. Carriers can be detected by a standard DNA procedure that identifies the specific mutation responsible for the condition (Robinson et al, 1993).

Syndactyly, or "mulefoot," is characterized by fusion of the claws on one or more legs. The condition is found in many breeds and cattle populations. This defect gained prominence in the United States in the 1960s by extensive use of a carrier Holstein AI bull. At that time, progeny testing was the only method for detecting carrier animals. Currently, the defective gene is known to exist on chromosome 15, but the specific locus has not been identified (Nicholas et al, 2000).

Deficiency of uridine monophosphate synthase (DUMPS) was traced in the United States to the AI bull Skokie Sensation Ned. The enzyme uridine monophosphate synthase catalyzes the conversion of orotic acid to uridine monophosphate, the precursor of all pyrimidine nucleotides, and is required for normal RNA and DNA metabolism. Embryos that are homozygous for this mutation die at about 40 days after conception. A consequence of mating a cow and bull that are both carriers of the defective allele is a subtle reduction in fertility resulting from early embryonic mortality. Lactating carrier animals exhibit half the normal enzyme activity and elevated orotic acid in both milk and urine. The latter two characteristics facilitate identification of animals with the carrier genotype. Carrier animals appear to have normal health and milk production characteristics. Carriers can be detected by DNA analysis or by orotic acid levels in milk or urine. A 1987 survey of active AI Holstein bulls in the United States found 1.4% were carriers (Shanks et al, 1987).

Progressive degenerative myeloencephalopathy, commonly known as "weaver," is a genetic defect in U.S. Brown Swiss cattle. This condition is particularly costly because symptoms only begin to appear at 5 to 8 months of age. Affected animals have difficulty controlling their rear legs, exhibit a staggering gait, and become progressively less able to walk or stand. The gene that causes the defect appears to be linked closely with a major gene for milk production. Results indicated that daughters of carrier bulls inheriting the defective allele from their sires produced 1500 lb more milk than their half-sibs inheriting the normal allele. This research found the weaver gene frequency in the cow population increased over time with frequency approaching 9% at the end of the study (Hoeschele and Meinert, 1990). Strong selection for milk yield, coupled with the apparent close linkage between the undesirable weaver allele and a major allele for high milk yield, likely propelled increased frequency of the weaver allele. The weaver allele occurred in many of the prominent Brown Swiss sires. Subsequent testing and culling of carrier bulls has reduced the occurrence of this defect.

Dynamics and Control of Genetic Defects

The prevalence of any one genetic defect follows a characteristic pattern over time. Such defects are numerous, but their allele frequencies and the frequency of affected animals are low and seldom observed (Dennis, 1993). Only when a carrier bull is widely used in AI does the frequency reach a noticeable level. In some cases the frequency may increase over two or three decades—four to six cattle generations—before it becomes apparent. Some level of inbreeding to the original carrier animal is often involved before the recessive allele appears in homozygous genotypes and the consequent defective phenotype. Studies of the pathology and inheritance of a defect may require another decade before control strategies can be developed.

Although AI is a powerful means of increasing the frequency of genetic defects, it is equally powerful for eliminating them. The AI industry and breed associations cooperate to test and identify carrier sires. In many cases the AI organization will immediately cull any known carrier bulls. Avoiding the use of carrier bulls (i.e., using only known homozygous normal bulls) leads to no further occurrences of defective genotypes. When carrier bulls are not used, the frequency of the defective allele in the cow population decreases by 50% of the population frequency of each cow generation. Although the defective allele is never completely removed from the population by this process, its frequency is reduced to low levels. When carrier bulls are continued in AI service, their carrier status is widely published. In this scenario the defective allele frequency may continue to increase or it may decrease at a slow rate depending on the number of progeny produced by carrier bulls.

In the United States, breed associations code animals with genetic defects (Table 8-16). These codes are published as an integral part of the animal's registered name. One set of codes indicates animals that are carriers of the defect. Another set of codes identifies animals that have been tested for the defective allele and found to be homozygous for the normal allele. Virtually all AI sires are tested for any defects they may have inherited from carrier ancestors. Few cows are tested. The absence of a code means the animal is not known to be a carrier, has not been tested for carrier status or is not likely to be a carrier based on pedigree data.

There are two strategies producers can use to control the frequency of genetic defects. The most effective strategy is to use only bulls known to be homozygous for the normal allele; this completely avoids the possibility of producing defective offspring and reduces the frequency of the defective allele in the herd. The second strategy, which allows the use

TABLE 8-16

Codes to Identify Animals Known to Be Carriers of Genetic Defects or Tested and Found to Be Homozygous for the Normal Allele

		Status Code for Genetic Defect	
Genetic Defect	**Breed**	**Carrier**	**Tested Normal**
BLAD	Holstein	BL	TL
DUMPS	Holstein	DP	TD
Mule foot	Holstein	MF	TM
SMA	Brown Swiss	M	TM
Weaver	Brown Swiss	W	TW

BLAD, Bovine leukocyte adhesion deficiency; *DUMPS*, deficiency of uridine monophosphate synthase, *SMA*, spinal muscular atrophy.

Downloaded From Vet-eBooks.com

of heterozygous, carrier bulls, is to avoid mating carrier bulls to daughters or granddaughters of known carrier bulls. Although the second strategy tends to increase frequency of the defective allele in the herd, it is not likely to produce affected animals. Affected animals result when both parents are carriers; if either parent is homozygous for the normal allele, no affected progeny can result.

EVALUATING A HERD'S GENETIC STATUS

Identifying problems in herd management and opportunities for improving herd profitability requires assessing the current situation and comparing these findings against industry benchmarks. Two approaches to evaluating a herd's genetic status are presented. One approach is based on herd average PTA of cows' sires; the other is based on cows' own PTAs. Each method requires its own benchmark for comparison. A crucial requirement for both methods is the availability of records. For some herds sufficient records may not exist for either method. Because the national genetic evaluation program is based on data from DHI herds, these herds have the best opportunity for evaluation of genetic status.

Average Sire Predicted Transmitting Ability

Average PTAs of sires and service sires directly measure genetic inputs. Although the sires represent only half of the genes that form a new generation of animals, they account for most of the genetic improvement. In an AI-sired population, more than 90% of genetic improvement is attributable to sire selection. Sires are proven to a higher level of reliability than cows, and only the most elite sires and dams are needed to produce a new generation of young bulls. While the average PTA of sires of milking cows represents decisions made years ago, the average PTA for service sires represents recent decisions. To identify and correct genetic problems in a herd, it is essential to understand and, if warranted, change the manager's sire selection policies.

