From a veterinary medicine perspective, genetics can be used as a tool for preventive medicine. The plant industries have used genetic resistance as a method for infectious disease control for many decades, yet this has seldom been applied in the animal industries. Preventive veterinary medicine has focused almost entirely on sanitation, management, and other environmental approaches to disease prevention and control. Genetic improvement for disease resistance can become an effective adjunct to these environmental approaches. Genetic disease resistance would enhance animal well-being, and it would reduce but not eliminate the need for antibiotics and drugs to treat diseased animals. Genetics could become a cost-effective strategy for slowing the development of pathogen resistance to antibiotics, improving food safety, and reducing the economic burden of disease morbidity and mortality.

The advent of genome studies and marker-assisted selection offers a most promising new opportunity to exploit genetics as a tool for disease prevention in livestock (O'Brien et al, 1999). Comparative studies of the genomes of cattle with those of humans, mice, and other species will facilitate the interspecies transfer of knowledge on the genetic basis for disease. Because of the large investment in the human and mouse genome studies, cattle genetics stands to gain heavily from this transfer of information.

DNA markers in cattle and other livestock species have been established at sufficiently close intervals to enable a rough approximation to the location of quantitative trait loci (QTL) for disease resistance (Kappes et al, 1997). The QTL are specific chromosome loci with two or more alleles that confer widely differing levels of disease resistance or susceptibility. Marker genes are ubiquitous, often nonfunctional differences in nucleotide sequence that are relatively easy to assay. Initially, marker genes closely linked to QTL are sought as indicators of genetically resistant or susceptible animals. Ultimately, the aim of research is to discover the QTL that directly cause genetic differences in disease resistance (Holmes, 1994; Soller and Andersson, 1998). Although many genes are involved in genetic disease resistance, the picture is emerging that alleles at a few loci cause major differences in resistance. Genetic resistance is not absolute, however; environmental methods of disease prevention and control will continue to be important in minimizing disease incidence.

Downloaded From Vet-e-Books.com

Development of programs for improving genetic disease resistance requires the collaboration of producers, practicing veterinarians, the animal genetics industry, and researchers in animal genetics and veterinary science. Producers need to better understand the economic value of disease prevention, become more aware of disease costs, and be proactive in reducing those costs. Disease record systems for individual animals must become a more important feature of herd management, and these systems must be useful to both the herd manager and practicing veterinarian. In addition, these systems must be standardized to allow aggregation of the records across herds. Centralized databases for disease records must be linked to existing pedigree, production recording, and genetic evaluation systems. Only in the Scandinavian countries does such a system currently exist (Emanuelson, 1988; Ruane et al, 1997). Finally, gene maps and genetic markers must be developed and QTL for disease must be discovered to facilitate selection for disease resistance.

CHAPTER 9

Health and Production Management of Dairy Calves and Replacement Heifers

A. JUDSON HEINRICHS and OTTO M. RADOSTITS

The successful rearing of dairy calves from birth to weaning depends on a well-managed combination of a healthy dam that calves without difficulty, a clean calving area, and the early ingestion of good-quality colostrum with adequate passive transfer of colostral immunoglobulins to the calf. In addition, clean, dry, and draft-free housing and adequate nutrition following the colostral feeding period up to the time of weaning are important components of a replacement program. Calf morbidity and mortality are perennial problems in all countries where cattle are raised. Most illnesses and deaths occur in the first few weeks of life because of the effects of infection pressure, lack of sufficient colostral immunity, inadequate housing, health care, and nutrition or the effects of adverse environmental conditions.

Today's dairy farms require managers who have skills in many areas, including financial planning, nutrient management, resource management, and, most importantly, dairy husbandry, in order to have a profitable operation. Unfortunately, an area that is neglected on too many dairy farms is the husbandry related to replacement animals. One of the most important aspects of a dairy enterprise is to raise enough replacements with high milk-production potential. Improvement of any herd is possible only when culled cows are replaced by young stock that are properly fed, bred, and managed.

The number of calves dairy farmers need to raise each year to maintain herd size depends largely on herd management and herd health. Approximately 30% of a milking herd is usually replaced each year as a part of normal management. In some herds dairy farmers are replacing over 30% of their cows each year. Assuming 50% of all calves born are heifers, farmers would need to raise 75% of their female calves to maintain herd size. If death losses are substantial, dairy farmers need to raise all heifers that survive and therefore are unable to cull selectively for any herd improvement.

When excellent management is applied with current knowledge and technology, dairy farmers should be able to raise sufficient quantities of well-grown heifers to calve by 24 months of age. Heifers that calve at an earlier age will begin returning their investment at a much earlier date and therefore be more profitable to the dairy farm operation.

Much research has been conducted on proper calf- and heifer-raising practices. In one study in California, dairy farmers were lacking in several areas of management (Goodger and Theodore, 1986). Among these were sanitation of the calving area, insufficient colostrum intake, inadequate veterinary service for young stock, and inadequate use of calf and heifer records. In dairy farms in other areas, the caring of calves was simply a nuisance job, and this was true especially on the larger farms where this job would be assigned to the hired labor. Pennsylvania research by Heinrichs et al (1987b) concluded that many of the farms studied did follow approved calf and heifer management practices, but there were several areas needing improvement, and additional practices involved in calf and heifer management should be followed to reduce age at first calving from 26.6 months. Other Norwegian, Canadian, and U.S. research found similar results relating to calf and heifer management practices (Curtis et al, 1988a; Simensen, 1986; Waltner-Toews et al, 1986d). The extension program in calf and heifer management provided in Pennsylvania reached dairy farmers in addition to individuals in agribusiness, veterinarians, and others who have frequent contact with dairy farmers through many information channels. Most (84.7%) of the farmers learned new information about calf and heifer management during the extension program, and 77.3% indicated that they received all of part of this new information from extension (Heinrichs and Kiernan, 1994).

Over the past 30 years, a large body of literature has accumulated on the anatomical and physiological development of the young calf. Prenatal care of the dam, neonatal behavior, immunoglobulin absorption, nutritional and feeding requirements, and various housing strategies have all been studied under experimental conditions (Waltner-Toews et al, 1986b). Using the literature, supplemented by field surveys and studies of the genetics of calving ease and rural sociopsychology, various authors have attempted to formulate what appears to be scientifically rational dairy calf rearing programs.

In spite of all the information just discussed, the effectiveness of prevention programs in reducing calf morbidity and mortality in the field remains to be demonstrated. We believe sufficient knowledge is available that can be applied at the farm level to manage the health and production of dairy calves so that morbidity and mortality can be maintained at reasonably low levels. Rearing dairy herd replacement animals represents a long-term investment in feed, labor, and other resources to ensure high-quality replacements for the lactating herd. Many of the management-related problems involving nutrition, housing, and health for replacement animals have been studied.

The first section of this chapter outlines the principles of health and production management of dairy calves from birth to weaning. The second section presents the health management of heifer replacements from weaning until first calving and entry into first lactation. It is the responsibility of the veterinarian to educate the producer about factors that are risks to calf health and performance and to determine how those risks can be managed to raise calves successfully and economically. It is the responsibility of the producer to apply the principles of good calf management. It is the responsibility of the manager and veterinarian to monitor calf health and production in the herd and, when necessary, for each to make recommendations to improve performance.

Downloaded From Vet-eBooks.com

Health Management of Dairy Calves

The infectious diseases of the digestive and respiratory tracts are the most important diseases of calves from birth up to several months of age. Approximately 75% of the mortality of dairy animals under 1 year of age occurs during the first month of life. This indicates the necessity of giving high priority to a health management system for rearing newborn calves, especially during the first month of life.

CAUSES OF ECONOMIC LOSS IN DAIRY CALVES

Economic losses in dairy calves from birth to weaning are caused by illness, suboptimum performance, and mortality resulting from a number of diseases or inadequacies in production management.

Abortions, Stillbirths, and Congenital Defects

Abortions, stillbirths, and congenital defects account for approximately 2% to 3% of calf mortality and include the common causes of abortion, such as brucellosis and leptospirosis, intrapartum hypoxemia caused by prolonged parturition, and inherited and noninherited congenital defects.

Acute Diarrhea

Acute diarrhea accounts for approximately 75% of the mortality of dairy calves under 3 weeks of age. The most important pathogens associated with diarrhea are enterotoxigenic *Escherichia coli* in calves under 3 to 5 days of age, rotavirus in calves 7 to 10 days of age, corona-virus in calves 7 to 15 days of age, *Cryptosporidia* sp. in calves 15 to 35 days of age, *Salmonella* sp., usually in calves several weeks of age, and coccidiosis (*Eimeria* sp.) in calves older than 3 weeks of age.

Chronic Diarrhea

Inferior-quality milk replacers can cause chronic diarrhea and undernutrition emaciation.

Omphalophlebitis and Arthritis

Omphalophlebitis and arthritis are commonly caused by a mixture of *E. coli, Corynebacterium pyogenes,* and other bacteria.

Septicemia

Coliform septicemia caused by invasive strains of *E. coli* occurs most commonly in calves under 4 days of age that are agammaglobulinemic because of the failure of passive transfer of colostral immunoglobulins.

Enzootic Pneumonia

This occurs primarily in housed calves over 2 months of age. It is caused by infection with respiratory viruses and inadequate ventilation and accounts for about 15% of calf mortality from birth to 6 months of age.

Nutritional Diseases

Suboptimum performance resulting from the inadequate nutrition of calves from birth to 6 months of age is common, but accurate data on the magnitude of the economic losses incurred are not available because dairy producers do not usually monitor calf performance during the first several months after birth. Enzootic muscular dystrophy caused by vitamin E and selenium deficiency occurs in calves 2 to 4 months of age that were raised indoors and then turned out to pasture. An inferior growth rate may have several causes.

Inadequate Dietary Intake of Energy, Protein, Vitamins, and Minerals

This occurs in housed dairy calves fed roughage and grain and in young calves reared on pasture where the quality of the pasture does not meet the nutrient requirements for optimum growth.

Mineral Deficiencies

These can be deficiencies of copper, zinc, or iron, but they are rare.

Postweaning Unthriftiness

This occurs in calves that have been weaned too early, before they begin consuming an adequate amount of dry feed. It also occurs in calves that have been weaned from cow's whole milk or milk replacer onto an inadequate diet. The diet may be inadequate because of poor-quality roughage, low energy and protein content of grains, or inadequate concentration of minerals and vitamins. In calves reared on pasture, the nutrient content of the grass may be inadequate to meet the needs of optimum growth following weaning. Some veterinary aspects of the nutrition of young calves are presented later in this chapter.

Parasitic Gastroenteritis

Parasitic gastroenteritis occurs especially in calves from 2 months of age and older that are being reared on pasture. The common parasites include *Trichostrongylus* sp., *Ostertagia* sp., *Nematodirus* sp., *Bunostomum phlebotomum,* and *Haemonchus contortus.*

Parasitic Pneumonia

Parasitic pneumonia is caused by *Dictyocaulus viviparus* in calves being reared on pasture after about 4 to 5 months of age.

Arthropods

Arthropods include lice *(Linognathus vituli, Haematopinus eurysternus,* and *Damalinia bovis),* ticks, and flies.

Miscellaneous

The miscellaneous category includes abomasal ulcers and poisonings (lead).

EPIDEMIOLOGY OF DAIRY CALF DISEASE

The development and application of the principles of dairy calf health and production management require some knowledge of the descriptive epidemiology of calf morbidity and mortality, achievable targets of performance, risk factors associated with calf morbidity and mortality, and the possible long-term effects of calfhood disease on subsequent performance. In addition, a system of monitoring calf health and production must be established and used to analyze performance and to make recommendations for improvement. All of these are discussed in the following sections.

Downloaded from Vet-e-Books.com

Calf Morbidity and Mortality

Dairy calf morbidity statistics are not as reliable as those on mortality. They depend on the producer's clinical diagnosis, whether the animal was treated for the illness, and the tendency of producers not to record every illness event. On the other hand, mortality data are more readily available, because it is easier to count dead calves. Some studies have indicated that the best available data on morbidity are based on treatment rates. In a survey of dairy calf morbidity and mortality in Holstein dairy herds, 20% of live-born calves were treated for diarrhea and 15% were treated for pneumonia before weaning (Waltner-Toews et al, 1986b). In a study of 1171 Holstein heifer calves born over a 2-year period in 26 commercial dairy herds in New York State, the crude incidence rates of diarrhea per 100 calves were as follows for the period of the study: within 14 days of birth (9.9%), diarrhea from 15 to 90 days of age (5.2%), dullness (7.7%), respiratory illness (7.4%) and death (3.5%) (Curtis et al, 1988a).

An analysis of the literature on calf mortality reveals wide variations in the data that are difficult to interpret because no standard time-of-death definition has been used. If abortions are excluded, mortality can be subdivided as follows:

1. Perinatal mortality (stillbirths at more than 270 days of gestation and mortality during the first 24 hours of life)
2. Neonatal mortality (calves born alive that die between 24 hours and 28 days).
3. Older calf mortality (calves born alive that die between 29 and 182 days).

Calf mortality rates from birth to weaning vary from about 1% to 30% and even higher (Curtis et al, 1988a). These mortality rates are misleading because they are mean mortality rates for herds. Mortality rates are known to be skewed to the right because many herds have zero mortality, depending on the length of the survey period. Thus the median mortality rate is a better measure of central tendency than the mean (Curtis et al, 1988a). One of the few studies to measure individual dairy calf mortality was performed in Canada; it was 3.8% for all calves, with a herd median mortality of zero (minimum to maximum, 0% to 67%) (Waltner-Toews et al, 1986b). A survey of dairy farms in Alberta, Canada, found that 60% of all calf deaths occurred at birth, 16% within the first week of life, 21% after 1 week but before weaning, and 3.3% after weaning (Spicer et al, 1994).

In a prospective study of 845 heifer calves born on 30 Holstein dairy farms in Minnesota, the incidence rates for overall morbidity, enteritis, and morbidity resulting from pneumonia were 0.2, 0.15, and 0.10 cases per 100 calf-days at risk, respectively (Sivula et al, 1996b). The average daily rate of gain from birth to 16 weeks of age varied between farms from 0.5 to 1.1 kg/day. The overall mortality rate was 0.08 deaths per 100 calf-days at risk. Enteritis was the most common cause of death followed by pneumonia. Herd management risk factors identified as risk factors for calfhood morbidity and mortality in dairy heifers from birth to 16 weeks of age included the following: feeding a coccidiostat to preweaned calves increased the incidence risk of pneumonia; feeding vitamins A, D, and E to preweaned calves had a protective effect against diarrhea; and management of group pens for postweaned calves in an all-in-all-out flow was associated with farms with an average daily gain above the median for all farms (Sivula et al, 1996a). Calves that required assistance during birth developed diarrhea sooner than calves born without assistance.

In a survey of 407 dairy herds in Virginia reporting 12,300 heifer calf births over a 6-month period, the mortality at birth averaged 1.2%, and the mortality of calves born alive and up to 3 months of age averaged 6.5%. In general, in European countries, the rate of stillborn calves ranges from 3% to 7% and the total mortality rate ranges from 9% to 13% of all calves born. In a 1-year survey of Norwegian dairy herds, the stillbirth rate and calves dying within 24 hours of birth was 2.80% and the overall mortality rate to 30 days was 3.95%, which is extremely low compared with that of other countries. The overall calf mortality rate from birth to 90 days was 18.8%. In a study of Irish dairy herds over a 9-year period, with a total of 9430 calvings, the average incidence of abortion was 1.8%, perinatal mortality (stillbirths and deaths within 48 hours) was 8.37%, and 73% were dead at birth (Mee, 1988).

In typical commercial dairy herds of 50 to 200 lactating cows in North America, the population mortality rate of all live-born calves from birth to weaning ranges from 5% to 10% from year to year and varies from 3% to 30% among individual herds from year to year. Some herds experience no calf mortality over short periods of time (e.g., several months), but on an annual basis some calves die from disease. High losses, up to 50% to 60% of all calves born, have been recorded in large dairy herds with 1000 to 2000 milking cows. This represents a major cause of economic loss on an industry basis.

A survey of calf losses on a Central Dairy Cattle Breeding Station in Bangladesh over a period of 12 years found a mean annual abortion rate of 7.6% and mean annual calf mortality rate from birth to 1 year of age of 13.4% (Debnath et al, 1995). Gastroenteritis was the most frequent cause of death at 30.7%, followed by respiratory diseases at 16.7%. Tuberculosis and foot-and-mouth disease caused 11.3% and 7.6% of the deaths, respectively. Calf mortality was higher in male calves and in calves of exotic breeding and lower birth weight.

The major causes of dairy calf mortality recorded over a 10-year period in an area in Kenya included gastroenteritis, pneumonia, and tick-borne diseases (Mulei et al, 1995). The alimentary and respiratory tract diseases were most common in calves from 1 to 30 days of age. Other causes of death included diseases of the musculoskeletal system (7.0%), septicemia (6.7%), malnutrition (6.1%), cardiovascular system (3.7%), nervous system (3.2%), liver (2.6%), and poisoning (2.6%).

The U.S. Dairy Association (USDA) National Animal Health Monitoring System (USDA, 1996) found rates of preweaned calf mortality in the U.S. dairy industry of 8.4% in 1991 and 10.8% in 1996. No reasons were given for the increase in 1996, which is above the standard errors for those studies of 0.4%. The first national estimates of mortality and morbidity for preweaned dairy heifers in the United States, determined by monitoring 906 herds in 28 states, found that the cumulative mortality incidence risk from birth to 8 weeks of life was 6.3% with a peak of 1.9% during the first week of life (Wells et al, 1996a). Season of birth was significantly associated with cumulative mortality incidence risk, and mortality risk was highest in the periods of January to March and October to December. Cumulative incidence of risk of diarrhea to 8 weeks of age was 24.6% with a peak of 15.4% during the second week of life.

Calves that are surplus to the requirements of the dairy and bull beef industries are slaughtered in New Zealand at 4 to 8 days of age (Biss and Hathaway, 1994). The lesions seen most commonly at slaughter include contamination, wounds, bruising, and omphalophlebitis. The total condemnation rate of carcasses was 2.20%, which decreased to 1.17% following implementation of a national farm-gate quality assurance program and a scientific investigation of traditional meat inspection carcass condemnation criteria.

The weak calf syndrome is a cause of calf mortality. In Northern Ireland it is characterized by the birth of full-term

Downloaded From Vet-e-Books.com

calves that either fail to breathe or did not breathe for more than about 10 minutes (Smyth et al, 1996). The cause is uncertain; several different causes have been explored.

Targets of Dairy Calf Health and Performance

Under good management conditions in developed countries, mortality rates according to age groups can be maintained as follows: perinatal mortality, 1% to 3%; neonatal mortality, 3%; and older calf mortality, 1%. In well-managed herds the annual mortality rate of calves under 30 days of age can be controlled at a level below 3% to 5% of all calves born alive and normal. In fact, most well-managed dairy farms do not have a problem with calf disease. However, this does not mean that calf performance is optimum in most dairy herds: it is not. For dairy herds raising their own heifer replacements, the economically important target of performance for the lifetime productivity of the heifer is age at first calving. To achieve optimum milk production for the lifetime of the cow, the heifer should calve for the first time at between 22.5 and 23.5 months of age (Gardner et al, 1988). Decreasing the average age at first calving nearer to 22 to 24 months is an important management practice for which the dairy farmer should strive, and it justifies the maintenance of desirable growth rates of replacement (Heinrichs and Hargrove, 1987).

Effects of Calfhood Disease on Subsequent Performance and Survivorship

Disease is the largest cause of mortality of dairy calves, and the two primary diseases are diarrhea and pneumonia. Pneumonia and umbilical infection occurring in dairy calves reduces body weight gain significantly in the first 3 months of life (Virtala et al, 1996c). In a sample study of New York dairy herds, crude risks for diarrhea, umbilical infection, and umbilical hernia were 28.8%, 14.2%, and 15.1% and the median ages at first diagnosis were 2, 1, and 3 weeks, respectively (Virtala et al, 1996a). The high incidence and long duration of umbilical infection, the finding that diarrhea was the primary cause of death, and the high case-fatality risk for diarrhea during the first week of life suggests that calf caretakers need training in the prevention and clinical management of these diseases. The incidence and case-fatality risk for clinician-diagnoses pneumonia were 25.6% and 2.2%, respectively (Virtala et al, 1996b). *Mycoplasma* sp. and *Pasteurella multocida* together were isolated from affected calves, suggesting a synergistic action.

Canadian research found that calf girth-growth during the first month of age was positively associated with serological titers of total immunoglobulin (total Ig) level. Conversely, girth-growth was negatively associated with a producers' treatment risk of pneumonia and a semimonthly veterinarian clinical examination. Based on radial immunodiffusion measurement, 27% of 325 calves from 17 herds had inadequate levels (total Ig $\leq$800 mg/dl) levels of passively acquired antibodies (Van Donkersgoed et al, 1993).

The effect of early calfhood health status on survivorship and age at first calving, after controlling for the farm effect, has been examined (Waltner-Toews et al, 1986f). Heifers that had been treated for pneumonia during the first 3 months of life were 2.5 times more likely to die after 90 days of age than heifers that had not been treated. Heifers with a calfhood history of being treated for diarrhea were 2.5 times more likely to be sold for dairy purposes than other calves, and heifers that had been treated for diarrhea were 2.9 times more likely to calve after 900 days (30 months) of age than other heifers. Other observations have found that a calving age less than 730 days (24 months) is much more economical to a dairy farmer based on the extra costs and lost production associated with older calving ages (Hoffman and Funk, 1992).

Further research by Waltner-Toews et al (1986g) revealed that the percentage of calves at risk that were first treated for diarrhea peaked during the second week of life (at 8.1%/week) then declined sharply (approaching zero by about 6 weeks). Pneumonia treatment rates peaked at about the sixth week of life (at 2.3%/week) but were more persistent than the treatment rates for scours. Calves were at greater risk of dying during the first week of life than at any time thereafter, and treatment rates for diarrhea and pneumonia were generally lower in spring and summer than during autumn and winter.

Curtis et al (1988a, 1989) followed 1171 Holstein heifer calves on several New York dairy farms. Their findings yielded incidence rates of scours of 9.9% within 14 days of birth, 5.2% from 15 to 90 days of age, 7.7% for calves displaying dullness, and 7.4% for calves with respiratory illness. The only seasonal effect displayed was for scours within 14 days of age, which was higher in winter compared with summer across both years of the study. They also found that the risks of clinical signs were highest in the first week of life, whereas risk of death was highest in the third week of life. This study was taken a step further by Correa et al (1988) by comparing the effects of calf morbidity on age at first calving. Heifers without respiratory illness as calves were twice as likely to calve and calved 6 months earlier compared with those with respiratory illness as calves. What came unexpectedly in this study was that heifers displaying dullness as calves were 1.6 times more likely to calve and calved 2 months earlier when compared to calves without dullness as calves. The researchers speculated that perhaps if dull calves managed to survive to breeding age, they were especially vigorous although no data were available to examine this. Heifers with dullness were dull and listless, had droopy ears, or were off feed. This would be expected to be a problem because of anticipated lower growth rates from inadequate feed intake and unthrifty behavior.

Another study of calfhood health status and subsequent survivorship was conducted among two university herds in Canada by Britney et al (1984). In a study of 460 calves, heifer calves with navel-joint illness within their first 4 months of life exhibited a significantly poorer survival distribution pattern than the other four cohort groups. The other cohorts were identified as those having respiratory, gastrointestinal, septicemic, or other diseases. Navel joint illness is an infection of a calf's navel and is prevalent in some herds. Because of the significantly poorer response of calves with this disease, the researchers concluded that heifer calves contracting navel joint illness cannot survive as well as other calves under such a management program and hence, from a biological point of view, may warrant culling immediately on diagnosis.

Some of the effects just described have now been measured under field conditions, with variable results. Based on the analysis of the records of 34 Ontario Holstein dairy herds, the effects of diarrhea and pneumonia in calves on their subsequent survivorship and age at first calving were assessed. Heifers that had been treated for pneumonia during the first 3 months of life were 2.5 times more likely to die after 90 days of age than heifers that had not been treated for pneumonia, after controlling for the farm effect. Heifers with a calfhood history of being treated for diarrhea were 2.5 times more likely to be sold for dairy purposes than other calves (Waltner-Toews et al, 1986f). Heifers that had been treated for diarrhea were 2.9 times more likely to calve after 900 days of age than other heifers, after controlling for the farm effect. In some studies calfhood morbidity was not significantly associated with subsequent decreased survival

Downloaded From Vet-eBooks.com

in the milking herd (Warnick et al, 1997). There was no significant detrimental effect of owner-diagnosed calfhood disease on first lactation milk production; however, affected heifers had higher mortality rates before calving and were less likely to enter the milking herd than unaffected herdmates (Warnick et al, 1995).

Health status of dairy calves and growing heifers has a significant effect on growth rate, especially during the first 6 months of life (Donovan et al, 1998). Season of birth and occurrence of diarrhea, septicemia, and respiratory disease can be significant variables decreasing heifer growth (height and weight). These variables plus farm, birth weight, and exact age when 6-month data are collected can explain 20% and 31% of the variation in body weight and pelvic height growth, respectively, in the growth period from birth to 6 months of age. Septicemia and pneumonia can slow growth by 13 to 15 days (to reach the same weight as healthy calves) during the first 6 months. Diarrhea has a much smaller influence on growth. Passive transfer of colostral immunoglobulins has no direct effect on growth but does influence weight and height growth through its effect on health.

RISK FACTORS FOR DAIRY CALF DISEASE

The epidemiological determinants or risk factors of disease and suboptimum performance that are important in dairy calves under 1 month of age include the *vigor* and health of the calf at birth; the level of *colostral immunity* achieved in the calf; *management practices of the personnel* caring for the calves; *nutritional program*, including the quality of *milk replacers* (if used); herd size; adequacy of the housing and environment, including the hygiene of the calf's microenvironment; and the season of the year (Simensen, 1986). Each of these factors is discussed here and then incorporated into the principles of control and prevention of diseases of calves presented in the second section of this chapter.

The epidemiological interrelationships influencing calf morbidity and mortality are complex. Path analysis of individual calf risk factors for dairy calfhood morbidity and mortality in New York dairy herds indicated that management appears to affect the risk of respiratory disease directly and indirectly (Curtis et al, 1988b). Being born in loose housing increases the risk of diarrhea within 14 days of birth and from 15 to 90 days of birth. Calves of first-calf heifers are at increased risk of respiratory illness, and calves whose dams were vaccinated against *E. coli* are at decreased risk of death. Calves with diarrhea within 14 days of birth, dullness, and diarrhea from 15 to 90 days of age are at increased risk of respiratory illness. Calves that are dull and listless, have droopy ears, and are off feed within 90 days of birth are at the greatest risk of death.

The effects of age and seasonal patterns, association of management with morbidity, and association of management with mortality in dairy herds in Ontario have also been studied (Waltner-Toews et al, 1986c,d,e). The risk of diarrhea peaked during the second week of life; the peak incidence of pneumonia occurred during the sixth week of life. Treatment rates for diarrhea and pneumonia were generally lower in spring and summer than during the autumn and winter. The larger farms had a significantly greater chance of experiencing mortality than did smaller farms, in both winter and summer. Farms that had policies of attending calvings and ensuring that calves received their first colostrum had a significantly lower probability of experiencing winter mortality than farms that did not have these policies. Farms that housed calves in hutches had a lower chance, and those that housed calves in group pens had a higher likelihood of experiencing summer mortality than farms that used individual indoor calf pens.

A survey of factors associated with calf mortality in South Carolina dairy herds revealed an average mortality rate of 19.1% in calves from birth to 6 months of age (Jenny et al, 1981). Mortality to 1 month of age accounted for 84% of the total mortality. Although the survey indicated that several management practices can be related to mortality, it is doubtful that any one practice in itself significantly alters overall mortality or compensates for poor management. However, one poor management practice may outweigh several good practices. It is clear that if dairy producers are to keep calf losses to a minimum, it is essential that sound management programs be implemented, with emphasis on the first month of life. Programs should include as many proven management practices as can be incorporated efficiently and economically, and they should be based on the dairy producer's knowledge, skill, and available resources (Jenny et al, 1981). Calves can be reared successfully under a variety of management conditions. Factors that are considered to have an influence on morbidity and mortality are presented here.

Vigor and Health of the Calf at Birth

Several factors can affect the vigor and health of the calf immediately after birth. If the nutritional status of the dairy female at the time of parturition is adequate, nutritional deficiencies at birth are usually rare. Calves born from dams affected with any disease associated with prolonged anorexia, fever, or septicemia may be weak. Morbidity and mortality in dairy calves are associated with difficult calving in first-calf heifers. Dystocia is affected by several nongenetic and genetic factors, including age and parity of the dam, size of the calf, season of the year, and degree of birth difficulty. In some studies, up to 52% of first-parity dams received assistance in calving (Sieber et al, 1989). Correlations between dystocia and calf mortality have been about 0.7 (Weller et al, 1988). The genetic relationship between calf survival and calving difficulty of Holstein cattle has been examined (Martinez et al, 1983a,b). The high correlation between calving ease and calf survival means that any resultant improvement in calving ease as a result of sire selection or selective breeding is expected to cause improvement of calf survival (Cue and Hayes, 1985). However, there is some evidence that cows with a maternal disposition to easy calving produce daughters with a disposition toward difficult calving. This negative, direct maternal relationship occurs because small calves are born with ease, the small calf becomes a small cow, and the small cow has difficulty calving at early parities.

Prolonged parturition, especially second-stage labor lasting more than 1 hour, can cause postnatal respiratory acidosis in calves, which can adversely affect colostral immunoglobulin absorption (Boyd, 1989; Besser et al, 1990). Risk factors predictive of postnatal acidosis are second-stage labor of more than 1 hour, dystocia requiring traction, and weakness of the calf at birth (Besser et al, 1990).

Colostrum and Colostral Immunity

Calves are born agammaglobulinemic, and the most important factors influencing the health of the newborn calf are the ingestion of liberal quantities of good-quality colostrum within a few hours after birth and the subsequent absorption of sufficient amounts of colostral immunoglobulins within the first 24 hours after birth, when closure occurs. The colostral immunoglobulins that are absorbed provide protection against systemic infections, such as coliform septicemia. The colostral immunoglobulins ingested after closure are not absorbed but remain in the lumen of the intestine and provide local or lactogenic immunity. This is

Downloaded From Vet-eBooks.com

particularly important for protection against the rotavirus and coronavirus infections that cause diarrhea in calves after a few days of age.

Some of the absorbed and circulating immunoglobulin G_1 (IgG_1) is transferred back to the intestine and retains significant functional antibody activity in the intestine (Besser et al, 1988a,b). This mechanism accounts for most of the IgG_1 clearance. The concentration of colostral immunoglobulins declines rapidly by 2 to 3 days after parturition to low levels in the postcolostral milk, which makes calves susceptible to viral infections. The mortality rate resulting from diarrhea is much higher in calves with low levels of serum colostral immunoglobulins than in calves with adequate levels. Partial or complete failure of passive transfer of colostral immunoglobulins is a major determinant of liability to neonatal disease and mortality in calves (Gay et al, 1988). When considering the causes of failure of passive transfer of colostral immunoglobulins, the transfer process is affected by the following three major factors.

Formation of Adequate Amounts of Concentrated Immunoglobulin in Colostrum

IgG_1 is concentrated in the colostrum beginning about 4 weeks before calving, and in most cows continues until parturition. IgG_1 is the predominant colostral immunoglobulin, whereas IgM, IgA, and IgG_2 are present in considerably lower concentrations. Dairy cows invariably produce large amounts of colostrum (10 to 20 kg), but the concentration of immunoglobulins varies widely among cows. IgG concentrations are lower in first- and second-parity dams than in later parities, and the concentrations may be lower as the volume of colostrum increases. Calves from first-lactation cows have lower serum immunoglobulin concentrations than calves of older cows. Total immunoglobulin concentration tends to reach a maximum in the third or fourth lactation, almost doubling in amount compared with the first lactation (Devery-Pocius and Larson, 1983). The secretion of immunoglobulin ceases by the time of calving, and over 90% of immunoglobulins transferred at parturition can be expected to appear in the mammary secretion in the first four milkings.

Adequate Immunoglobulin Ingestion

The calf must ingest an adequate total mass of immunoglobulin within a few hours after birth. The concentration of IgG_1 in the colostrum, the age at first feeding, and the volume of colostrum are major factors affecting colostral IgG absorption. IgG concentration in the serum of the calf at 24 hours after colostrum feeding has a positive linear relationship with the IgG concentration in the colostrum. The calf must ingest an immunoglobulin mass of 80 to 100 g to achieve adequate serum levels of immunoglobulins. Natural sucking is the desired method of colostrum intake and is the most efficient, but it is influenced by the sucking drive and the vigor of the calf at birth. Delayed sucking is a major cause of failure of passive transfer in dairy calves. Surveys have shown that 25% to 34% of dairy calves fail to suck by 6 to 8 hours of age, and 18% fail to suck by 18 hours of age. Lack of sucking assistance is also a major contributing factor.

A comparison of three methods of feeding colostrum to dairy calves revealed that, in a dairy herd that allowed its calves to suck naturally, the prevalence of failure of passive transfer (calf serum IgG_1 concentration <10 mg/ml) was greater than 50%, even among calves suckled by cows with above-average concentrations of colostral IgG_1 (Besser et al, 1991). Failure of passive transfer occurred in 19.3% of calves fed colostrum using a nipple bottle and in 10.8% of calves from a herd using tube feeding. The management factor determined to have the greatest influence on the probability of failure of passive transfer in the herds using artificial methods of feeding colostrum was the volume of colostrum fed, since it affected the total amount of IgG_1 received by the calf (Besser et al, 1991). The prevalence of failure of passive transfer can be minimized by artificially feeding all calves large volumes (3 to 4 L) of fresh or refrigerated first-milking colostrum from cows that had nonlactating intervals of normal duration. The administration of colostrum by esophageal tube is an effective method for feeding colostrum to calves too weak or otherwise reluctant to nurse after birth.

One of the major causes of failure of passive transfer in naturally sucking dairy calves is the ingestion of colostrums with inadequate concentrations of immunoglobulins (Gay et al, 1988). There is considerable variation in the intake of colostrum by naturally sucking calves, but the average intake approximates 2.5 L. At this average intake, the colostral immunoglobulin concentration must be 40 g/ml IgG_2 in order to achieve a mass intake of 100 g of Ig. A significant percentage of colostrums do not contain this concentration, and mass intakes are reduced even further in calves that ingest volumes below the average. Passive transfer failure can be minimized by assisting the calf to the udder early in its life and ensuring a long sucking period to the point at which the calf reaches satiation.

The concentration of immunoglobulins in colostrum can be measured indirectly using a hydrometer as a colostrometer (Fleenor and Stott, 1980). The colostrum is placed in a graduated cylinder, and the hydrometer indicates whether the colostrum is superior, adequate, or inferior. This should enable the dairy producer to establish the quality of colostrum prior to feeding and to avoid a first-stage failure in passive transfer of immunity from inferior colostrum. It also allows pooled colostrum to be extended over a greater number of neonates by adjusting the amount fed to a minimum volume that delivers a fixed mass of immunoglobulin.

Systemic Immunoglobulin Absorption

The absorption of immunoglobulins by the intestine into the systemic circulation of the calf is another important factor. Colostral immunoglobulins are absorbed for up to 24 hours after birth in calves, but the maximum efficiency of absorption occurs during the first 6 to 12 hours after birth. This rapid decline in absorption combined with delayed ingestion of colostrum results in failure of passive transfer, which occurs in 10% to 30% of calves, even under ideal conditions. The termination of absorption of colostral immunoglobulins in the calf occurs spontaneously with age at a progressively increased rate after 12 hours postpartum.