Many DHI processing centers provide a summary of average sire PTAs similar to that in Table 8-17. Typically these reports show average PTAs for service sires (i.e., sires of calves in utero and other recent inseminations) and several age categories for heifers and milking cows. The producer must report sire identification for individual animals to enable the DHI processing center to compile this report. To assess the quality of this report for a particular herd, it is important to determine what percentage of animals are included in these averages. A low percentage of reported sire identifications in any age category limits the usefulness of the report. Because of the constant increase in average PTA of bulls available through AI, a trend of increasing average PTA with younger age groups, as in Table 8-17, will be seen in herds that are making good genetic progress.

For herds not on the DHI program, evaluation of a herd's genetic status requires additional work. If AI sires are used and if service sires and sires of animals in the herd have been recorded, the task is not difficult. Tables such as Table 8-17 can be constructed by hand. PTAs of AI bulls can be obtained from the bull stud or from one of the web resources (e.g., http://aipl.arsusda.gov/main/queries.html). For traits and years of interest, calculate average PTA of sires in categories of animals' years of birth; the average should be weighted by the number of animals or services by each bull. Most important is the average PTA of recently used service sires because this documents recent decisions. Without sire identification, no assessment is possible.

If the herd uses non-AI bulls, it may still be possible to obtain a genetic measure of the genetic merit of the herd; whether this can be done depends on the source of the bulls. If the bulls are from a purebred herd that participates in the DHI program, it will often be possible to identify the sire and dam of the non-AI bull, and the PTAs of the sire and dam can be obtained from http://aipl.arsusda.gov/main/queries.html. A PTA for the non-AI bull is not likely to be available, but analysts can calculate a PA for the bull as follows:

$$PA = [PTA\ (sire) + PTA\ (dam)] / 2 \quad [5]$$

Reliability of the PA is as follows:

$$Reliability\ (PA) = [Reliability\ (sire\ PTA) + Reliability\ (dam\ PTA)] / 4 \quad [6]$$

A table such as Table 8-17 can be compiled using PAs of sires and service sires. For herds that use both AI and non-AI bulls, PAs and PTAs can be co-mingled in the same herd average because the genetic base is the same in all cases.

Herd Average Cow Predicted Transmitting Ability

Herd average cow PTAs for the yield traits provide an easy opportunity to evaluate a herd's genetic status. Some DHI processing centers provide a summary similar to Table 8-17 for average PTA of cows. Only cows with reported sire identification can be included in a summary of this kind. Cows without reported sire identification cannot contribute to the genetic evaluation system; nor can such cows have their own PTA. Average PTA can be calculated for all cows in production, or a separate average could be computed for each year

TABLE 8-17

Typical Dairy Herd Improvement Summary of Herd Average Sire Predicted Transmitting Abilities.

Genetic Group	Total Number	Milk (lb)	Fat		Protein		Net Merit ($)
			%	lb	%	lb	
Service sires	142	+2049	−0.06	+62	+0.02	+69	+250
Heifers	221	+1479	−0.01	+51	+0.03	+52	+190
First lactation	98	+1414	+0.00	+51	+0.01	+46	+177
Later lactation	171	+ 841	−0.04	+40	+0.03	+32	+123
All cows	269	+1049	−0.03	+44	+0.02	+37	+142
State average	—	+ 715	+0.00	+26	+0.02	+25	+ 88

Downloaded From Vet-eBooks.com

by cows' year of birth. Because of rapid genetic advance through AI, cows born recently should have higher average PTA than cows born longer ago. A listing of PTAs for each cow in the herd is available from DHI processing centers. To evaluate the quality of this measure, observe the percentage of cows for which PTAs are available. If this percentage is low, other means of herd evaluation will be necessary. Nevertheless, the herd average is a good measure of the genetic merit for that portion of the herd that does have PTAs. A report of this kind is not possible for non-DHI herds.

This approach to genetic evaluation of a herd is appealing because animals that contribute to herd average production can be included in the genetic measure of the herd. A disadvantage of this method is that the breeding decisions reflected in this measure were made from 4 years to as many as 10 years ago, depending on the ages of the cows. Whereas average sire PTA measures genetic inputs, herd average cow PTA measures the outcomes of the herd manager's breeding decisions. A year-by-year summary of the herd lactation average and average PTA demonstrates progress in both genetics and management. This can be a great source of satisfaction for a producer to trace the herd's genetic progress over time.

Benchmarks

Assessing a herd's genetic status involves comparing the herd average PTA with an appropriate benchmark. Because genetic improvement for the yield traits is so rapid, it is important to use benchmarks that correspond to the animals' years of birth. In addition, it is crucial that herd average PTAs and benchmarks are from the same genetic base.

The average PTA of currently active AI bulls is an appropriate benchmark for herd average PTA of service sires; recent service sires are drawn from this population of active AI bulls. Among several other sources, this benchmark can be found for all breeds in the United States at the USDA website (ftp://aipl.arsusda.gov/pub/bulls/evalrpt.txt). Because of the large number of AI bulls marketed in the industry, it should seldom be necessary to use an individual bull that is below average for the yield traits. Also, because better bulls are used more heavily in the industry than poorer bulls, the simple average of bulls' PTAs that is calculated by USDA is below the average PTA weighted by units of semen sold. For these reasons, the herd average PTA of service sires should be above the national average PTA of active AI bulls.

Benchmarks for PTAs of sires of milking cows can be found at the website http://aipl.arsusda.gov/main/data.html#gtrend. This site tabulates national average breeding values of cows and their sires by year of birth. The national average breeding values of sires must be multiplied by one half to make the results comparable with the herd average PTA of sires of cows (see Equation 1). Comparisons between herd average and national average should be made for the same year of birth. This comparison shows only the extent to which the sires of cows in a herd are above or below the national average; it's not possible to determine where a herd would rank among all herds.

Benchmarks for cow PTAs are available from the USDA website listed in the previous paragraph. In addition to sire breeding values, this site shows national averages for cow breeding values by year of birth. Similar tables are available for all dairy breeds and are updated quarterly as new data are added to the system. As genetic base changes are introduced, individual cow PTAs and national averages are updated simultaneously. Comparison of the herd average cow PTA with the national average breeding value requires the conversion between breeding value and transmitting ability shown in Equation 1.

PLANNING A HERD'S GENETIC FUTURE

Planning genetic improvement is a process that should be carried out with due consideration; this is too important to leave to the whims of fate! Two kinds of decision making must be distinguished. Long-term decisions are established at the outset and reviewed periodically but changed infrequently. Short-term decisions are the sire selection and culling decisions that are made almost daily. The long-term decisions set the direction of genetic change and reflect the herd manager's strategy for improving long-term profitability for the dairy enterprise. Genetic improvement itself is a gradual, long-term process; the genetic background of a herd cannot be changed overnight. Through sire selection, only half of the genes in the herd are replaced in each 4- to 5-year generation of cows. One half of the genes in the current herd are from the cows' sires; one quarter of the genes are from the cows' maternal grandsires (e.g., sires of the cows' dams); one eighth of the genes are from the sires of the cows' maternal granddams; and so on. Genetic decisions made more than 10 years ago still affect performance of today's cows; genetic decisions made today will influence performance of the herd 10 years in the future. Both long-term and short-term genetic decisions must be made in this context. Short-term decisions that follow different goals from one year to another will produce a slower rate of improvement toward the desired goal. It is essential to make short-term decisions that are consistently based on pursuit of the long-term objectives.

Long-Term Decisions

The long-term decisions require answers to questions like these:

- What is the relative economic importance of milk volume, fat yield, and protein yield traits in the milk market, now and in the future?
- How important is type in profitability of the herd's economic enterprises? Does the herd plan to sell purebred animals based on a high quality of body conformation? Will surplus animals be merchandised mostly on their production or type characteristics? Is type valued only as it contributes to longer herd life?
- What is the manager's desired balance between increasing revenues (e.g., increasing production) and reducing costs, especially health and reproductive costs?
- What are the current problems in the herd that can be corrected realistically by sire selection?

With answers to these business and strategic questions, the manager can proceed to make rational, long-term decisions for the breeding plan. These decisions include the following:

- Which of the several selection indexes published in the industry is most consistent with the milk market and business strategy of the herd? This index will be used as a tool for screening lists of available bulls and as an aid in selecting individual bulls.
- Does participation in the young sire progeny testing programs of the AI industry contribute to the genetic and business goals of the herd? What are the obligations and benefits of the young sire programs?
- To what extent and under what conditions will AI and non-AI bulls be used? How does each contribute to the genetic and business goals of the herd? What changes in facilities and management system are needed to effectively use AI and non-AI bulls?
- What is the importance of cost control versus long-term genetic improvement? As a business decision, what is the manager's relative sensitivity to semen price differences versus genetic differences among bulls?

Downloaded from Vet-eBooks.com

- Does crossbreeding contribute to the business and genetic goals of the herd?
- If breed crossing is not desired, what is the herd's strategy and goal for controlling inbreeding? Would a corrective mating program contribute to the herd's genetic and business success?
- Have sires known to be carriers of specific genetic defects been used in the past? It would be important to avoid using new sires that carry the same defects.

Short-Term Decisions

The most important short-term decisions involve selection of bulls. Outlining a routine process for selecting bulls will enable the manager to stay focused on long-term goals and avoid quick, impulsive decisions that are not consistent with the long-term plan. The elements of this process should include the following:

- Determine the amount of semen needed for the current breeding period and the number of bulls from which to purchase semen. Do not purchase semen too many months in advance of use because genetic evaluations are updated periodically; make selections based on the most reliable information. Do not buy more semen than needed; unused semen is costly!
- Decide on semen sources and whether AI or non-AI bulls are to be used.
- Among all bulls provided by the chosen sources, rank them on the chosen selection index.
- Based on this ranking, select three to five times more bulls than will be purchased; consider only these bulls in further selection decisions.
- Remove from the list any bulls that are carriers of known genetic defects or that have extremely low fertility ratings, extremely high SCS, extremely high calving difficulty, or other extremes that are to be avoided; this step should focus only on the extreme 5 or 10 percent of bulls. Also remove any bulls whose semen cost is so high as to not be warranted by their genetic merit, even as mates to the best cows in the herd.
- Identify bulls with below average calving difficulty ratings; about 40% of the semen purchase should be from this group for mating with nulliparous heifers.
- Identify bulls with high fertility rating and low semen cost to mate with cows having reproductive problems; perhaps 20% of the semen purchase would be from this group. Reduce the list of chosen sires to the desired number considering the selection index and PTAs for type traits, fat or protein percentage, SCS, semen cost, and other desired characteristics.
- Finally, consider reliability of PTA. Among the selected bulls, purchase less semen from those with low reliability (e.g., below 70%) and more semen from bulls with high reliability (e.g., above 80%). Also, reconsider semen cost at this final stage; to reduce average semen cost, consider purchasing less of the most expensive bulls and more of the intermediate- and lower-priced bulls.

The process just described is designed to avoid some of the common errors in decision making. Perhaps most important is that all bulls will be high for the chosen selection index and consistent with long-term goals. Reliability is considered only in the final stage of the decision process; producers often use it as an initial screening tool and place too much importance on it.

Expected Genetic Gain

There are two aspects to forecasting genetic gain. One aspect is the improvement in herd average that can be expected from sire selection. Genetic improvement in the herd average from the current cow generation to the next cow generation can be predicted by Equation 7:

$$\text{Average PTA of service sires} - \text{Average PTA of cows} = \text{Genetic gain} \quad [7]$$

Genetic gain is the increase in performance of herd replacements compared with the performance of their dams. It is not uncommon for this difference to exceed 1000 lb milk, and with careful attention to sire selection, the difference can exceed 1500 lb. Thus, for a typical mating, the daughter's genetic merit will be 1000 lb milk above her dam's genetic merit. The actual production of the daughters will typically be even more than what is predicted by Equation 7 because of improvements in feeding, management, and health care that are made during the 4 or 5 years between the dam's first lactation and the daughter's first lactation.

It is worth noting that herds with previously poor sire selection practices can make greater genetic improvement from one generation to another than herds with previously excellent breeding programs. In Equation 7, notice that if average PTA of service sires is the same for two herds, genetic gain is larger for the herd with lower average cow PTA. The lower herd will realize a greater genetic response from sire selection. Over a period of three or four cow generations—15 to 20 years—a herd with low average genetic merit can approach the genetic level of herds with top breeding programs.