The rate and amount of absorption are a function of the concentration of immunoglobulins in the colostrum, the amount fed, and the age at first feeding. Increasing amounts of the colostrum fed (up to 2 L to Holstein calves) increases the amount of absorption. The rate of absorption and maximum absorption is superior in calves that suck their dams. However, up to 42% of calves left with their dams for 1 day after birth fail to either suck or absorb immunoglobulins from colostrum and are hypogammaglobulinemic or agammaglobulinemic. Forced bottle-feeding of calves following sucking for 1 day improves the serum levels of immunoglobulins. To overcome the problem of insufficient absorption of colostral immunoglobulins, it is generally advisable to force-feed colostrum to calves as soon as possible after birth. Calves force-fed colostrum at a dose of 80 ml/kg body weight by stomach tube at 6 hours of age achieve high levels of serum immunoglobulins by 24 hours of age.

Downloaded from Vet-a-Books.com

Higher levels are achieved in calves fed colostrum compared with those allowed to suck their dams.

The serum immunoglobulins of newborn calves may vary according to the season of the year. Mean monthly serum IgG_1 concentrations may be lowest in calves born in the winter months (November to May) in temperate climates such as Washington State and Scotland and increase in calves born in the spring and early summer to reach peak levels in September, after which they begin to decrease again (Gay et al, 1983). The opposite has been described for calves born in warmer climates such as Florida, where the highest levels occurred in February and March and lowest levels during the warm summer months.

The serum concentrations of colostral immunoglobulins that are considered adequate in the calf at 24 hours of age and after it has ingested colostrum vary widely, from 5 to 15 mg/ml (Gay et al, 1988). It is important to note that there is no precise level of serum immunoglobulin above or below which resistance or susceptibility to infectious disease exists. The threshold of circulating immunoglobulin concentration associated with increased susceptibility varies from farm to farm; on some farms there is no apparent relationship between immunoglobulin concentration and the incidence or severity of disease. Farms with high calf mortality may have calves with low levels of serum immunoglobulins, but other farms with calves having low levels may have low calf mortality.

Other closely related factors include infection pressure and management practices. An epidemiological study of serum IgG levels in dairy calves from birth to 180 days of age in 300 herds visited during the winter season found that 32% of calves between 1 and 10 days of age were hypogammaglobulinemic (Norheim and Simensen, 1985). There was considerable variation based on age of calf, geographic area, season of the year, parity of dams, method of feeding, and housing factors. The selection of a serum immunoglobulin concentration of 10 mg/ml as a threshold indicator for successful passive transfer is an attainable goal that can be reached with most calves if they ingest a mass of 150 g of IgG_1 (Gay et al, 1988). This means that calves must ingest from 3 to 4 L of colostrum, which may contain 50 to 150 g/L of IgG, within the first day of life. The mean concentration of IgG in fresh colostrum is about 100 g/L IgG, but some colostrums contain only approximately 50 g/L and others contain more than 150 g/L, depending on the interval between calving and sampling and on the volume of the colostrum (Besser et al, 1991).

The variation in immunoglobulin concentration of colostrum among cows can be large. The mean immunoglobulin concentration was 121 g/L at the first milking (7 hours), 61 g/L at the second milking (19 hours), and 24 g/L at the third milking (25 hours) (Fallon et al, 1989). The IgG concentration was less than 50 g/L in 7% of cows, less than 100 g/L in 36%, and less than 150 g/L in 26%. Calves relying on the colostrum with low levels could not attain sufficiently high levels, even with normal levels of colostrum intake. Based on the evaluation of published literature in the United Kingdom and United States over 20 years involving a total of 6566 calves, those with serum levels lower than 10 mg/ml of IgG_1 are four times more likely to die and twice as likely to be affected with disease as calves with adequate levels (White and Andrews, 1986).

Infectious Agents

Knowledge and understanding of the prevalence and virulence characteristics of infectious disease agents in the environment of newborn dairy calves would assist in developing rational disease control programs.

In most cases, the calf is born without any pathogens in its body. However, within minutes after birth, it becomes contaminated with the wide variety of pathogens that are in the immediate environment. It has always been assumed that the level of infectious disease pressure experienced by the newborn calf is directly proportional to the concentration of pathogens in the environment, which includes the bedding or ground surface, walls of the pens, air, and other environmental structures with which the calf comes in contact soon after birth. The dam of the calf and other animals in the immediate vicinity, particularly diarrheic animals or animals ill with other infections, constitute the main source of most pathogens. Calves born into a highly contaminated environment may become infected during birth with enteropathogens carried by their dams or other cows. Enteric pathogens are spread within a herd through the feces of infected animals and all inanimate objects that can be contaminated by feces, including bedding, pails, boots, tools, clothing, and feed and water supplies. Heavily used calving pens can become heavily contaminated with enteric pathogens, such as *E. coli*, *Salmonella* sp., rotavirus, coronavirus, *Cryptosporidium* sp., and *Eimeria* sp. Enterotoxigenic *E. coli* (ETEC) are relatively resistant to environmental factors and can survive for long periods under the right conditions. One serogroup of the organism survived as long as 6.5 months in calf crates contaminated with calf feces (Acres, 1985). The total numbers of bacteria in a calf pen or barn continue to increase as newborn calves are introduced successively into the facility and the facility is continually occupied by animals without depopulation, clean out, disinfection, and period of vacancy (Roy, 1990). This increased occupation time causes a buildup of infection associated with an increasing incidence of enteric disease and suboptimum performance. This can be resolved by moving the animals out of the facility with a clean out and disinfection, followed by a period of vacancy for several days.

The ecology of *E. coli* in market calves fed a milk-substitute diet or in calves reared as dairy cow replacements is dynamic and complex (Hinton et al, 1985a,b). The fecal *E. coli* flora changes continually with time, and an increase in the incidence of resistance among *E. coli* flora can occur independently of oral drug therapy (Hinton et al, 1985a). Multiple resistant strains may appear, and, although their source is uncertain, they may emerge from the use of antibacterial drugs over the years (Hinton et al, 1985a). In calves reared as replacements, there is a continual turnover in the strains forming the majority of fecal *E. coli* (Hinton et al, 1985b). The incidence of antibiotic resistance is low when the calves are a few days of age and housed with adult animals. The antibiotic resistance index (ARI) may then increase during the first week after the animals have been weaned and moved into nursery pens (Hinton et al, 1985b). The ARI then decreases from the third week after weaning to low levels by the time the calves are 5 months of age and the flora is dominated by an increased proportion of sensitive *E. coli*.

ETEC, rotavirus, coronavirus, and *Cryptosporidium* sp.—the four major causes of diarrhea in calves—are responsible for 75% to 95% of enteric infections of calves worldwide. The relative frequency of each of these pathogens varies from farm to farm, year to year, season to season, and country to country. Infections with one pathogen or mixed infections may predominate (Pohjola et al, 1986). The prevalence and incidence of enteropathogens in calves are also age dependent. ETEC affects calves primarily under 2 days of age (Acres, 1985). In contrast, rotavirus, coronavirus, and *Cryptosporidium* affect calves from 3 days of age up to 4 weeks of age. Although these pathogens may be necessary causes of the diarrhea, they may not be sufficient causes. It is important to remember that these pathogens can also be found in

Downloaded From Vet-e-Books.com

healthy calves. In some surveys the rotavirus can be found in the feces of up to 50% of healthy calves (Reynolds et al, 1986). In microbiologic surveys of diarrheic and healthy calves, it is common to find mixed infections in diarrheic calves, whereas in healthy calves it is unlikely to find three or more pathogens (Reynolds et al, 1986). In a survey of the fecal samples of diarrheic calves on farms experiencing outbreaks of diarrhea, the rotavirus was the most common enteropathogen found, being excreted by more than half the diarrheic calves (Snodgrass et al, 1986).

Experimentally, there is evidence of synergistic interaction between concomitant rotavirus and ETEC infections of calves about 1 week of age (Runnels et al, 1986). Coronavirus, *Cryptosporidium*, and ETEC were also found in diarrheic calves. Rotavirus was excreted by 18% of healthy calves, coronavirus by 4%, and *Cryptosporidium* by 14%, but no ETEC or *Salmonella* sp. were detected (Snodgrass et al, 1986). In another survey of the prevalence of ETEC in calves in Scotland and northern England, it was found that enterotoxigenic colibacillosis is a major cause of diarrhea in calves less than 3 days old but is not associated with the typical diarrhea problems seen on most farms in calves more than 3 days old.

Enteropathogenic *E. coli* that are not enterotoxigenic but that cause attaching and effacing lesions in the intestines of calves are being recognized with increasing frequency (Wray et al, 1989). These enteropathogenic *E. coli* attach to and efface the microvilli of the intestinal epithelium and resemble the well-known human enteropathogenic *E. coli* (Okerman, 1987). They are associated with dysentery in calves 8 to 21 days of age (Chanter et al, 1986). These strains produce high levels of Shiga-like toxin (Moxley and Francis 1986), attach to the epithelium of the large intestine, and cause degeneration of the enterocytes, which causes dysentery (De Rycke et al, 1987; Schoonderwoerd et al, 1988). These enteropathogens are important zoonoses. Verotoxin-producing *E. coli* serotype 0157H:7 have been incriminated as a causative agent in single cases and outbreaks of hemorrhagic colitis and hemolytic-uremic syndrome in Canada, the United States (Dorn, 1988), England, and Wales (Chapman et al, 1989). Cattle can be a reservoir for the organism, and there is a significant association between an outbreak of diarrhea affecting children in Canada and the consumption of unpasteurized milk (Orskov et al, 1987).

A survey of the prevalence of selected calf pathogens on Holstein dairy farms in Ontario found that 22% of farms had calves infected with *Salmonella* sp., 13% with *Campylobacter jejuni/E. coli*, 41% with enteropathogenic *E. coli*, 19% with rotavirus, and 5% with coronavirus (Waltner-Toews et al, 1986g). The use of nipple feeders for calves was associated with an increased probability of farms having calves shedding detectable fecal levels of *Salmonella* sp., *E. coli*, or one of the two viruses. The use of group pens was associated with increased odds of finding *C. jejuni*. Calves with diarrhea tended to have increased odds of shedding rotavirus and of the presence of *E. coli* with the K99 antigen.

Surveys of the use of antimicrobials prophylactically and therapeutically in calves in dairy herds found that only about 20% of farms administer antimicrobials prophylactically (Waltner-Toews et al, 1986a). About 30% of farms used vitamins prophylactically. There was some evidence that the prophylactic use of antimicrobials was associated with a decreased risk of being treated for pneumonia and of dying, but with an increased risk of being treated for diarrhea.

Several different viruses cause diarrhea and intestinal lesions in calves. The rotaviruses and coronaviruses have been established as major viral agents of diarrhea in young calves (Saif and Smith, 1985). Rotavirus infections cause diarrhea in calves from 5 to 15 days of age. The virus is ubiquitous in the environment of most cattle herds, and serologic surveys have indicated that about 90% of adult cattle have been exposed to the virus and seroconverted. The intestinal tract is the site of multiplication of the rotavirus, and it is excreted in the feces in large numbers, as many as 10^{10} virus particles/g of feces. Because rotaviruses are stable in feces and relatively resistant to commonly used disinfectants, it is extremely difficult to prevent gross contamination of calf barns once infection has been introduced. However, the cycle of rotavirus infection can be broken by thorough cleaning and disinfection of the calf barn (McNulty and Logan, 1983). The mature animal is the source of the virus for the newborn calf, and both calves and adult cattle may excrete the virus for several weeks.

There are at least four serotypes of rotaviruses. The most clinically significant strains in the animal and human populations belong to group A. Those strains belonging to groups B and C and possibly others are known as atypical rotaviruses. There are differences in virulence among the bovine rotaviruses, which may explain the variability in the severity of disease in natural outbreaks, and this must be considered when developing vaccines.

A unique characteristic of rotavirus infection in calves is the short-term nature of the lactogenic immunity provided by colostrum. Newborn calves are protected from the rotavirus only during the first few days after parturition, during which time the colostrum contains a sufficiently high titer of specific rotavirus antibody, which is active in the lumen of the intestine. Calves become susceptible to rotavirus diarrhea at about 5 to 7 days of age. This coincides with a marked drop in colostral immunoglobulins by the third day after parturition and allows for an incubation period of 18 to 24 hours for the disease to occur. The levels of serum and colostral antibody are also lower in first-calf heifers, which may explain the higher morbidity and mortality in their calves.

Bovine coronavirus can cause a severe enteritis in dairy calves. The virus is frequently found in the feces of calves, and a high prevalence of coronavirus antibody has been reported in adult cattle (Collins et al, 1987). In large dairy herds, approximately 50% to 60% of adult cows may shed the virus during the winter months and at parturition, with a smaller percentage during the summer months. Vaccination of the cows with a modified live rotavirus and coronavirus–*E. coli* combination vaccine may cause a decrease in the incidence of shedding at parturition, which may explain the reduction in the incidence of neonatal diarrhea (Collins et al, 1987).

Zoonotic Infections in Dairy Calves

Cattle may excrete certain *E. coli* serotypes associated with human disease, including enterohemorrhagic *E. coli* 0157H:7, which cause bloody diarrhea, hemorrhagic colitis and hemolytic uremic syndrome, and thrombocytopenic purpura. Several strains of enterohemorrhagic *E. coli* associated with enteric disease in humans produce a verotoxin also known as a Shiga-like toxin (Whipp et al, 1994). They do not cause clinical disease in cattle. The most prevalent serotype among human patients in North America, Europe, and the United Kingdom is *E. coli* 0157H:7. Transmission of the organism is thought to occur through the ingestion of uncooked ground beef and consumption of raw milk, although outbreaks have been associated with fresh-pressed apple cider, unchlorinated drinking water, and person-to-person transmission.

Serotype 0157H:7 *E. coli* is classified as an enterohemorrhagic *E. coli* because it causes hemorrhagic colitis, produces a Shiga-like toxin, does not produce either heat-stable or heat-labile toxin (which is characteristic of ETEC), and is not invasive. *E. coli* 0157H:7 is considered the epidemic strain

Downloaded From Vet-e-Books.com

because it has been responsible for major outbreaks reported in the United States, Canada, and the United Kingdom.

The prevalence of *E. coli* 0157H:7 in the cattle population is low, but there is a higher prevalence of the organism on dairy farms linked to human illness than on farms representing the general cattle population. The organism resides in the gastrointestinal tract of animals and is shed in the feces of cattle. The excretion period ranges from hours to weeks. Dairy cows are more often implicated in human outbreaks because hamburger contains more meat from dairy cattle than from beef cattle and because they were the source of milk responsible for several well-documented milkborne outbreaks.

In a survey in the United States, the prevalence in dairy heifers and in all cattle was 0.37% and 1.85%, respectively (Whipp et al, 1994). Surveys in cattle in Spain indicate that cattle are reservoirs of verocytotoxigenic *E. coli* (VTEC), which are pathogenic for man (Blanco et al, 1996), and that VTEC and cytotoxic necrotizing *E. coli* (NTEC), which produce cytotoxic necrotizing factor, are normal intestinal flora of cattle.

The organism has been isolated from dairy calves less than 8 weeks of age, and calves were three times more likely to shed the organism after weaning (Garber et al, 1995). Estimates of the prevalence of VTEC fecal carriage among populations of cattle vary considerably. An observed prevalence of 79% for VT1-neutralizing antibodies suggests that exposure to VT1 toxin-producing *E. coli* is widespread in dairy cattle in Ontario (Borman-Eby et al, 1993). In a survey in Germany, 84% of the bovine colostrum samples examined contained Shiga-like toxin activity, which is four to eight times higher than reported isolation rates of Shiga-like toxin *E. coli* from the feces of cattle (Pirro et al, 1995). This suggests that exposure of cows in Germany to these strains of *E. coli* is more widespread than expected from epidemiological studies based on bacterial isolation.

A study of the distribution and characteristics of VTEC isolated from Ontario dairy cattle showed that the prevalence rates in cows and calves were estimated at 9.5% and 24.7%, respectively. The proportion of animals infected on each farm ranged from none to 60% for cows and none to 100% for calves. Of 206 VTEC isolates from 100 dairy farms, few were of serotypes that have been isolated from humans and none were *E. coli* 0157H:7 (Wilson et al, 1992). A case-control study of diarrheal disease in veal calves in Ontario did not identify any VTEC in diarrheic cases or controls (Wilson et al, 1992b). In Ontario, dairy farms with a high prevalence of VTEC infection in calves tended to be small and have open herds Similarly, dairy herds with a high prevalence of VTEC infection among cows tend to be small and more likely to use traditional tie-stall housing systems and bucket milkers than herds with a low prevalence of VTEC infection (Wilson et al, 1993). Shedding of *E. coli* 0157H:7 by infected dairy cattle appears to be transient, and persistence of the organism in the environmental sites is not characteristic (Rahn et al, 1997).

In Washington State, *E. coli* 0157H:7 was found in 0.28% of fecal samples from dairy cattle in 8.3% of herds. Fecal samples, bulk milk samples, and milk filters were negative for the organism. The strain was also isolated from 0.71% of fecal samples from pastured cattle of 16% of herds sampled (Hancock et al. 1994). In a longitudinal study in 14 herds for up to 13 months, the overall prevalence was 1% and 9 of 14 herds were positive (Hancock et al, 1997). Weaned heifers had a higher prevalence (1.8%) than did unweaned calves (0.9%) or adults (0.4%).

In a survey of Wisconsin dairy farms, the herd prevalence was 7.1% and the animal prevalence of 1.8% (Faith et al, 1996). Observations made during the follow-up study suggested that horizontal transmission was an important means of *E. coli* 0157H:7 dissemination on the farms. Drinking water on dairy farms in Wisconsin has also been identified as one source and, because of the failure to detect the organism in a limited number of other environmental samples, indicates that contaminated water may be an important source of the organism on some farms.