The second aspect of genetic gain deals with the question of whether the response to sire selection is the same in well-managed and poorly-managed herds. Geneticists work from the assumption that genetics and environment operate independently on animal performance. This means that an improvement in feeding, management, or health care will produce the same desired effect in genetically elite animals as it does in animals with average or below average genetic value. It also means that the difference in average performance between daughters of any two bulls is the same in poorly managed herds as in herds with excellent management.

This issue was thoroughly examined using data from Holstein cows throughout the United States that calved in 1979 (Powell and Norman, 1984). Regressions were calculated within herd of cows' milk yields on their sires' PTAs for 10 strata of herd average yield. The strata were increments of 1100 lb milk from less than 12,000 lb to more than 21,000 lb. The results are shown in Fig. 8-6. In the mid-range of herd averages, those from 12,000 to 15,000 lb, a 100-lb difference in the sire's PTA was associated with about a 100-lb difference in daughter milk yield, as expected. Interestingly,

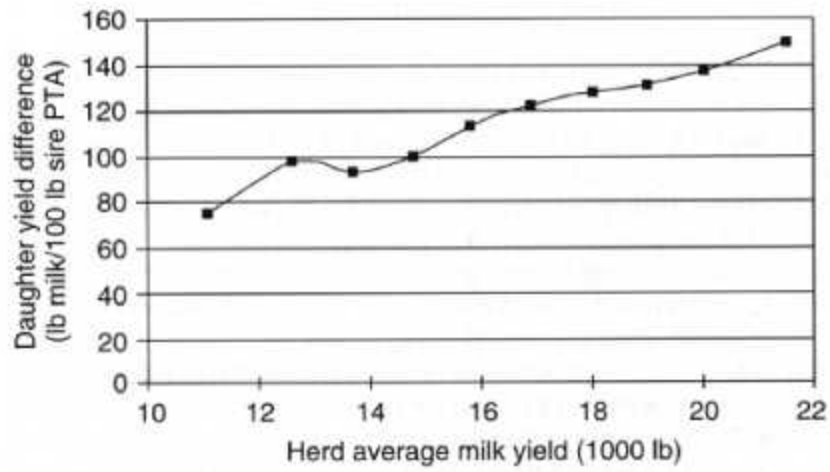

FIG. 8-6 Differences in daughter milk yield per 100-lb difference in sire predicted transmitting ability *(PTA)* milk by level of herd average milk yield. (Adapted from Powell RL, Norman HD: *J Dairy Sci* 67:2021-2027, 1984.)

Downloaded From Vet-eBooks.com

in the lowest group of herds, a 100-lb difference in sire's PTA resulted in only a 75-lb difference in daughter performance; and in the highest herds, a 100-lb difference in sire's PTA produced nearly a 150-lb response in production. This evidence indicates that environment and genetics operate in a somewhat multiplicative fashion: Genetic differences between bulls are amplified in herds with high management levels and diminished in low herds. Although two decades have passed since this study was conducted and the top tier of herds at that time are only average by today's standards, the principle still holds. In fact, research continues to demonstrate that heritability increases as breed average increases (Van Tassell et al, 1999).

SOURCES OF IMPROVED GENETICS

Three types of bulls are available and there is a legitimate use for each: AI proven bulls, AI young bulls, and non-AI bulls. Many herds use a combination of two or even all three types of bulls. The decision on which sources are best for a particular dairy depends as much on reproductive management as on genetic improvement goals. Successful use of AI requires careful observation of estrus. Estrous synchronization systems may be used as an aid to managing AI. The producer and veterinarian must collaborate to decide on a reproductive management program, including the decisions to use reproductive management technologies and the types of bulls to be used. Discussion here will emphasize the genetic aspects of these decisions.

Artificial Insemination Proven Bulls

Selecting proven AI bulls is one of the industry's best bargains for improving economic efficiency of dairy herds. The production advantage per lactation of AI bulls over their non-AI counterparts exceeds 1000 lb milk, 30 lb fat, and 30 lb protein with a revenue advantage of $120 per lactation (Animal Improvement Programs Laboratory, 1999a). This is a conservative measure because only the better non-AI bulls are evaluated through the national genetic evaluation system. Depending on how a producer selects natural service bulls, the revenue advantage for above-average AI bulls over nondescript non-AI bulls exceeds $200 per cow per lactation in many cases.

AI bulls are a proven commodity. The buyer acquires a wealth of information along with semen, and this information reduces some of the risks of herd management. Genetic merit of bulls for the most important performance traits has been measured with known reliability. AI bulls are tested for genetic abnormalities. Proven carriers of genetic defects are identified as carriers and bulls that are suspected carriers are tested for the defect and identified as noncarriers if appropriate. A calving difficulty rating is available for most proven AI bulls. A portion of bulls also is rated for fertility. A by-product of managing AI is an accurate record of breeding dates and the ability to project calving dates. This information enhances the manager's ability to manage length of the dry period and properly prepare the cow for calving and the beginning of a new lactation. This information enables the herd manager to avoid problems and make more profitable decisions.

Other advantages for AI include reduced risk of venereal and other infectious disease. Risk of injury from bulls on the farm is completely eliminated by 100% use of AI. It is impossible to place a value on risks such as these. The AI industry offers a wide selection of bulls with proven characteristics; no individual bull has a large impact on the herd. Non-AI bulls can leave many progeny in a herd and these progeny will inherit any undesirable characteristics of the bull; every bull, AI or non-AI, has some undesirable traits. The veterinary and feeding costs used for maintaining natural service bulls can often produce a greater return by milking more cows in place of the bulls.

Artificial Insemination Young Bulls

The AI industry uses well-established methods for developing proven AI bulls. The process begins by mating elite proven AI bulls with cows in the top 1% or 2% of the breed based on PTA. Matings are designed to produce young bulls with the highest possible genetic values. Bulls from these matings constitute the category young AI bulls. Semen is distributed for these young bulls as yearlings. Four years after the initial distribution of semen, daughters of these young bulls complete their first lactations and a PTA is computed based on both progeny and pedigree data. Only the top 10% of these progeny-tested bulls are promoted to active AI status. This final selection step adds around 1000 lb milk to the average PTA of bulls in active AI.

Distribution of semen for the young bulls is done randomly in cooperating herds to achieve an unbiased genetic evaluation of the bull. Usually, only five units of semen per young bull are distributed to each cooperating herd; in most cases this will result in only one milking daughter per herd. Cooperating herds provide data in a timely manner for production, calving difficulty, and other traits; the data are necessary for genetic evaluation of the bull. Herds on the DHI program with excellent record-keeping systems may qualify to cooperate in the young bull progeny-testing program of one or more AI companies. Compensation in the form of credits for service from the AI company is provided to the cooperating herds. Other herds, also, may purchase semen from these young bulls; semen price of young AI bulls is often substantially less than the price of proven bulls.

Genetic merit of the three categories of bulls can be compared directly using PA or PTA. For the most part, only proven AI bulls have genetic evaluations based on PTA; most young AI bulls and non-AI bulls are evaluated on PA as outlined in Equation 5. Research has shown that the PA of young AI bulls is directly comparable with the PTAs of proven AI bulls (Samuelson and Pearson, 1995; Weigel et al, 1995). Although the PAs and reliabilities of young bulls are available, the information is not as widely published as the PTAs of proven bulls. Producers can request this information from the AI firm. The PAs of young AI bulls compares favorably with the PTAs of proven AI bulls. In general the highest PTAs of proven bulls may be above the highest PAs of young AI bulls; however, the PAs of most young AI bulls are higher than the PTAs of lower ranking proven bulls.

Both PA and PTA are unbiased predictors of bulls' true transmitting abilities. Therefore subsequent PTAs of bulls are as likely to increase as decrease while new progeny records enter the evaluation system. The lower reliabilities of PA compared with PTA means that the changes in predicted genetic merit have a larger magnitude for PA than for PTA. In fact, the eventual PTAs of some young bulls will far exceed the PTAs of some of the current proven bulls; unfortunately, there is no way to forecast which young bulls will be the elite sires of the future. Because reliabilities of PA for young AI bulls are only around 30% to 40%, it is important to limit the use of individual young bulls. Several young bulls with high PAs should be used: When their daughters records are incorporated into PTA, their average PTA should not differ appreciably from their average PA, although individual bulls' PTAs may change considerably. By making only a few matings to each of several young bulls, the herd is not being subjected to great risk. A herd that uses young AI bulls may have some of the first daughters of the next generation of high-ranking active AI bulls.

Downloaded From Vet-e-Books.com

Non-Artificial Insemination Bulls

In spite of the great advantages for AI bulls, the use of non-AI bulls is clearly a better choice in herds that experience difficulty in managing AI. When labor or skills are inadequate to detect estrus, well-chosen non-AI bulls may lead to a more profitable dairy enterprise. Three considerations are important when selecting non-AI bulls: semen quality, bull health, and genetic merit. Failure to test semen quality subjects the herd to great risk of reproductive failure. Several months can pass before poor fertility of a bull is discovered. Also, it is important to buy bulls that are free of venereal and other infectious diseases. The spread of disease from herd to herd and animal to animal can be a costly risk when using non-AI bulls. Veterinarians and herd managers should insist on disease tests before bulls are purchased to reduce the introduction of costly infections.

Producers must be strongly encouraged to place a high value on genetic merit when selecting non-AI bulls. Too often, buyers of non-AI bulls fail to set discriminating standards for the genetic merit of their bulls. Non-AI bulls of high genetic merit are sons of proven AI bulls with high PTAs out of cows with high PTAs. The PAs and reliabilities for non-AI bulls can be calculated quickly from the PTAs of the bull's sire and dam using Equations 5 and 6. Plenty of bulls are available from sires and dams that meet these standards; producers should insist on these criteria when selecting non-AI bulls. Production of the bull's dam is not a reliable measure of her genetic merit. For example, a cow that produces 20,000 lb milk in a herd that averages 25,000 lb is not a good candidate as the dam of a herd sire. The PTA takes account of all the information available to measure the cow's genetic value. The PTA of a nondescript bull can easily be 1000 to 2000 lb milk below that of a bull with good pedigree data. This translates to a loss of 1000 to 2000 lb milk/lactation in performance of the bulls' daughters. No producer can afford to disregard genetics when selecting non-AI bulls.

INTERNATIONAL GENETIC EVALUATION

The dairy genetics industry is a truly global one. Currently, more than 40% of semen produced in the United States is exported. North American dairy farms increasingly are a marketing target for dairy semen suppliers in other countries. The AI industry is progeny testing more of its young sires in more than one country. Multinational AI companies are another part of this international picture. This international trade in semen has created extensive genetic ties among dairy cattle populations in many countries and has made it possible to accurately compare bulls regardless of country of origin.

The International Bull Evaluation Service, Interbull, coordinates the genetic evaluation of dairy bulls in 25 countries (Interbull, 2000a). The service documents the genetic evaluation methods used in each country and coordinates an active research program on methods for international evaluation. Each country evaluates bulls based on daughter performance within its own borders. Subsequently, each country submits its domestic results to Interbull. The Multiple Across Country Evaluation (MACE) method is employed by Interbull to evaluate all bulls on a standard basis regardless of country of origin (Schaeffer, 1994). Because of sire by environment interaction, the ranking of bulls varies from country to country. Interbull returns the results for all bulls to each contributing country. For each country these results are presented in terms such as breeding value or transmitting ability, same units of measure (kilograms or pounds), and same genetic base that are the norms for that country. By this approach, producers in all participating countries see the international evaluations in terms familiar to each. The program enables producers to correctly compare bulls from their domestic populations with bulls from populations in other countries. These developments began with the yield traits, but over time additional traits, especially health, fertility, and conformation, are being added to the international evaluation procedure.

MATING CONSIDERATIONS

After bulls are selected for breeding the herd, the next set of decisions is how to arrange the matings between cows and bulls. Three aspects of mating are discussed in this section. Controlling inbreeding is the most important consideration in arranging the matings of cows with bulls. The costs of inbreeding in the form of degraded animal performance are subtle but real and should be considered when matings are planned. Corrective mating programs are widely popular among producers. These afford an opportunity to improve the desirability of a few of the type traits. Crossbreeding has not been practiced widely in the dairy industry although it is a predominant practice among commercial producers in virtually all of the other animal industries. This is an opportunity that commercial dairy producers need to explore. Each of these mating systems is discussed separately.