In a 15-month study of *E. coli* 0157H:7 in a dairy herd, maximum prevalence at any one visit was 14% in lactating cows, 40% in nonlactating cows, 56% in calves, and 68% in heifers (Mechie et al, 1997). Excretion rates in lactating cows were highest during the first month after calving, falling during lactation and rising to another peak at 7 months prepartum. Between November and May there was no evidence of excretion in any group. The organism was not isolated from milk taken from the bulk tank, but it was isolated from individual milk samples from two animals previously shown to be fecal excreters. All isolates of the organism on that farm were of the same phage type, toxin genotype, and plasmid profile.

ENVIRONMENTAL, HOUSING, AND MANAGEMENT PRACTICES

Nutrition and Management of the Cow During the Dry Period

The vigor and health of the newborn calf at birth can be influenced by the nutrition and management of the cow during the dry period (Quigley and Drewry, 1998). Nutritional and management strategies for dairy cattle are designed to prepare the cow for lactation and to minimize the incidence of metabolic diseases at calving time. Strategies during the dry period should also be used to ensure the birth of a healthy and vigorous calf. Fetal requirements for energy and protein are significant, particularly during the last trimester of gestation. Energy requirements increase 1.3 to 1.5 times maintenance in late pregnancy, which necessitates that formulation of dry cow rations contain sufficient energy to support fetal growth plus maintenance. Protein requirements during pregnancy increase, especially in the last 2 months. Colostrum is a source of immune components and nutrients for the neonatal calf and contains more protein, immunoglobulins, nonprotein nitrogen, fat, ash, vitamins, and minerals than does milk. Because some vitamins do not cross the placental barrier, colostrum is the primary source of these nutrients for the calf after birth. The vitamin E content of colostrum is usually low unless the cow is provided supplementary dietary vitamin E. Calves are born with very low liver reserves of vitamin A and low concentrations of vitamin A (Franklin et al, 1998). Vitamins A and D also do not cross the placenta in significant amounts, and the calf is dependent on the ingestion of colostrum for these vitamins. Dairy producers often inject calves with vitamin A at birth or feed milk replacers with high concentrations of vitamin A (66,000 IU/kg) to ensure that calves are provided with sufficient vitamin A to improve their vitamin A status quickly. However, supplementation of milk with vitamin A from birth to 6 weeks of age did not enhance the plasma vitamin A status or health and immune parameters (Franklin et al, 1998). Selenium readily crosses the placenta. Dry cow diets should be supplemented with vitamins and minerals to improve the quality of colostrum.

Personnel

Those feeding and caring for calves have a marked influence on their health. In a field study, calf survival was highest when the owner's wife fed and cared for the calves, whereas survival was lower when hired labor was responsible for the

Downloaded from Vet-e-Books.com

feeding and care of the animals. In 16 large dairy farms in California where the calf mortality rate over a period of at least 2 years on individual farms varied from 3% to 30%, the calf management personnel was the only factor significantly related to the mortality rate. A large study found that dairy operations in which males had primary responsibility for the care and feeding of calves were more likely to have a higher level of mortality (Losinger and Heinrichs, 1997). Herd-management policies directly and indirectly influence the cumulative incidences of morbidity and mortality (Curtis et al, 1993). Path models of the interrelationships between herd-management practices and herd cumulative incidences of calfhood morbidity and mortality have been developed (Curtis et al, 1993). Management practices in Holstein dairy herds associated with higher rolling herd average milk production include calves born in individual areas in buildings, calves hand-fed first colostrum, starter fed to preweaned calves, and ionophores fed to heifers from birth to first calving (Losinger and Heinrichs, 1996a).

Considerably fewer death losses occur on farms in which the owner manages the calves than those in which employees perform the duties. In general, other factors, such as herd size, calving location, and calf housing, were not related to calf deaths in the survey. In a management study that compared management techniques used by various farm personnel that were in charge of calves and heifers (Kiernan and Heinrichs, 1994), they were able to identify several subgroups of people that shared various management techniques. Within the study there were 5 distinct groups based on behavior and management techniques used. Understanding the human behavior can allow the veterinarian to focus education and prevention strategies used for the calf and heifer employees and owners.

This discussion of personnel suggests that—regardless of herd size, housing pen construction, calving site, and many other factors that have been associated with calf mortality—calf rearers and their motivation to raise healthy calves have the greatest influence on calf survival.

Herd Size

As herd size increases, mortality commonly increases. In an expansion program, the total number of cows and milking facilities might be enlarged without a parallel increase in calf-raising facilities and labor. A marked increase in population density commonly causes an increase in the incidence of infectious disease. Outbreaks of infectious disease in calves under 4 weeks of age occur more commonly in large herds (over 100 cows) than in smaller herds and can cause major economic losses because of death, the costs of treatment, and suboptimum calf performance. Dairy herds that house calves in large groups before weaning may need to provide extra care and management to minimize the clinical disease and mortality associated with respiratory disease (Losinger and Heinrichs, 1996b).

In Michigan dairy herds, larger herd size (more than 200 adult cows) was associated with an increased incidence density of calf diarrhea (Frank and Kaneene, 1993).

Season of the Year

Dairy calf death losses increase during midsummer (June, July, August) and midwinter (November, December, January), with mortality rates being 20% higher than those in summer. The risk of death of calves is greatest in their first week of life on most farms. Of all deaths in calves less than 5 weeks of age, 55% occur during the first week of life and 25% to 30% during the second week. In general, the death loss in calves between 5 weeks and 3 months of age is lower than 5%. The season of the year during which the calf barn is occupied by the largest number of calves has a major influence on calf mortality. Many studies have shown that calf mortality is significantly higher during the winter months in colder climates when all calves born may be housed from 2 to 6 months, depending on the length of the winter. This long period of occupation causes an increase in the infection pressure, discomfort because of wet bedding, and perhaps poor ventilation.

During the winter months, increases in calf mortality were associated with cold, wet, windy weather; in summer, greater death losses were associated with hot, dry weather. In general, calf losses in winter were more closely related to the effects of extreme weather than losses in summer. Under Israeli conditions, the critical period for calf mortality is winter, which is cool and rainy. Low temperatures and high humidity are not conducive to calf health and can increase calf mortality. A comparison of calf mortality in two farming systems indicated that the larger farms invested the resources necessary to care for newborn calves in contrast to smaller farms, which did not have the same resources, and mortality was higher.

Relationship Between Housing and Health of Dairy Calves

The provision of a proper environment for calves, in addition to adequate nutrition and other health-related programs, is critical to the success of raising herd replacements. The diagnosis and treatment of sick calves has long been recognized, but the need for effective management of environment to ensure optimum calf health has received much less attention (Bates and Anderson, 1984). On most dairy farms, calves are taken from the maternity area soon after birth and placed in the calf-rearing part of the main barn. Calves raised for herd replacements are commonly maintained in facilities that range from total confinement in narrow, elevated, individual stalls; being tethered along an inside wall of the main barn; group pens; and individual calf hutches to open pastures. The greater the degree of confinement, the more the calves' environment is under the control of the producer, and the less calves are able to make behavioral responses to that environment. Morbidity and mortality rates are usually higher in calves housed indoors than outdoors, but there may be no difference between the health of calves raised in individual pens in an insulated, heated barn and the health of calves raised in outdoor hutches. The increased illness and mortality in calves that are reared indoors is often attributed to a combination of inadequate control of the thermal environment, poor air quality, undesirable relative humidity, inadequate exchange of air, and poor sanitation. However, open sheds and hutches can also become contaminated with common calf pathogens and, when combined with environmental stressors, can cause disease.

Surveys of dairy calf and heifer housing have found that many housing practices are less than adequate (Heinrichs et al, 1987a,b). Dairy producers also recognize calf housing as a problem that is important to the veterinarian, building designer, and manufacturer. Producers who recognize the problem are more receptive to logical and economical solutions through educational programs, new building designs and equipment. Under controlled conditions many different types of calf and heifer housing systems yield satisfactory results when proper management for that housing is undertaken.

Downloaded from Vet-eBooks.com

Acute undifferentiated diarrhea of calves under 30 days of age and enzootic pneumonia complex are the two major diseases of concern in housed dairy calves from birth to weaning (Van Donkersgoed et al, 1993). Acute undifferentiated diarrhea is associated primarily with *E. coli*, rotavirus, coronavirus, and *Salmonella* sp. These pathogens are excreted by calves, and the level of contamination in calf pens is dependent on the population density and level of sanitation and hygiene practiced by management. The viruses most commonly associated with enzootic pneumonia include the parainfluenza-3 (PI-3) virus, bovine respiratory syncytial virus (BRSV), and some others, such as the adenovirus. These viruses are considered as primary pathogens and can produce an interstitial pneumonia and atelectasis, which are characteristic lesions. *Mycoplasma* sp. have also been isolated from the lungs of calves with enzootic pneumonia (Kiorpes et al, 1988). Secondary bacterial pneumonia caused by *Pasteurella* sp., *Haemophilus somnus, Actinomyces pyogenes, Streptococcus* sp., and *Salmonella* sp. is a common occurrence in enzootic pneumonia and usually accounts for the severe clinical disease that is characteristic of the advanced stages of the disease.

Sole hemorrhages can be found in female dairy calves examined between 2.5 and 12 months of age (Frankena et al, 1992). The etiology is not well understood, but housing on straw was a preventive factor compared with housing on slatted floors.

The calf is a *homeotherm* and is capable of maintaining a relatively constant body temperature throughout a wide range of ambient temperatures. The internal core temperature of the calf is regulated by the animal's ability to achieve a balance between the heat it produces in metabolism and the heat gained or lost from the environment (Bickert and Herdt, 1985). The calf exchanges heat energy with its surroundings through conduction, convection, radiation, and evaporation. Changes in the immediate physical and thermal surroundings of the calf that affect heat exchange through one or more of its four modes can affect thermoregulation and increase susceptibility to disease.

The *essential environmental* needs of the young calf are *comfort, space,* and *hygiene* (Webster, 1984). The thermal environment, which includes air temperature and air movement, and the physical space, such as the floors and surfaces with which the calf makes contact, must be comfortable. The space available to each calf should at least give it sufficient room to stand up, lie down, turn around, stretch its limbs, and groom itself. It should also provide calves with a reasonable degree of social intercourse. The microbiological environment consists of the floor and wall surfaces, the bedding used, the air quality, the contact the calf makes with other calves, and the utensils and materials used by personnel in feeding and handling the animals.

Many cases of poor health in dairy calves have been traced to inadequate management and ventilation in the calf nursery. Calves reared indoors are commonly affected with pneumonia caused by viruses and bacteria, which may reach high concentrations in the air of poorly ventilated, damp, and cold calf barns (Heinrichs et al, 1994b). Calf barns that are overcrowded, dark, and damp in the winter months and hot and poorly ventilated during the summer months commonly predispose to diseases of the respiratory tract. Unfortunately, in most dairy herds, the emphasis is on the milking cow, and the calf barn traditionally has received low priority, causing uncomfortable rearing conditions that predispose to infectious diseases. Some producers have had so much difficulty raising calves indoors that they have resorted to rearing young calves in calf hutches outdoors. Whereas considerable research and effort have been expended in elucidating the infectious causes of respiratory diseases in calves raised indoors, only a few studies have been done to develop economical and practical methods of providing an optimum environment for calves raised indoors. Enzootic pneumonia of dairy calves often clusters strongly within herds, which may be related to certain risk factors in individual farms (Van Donkersgoed et al, 1993).

The effects of environment and management on mortality in dairy herds were determined by monitoring the herds for 1 year as part of the National Animal Health Monitoring System (Lance et al, 1992). Herd size, days on a nipple feeder, navel disinfection, type of housing, and whether each calf observed with diarrhea was treated with antibiotics were the factor with the most effect on herd mortality. These variables explained approximately 39% of the variation in mortality among herds.

Some common environmental problems in calf barns include the following:

1. Calf-rearing facility not well designed for the size of the herd, ease of cleaning pens, feeding calves, and identification and management of sick calves. Many calf pen areas in the main barn are dark because of lack of lighting, and the attendants do not have a good look at the calves on a daily basis.
2. Overcrowding. This is common in situations in which calves are grouped in pens and calves of different sizes and age groups are raised in the same pens.
3. High relative humidity because of overcrowding, low temperature of incoming air, and lack of supplemental heat. As a result, many calf pens are wet, cold, and uncomfortable, and the calves suffer chronic cold stress.
4. Inadequate movement of air in and out of the building. This can be the result of inadequate inlets, insufficient capacity, or poor location of fans.
5. Rearing calves in close proximity to adult cows. This allows for the spread of pathogens from older, immune animals. A ventilation system that draws air from the adult stock to the calf pens promotes the spread of infectious disease.

The important principles of calf housing include the following:

1. A calf-rearing facility completely isolated from the adult herd.
2. Periodic depopulation for cleaning and disinfection. An ideal system would involve rearing calves in separate groups of stalls or pens to allow serial depopulation, with some of the units being emptied, sanitized, and ready for the next batch of calves. The pens must be designed and located so that they are cleaned easily on a regular basis.
3. An independent and effective ventilation system that is flexible according to the seasonal changes of outside weather. This includes supplemental heat when necessary.
4. Sufficient space for each calf according to its size.
5. An effective feeding system.
6. An adequate lighting system so that each calf can be seen daily.
7. A system that allows regular monitoring of calf performance, such as body weight and height measurements.

Calves can be raised indoors in warm housing facilities that are designed to provide a relatively uniform environment throughout the winter. Attention must be given to ventilation, heating, insulation, controls of ventilation and heating, and management of the system (Bickert and Herdt, 1985). They may also be reared outdoors in cold housing in hutches or other naturally ventilated facilities.

Downloaded from Vet-eBooks.com

CALF HOUSING REQUIREMENTS

The following descriptions of an optimum environment for housed calves are offered as guidelines for the veterinarian who may assist the producer in designing a calf barn or evaluating existing calf barns. The reader is encouraged to consult the review literature and general references for more information on details of calf housing (Anderson and Bates, 1984; Bates and Anderson, 1984; Bickert and Herdt, 1985). Veterinarians should seek the assistance of the state or provincial department of agriculture, which usually provides the necessary assistance in designing calf barns and in modifying existing calf barns. Reducing the incidence of pneumonia in dairy calves in a warm calf barn is a complex, multidisciplinary problem (Bantle et al, 1994). Changing the heating and ventilating system in a calf barn can improve the environment and improve the health of the calves, but it may not reduce the incidence of pneumonia. Factors other than simply changing the ventilation system must be considered.

Insulation

For indoor housed calves, adequate insulation of calf barns is normally considered essential to avoid extreme temperature variations in winter and to keep the calf barn cool in summer. The main aim is to use construction materials with a low thermal conductivity in the walls and ceilings. Resistance values (R values) for the various insulating materials are available (Bates and Anderson, 1984). Insulation of the roof is of utmost importance. It is essential to have a vapor barrier, such as a layer of plastic sheeting over the insulating material, to prevent moisture produced in the calf barn from penetrating the insulation and reducing its effectiveness.

Thermal Environment

One of the aims of a well-ventilated calf barn is to keep the calf's body temperature within narrow limits. Newborn calves have a slightly reduced body temperature, rising to 38.7° C (101.6° F) on the first day of life and 38.9° C (102.1° F) on the second day. Thereafter, the body temperature remains at about 38.8° to 39° C (101.8° to 102.2° F) for the first 3 weeks of life. With high levels of feeding there is an increase in body temperature; low levels of feeding cause a reduction of temperature. The environmental comfort zone for calves ranges from 10° to 21° C (50° to 70° F), and achievement of this range depends on the number of calves, their total heat and moisture production, the total surface area and volume of space available, the outside temperature, the insulation properties of the building materials, the type of bedding used (if any), the ventilation rate, and whether supplemental heat is provided. If the environmental temperature of the calf barn goes above the upper limit of the comfort zone, productivity falls progressively. On the other hand, the effect of a drop in temperature below the lower limit of the comfort zone may be slight at first, except for the "wastage" of part of the calf's feed intake in increasing its metabolism to keep warm. The cost of feed intake used as internal fuel is approximately four times the cost of external fuel sources, such as electricity or gas used to keep the calf barn at least at the lower critical temperature.

Calves must be kept on clean, dry bedding and free from cold drafts. The construction and ventilation system of the calf barn depends on the geographic location of the calf barn and on the mean maximum and minimum ambient temperatures experienced in that area. It is much more difficult to ventilate a calf barn during the winter months when the mean outside temperature is −26° C (−15° F) than during other seasons, when the mean outside temperature may be 9.4° C (15° F).

In some areas and under certain circumstances, it may not be economically justifiable to construct or maintain a controlled environment calf house. In the northeast of Scotland, calf house temperatures within the range of 1° to 20° C (34° to 68° F), with relative humidities from 64% to 96%, had no demonstrable effect on calf health and performance (Mitchell and Broadbent, 1973). The extra capital cost involved in a controlled environment type of calf house did not appear to be justifiable in terms of calf health or performance of calves in the northeast of Scotland. The controlled house was insulated, of concrete block construction with an insulated roof, and had fan-assisted ventilation and provision for supplementary heat. The temperature and ventilation were controlled. In the climatic house the salient features were its low-cost wooden frame constructed of exterior grade hard board, without insulation and with no supplementary heat. Ventilation was by ridge outlet and perforated inlets in the upper half of the walls. In both types of calf houses the calves were straw bedded.

Relative Humidity

The generally accepted ideal range of relative humidity for calf barns is 70% to 80%. The relative humidity and inside temperature are interdependent, in that a high relative humidity and low temperature promote condensation on walls and ceilings and ultimately on calves, causing cooling, shivering, discomfort, and a high incidence of respiratory tract disease. Calves give off considerable sensible heat loss and moisture, but the heat production is not sufficient to lower the relative humidity. Thus, under most conditions, supplemental heat is necessary to counteract the additive cooling effect of cold incoming air, which tends to decrease the inside temperature and increase the relative humidity. In Canada and the northern United States, where the mean daytime temperature during the winter months may be as low as −15° C (5° F), owners usually close the air inlets in the calf barns because the incoming air is too cold. However, this is counterproductive because it effectively reduces the ventilation rate to almost nothing, which increases the concentration of aerosol infection. Under these circumstances, supplemental heat is a requirement.