Inbreeding

An inbred animal results from the mating of a cow and bull that are related. The parents of an inbred animal have one or more ancestors in common. In other words, the pedigree of an inbred animal traces back to certain individuals through both the sire and dam. The most important consequence of inbreeding is somewhat impaired performance of inbred offspring. The amount of impairment is called *inbreeding depression*. Impaired performance is most dramatic for genetic defects caused by a single gene, such as BLAD. BLAD animals are homozygous for the defective allele (i.e., they have two copies of the BLAD allele). Carrier animals—those with only one copy of the defective allele—and homozygous normal animals—those with two copies of the normal allele—have normal leukocyte function. Inbreeding reduces the frequency of carriers and increases the frequency of both homozygous types. It is the reduction of carrier animals coupled with the increased number of homozygous defective types through inbreeding that causes the increased frequency of undesirable animals. Often, mild inbreeding leads to the discovery of undesirable recessive alleles such as BLAD. Reduced reproductive performance, increased fetal losses, increased calf mortality, and reduced herd life are all consequences of inbreeding.

Standard animal breeding textbooks, such as Bourdon (2000), outline the process for calculating inbreeding coefficients. The inbreeding coefficient measures the expected percentage of gene loci at which both chromosomes have the same allele inherited from one or more common ancestors through both the sire and dam; such alleles are said to be inherited identically by descent. Table 8-18 shows the inbreeding coefficients that result from a few simple cases of inbreeding. All of these examples involve only a single common ancestor of the parents; pedigrees often involve more than one common ancestor, especially among distant ancestors. When parents have more than one common ancestor, the inbreeding coefficients of progeny will be larger than those shown in Table 8-18.

Inbreeding naturally accumulates in small populations and in populations, like dairy cattle, that are undergoing intense selection. The best cows and the best bulls are both descendants of the best animals from earlier generations. In-

TABLE 8-18

Inbreeding Coefficients That Result from Matings of Related Parents

Mating parents	Inbreeding coefficient	Common ancestor
Sire × daughter	0.25	Sire is also maternal grandsire
Half brother × half sister	0.125	Paternal grandsire is also maternal grandsire
Grandsire × granddaughter	0.125	Sire is also a great-grandsire on the maternal side
Half uncle × half niece	0.0625	Paternal grandsire is also a great-grandsire on the maternal side
Half first cousin × half first cousin	0.03125	A great-grandsire on the paternal side is also a great-grandsire on the maternal side

evitably, related cows and bulls are mated and produce inbred progeny. Fig. 8-7 shows the average inbreeding coefficients for U.S. Holsteins and Jerseys by year of birth. Inbreeding has increased substantially in recent years (Fig. 8-7). These increases are due to increased intensity of selection and due to the fact that more generations of ancestors are included in the calculation of inbreeding coefficients for recently born animals. These inbreeding calculations are based on pedigree records that trace back to animals born in the 1950s and 1960s.

Inbreeding effects have been measured for several performance traits. Table 8-19 lists recent estimates of inbreeding depression in registered U.S. Holsteins (Smith et al, 1998). Inbreeding depression is the average loss in performance resulting from a 1% increase in the inbreeding coefficient. The table also shows inbreeding depression that would be expected from 12.5% inbreeding and inbreeding depression as a percentage of the breeding value standard deviation. The latter statistic measures inbreeding depression in relation to the opportunity for genetic improvement by selection. When this measure is small, selection can more easily offset the detrimental effects of inbreeding. Two important conclusions emerge from these results: The effects of inbreeding are substantially greater for lifetime measures of performance than single lactation measures, and inbreeding affects yield and herd life to a greater extent than conformation. Clearly, inbreeding should be avoided to produce more profitable animals.

Controlling inbreeding is the most important consideration in arranging the matings of cows with bulls. The goal should not be to avoid inbreeding altogether because that is not attainable. Mating strategies that maximize expected lifetime profit adjusted for inbreeding depression provide greater profits than strategies that maximize profit while placing an upper limit on inbreeding (Weigel and Lin, 2000). In some cases an inbred mating to a genetically superior bull is more profitable than a mating to a bull with lower genetic merit and lower inbreeding; the difference in genetic merit more than offsets inbreeding depression in these matings.

Records for at least two or three generations of ancestors are needed to control inbreeding; this amount of information can be managed manually when planning matings. Additional generations of ancestry are also useful if available because much inbreeding can trace back several generations (Weigel and Lin, 2000). Computer programs are needed to compute inbreeding coefficients for proposed matings when several generations of ancestry are considered. Purebred breeders by virtue of their consistent registration of pedigrees have the best opportunity to manage inbreeding. Participation in pedigree registration programs should be profitable for commercial producers if for no other reason than to plan matings with reduced levels of inbreeding. Herds without records of ancestry almost certainly will make a percentage of matings with somewhat high levels of inbreeding and suffer the consequent impairment of performance.

The easiest recommendation to implement for controlling inbreeding is to avoid matings of cows and bulls that have any parents or grandparents in common. This requires a minimum of pedigree records, avoids the most serious levels of inbreeding, and is an attainable goal. A better goal

would be to avoid matings that have parents, grandparents or great-grandparents in common. This requires additional records that are sometimes more difficult to obtain and requires more work to plan the matings; this goal ensures lower levels of inbreeding. Considering relationships beyond great-grandparents is difficult without the aid of computer software; when software is available, records of ancestry for many generations can be and should be included.

In the United States, the Animal Improvement Programs Laboratory provides an expected inbreeding of future progeny for bulls. Essentially, this measure indicates the relationship of the bull to cows in the breed. A bull with strong pedigree ties to ancestors with large numbers of descendants will have a high expected inbreeding of future progeny. For herds with good records of ancestry, this measure has little usefulness. Herds without pedigree information can be advised to use bulls with lower values of expected inbreeding of future daughters. This may reduce the chance of inbreeding, but high levels of inbreeding can still occur inadvertently.

Producers who use non-AI bulls must concern themselves with inbreeding when bulls are purchased. Records of ancestry should be obtained with the purchase of a bull. When selecting bulls for purchase, producers should avoid bulls that have parents or grandparents in common with bulls that have been used in the most recent 5 or 10 years. As with the use of AI bulls, matings with natural service bulls should be arranged to control inbreeding.