If the relative humidity in the building is high at an abnormally high air temperature, the ability of the animal to dissipate heat by vaporization of water (by sweating or through the lungs) may be seriously impaired, whereas with a low temperature, high humidity can intensify the loss of heat from the animal. A high humidity (over 70% to 80%) at normal or subnormal temperatures almost invariably leads to condensation on the inside surfaces of the building and to damp floors, which may adversely affect the livestock and the building. The humidity is also closely connected with the ventilation of animal barns. The ventilation rate should be adjusted to remove all the moisture produced by the animals. This ensures that the relative humidity of the air remains within the correct range and prevents condensation; in addition, it reduces the danger of cross-infection by respiratory droplets.

Air Intake, Circulation, and Outlets

The amount of air coming into a calf barn must equal that being exhausted. The air is extracted by fans vented through the roof or through the walls or gable ends. The incoming air is introduced through inlets high in the walls or in the ceilings. The movement of air in the calf barn should function to remove excess moisture, dust particles, gases, and infectious agents without creating drafts that increase the loss of heat from the calves and result in chilling. Good

Downloaded from Vet-eBooks.com

ventilation, which removes dust and other respirable particles as well as reduces noxious gases, is essential. Undesirable drafts that occur near inlets, doors, and fans must be minimized.

Ventilation Rate and Heating Requirements of Calf Barns

In an inadequately ventilated calf barn, the stagnant air becomes humid and there is a progressive increase in the concentration of dust, ammonia, and other gases. Bacteria and viruses adhere to dust particles, and the combination of these factors predisposes to a high incidence of both acute and respiratory diseases and poor growth rates. In cold climates these effects are most marked in the winter months and lower during the summer months.

Three levels of ventilation must be provided to accommodate seasonal changes that can be achieved with three fans (Bickert and Herdt, 1985). The first fan provides a minimum continuous rate to ensure that moisture removal takes place, even under very cold conditions. As the weather warms, the outside air absorbs less moisture as it moves through the building and a second fan moves more air to keep the relative humidity down to an acceptable level. The second fan is set to turn on when the outside temperature rises above −4° to −1° C (25° to 30° F) and increases the ventilation rate. The third fan is for additional summer ventilation. The sizes of the three fans are determined by the number of calves in the building. The following fan rates are given in cubic feet of air per minute (cfm) for each 45 kg of calf weight (Bickert and Herdt, 1985):

- Fan 1: 15 cfm/45 kg; minimum continuous ventilation with thermostat or timer; total ventilation is 15 cfm/45 kg
- Fan 2: 25 cfm/45 kg; on when outside temperature rises above −4° to −1° C (25° to 30° F); also on when inside temperature rises above 10° C (50° F); total ventilation is 40 cfm/45 kg
- Fan 3: 60 to 100 cfm/45 kg; primarily for the summer; on when inside temperature rises above 13° C (55° F); total ventilation is 100 to 140 cfm/45 kg

If calves are housed during the summer months, the main aim of ventilation is to limit the temperature rise in the calf barn above the outside temperature. This is accomplished by providing sufficient fan capacity. The aim is to provide sufficient ventilation to keep the calf house at or below the upper limit in the optimum temperature range and also to provide a degree of air movement that allows sufficient dissipation of heat to keep the calf cool and comfortable. The ventilation required to meet these standards is based on empiric evidence but, for calves housed in temperate climates during the coldest weather, the minimum ventilation rate recommended is 8 cfm/calf and the maximum for the warmest weather is 50 cfm/calf and even higher in subtropical climates.

Population Density

The floor area requirement per calf depends on whether the calves are to be penned individually or in groups and on the decision of the producer as to what minimum area is acceptable as humane. The smallest area used in veal calf crates for calves up to 300 lb (135 kg) is 10 ft^2 (0.92 m^2), but this area does not allow such calves to turn around after they weigh more than 170 lb (77 kg). Some have suggested a minimum area of 17.5 ft^2 (1.63 m^2) at this weight. At 3 months of age a well-fed calf that is individually penned requires 18 ft^2 (1.67 m^2) of total area or a pen size of 6 × 3 × 5 ft (180 × 90 × 150 cm). Younger calves can be kept in 15-ft^2 (1.39-m^2) pens (5 × 3 ft; 150 × 93 cm), but an area of 12 ft^2 (1.12 m^2) should be considered the absolute minimum for newborn calves. Sufficient space is essential for the expression of play behavior in domestic calves (Jensen et al, 1998).

Sanitation and Disinfection

When large numbers of calves are housed in a calf barn, there is a gradual increase in the population of infectious agents, which creates the potential for increasing the incidence of clinical and subclinical diseases. The infection rate increases with the length of time over which the calf barn is occupied by calves. This buildup of infection can be minimized by depopulating the calf barn and by cleaning and disinfecting the calf pens. This principle has been applied successfully in veal calf operations, in which the previously cleaned and disinfected barn is filled with newly purchased calves within a few days. The calves are fed as a unit for several weeks and then marketed as a unit. This has been called the *all-in, all-out system,* and it has been found to be an effective method.

Cleaning and disinfection of calf pens includes removing all bedding and manure, scraping the floors and walls of pens, washing them with a high-pressure sprayer (300 to 500 lb/in^2), applying a suitable disinfectant, and leaving the pens dry and vacant for at least 2 weeks. The type of disinfectant used is not critical provided that cleaning and washing are scrupulous. Many disinfectants are available, but some of the cheaper ones include 2% sodium hydroxide (caustic soda or lye) and 5% sodium carbonate (washing soda). The reader is referred to a review article on disinfection in veterinary practice. Efficient precleaning and sealing prior to fumigation are of paramount importance.

After having been born in a clean and dry calving pen or area away from the milking herd, the newborn calf should be moved to an isolated pen, stall, or hutch. The major requirement of any calf housing facility is that it be clean, dry, and draft free. Other essentials are that it be located conveniently, be arranged to encourage frequent observation and proper care, and be designed to minimize labor.

Calf Hutches

A proven housing system for the dairy calf in all types of weather is the calf hutch. Hutches should be located in well-drained, protected areas with the open front facing south. A 4 × 8 individual hutch or similar sized solar-type calf hutch is recommended. Only one calf should be placed in each hutch. Clean and disinfect hutches or let them stand upright in the sun for two or more weeks after each calf has been removed. The hutch can be reused in a new location and/or clean the ground area and place fresh fill and bedding under the hutch prior to its reuse.

When sufficient bedding is provided, hutches are comfortable for newborn calves, even when the ambient temperature is well below freezing. Severely cold temperatures (−30° to −18° C; −22° to 0° F) alone are not detrimental to the health and well-being of calves (Rawson et al, 1989a,b). During extremely cold weather the amount of whole milk fed or its equivalent in a milk replacer must be increased by 25% to 50% to a level that approaches the equivalent of 20% of the calf's body weight daily (Anderson and Bates, 1984). If they are not fed sufficient milk during cold weather, calves may suffer clinical cold stress characterized clinically by loss of weight, reduced body temperature, and increased susceptibility to infectious diseases. For calves consuming grain, allowing increased grain intake may supply most of the additional required energy.

Hutches are not a substitute for poor management. They can be labor-saving devices, but each calf must be fed each

Downloaded From Vet-eBooks.com

day and monitored for evidence of good health. When properly managed, they can be an excellent system for rearing calves, with a minimum incidence of enteritis and pneumonia. They are sometimes used as an alternative for housing calves during the summer months when the calf barn can be depopulated, cleaned, disinfected, and left vacant for several months. One-piece plastic-fiberglass hutches that are easy to use, clean, and move are now available. Care should be used with some of the translucent types of hutches in warmer climates because the temperature can be very high in these units in the summer months (Lammers et al, 1996b). The provision of supplemental shade for dairy calves reared in commercial calf hutches in southern climates of the United States alters the calf environment but has little effect on overall growth and health (Coleman et al, 1996),

At about 5 to 6 weeks of age, when calves are weaned from milk, they have outgrown individual hutches and must be moved to alternative housing. A super calf hutch measuring 12 × 19 ft, which can house eight calves from 6 weeks of age until they weigh about 180 kg, is available, after which time they are then moved to a heifer-growing facility.

Calf Barns

An alternative to outside portable hutches is a new or existing cold, but well-ventilated, barn with floor level pens. Pens measuring 4 × 8 ft with three solid sides and a slatted opened feeding end should be used. Wire mesh may also be used, but they should be separated by a foot or more to eliminate calf-to-calf nose contact and thus disease transfer. These should be removed to allow for their cleaning and disinfecting and the cleaning of the floor in the barn between calves. If small pens are used, it is necessary to clean the pen during the birth-to-6-week or preweaning period to prevent buildup of manure, urine, and ammonia. Portable pens also allow for use in more than one building or one area of a building as a way to break disease cycles.

Greenhouse-type structures are becoming popular for calf raising. These types of buildings use all of the same principles of a barn, except that with more solar radiation, they are often drier and warmer during the daytime. Ventilation is a key component of these facilities because of the additional solar radiation. These systems often require more management and upkeep than a traditional barn, but are economical to build. Daily temperature fluctuations are a drawback, since they can add stress to newborn calves.

Another popular method of calf housing is the incorporation of calf hutch–type structures in a building with three enclosed sides. This method allows the calves to have outside runs yet allows the operator to be under cover when feeding and caring for the calves.

Newborn calves can be raised successfully inside well-ventilated barns that are kept near outside temperature. It is unwise to try to keep this barn above freezing. Properly fed calves in well-bedded cold barn pens with three solid sides to reduce drafts will grow well in colder climates. An open-front shed or four-sided, naturally ventilated building is recommended. For adequate natural ventilation a continuous opening along the high point of the barn (usually the ridge) should be provided for warm moist air to escape. Provide openings along the eaves to supply fresh air summer and winter. During the winter it may be necessary to shield (not close completely) these openings to prevent cold air from falling directly onto the calves. Plywood covers can be placed over the rear portion of exposed pens for additional protection. It is also important to provide sidewall opening about 4 ft above the floor for additional summer ventilation.

Some existing buildings can be converted to satisfactory cold calf housing if they can be ventilated adequately and cleaned and disinfected properly. If obstructions prevent good natural ventilation, a pressure ventilation system can be installed to ensure a continuous supply of fresh dry air to the calves. A fan and distribution duct should be arranged to blow air along the center of the housing area or along the bank wall. The fan and duct should be sized to change the building air about 15 times an hour during normal winter weather. During extremely cold weather this can be reduced to 10 air changes per hour. A two-speed fan with a thermostat set to reduce it to low speed at about 30° F works well. Care must be taken to ensure that the air coming out of the duct is not directed on animals. If the barn is to be full during hot weather, 50 air changes per hour should be provided.

A good calf-raising facility must minimize environmental stresses on the calf as well as for the operator. Minimization of the environmental stress on the part of the operator encourages a higher level of care that should lead to less sick calves and lower mortality rates.

Weaning pens are an important and often overlooked aspect of a calf-raising system. A small group housing facility for three to five dairy calves should be provided for the immediate postweaning period for at least 1 month. This postweaning area should be a similar housing type and environment to that of the preweaned calf facility and located in a similar area. This allows for regular feeding and observation of this group as part of the feeding of baby calves. Large super hutches located adjacent to a calf hutch area, with an outside yard, can be used in conjunction with hutches. Buildings with inside individual pens should also provide for a 12- × 12-ft group pen for three to five calves. Continuously available frost-free water should always be in any of these pens. Current recommendations are for at least 12 to 18 in of bunk length for each calf, with stanchions or dividers to define the eating position for each calf.

A good, healthful replacement housing system should always meet the following requirements:

- Be clean, dry, and draft free where the animal resides
- For animals up to 3 months old should be isolated from the milking herd and older replacement animals
- Be in a convenient location and arrangement to encourage good care and observation
- Provide for as little manual labor as possible
- Always provide adequate ventilation for the calves

A healthy, strong calf can survive in less than optimum housing conditions in good weather; however, weak calves and harsh weather conditions often cause sick and slow-growing calves. While all the stress on a growing calf is impossible to eliminate, it can be minimized with adequate weaning pens. Sooner or later the calf must adjust to new diets, different surroundings, other calves, and less individual care. The good operator will arrange management methods and facilities to minimize stress on the calf. To make the transition to group living easier on the calf, only a few changes should be made at any one time.

Effects of Rearing Systems on Calf Behavior and Health

There is growing concern about the effects of different calf-rearing systems on calf behavior and health. Some researchers have observed the development of the natural behavior of calves in commercial rearing units selected to represent the range of calf-rearing systems currently in use (Webster et al, 1985a,b). The physiological responses of calves maintained in four types of housing indicate that calves raised in narrow, elevated stalls or individual elevated pens are under more chronic stress than those reared in hutches outdoors or in groups of three to six in

Downloaded From Vet-eBooks.com

pens outdoors (Friend et al, 1985). Calves were placed in one of four different housing systems at a few days of age and were open field–tested at about 6 weeks of age. Stall and pen calves performed more actions used in locomotion and defense and engaged in more social behavior than hutch- or group-reared calves when open field–tested (Dellmeier et al, 1985).

PRINCIPLES OF CONTROL AND PREVENTION OF INFECTIOUS DISEASES OF DAIRY CALVES

In general, dairy calf mortality is minimized best by a comprehensive management program that is followed stringently. Published studies have emphasized the interrelationships of a multitude of management factors to calf mortality.

Most common diseases of dairy calves under 1 month of age cannot be prevented totally, and control at an economical level must be the major objective. With good management and disease control techniques, mortality can be maintained economically at a level below 3% to 5% of live-born calves under 1 month of age. A prerequisite for effective, economical control of calf disease is to establish a simple recording system that the producer can understand and use. An effective monitoring system records the following data on a regular basis:

- Dates of birth of each calf
- Dates of illness, diagnosis, and treatments given for each sick calf
- Dates of deaths and results of necropsy, if done
- Growth rate (weight or average daily gain) and height of calf according to age and breed
- Daily amount of milk or milk replacer fed on a weekly basis; nature and amount of grain fed regularly

This information should be collected, collated, and interpreted at each regular herd health visit. The causes of any increases in morbidity and mortality should be explored and recommendations made to implement any necessary changes in management practices.

The most common diseases of calves under 2 months of age are infectious diseases of the digestive and respiratory tracts. The National Dairy Heifer Evaluation Project (USDA, 1994) also found that the diarrhea complex was the most common cause of preweaned calf death (52.2%), followed by respiratory problems (21.3%). This provides a basis for a calf herd health program that should give high priority to the control of these infectious diseases, using the details of the three major principles outlined here.

Reduction of the Degree of Exposure of Calves to Infectious Agents

Infections of newborn dairy calves may occur congenitally or be acquired postnatally. An example of a congenital infection is *Neospora caninum*, which is common in dairy cattle herds throughout the world. The protozoan has been associated with epidemics of abortion and endemic fetal loss in many dairy herds. Congenital infection of dairy calves may represent the main method of transmission in some dairy herds (Dubey and Lindsay, 1996). The life cycle of the organism is unknown but transplacental transmission is the only recognized mode of transmission. Abortion is the only clinical finding in infected cows. Cows of any age may abort from 3 months of gestation to term. Fetuses may die in utero, be resorbed, mummified, autolyzed, stillborn, born alive and clinically affected, or born clinically normal but persistently infected. Congenital infection does not necessarily have a detrimental effect on calf health (Pare et al, 1996), but retention of persistently infected calves contributes to maintenance of infection in the herd. Strategies to control congenital infection include culling of infected seropositive cows and minimizing the introduction of infected replacements into the herd. Control of postnatal transmission is based on the assumption that the protozoan may be transmitted through definitive hosts such as carnivores.

From birth to about 6 months of age, the calf is exposed to different infection pressures. In the first few days of life, the calf is susceptible to ETEC. Between 5 and 15 days of age, and sometimes later, rotavirus and coronavirus infection are the most common causes of enteritis. Salmonellosis may occur at any age but commonly occurs in calves from 1 to 2 months of age; respiratory infections occur most commonly between 2 and 6 months of age. The prevalence of infection of *Cryptosporidia* may be as high as 60% of dairy farms, and farms with multiple-cow maternity facilities and over 100 milking cows are most likely to have calves infected with *Cryptosporidia* (Garber et al, 1994). Therefore every economically feasible management effort should be made to reduce the infection pressure on the calf from birth to several months of age.

The reduction of the degree of exposure to infectious agents begins with the birth of the calf, which should take place in a clean environment. The perineum and udder of dirty cows should be washed shortly before calving. The umbilicus of the calf may be swabbed with 2% tincture of iodine or tied off with nylon thread immediately after birth to control the entry of environmental pathogens. Calves affected with diarrhea should be removed from the main calf nursery and treated in isolation. Well-bedded calving barn stalls, calving corrals in large herds, and pastures provide the ideal environment for the newborn calf. A common traditional practice has been to leave the calf with the dam in the calving pen, allowing it to suck its dam for 2 to 4 days and then transferring it to an individual stall for rearing up to weaning age. This has been a satisfactory system for rearing calves because it allows the dairy producer to minimize exposure of the newborn calf to infectious agents and to provide individual care and feeding during the first month, which is the most critical time in the calf's life. Individual stalls vary considerably in construction, but the most important concerns are that they should be cleaned and disinfected between calves and should be comfortable. In colder climates, where calf hutches are used, the calf may be placed in the hutch within hours of birth, after the calf has been fed a sufficient amount of colostrum and its hair coat has completely dried off.

In large dairy herds, in which the animals are confined during the winter months, diseases such as enterotoxigenic colibacillosis and enzootic pneumonia may be endemic because of the long occupation time of the barns in which adult cows and calves are housed closely together. Disease may become a major problem and may necessitate the construction of a separate calf barn detached from the main barn. With such a system, the calf is born in a box stall in the main barn, force-fed colostrum or allowed to nurse its dam for 2 or 4 days, and then transferred to the calf barn. After the colostral feeding period, newborn calves can also be transferred to calf hutches, which provide an excellent semiisolation rearing facility and help prevent infectious enteric and respiratory diseases.

Regular sanitation and hygiene are of paramount importance in the calf nursery, especially during the first few weeks of life, when the calf is most susceptible to infectious disease. From 2 to 6 months of age, the major concern is the control of respiratory disease, which is dependent on the effectiveness of the ventilation system in maintaining a low level of aerosol infection. The optimum environmental conditions for housed calves were presented earlier.

Downloaded from Vet-eBooks.com

Coccidiosis may cause significant economic loss in some dairy herds. Coccidiostats have been used successfully in calf starters to reduce the incidence and severity of coccidiosis in young dairy calves that may be infected as early as 3 weeks of age. Lasalocid has been used in the milk replacer or calf starter to prevent coccidiosis (Quigley et al, 1997). When used in the milk replacer it is superior to its use in calf starters.

Maintenance of High Level of Nonspecific Resistance

The maintenance of high level of nonspecific resistance is dependent on the ingestion of adequate quantities of colostrum within a few hours after birth and on the management and nutrition of the calves.

Management of Newborn Dairy Calves

Keeping dairy calves alive and healthy starts with the maternity area. Herds that use well-bedded box stalls for calving and for the calf during the colostral feeding period have consistently lower calf mortality. Maternity pens should be well bedded and dry. A Michigan study showed a significant relationship between the dry matter content of the bedding and calf mortality. Calf mortality was significantly lower when the bedding in the maternity pen was dry compared with a maternity pen with wet bedding. Straw is considered the ideal bedding; sawdust is questionable because it does not absorb equivalent amounts of moisture. Also, calves tend to eat sawdust, which may precipitate digestive upsets and serve as a vehicle for the entrance of pathogenic organisms into the digestive tract.

The nonspecific resistance of the newborn calf is markedly influenced by the type of housing, the temperature of the calving facilities, the temperature of the calf barn, the person caring for the calves, and whether attendance and assistance are provided at birth. Calf mortality may be higher in herds housed in loose housing than in stanchion-type barns. Calf mortality is also lower in herds that provide heated calving facilities, when the calf house is provided with supplemental heat, and when the calves are cared for and fed by the owner than when managed by hired help. This is particularly important in large herds, in which hired help may be necessary.

Dehorning calves is a common management practice in dairy herds. Cattle that are dehorned represent less danger of injury to the handlers and other animals as well as less disruption by dominant cows during feeding. Some concern has been expressed about the effects of dehorning on production. Electrical dehorning at 8 weeks of age does not affect feed intake and growth rate compared with those of controls.

The practice of collecting and transporting calves from farms to sale yards during their first week of life, and especially during cold weather, has contributed to high mortality from pneumonia and enteritis. Losses in young calves after transportation are highest in those under 2 weeks of age compared with older calves. This suggests that calves should be retained on the home farm for 2 to 3 weeks before being moved. Calves transported from one farm, through sale yards, and to their final destination during the first week of life are prone to disease because of the combined effects of inadequate intake of colostrum; the stress of transportation, starvation, and overcrowding during transportation; and the type of starting feed used in the new premises. Mortality is usually higher in calves started on milk replacers than in those fed milk or skim milk.

One of the greatest needs in the calf industry is the development of an orderly marketing system for newborn calves that are sold from farms and transported to specialized calf-rearing units. The system must consider that, during the first 10 days to 2 weeks of life, the calf is extremely susceptible to the effects of stress, irregular feeding practices, and rough handling, all of which predispose to infectious disease, high mortality, and major economic losses.

Colostrum

Newborn calves have very low concentrations of serum immunoglobulins at birth but have the ability to absorb IgG_1 and other immunoglobulins from colostrum during the first day of life (Besser and Gay, 1993). Many infectious diseases of the newborn calf can be controlled by management interventions to decrease the percentage of hypogammaglobulinemia in calves. Serum IgG_1 concentrations of 10 mg/ml or more are sufficient to protect calves from increased risk of infectious disease in most environments. Successfully obtaining adequate (greater than 10 mg/ml IgG_1) passive serum immunoglobulin concentration in calves requires provision of an adequate mass of immunoglobulin in the colostral meal (approximately 100 g IgG_1/45 kg body weight) and efficient absorption of the colostral immunoglobulin by the calf. Thus the two major requirements are *colostral immunoglobulin mass* and *efficiency of absorption of colostral immunoglobulin*.

Ingestion of liberal quantities of colostrum by the newborn calf within the first 6 hours after birth is the first and most important nutritional requirement of the newborn calf (Gay et al, 1988). The average volume of colostrum ingested by nursing Holstein calves in the first 24 hours of life is reported as 2.4 L (Besser and Gay, 1993). Thus a significant proportion of American Holstein calves fail to ingest an adequate mass of immunoglobulins in management systems that provide colostrum solely by allowing the calf to suck its dam. Control of the amount of colostrum ingested can only be achieved by artificial feeding methods, such as nipple bottle feeders or esophageal tube feeders. Of the artificial feeding methods, the esophageal feeder can ensure that an adequate volume of colostrum is administered early in the absorptive stage. The traditional recommendation for the volume of colostrum to be fed at first feeding is 2 L. If calves refuse to ingest a total of 2 L by nipple bottle, or if calf rearers do not have the time or are impatient to persist with nipple bottle feeding until the required volume is ingested each time by each calf, then the use of an esophageal feeder is recommended. For American Holstein calves, and other breeds of cattle with low colostral immunoglobulin concentrations, attaining protective immunoglobulin concentrations for a high percentage of calves requires large colostrum feeding volumes. Single feedings of *relatively high volumes of colostrum (3.5 to 4 L/45 kg body weight)* cause the lowest percentage of calves with failure of passive transfer by allowing calves fed colostra with relatively low immunoglobulin concentrations to receive an adequate immunoglobulin mass before closure. It is important to note that this volume of colostrum (4 L/45 kg body weight), fed by tube within minutes of birth, causes no apparent discomfort to a minimally restrained calf.

Mixing colostrum from different cows to form pools from which individual calves can be fed may reduce the variation in colostral immunoglobulin concentration as well as provide antibodies to the calf that reflect the antigenic experience of more than just one cow. However, pooled colostrum usually contains immunoglobulin concentrations substantially below the average of the constituent colostra because of the relationships between volume and immunoglobulin concentration. High-volume colostrum supplies can be limited by restricting any individual cow's contribution to the pool to 9 kg.

Downloaded From Vet-eBooks.com

The time from birth to feeding is a crucial factor affecting absorption of colostral immunoglobulins by calves (Odde, 1988). The ability of the newborn calf to absorb intact immunoglobulin from colostrum across the intestinal wall to the bloodstream decreases with time, so that any delay beyond the first few hours of life significantly reduces the amount of immunoglobulin absorbed. Delayed nursing may occur because of perinatal asphyxia, environmental conditions, edema of the head and neck because of prolonged parturition, and other managemental factors.

Surveys of calf and heifer management practices in dairy herds have found that husbandry practices for the newborn dairy calf are deficient in many aspects (Heinrichs et al, 1987a,b). The timing and amount of colostrum feeding can be problematic. Field studies have indicated that if dairy calves are left with their dams, up to 25% may not suck within 8 hours and 10% to 25% do not get an adequate amount of colostrum. Newborn dairy calves should be encouraged and assisted to suck their dam within an hour after birth. Assisting the newborn calf to suck to satiation is an effective method of ensuring an adequate intake of colostrum and maximizing the absorption of colostral immunoglobulins (Petrie, 1984). If the calf does not want to suck, it may be necessary to force-feed colostrum using an esophageal feeder tube to ensure that a minimum amount has been ingested early enough. The prevalence of failure of passive transfer in dairy herds could be minimized by artificially feeding all calves large volumes (3 to 4 L) of fresh or refrigerated first-milking colostrum during the first 12 hours after birth, from cows that had nonlactating intervals of normal duration (Besser et al, 1991). Colostrum should be fed for at least 3 days. Absorption of colostral immunoglobulins ceases by 24 hours after birth, but the continued ingestion of colostrum containing adequate levels of specific antibody provides local intestinal immunity against acute undifferentiated diarrhea for as long as the colostrum is fed. Colostrum that is preserved for several days or for up to 2 to 3 weeks is practical, economical, and reliable and may assist in reducing the incidence of infectious diarrheas because of the presence of colostral immunoglobulins, which provide local immunity.

Absorption of immunoglobulins is greatest in the first few hours after birth. In addition, the longer the calf goes without colostrum, the more the chance the calf has of ingesting other harmful pathogens that will also be absorbed. Some of the absorbed and circulating IgG_1 is transferred back to the intestine and retains significant functional antibody activity in the intestine (Besser et al, 1988a,b). This mechanism accounts for most of the IgG clearance.

Passive Transfer Status of Calves. Effectiveness of passive transfer of colostral immunoglobulins depends on the volume of colostrum ingested, the concentration of immunoglobulin in the colostrum, and the time after birth ingested (Gay et al, 1988). Several methods are available to detect failure of passive transfer in calves, including evaluation of total serum protein concentrations by refractometry, zinc sulfate and sodium sulfite turbidity assays, quantitation of serum IgG_1 concentration by radial immunodiffusion, and a commercially available serum glutaraldehyde coagulation test (Garry et al, 1993). Calf mortality can be predicted by using tests for passive transfer of colostral immunoglobulins (Fig. 9-1). The greatest risk of mortality occurs in calves with serum protein concentrations of less than 4.5 g/dl, serum concentrations less than 500 mg/dl, and sodium sulfite test scores below 1 (Rea et al, 1996).

In a study of mortality risk in a large number of dairy calves, 39% of the observed mortality was attributed to inadequate passive transfer (Tyler et al, 1999). Partitioning of the mortality risk associated with failure of passive transfer permits the practitioner to focus on other risk factors that may be responsible for risk factors.

Taking blood from 24- to 28-hour-old calves and measuring the serum total protein can indicate if immunoglobulin absorption has been adequate in the young calf. This measure of the total amount of protein in the serum is highly correlated to immunoglobulin levels obtained and can reflect either the quality of the colostrum fed or the management used in feeding it to the calves. If calves have received

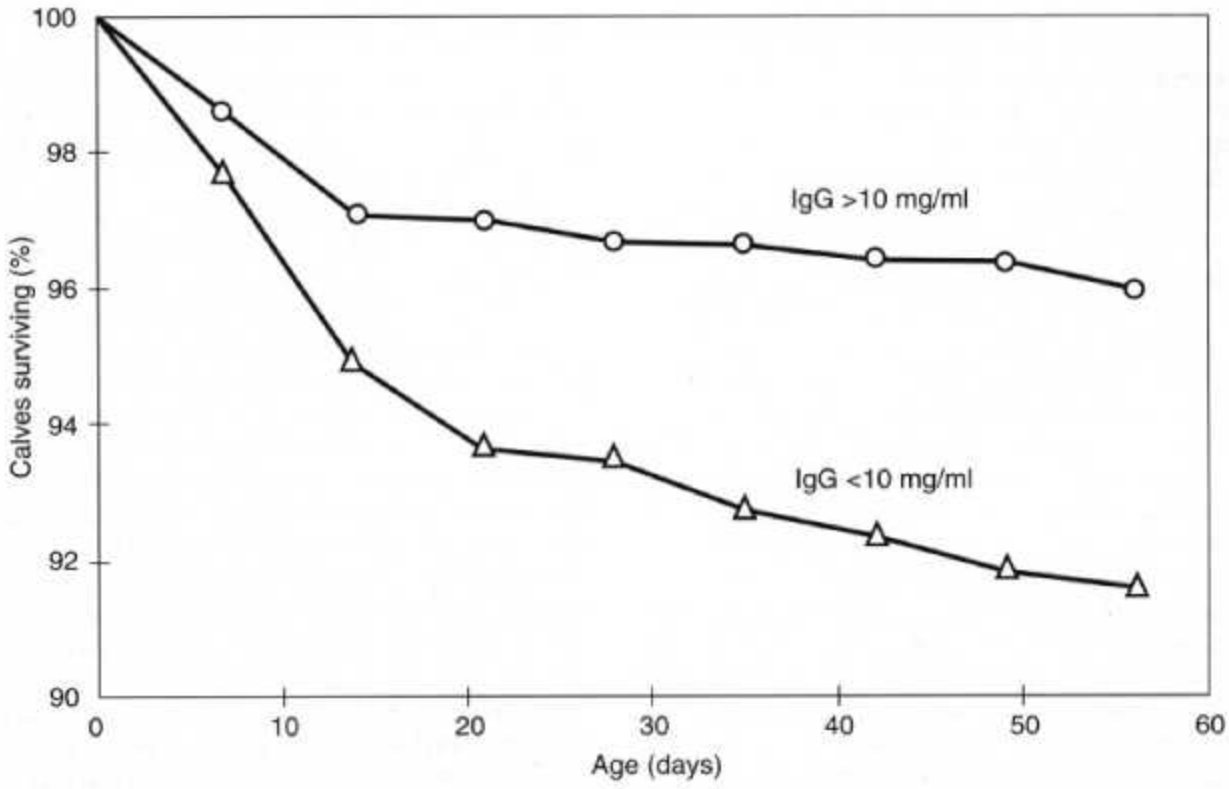

FIG. 9-1 Survival of calves with adequate (>10 mg/ml) or inadequate (<10 mg/ml) immunoglobulin G *(IgG)* concentrations in serum. (From National Animal Health Monitoring Systems: National Dairy Heifer Evaluation Project, 1993. Available at http://www.aphis.usda.gov/vs/ceah/cahm/Dairy_Cattle/ndhep/bamn2.htm [accessed May 17, 2001].)

Downloaded from Vet-e-Books.com

adequate levels of colostrum and it is of moderate to excellent quality, the serum total protein levels in the calf should be 5.4 g/dl or greater. When the range falls between 5.0 and 5.4 g/dl, there is a marginal risk for mortality and morbidity. Total serum protein levels less than 5.0 g/dl put the calf at a high risk of health problems.

The goal of a good colostrum program is to achieve high levels of passive antibody protection in calves. It is important to maintain sufficiently high levels until the calves are able to produce their own antibodies. This time period is about 21 to 28 days of age. Calves that have a higher stress of pathogens may have a need for a higher level of passive antibody protection from colostrum.

A study conducted in 1991 and 1992 by the USDA (National Dairy Heifer Evaluation Project) (Heinrichs et al, 1994a) found that calves with lower levels of total serum protein in their blood at 24 to 48 hours of age were twice as likely to die within the first 56 days of age. There are a variety of reasons why calves do not get enough colostrum antibodies, but the quality and quantity of colostrum fed are two very important reasons. It has always been recommended to feed calves 2 to 3 quarts of colostrum within 1 hour after birth and another 2 quarts within 12 hours so that some additional antibody absorption can occur from this second batch of colostrum. On many farms today, because of increased stresses and more pathogen exposure, it is recommended that calves receive 3 quarts of colostrum and some strive for 4 quarts.

One area of controversy is whether all 3 or 4 quarts should be given in one or two feedings. The main question is, does one feeding versus two affect IgG absorption by the calf. A recent study conducted by researchers from North Carolina and Tennessee (Hopkins and Quigley, 1997) showed that providing colostrum at a single feeding did not affect dry matter intake, weight gain, or the serum IgG concentration at 48 hours of life compared with a split feeding. High-quality colostrum can be fed at either one or two feedings without affecting IgG absorption. Feeding adequate amounts of colostrum soon after the calf is born can help offset the environmental and pathogenic challenges that face the newborn calf during the first few weeks of life.

In situations in which calves cannot or do not drink the desired amount of colostrum, an esophageal feeder can be used. This device represents a way of getting colostrum into a weak calf without a great deal of struggling.

A study with data from the National Dairy Heifer Evaluation Project (Wells et al, 1996b) was done on the risk factors for calf mortality and morbidity. Most dairy farmers feed colostrum with a bucket, 2 quarts or less within 6 hours (31.2% of the calves in the United States), 2 quarts or less within 6 or more hours (16.4% of calves), or nursing within 6 hours (22.4% of calves). A small percentage of calves in the United States were fed with esophageal feeders as a means of feeding first colostrum. Bucket-fed calves being fed 2 quarts or more had similar odds of mortality within the first 21 days of life. Calves that were allowed to nurse had just slightly greater odds of mortality. Most of the groups of calves fed first colostrum with an esophageal feeder had much higher odds of mortality within the first 21 days of life. The group fed using an esophageal feeder within 6 hours of birth and getting between 2 and 4 quarts were 5.7 times more likely to die than the average calf in the survey, and the group fed 4 quarts or more with an esophageal feeder at 6 or more hours of age were 9.7 times more likely to die. Thus the esophageal feeders, while being a convenient method of feeding newborn calves, should not be used as an alternative to a bucket or bottle unless necessary.

Delayed intake of first colostrum after birth can decrease serum immunoglobulin concentration by about 2 mg/ml for each 30-minute delay (Rajala and Castren, 1995). High colostral immunoglobulin concentrations do not ensure high serum immunoglobulin concentrations among calves that suck naturally, and when calves are left with their dams after birth, they should be assisted so that they suck their dams as soon as possible to ensure the acquisition of high serum immunoglobulin concentrations. Whether the calves are left with their dams for up to 5 days after birth, or if they are weaned immediately after birth and fed colostrum from open pails, the most important factor is the amount of colostrum ingested within the first several hours after birth (Besser and Gay, 1993). Jersey calves allowed to nurse their dams for 3 days and then placed in hutches achieved optimum transfer of passive immunity (Quigley et al, 1995).

Colostrum Quality. Only the first milking of colostrum after calving should be considered for feeding to calves for immunoglobulin transfer. Second or later milkings of colostrum contain considerably lower immunoglobulin concentrations and are unsuitable for transfer (Table 9-1). Colostra from cows that have been premilked or that leak milk before first milking are also not suitable for first feeding of calves. Some breeds of cattle, including American Holsteins, produce colostra of relatively low immunoglobulin concentration. In a study of over 900 first-milking colostra from American Holstein cows, only 29% of the colostra contained a sufficiently high concentration of immunoglobulin to provide 100 g of IgG_1 in a 2-L volume. The equivalent percentages for a 3- and 4-L volume of feedings were 71% and 87%, respectively.