Corrective Mating

Corrective mating is a popular, widely used service, although little research has been carried out to evaluate the practice. All of the major AI organizations and some breed associations offer corrective mating services. Corrective mating is the practice of mating cows with low PTA for a trait with a bull that is high for that trait. When PTAs aren't available, phenotypic observations are used instead. For example, a cow whose PTA indicates a genetic tendency for rear legs that are too straight would be mated with a bull whose PTA indicates a tendency for daughters to have legs are somewhat too curved as viewed from the side. In other words, corrective mating is designed to produce individuals that are intermediate in genetic value and phenotype for the traits involved in corrective mating. Compared with random mating or some other standard, corrective mating does contribute to producing intermediate types, avoiding extreme types, and improving uniformity of individuals. However, such matings have a limited ability to control variation; producers should not expect corrective mating to produce the kind of uniformity seen in a truck assembly line!

Corrective mating can be useful for some traits, but it clearly does not make sense for others. Most traits have linear economic value: The higher (or lower), the better; each added unit of increase (or decrease) has the same value, regardless of the level of performance. Milk yield, protein percent, and PL are examples of traits with linear economic value. Corrective mating for these traits will increase uniformity but will have no effect on the herd average or economic value of the herd. Uniformity has little merit for traits in this category except when they are uniformly high. It is always important to select sires that have high PTAs for traits with linear economic value.

A few traits have economic values with intermediate optimums (i.e., intermediate values of the trait are more desirable than either high or low extremes). A few of the conformation traits fit this category: teat length, teat placement, udder depth, rear leg set, pin setting or rump angle, and perhaps body size. Animals that are extremely high or extremely low for traits such as these may have more health problems or shorter herd life or require more milking labor than

Downloaded from Vet-e-Books.com

animals with intermediate phenotypes. Nonlinear economic values are illustrated in Fig. 8-8 for pin setting and front teat placement. The relative risk of culling is lowest for animals with intermediate scores of these traits; also, relative risk is greatest for both extremely high and extremely low values of the traits. In other words, intermediate values of these traits are most desirable.

Corrective mating can be useful, although it is not critical, for traits with intermediate economic value. The increased uniformity of phenotypes clearly has economic merit for these traits because individuals either above or below the intermediate levels have lower measures of desirability.

Crossbreeding

Crossbreeding is the practice of mating females of one breed with males of another breed. It is widely used by commercial producers of the meat animal species but has been used very little by dairy producers. Recent years have seen a slow growth in use of crossbreeding by dairy managers. Research on crossbreeding among dairy breeds has also been limited. Several crossbreeding trials of modest size were launched in the 1940s and 1950s (Touchberry, 1992). Few important studies have been undertaken since. Modern dairy breeds are vastly different genetically from animals used in those early crossbreeding studies; inferences from those studies to current times would be risky. The growth of interest among producers in crossbreeding and the realization that crossbreeding may offer profitable opportunities for commercial producers is expected to stimulate new research and increased use of crossbreeding in dairy cattle.

In many ways crossbreeding is the genetic opposite of inbreeding: Crossbreeding increases the percentage of genetic loci that are heterozygous (i.e., the two alleles at a locus are different); inbreeding increases the percentage of loci that are homozygous (i.e., the two alleles are identical by descent). For many traits, crossbred animals exhibit higher levels of performance than the average of their purebred parents. *Hybrid vigor* is the term used to describe this advantage in performance of crossbred animals. Inbred animals, on the other hand, tend to exhibit poorer performance than noninbreds. The performance advantage of heterozygous genotypes in comparison with homozygous genotypes was explained in the discussion of inbreeding.

One important criterion for judging the usefulness of crossbreeding is that the performance of crossbreds must exhibit a higher level of performance than the better of the purebreds. For this reason crossbreeding is more often advantageous when the pure breeds are similar in their levels of performance. One reason for the absence of crossbreeding in commercial dairy production is the substantially higher level of milk production by Holsteins compared with other breeds. In a study of Holstein and Jersey crosses on commercial farms in New Zealand, it was shown that the crossbreds produced less milk per lactation than the pure Holsteins and had a lower milk fat percentage than the pure Jerseys. When judged by fat yield, however, the crosses were higher than either pure breed (Ahlborn-Breier and Hohenboken, 1991). As expected, a study of Holstein-Guernsey crosses in the United States found Holsteins produced more milk and fat than the crossbreds. However, survival rates at three ages through second calving were higher for the crossbreds than for either pure breed in this study (Touchberry, 1992).

A well-designed crossbreeding system involving Holstein by Ayrshire-based crosses was conducted in Canada (McAllister et al, 1994). The most striking result in this study was that for various measures of lifetime performance, the crossbreds exceeded the average of the purebreds by 15% to 20%. For single lactation measures of yield traits, the crossbreds were less than 5% above the purebred average. For the lifetime measures, performance of the crossbreds was not significantly different from purebred Holsteins. These results demonstrate that breeding systems should be evaluated on the basis of lifetime performance to allow effects of crossbreeding on survival, reproductive performance, and disease resistance to be expressed.