The specific gravity of colostrum is linearly related to colostral immunoglobulin concentration. The specific gravity cut-off point appropriate for selection of colostra for feeding on a given farm depends on the volume of colostrum routinely fed to each calf. For example, if 2 L of colostrum are fed to each calf, an IgG_1 of 50 mg/ml is needed to provide the calf with 100 g of IgG_1. The cut-off point recommended to distinguish moderate from excellent colostrum was 1.046 (Fleenor and Stott, 1980). While most colostra with a specific gravity of less than 1.046 g/ml have IgG_1 concentrations of less than 50 mg/ml, the fact that more than half the colostra with IgG_1 concentrations of less than 50 mg/ml have a specific gravity greater than 1.046 limits the value of this test. Categorizing colostra using a cut-off point value higher than 1.046 reduces the percentage of selected colostra with less than 50 mg/ml IgG_1 and thereby increases the benefit of selecting colostra by specific gravity.

At temperatures less than 68° F colostrometer readings overestimate immunoglobulin concentration; readings underestimate immunoglobulin concentration of colostrum over 68° F (Mechor et al, 1991, 1992). Actual immunoglobulin measurements of colostrum are time-consuming procedures and impractical for routine samples.

The concentration of antibodies in colostrum varies because of a variety of factors such as the disease history and exposure of each individual cow, the volume of colostrum produced, the season of year (Gay et al, 1983), nutrition of the cow, and the breed, to name the most important ones. Research has shown tremendous variation in colostrum immunoglobulin concentration. Values for IgG can easily range from 20 to 100 g/L of IgG. Cows that have been exposed to a greater number of disease organisms and pathogens will produce a greater number and variety of immunoglobulins than those exposed to fewer organisms. These immunoglobulins have various degrees of specificity, and therefore each different organism that the cows are exposed to tend to increase the IgG content of the subsequent colostrum produced by the cows. When fixed volumes of colostrum are fed to neonatal dairy calves, higher serum

IgG_1 concentrations are achieved with high Ig colostrum (60 mg/ml) than with low Ig (24 mg/ml) colostrum (Morin et al, 1997).

IgG_1 is concentrated in the colostrum beginning about 4 weeks before calving, and in most cows continues until parturition. IgG_1 is the predominant colostral immunoglobulin, whereas IgM, IgA, and IgG_2 are present in considerably lower concentrations. Dairy cows invariably produce large amounts of colostrum (10 to 20 kg), but the concentration of immunoglobulins varies widely among cows. IgG concentrations are lower in first- and second-parity dams than in later parities, and the concentrations may be lower as the volume of colostrum increases. Calves from first-lactation cows have lower serum immunoglobulin concentrations than calves of older cows. Total immunoglobulin concentration tends to reach a maximum in the third or fourth lactation, almost doubling in amount compared with the first lactation (Devery-Pocius and Larson, 1983). The secretion of immunoglobulin ceases by the time of calving, and over 90% of immunoglobulins transferred at parturition can be expected to appear in the mammary secretion in the first four milkings.

Frozen Colostrum. If colostrum quality is measured and determined to be inferior, or if the cow does not have enough colostrum, then a source of high-quality colostrum is needed for the calf. This may not be a problem on large farms where other fresh high-quality colostrum is available, but on many farms, there may not be a fresh source. In these cases, having some high-quality frozen colostrum could solve this dilemma.

Freezing colostrum virtually eliminates nutrient loss during storage, providing an indefinite shelf life. Frozen colostrum is usually saved for newborn calves that need a colostral supplement because they did not receive enough or any colostrum. For this purpose, the colostrum from the first few milkings should be collected and frozen. The acceptability of thawed colostrum by calves is excellent. However, freezer facilities are required for this method of storage, and some extra handling of the colostrum is required to package it for freezing and to thaw it for feeding. Freezing colostrum in 1-L plastic bags, which can be frozen in a flattened form in a wafer measuring 18 cm^2 and 1.5- to 2.0-cm thick, facilitates more rapid thawing, in contrast to freezing and thawing in a bottle, which results in a much thicker mass to be thawed.

Two methods of thawing frozen colostrum before feeding to newborn calves have been compared. Thawing and warming colostrum to 104° F (40° C) in quart quantities in a pail containing boiling water required approximately 20 minutes, whereas the time required in a microwave oven was about 45 minutes. IgG_1 and IgG_2 concentrations in the sera of calves at 24 hours of age fed colostrum treated in boiling water were slightly lower than the respective immunoglobulin concentrations in calves fed colostrum treated in a microwave oven. Thus frozen colostrum thawed in a microwave oven provides a good source of immunoglobulins.

Colostral Supplements or Substitutes. Another option available to producers when high-quality colostrum is not available is the use of colostrum supplements. These supplements can be used as a means of increasing the quality of marginal colostrum, or they can be used when no other source of colostrum is available (Haines et al, 1990). These supplements alone do not replace high-quality colostrum. They do not contain sufficient quantities of immunoglobulins to raise the blood level in calves beyond what average quality colostrum can do. Commercially available colostral supplements are less efficient at providing immunoglobulin transfer and disease protection to newborn calves when fed at equal volume and similar immunoglobulin concentration (Garry et al, 1996). Similarly, the use of whey protein concentrate derived from ultrafiltrated and freeze-dried cheese whey, as a supplement to poor quality colostrum or as a replacement for colostrum, is unsatisfactory in preventing neonatal morbidity and

Downloaded from Vet-e-Books.com

mortality compared with a single feeding of pooled colostrum (Mee, et al, 1996). However, in emergency situations they do provide a viable option that is better than no colostrum feeding at all.

Parenteral Immunoglobulins. The administration of injectable immunoglobulins to calves that are hypogammaglobulinemic can increase the serum concentration of IgG but does not markedly influence incidence or severity of disease in young dairy calves (Quigley and Welborn, 1996).

Stored Colostrum as Feed for the Newborn Calf. The availability, storage, treatment, composition, and feeding value of surplus colostrum have been reviewed. Surplus colostrum may be considered a cost-free liquid feed for calves because it is unmarketable for human consumption. Sufficient excess colostrum should be available to feed heifer calves through 28 to 35 days of age. First-calf Holstein heifers and mature cows yield from 30 to 50 kg of colostrum from the first five postpartum milkings. With an average of about 44 kg of colostrum per cow and an average consumption of 11 kg per calf during the first 3 days of life, 33 kg of colostrum would be available per cow for feeding calves over 3 days of age. Calves commonly have been fed 1.8 to 3.2 kg of undiluted colostrum daily from day 4 of life to weaning. With an average daily consumption of 2.5 kg, colostrum from one cow can feed one calf through 16 days of age. If bull calves are sold within several days of birth, sufficient colostrum should be available to feed heifer calves to 4 weeks of age.

Stored colostrum is usually allowed to ferment and is fed as fermented colostrum. All the surplus colostrum collected from cows for the first six milkings after calving is stored. Dairy herds with 50 or more cows with calvings spread out over the year may benefit from feeding fermented colostrum. The major advantage is its low cost as a calf feed. When properly handled, fermented colostrum is an excellent feed, causing weight gains equal to those of calves fed whole milk or milk replacers.

Colostrum can be stored economically at ambient temperatures in plastic-lined containers with minimum handling requirements. The ideal temperature for fermenting colostrum is between 60° and 80° F (15.4° to 26.7° C). Under 60° F, fermentation is slow; over 80° F, fermentation is rapid and undesirable organisms can dominate the process. Plastic 20-gallon garbage cans make ideal colostrum containers. A disposable plastic bag lining the container makes cleanup easier.

The container is filled with colostrum as it becomes available over a period of several days. A tight lid should be provided to keep out flies and vermin. Daily stirring is not necessary, but the colostrum should be stirred before it is used so that the fat, curds, and whey are adequately mixed. Fermented colostrum should not be stored for more than 15 to 20 days, after which time the nutritional quality may be affected, the colostrum becomes malodorous, and calves are reluctant to consume it. Mold that might form on the surface of the colostrum should be skimmed off before use.

Losses resulting from spoilage and undesirable fermentation can limit the shelf life of stored colostrum. Warm temperatures may enhance putrefactive fermentation, which may be decreased by the use of chemical preservatives such as formic, acetic, and propionic acids and formaldehyde. Although chemical additives have not decreased the total number of microbes, some preservatives have decreased the numbers of coliform bacilli, molds, and yeasts while preserving a greater portion of the nutrient content of colostrum than is possible with natural fermentation. However, some unavoidable nutrient losses occur during storage at ambient temperatures, with and without chemical additives.

A given amount of colostrum can replace more than an equal weight of whole milk in calf feeding programs because of its high content of total solids. Dilution of colostrum diets with water is not necessary, but dilution may provide a more filling diet for calves fed once daily. Dilution with warm water may provide a more acceptable diet to the calf but does not increase calf performance. The amounts of colostrum fed and the rates of dilution should be designed to supply a desirable intake of solids to the calf. If the supply of colostrum is limited, a 2:1 dilution is effective. This can be changed to a 1:1 dilution with warm water as the calf becomes older. Colostrum with a total solid content of 18% can be diluted 2:1 with water to approximate the total solid content of whole milk at 12%. The diluted colostrum is then fed at a rate of 8% to 10% of body weight per day.

Increasing Specific Resistance of the Newborn Calf by Vaccination of Pregnant Dam

The passive immunization of calves against the infectious diarrheas caused by enterotoxigenic K99+ *E. coli*, rotavirus, and coronavirus by vaccination of the pregnant dam several weeks before parturition has received considerable research attention, and the results are promising. The pregnant cow is vaccinated at 6 and 3 weeks before parturition to stimulate the production of specific antibodies against the common enteropathogens; these antibodies are then transferred to the colostrum. The calf must ingest the colostrum and absorb the colostral immunoglobulins within 24 hours after birth for protection against systemic infection. The colostral immunoglobulins also provide local immunity in the intestine for the duration of their presence in the colostrum. This is known as lactogenic immunity, and it is contingent on the continued daily ingestion of colostrum or milk containing adequate levels of protective antibodies. The serum antibodies may provide protection against enteric infection if present in high titers and are transferred from the serum into the intestine. The knowledge that immunological dysfunction may occur in dairy cows from approximately 3 weeks precalving to 3 weeks postcalving may have practical implications for health management practices. In order to maximize the response to vaccination, it may be beneficial to vaccinate prepartum cows up to, but not past, 3 weeks precalving (Mallard et al, 1998).

Vaccination is an aid to good management and is not a replacement for inadequate management. The success of the vaccine is dependent on several factors. The pregnant cow must be vaccinated at the optimum time before parturition to ensure maximum production and transfer of antibodies in the colostrum. The concentration of antibody in the colostrum of vaccinated cows may vary widely, depending on the nutritional status and size of the cow, the amount of colostrum produced, the concentration of antigens in the vaccine, and the parity of the animal. The calf must still ingest colostrum in sufficient quantities soon enough after birth to acquire protection before invasion by pathogens. For the control of enterotoxigenic colibacillosis, the pregnant cow is vaccinated 2 to 6 weeks before parturition with either purified K99+ *E. coli* pili or a whole-cell preparation containing sufficient K99 antigen. Good protection is also possible when dams are vaccinated with a four-strain *E. coli* whole-cell bacterin containing sufficient K99+ pili antigen and the polysaccharide capsular K antigen.

The levels of K99+ *E. coli* antibodies in the colostrum of vaccinated cows are high for the first 2 days and then decline rapidly. These high levels of specific antibody protect the calf from enterotoxigenic colibacillosis during the first few days of life, which is the most susceptible period for the disease. Oil emulsion bacterins may elicit high amounts of antibody

Downloaded from Vet-e-Books.com

production after primary immunization, which may be sustained for up to 87 weeks after vaccination. Calves from these dams were protected from experimental challenge with ETEC.

Because mixed infections with rotavirus and coronavirus are common in diarrheic calves, the passive immunization of calves by vaccination of the pregnant cow with rotavirus and coronavirus vaccines has been examined (Saif and Smith, 1985). The colostrum of the majority of cows contains antibodies against rotavirus and coronavirus, but the levels decline rapidly in a few days to nonprotective levels in the milk at 3 to 5 days after parturition. These low levels in part explain the common occurrence of the disease in calves after 5 days of age. The colostral levels of rotavirus and coronavirus antibodies can be increased above naturally occurring levels by vaccination of the pregnant cow (Van Zaane et al, 1986).

The results of the field evaluation of the combined vaccines have been contradictory. The original rotavirus and coronavirus vaccines did not stimulate the production of antibodies that persisted at high enough levels in the milk of vaccinated cows compared with unvaccinated cows. The development and use of a combined, inactivated, adjuvant rotavirus and *E. coli* vaccine caused increased neutralizing antibodies in serum and colostral whey. The vaccine resulted in a decrease in the incidence of rotavirus shedding and of diarrhea in calves fed colostrum and milk from the vaccinated cows. Vaccines made from water-in-oil emulsions induce marked enhancement of rotavirus antibody titers in the serum, colostrum, and milk of vaccinated cows (Archambault et al, 1988).

An adjuvant vaccine containing inactivated rotavirus and coronavirus and K99+ *E. coli* significantly increased the serum rotavirus antibody level at the time of parturition by about six times in vaccinated cows compared with unvaccinated cows and increased the colostral whey antibody level by about 30 times in vaccinated cows compared with unvaccinated cows. However, by 7, 14, 21, and 28 days after parturition, the milk whey antibody levels had dropped by about 27-, 46-, 70-, and 93-fold, respectively (Sharpee et al, 1986).

Such sharp drops in colostral and milk antibody levels illustrate why vaccination for the viruses is not as effective as the *E. coli* vaccines. The colostral and milk viral antibody levels are not sufficiently high enough to provide protection when calves are most susceptible to rotavirus and coronavirus infections. One clinical field trial using an inactivated rotavirus vaccine combined with a K99+ *E. coli* antigen emulsified in oil adjuvant given intramuscularly to pregnant cows provided protection against diarrhea in calves under experimental and field conditions. However, in another field trial to evaluate the efficacy of a combined rotavirus-coronavirus and *E. coli* vaccine in Ontario dairy cattle herds, the vaccine was not effective in protecting individual calves from disease in general or diarrhea in particular, or in improving weight gain.

There may be several reasons for the poor performance of the vaccine. Continued feeding of immunoglobulin-rich colostrum for several days would be necessary to provide protection against rotavirus-associated diarrhea. Normally, dairy calves would not receive colostrum or milk from their dam for more than a few days compared with beef calves. This is why the daily feeding of stored colostrum from the first few milkings of unvaccinated or vaccinated cows can provide continued protection against the viral diarrheas. Also, the vaccine may not have been sufficiently antigenic to boost colostral antibody titers. Another explanation for the apparent ineffectiveness of the vaccine is that the vaccinated part of the herd protects the unvaccinated part or, conversely, that the unvaccinated part so badly contaminates the whole herd that the vaccinates are overwhelmed by the microbial challenge. There is also the possibility that producers who had vaccinated would expect their calves to remain healthy and hence might have ignored certain diarrheic calves or waited a few days longer than usual to treat a diarrheic calf. This could distort the comparison of the incidence of disease between vaccinated and unvaccinated calves.

One method of providing a daily source of viral antibody in the milk of calves for up to 2 to 3 weeks is to feed pooled, stored colostrum containing the antibody. Another method is to supplement the daily milk supply with colostrum containing high rotavirus antibody titers from vaccinated cows (Saif et al, 1983). Experimentally, a simultaneous intramuscular and intramammary vaccination of pregnant cows with a modified live adjuvant bovine rotavirus greatly enhanced colostral rotavirus antibody titers (Saif et al, 1983). This colostrum protects calves against experimental challenge with rotavirus when fed as a 1% supplement of the daily intake of milk. On a practical basis, feeding one-half colostrum from vaccinated or unvaccinated cows and one-half whole milk protects calves from rotavirus- and coronavirus-induced diarrhea from birth to 2 to 3 weeks of age, during which time they are most susceptible to these viral diarrheas.

Specific passive antibody immunity can be provided to newborn dairy calves against infectious bovine rhinotracheitis (IBR) by the vaccination of pregnant cows with the intranasal IBR vaccine, which is not abortigenic (Mechor et al, 1987). Vaccinated cows produce increased concentrations of specific antibody in the colostrum, which is transferred to the calves and protects them against the highly fatal form of systemic IBR. Vaccination of calves at 4, 6, and 12 weeks of age with an inactivated IBR vaccine may also provide protection (Straub and Mawhinney, 1988). Vaccination of pregnant cattle is also a successful method of controlling salmonellosis and may protect calves when they are most vulnerable to infection (Jones et al, 1988). A quadrivalent vaccine containing the killed antigens of BRSV, parainfluenza-3 virus, *Mycoplasma bovis*, and *M. dispar*, when given to housed calves at about 5 weeks of age, may provide some protection against respiratory disease associated with the above pathogens.

CALF NUTRITION FROM BIRTH TO WEANING

The major objectives during the period of birth to weaning are to control the incidence of dietary and infectious diarrheas, to obtain satisfactory growth rates, and to wean the calf successfully at about 2 months of age. Heifer replacements are expensive; therefore all available economical resources should be used to raise the heifer calves in a dairy herd, and they should be given high priority.

Digestive System of Newborn Calf

Certain parts of the intestinal tract of the young calf and its respective digestive enzyme activities have particular nutritional significance. These are reviewed briefly as background to understand the digestive disturbances of young calves that are nutritional in origin.