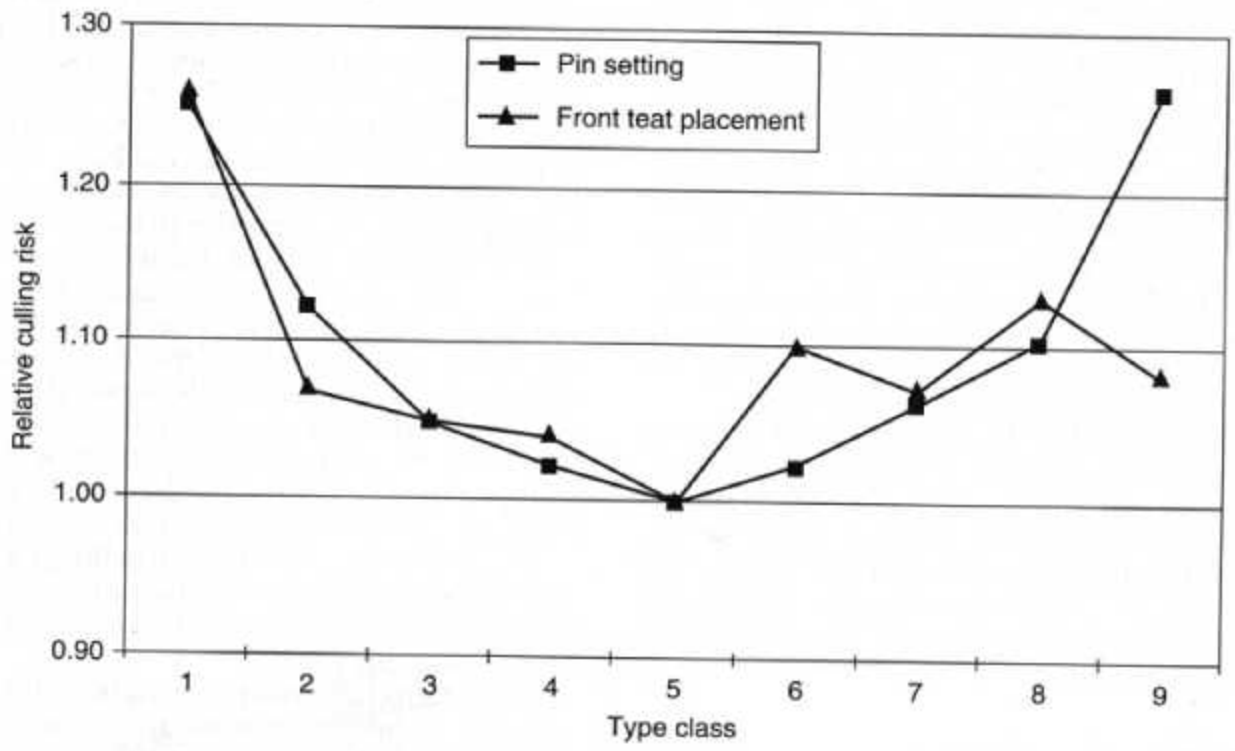

FIG. 8-8 Relative risk of culling by type class for pin setting and front teat placement. (Data from Schneider MDP, Monardes HG, Cue RI: Effects of type traits on functional herd life in Holstein cows. In Proceedings from the International Workshop on EU Concerted Action Genetic Improvement of Functional Traits in Cattle: Longevity, Bulletin 21, International Bull Evaluation Service, 1999, Uppsala, Sweden, 1999, pp. 111-116.)

Downloaded From Vet-eBooks.com

Ideally, crossbreeding should be conducted in a systematic manner that exploits to the fullest extent the genetic characteristics of the pure breeds and hybrid vigor in the breed crosses (Bourdon, 2000). The production of F_1 (i.e., two-breed) crosses is an easy first step into a crossbreeding system. The question then becomes how the F_1s should be mated to produce the subsequent generation of animals. Unfortunately, much of the research in dairy cattle has been limited to the study of F_1 crosses. Systems of crossbreeding have been designed in the meat animal species to produce desired types of animals for breeding females, breeding males, and market animals. Much has been learned about the biology of crossbreeding in meat animals that can advance crossbreeding in dairy cattle. However, there are many differences between dairy production and meat production that limit the transfer of information from one industry to the other. Theory cannot predict the ideal crosses and crossing systems; these must be discovered through practice and research.

Rotational crossbreeding systems involving purebred sires and crossbred cows are relatively easy to operate. A two-breed rotation, for example, might begin with purebred cows of breed A. The first cross would be with sires of breed B. The AB females could be mated with sires of either breed, but the breed considered more favorable should be chosen. Thereafter cows would be mated with purebred bulls of the breed opposite that of the cow's sire. Although only two breeds can be involved in the production of the initial crosses, a crossbreeding system can involve three or more breeds. It is known, for example, that a three-breed rotation retains 86%, whereas a two-breed rotation retains only 67% of the hybrid vigor exhibited in F_1 crosses (Bourdon, 2000).

How should a consultant advise a producer who wants to practice crossbreeding with dairy cattle? A critical first step is the choice of breeds. Unfortunately, little research is available to guide a crossbreeding enthusiast on the choice of breeds for dairy production. Because of the substantial advantage of Holsteins over other breeds for the yield traits, Holsteins will be chosen as one of the breeds in most situations. Many factors go into the choice of a second breed; perhaps most important among these is availability of breeding females or semen and average genetic merit of the alternative breeds. The average performance of crossbred animals will be about 5% to 20% above the average of the component breeds. Crossbreeding produces a greater advantage for the survival, reproductive, and lifetime traits than it does for lactation yield. Lactation yields will be around 5% above the midpoint between the parental breeds, survival and reproductive performance is often 10% to 15% above the midpoint, and lifetime production is 15% to 20% above the midpoint (McAllister et al, 1994). Performance measures are readily available for the yield traits, but are sparse for survival and reproductive traits. A fair comparison between pure breeding and cross breeding must be based on lifetime performance.

A second critical decision is the selection of individual animals that are used in the initial breed crosses. These choices should be based on PTAs, selection indexes, and other tools used to select purebred animals. Any breeding system, whether pure breeding or crossbreeding, must be based on animals with high genetic merit.

FUTURE ROLE OF GENETICS IN ANIMAL HEALTH

Genetic improvement for milk production has advanced dramatically during the past 30 years (Fig. 8-1). However, the improvement in production has come at the cost of some loss in virtually every other aspect of animal function. For example, the genetic correlation between milk yield and clinical mastitis is around 0.30, which means that genetic improvement for production is accompanied by a slow increase in incidence of clinical mastitis. Also, improved yield is accompanied by longer days open. Each 1000-lb increase in milk yield was associated with an average increase of 3.2 days open in first lactation and 5.7 days open in second and later lactations (Hageman et al, 1991). A large study of field data found an increase of 5 to 6 days open per 1000-lb increase in milk yield within herd. The smaller effect was observed in high-producing herds and the larger effect occurred in lower-producing herds (Marti and Funk, 1994). The revenues from increased production more than offset these additional costs in health and reproductive performance. However, the current breeding programs are not sustainable over the long term. It is imperative that health and reproductive performance be given increased emphasis in genetic improvement programs. At the current time only rudimentary genetic tools exist for improvement of health and reproduction; the existing genetic evaluations for calving difficulty, SCS, PL, and male fertility are initial steps toward an effective genetic improvement program for health and fertility. Fortunately, industry leaders and researchers in both animal genetics and veterinary science are turning increased attention toward development of genetic programs for health traits.