Abomasum

In the newborn calf, the abomasum makes up about 70% of the total stomach volume, in contrast with the adult ruminant, in which it makes up only about 8%. In the preruminant calf, liquid food flows through the closed esophageal groove directly into the abomasum, thus bypassing the

Downloaded From Vet-eBooks.com

forestomachs. The abomasum of the newborn calf is capable physically and biochemically of initiating the digestion of milk. It can undergo considerable expansion and hold large quantities of liquid. It secretes rennin, the milk-coagulating enzyme that clots the milk, yielding a casein clot and whey. The whey enters the duodenum within 5 minutes of feeding, and the casein clot remains in the abomasum. Rennin is also a proteolytic enzyme and is probably responsible for the breakdown of the milk clot in the early life of the calf before it develops any appreciable pepsin-hydrochloric acid proteolytic enzyme activity. The casein clot is degraded gradually by the enzyme action of rennin and/or pepsin and hydrochloric acid, and the partially digested proteins and fat are released at a fairly continuous rate over 24 hours. The main passage into the small intestines as well as further enzyme action by trypsin, chymotrypsin, and carboxypeptidases present in the pancreatic juice and by other peptidases secreted in the small intestine are followed by absorption from the small intestine as amino acids.

A gradual changeover from rennin to pepsin secretion in the abomasum occurs as the calf grows older. Rennin activity reaches a peak at a pH of 4, whereas the optimum pH for pepsin activity is about 2. Pepsin activity is low until the calf is about 3 weeks of age, at which time it begins to digest nonmilk proteins efficiently. Before the calf can digest nonmilk proteins (plant proteins, meat meal, and fish by-products), the abomasal juice must attain a pH of 2 and pepsin activity must be adequate.

Digestive Physiology of the Colostrum Fed Calf

Ideally, the neonatal calf should be fed colostrum from birth through the third or fourth day of life. Within the first 24 hours of life, the calf requires an abundant supply of immunoglobulins that must be readily absorbed into its bloodstream to establish immune competence. The syneresis of the abomasal clot allows the immunoglobulins in the whey to pass to the small intestine for immediate absorption before digestion by pancreatic enzymes while retaining casein and fat in the abomasum (Roy, 1990; Cruywagen et al, 1990). Adequate digestion of alternative liquids feeds, such as milk replacers, after the third or fourth day of life do not depend on this clotting action.

The preruminant calf is dependent solely on its own digestive enzymes in the absence of rumen bacteria and protozoa for the breakdown and assimilation of nutrients. Pregastric esterase and pancreatic lipase are added to liquid feedstuffs during the swallowing process through saliva and are important for the hydrolysis and digestion of the milk fat within the casein. All enzyme activity in the intestine is high at birth and dramatically increases between birth and 2 days of age because of the rise in mucosa protein content. Isomaltose, maltose, and sucrose are not present during preruminant stage. Lactose is the only known carbohydrate that the preruminant calf can digest before 1 month of age (Roy, 1990). The calf can use colostrum and postcolostral milk containing high levels of lactose because of the relatively high quantity of intestinal lactase that is produced shortly after birth. Calves less than 1 month of age are virtually unable to use starch, maltose, sucrose, or dextrin because of the lack of the digestive enzymes required to break these sugars down to their respective monomeric forms postruminally. When these undigestible sugars are added to milk replacers as an energy source before 1 month of age, diarrhea and other health problems often occur. The activity of intestinal lactase decreases at the time of weaning, along with increases of enzyme activity responsible for the digestion of more complex carbohydrates. This gradual turnover of enzyme activity allows the calf to digest and use the other carbohydrates added to milk replacers with less instances of diarrhea.

Curd formation occurs because chymosin (rennin) binds much of the casein and fat in milk and milk replacers within 10 minutes of feeding into a slowly digested curd. This curd is slowly digested over a period of 24 hours and its digesta empties from the abomasum. Abomasal enzyme action is maximal at 2 days of age and decreases during the first month, whereas pancreatic enzyme activity is minimal at 2 days and increases during the first two weeks. Peptic activity does not seem to vary with age (Toullec et al, 1992).

Following coagulation, the abomasal clot is degraded by proteolytic enzymes. Lactose and whey are expelled from the abomasum because of the contracting clot—a synergistic effect—and released into the duodenum where they are digested rapidly. The duodenal receptors modulate stomach emptying of digesta through the actions on the contractile processes of antral smooth muscle. When gastric emptying nears completion, the hydrogen ion mass appears to activate the release of somatostatin, which may be associated with the inhibition of gastric motility. Somatostatin does not seem to respond to the nonionic substances including butterfat and sucrose. Therefore the alteration in the physical or chemical nature of a milk-substitute diet may influence the nutrient delivery from the abomasum to the small intestine.

Most abomasal enzymes are in low concentrations in young calves but increase within the first 3 weeks of age. At approximately 3 weeks of age, the calf's digestive enzyme production diversifies and changes the digestibility and use of carbohydrates and protein sources dramatically. Therefore it is important that a neonatal calf milk replacer be formulated for proper digestion and use by the underdeveloped digestive system of the young calf that is less than 3 weeks of age.

Abomasal Clotting and Calf Performance

Clotting of milk in the abomasum of the calf has long been accepted as an important component of the milk digestion process in preruminant calves. Abomasal curd formation, consisting primarily of casein protein and milk fat, appears to be advantageous to the milk fed calf because of its function in slowing the release of digesta out of the abomasum and into the small intestine (Toullec et al, 1992). The clot slows down the passage of crude protein, dry matter, and fat (Cruywagen et al, 1990). Consequently, a gradual and more complete digestion and absorption of the nutrients consistently occurs between feedings. This is especially important for the newborn calf receiving colostrum; however, it has not been shown to have any effect on calves beyond 3 days of age (Heinrichs et al, 1994).

FEEDING THE DAIRY CALF FROM BIRTH TO WEANING

Details of the nutrient requirements of the preruminant calf in the first few weeks of life have been presented (National Research Council, 1989). The ingredients of major importance for satisfactory growth are energy, protein, and fat. The average digestible energy requirements in nursing calves has been reported to be 50 kcal/kg body weight per day for maintenance and 3 kcal/g body weight gain per day for growth (Medina et al, 1983). A 40-kg calf gaining 500 g per day requires 3500 kcal of digestible energy daily. The gross energy density of cow's whole milk is approximately 0.73 kcal/ml, and, with a digestibility of the nutrients in whole milk at 95%, the digestible energy content should be about 0.69 kcal/ml (Hand et al, 1985). A variety of liquid feeds including whole milk, waste milk, and milk replacers can be fed to calves that can provide all the nutrient requirements of the calf from birth to

Downloaded From Vet-eBooks.com

weaning and produces acceptable growth rates when fed in adequate amounts along with supplemental grains.

There are marked variations in the estimated protein and energy requirements of calves, particularly in the ruminant stage. These requirements are influenced by rate of gain, body size, age, diet, and other factors. A number of studies have shown that milk replacers, on an air-dried basis, should contain at least 20% crude protein, assuming good-quality protein. The optimum crude protein level for calf starters usually is considered to be about 18%. Other components of the diet and the rate of gain desired have a major effect on the amount of protein needed in feeds of the young calf. As the rate of growth increases, the optimum ratio of protein to energy increases markedly.

On the basis of data derived from four studies, the average requirements (and range) of the 50-kg, nonruminating calf for digestible energy are 47 kcal/kg (range, 41 to 52) body weight for maintenance and 3.3 kcal/g (range, 2.7 to 3.8) body weight for gain. The requirements for the ruminating calf weighing 50 to 100 kg are slightly higher for both digestible energy and protein.

Whole Milk

Following the 3-day colostral feeding period, dairy calves may be fed whole milk, a milk replacer, or a combination of these, depending on preference, availability, and economic considerations.

Whole milk is excellent for use in feeding calves, especially those that are being raised as heifer replacements. Whole milk is usually fed in two divided feedings at a total daily rate of 8% to 10% of body weight, depending on the size of the calf. Small-breed calves are usually given the smaller amount. Calves raised in hutches during cold weather should be fed at least 10% daily (Schingoethe et al, 1986). Calves may be fed solely on whole milk until weaning at 35 to 56 days of age. A calf starter diet containing 16% to 20% protein should be made available in small quantities (100 g/day) beginning the second week of life. This should be increased every several days so that the calf is consuming about 450 g/day before weaning, in addition to small quantities of good-quality hay. Calves should not be weaned until they are consuming about 400 to 600 g of dry feed per day. When the amount of milk or milk replacer is fed over a shorter period (3 to 4 weeks), the calf must be encouraged to eat dry feed at an early age. Early weaning at 3 to 4 weeks is a low-cost feeding method that accelerates the transition of the calf from a preruminant to a ruminant. However, some calves do not adjust effectively and are unthrifty for up to several weeks. They may also develop a chronic dietary diarrhea.

In a dairy herd on a milk production quota system, overquota milk can be marketed by feeding it to calves, which gives some return for the milk fed. The daily amount of whole milk and the duration of milk feeding can be extended beyond the usual weaning period, causing increased calf weights and reduced cost of dry calf feed. The amount of milk that can be disposed of through calves can be varied by extending milk feeding for up to 6 months. Cost-benefit analyses have suggested the following: (1) calves can be productively fed milk long past early weaning if selling the milk is not economical; (2) the value of milk fed to calves that are sold at market exceeds the cost of feed grains necessary to maintain milk production; (3) the feeding value of milk as measured by relative feed-to-grain ratios is greater than for calf starter, hay, or fishmeal; and (4) to avoid growth setbacks, calves should have their daily milk allotment gradually decreased before weaning.

Calves can also be fed a combination of whole milk and reconstituted skim milk powder (Jenkins and Bona, 1987). As much as 75% of whole milk fed to calves up to weaning could be replaced by reconstituted skim milk powder (10% weight/weight) fortified with vitamins and minerals, without any reduction in calf performance.

Antibiotic-Contaminated Waste Milk

The use of milk discarded from cows with mastitis and containing antibiotics (hospital-pen milk) as a feed source for calves (rather than discarding it) appeals to many producers (Wray et al, 1990). The practice is common, and hospital-pen milk is probably the most economical feed for young dairy calves (Goodger et al, 1993). In some herds, colostrum is pooled with milk from treated cows. However, hospital-pen milk should not be fed to calves during the first day of life to prevent bacteria from permeating the intestine during the period of absorption of colostral immunoglobulins. Milk from antibiotic-treated cows cannot be sold but, along with other waste milk, such as colostrum, has the potential to make a valuable calf feed. However, milk from cows that have mastitis that has been treated with antibiotics might cause infectious disease in calves, promote the development of drug resistance of enteric bacteria, and lead to the presence of drug residues. When milk containing antibiotic residues is allowed to ferment naturally, a reduction of the antibiotic levels occurs through degradation. However, the voluntary intake of antibiotic-containing milk fed fresh or fermented may be reduced because of decreased palatability, which causes less than optimum growth rates (Wray et al, 1990). Mastitic milk should only be fed to individually housed calves that will not come into direct contact with other calves. Mastitis pathogens can be transferred by direct contact, such as calves sucking other calves. Waste milk that is known to come from a cow with coliform mastitis, Johne's disease, and enzootic bovine leukosis should not be used. The economics and health implications of feeding such waste milk rather than good-quality milk replacers or whole milk must be considered before deciding on this feedstuff.

In some dairy cattle areas, male dairy calves are sold between 1 and 7 days of age and moved directly to abattoirs with no more than 1 day of movement through sales channels. Some of these calves may have been fed hospital-pen milk containing antibiotics, which could cause drug residue violations (Carpenter et al, 1995). In the United States over a 4-year period, the nationwide violation rate in samples from calves examined in abattoirs averaged 2% (Carpenter et al, 1995). A case-control study of Washington dairy herds experiencing drug residue violations in market calves found significant associations between violation occurrence and the management of calving cows, colostrum volume and management, and the person responsible for calf care (Carpenter et al, 1995).

Surveys of the management factors that contribute to antibiotic residues in dairy calves indicate that producers are not fully aware of the factors that influence antibiotic residues in the herd (Goodger et al, 1993). Veterinarians must inform producers about the importance of monitoring and record keeping, of limiting exposure of calves to pathogenic bacteria in waste milk, and of ensuring that label instructions for the use of antibiotics in the herd are followed.

The microbial content of milk fed to calves may vary widely depending on various interacting factors such as the origin of the milk or milk substitutes, preparation and handling procedures, storage conditions, environmental conditions, cleaning equipment, and management strategies. Fluid milk used as feed for calves in commercial dairy herds can contain a mixed bacterial flora, including some potential pathogens (Selim and Cullor, 1997).

Downloaded from Vet-eBooks.com

Milk that contains any hospital milk (categorized as waste milk) may have more viable bacteria than other types of milk, indicating that calves fed waste milk are exposed to a higher bacterial load than calves fed milk replacer or other nonhospital milk. Milk replacer and bulk-tank milk are less likely to have a high viable bacterial flora. Waste milk samples may contain *Streptococcus* sp. *Enterobacteriaceae,* and *Staphylococcus* sp. *E. coli* was isolated most commonly. Waste milk that has not been treated effectively by pasteurization to reduce the bacterial load before use as calf feed should be used with caution because it may contain a high number of bacteria that may be pathogenic to cattle and humans.

Milk Replacers

Brief History of Milk Replacers

The first widely accepted and used milk replacers for dairy calves were developed in the 1950s and were composed primarily of dried skim milk, dried whey, dried buttermilk, and animal fat (Heinrichs, 1994, 1995). Dried skim milk was the principal ingredient because of its low cost. These early products were poorly used by calves and contained limited fat content (10% versus 30% in whole dry milk). In addition, these early milk replacers contained large amounts of skim milk that had been heated severely during the drying process. This caused severe diarrhea in neonatal calves because of denaturing of casein proteins. Because of this and other factors, calves performed poorly on these early products; thus milk replacers were not as popular as they are currently. Current data from the National Dairy Heifer Evaluation Project (Heinrichs et al, 1995) found that 53% of calves in the United States were fed medicated milk replacer, and 12% were fed nonmedicated replacers. Nearly 60% of U.S. dairy farms use milk replacers for some or all of the feeding program for neonatal calves (Heinrichs et al, 1995). Approximate savings of $15 to $25 per calf compared with feeding whole milk can be realized by feeding calf milk replacers in the United States (Fowler, 1998).

Throughout the 1980s, continued efforts by the industry to find alternate sources of protein yielded mixed results. The addition of soy flour caused severe allergic reactions, abnormalities of the small intestine, and poor performance in calves because of the presence of trypsin inhibiting enzymes and allergens. Fish proteins, meat solubles, and other nonmilk proteins including cottonseed, oat, pea, rapeseed, potato, soy and wheat flour, corn, alfalfa, field bean, bacterial sludge, and blood were found inadequate for use in milk replacer formulations. Although there has been some success in using fish protein in milk replacers, investigations reported in the literature have generally not yielded satisfactory results.

The issues and problems of technological processing methods of both milk and nonmilk proteins were addressed in experiments, and as a result the use of some alternative proteins began to improve and eliminate the nutritional diarrheas associated with feeding high heat-treated, low-fat products. Greater concentrations of fats in milk replacers have been shown to significantly reduce the incidence of diarrhea. Both homogenization and low-pressure dispersion of fats cause good calf gains, feed efficiency, and digestibility. This is accomplished at moderate levels of total fat (20%). At higher fat levels (40%), however, homogenization causes markedly reduced calf performance and lowered nutrient digestibilities.

The National Research Council (NRC) has recommended that milk replacers contain certain minimum levels of nutrients, as shown in Table 9-2. Many of these can be adjusted depending on several factors as described below.

TABLE 9-2

General Nutrient Content Recommendations for Dairy Calf Milk Replacers

INGREDIENT	PERCENT OF DRY MATTER
Crude protein	18-24
Fat	10-22
Calcium	0.7
Phosphorus	0.6
Potassium	0.8
Magnesium	0.07
Sodium	0.09
Chlorine	0.18
Sulfur	0.26
	CONCENTRATION (PPM)
Iron	90
Cobalt	0.09
Copper	9
Manganese	36
Zinc	36
Iodine	0.23
Selenium	0.27
	CONCENTRATION (IU/LB)
Vitamin A	25,000-35,000
Vitamin D	5000-7500
Vitamin E	50-125

Since digestibility and utilization of different proteins used in milk replacers vary greatly, these recommendations serve as minimum guidelines to be followed and modified as situations dictate. In early life, digestibility is generally limited but digestibility and utilization of milk are high in the young dairy calf. A good approximation for whole-milk digestibility in a young calf is 95%. The same applies to milk products used in milk replacers as long as the processing procedures are such that quality is maintained. In general, milk replacer ingredients that are from nonmilk sources are used less efficiently than milk products, especially in the calf that is less than 3 weeks of age. Both the source and processing method of milk replacer ingredients have marked effects on the value of the overall product. In addition, human grade milk products must be used rather than the less-expensive animal grade milk products. This is due to the protein denaturation that occurs in the animal grade products when they are dried down under higher heating methods.

Protein Concentration and Sources

Whereas studies show that the protein concentration of milk replacers for the calf should be 22% (dry matter [DM] basis), other studies have demonstrated that levels of 23% to 25% may improve growth rates. In interpreting these studies, it is important to understand that some of the studies using high levels of curd protein are using nonmilk protein sources for all or part of the total protein. These studies demonstrate the effects of a lesser-quality amino acid profile in the protein source used, than that found in milk and milk products (lysine, methionine, and histidine in nonfat dry milk (lysine 2.868, methionine 0.907, and histidine

Downloaded From Vet-e-Books.com

0.981), skim milk (lysine 0.270, methionine 0.086, and histidine 0.092), and dried whey (lysine 1.030, methionine 0.241, and histidine 0.237). Therefore, even if higher levels of nonmilk or noncasein proteins are included in the milk replacer, this does not ensure adequate protein for the calf that is less than 3 weeks of age. Skim milk and whey protein concentrate are nearly equal in protein level (34%), whereas dried whey is only 11% to 12% protein. Because of the vast differences in level of protein between the two milk based feedstuffs, dried whey can serve as an energy source to substitute for skim milk in replacer; however, it must be included with another protein source for the replacer to meet the animals nutritional requirements. The 22% protein recommendation is suggested for milk replacers comprised only of milk proteins based on high digestibility. Crude protein levels should be increased in replacers that contain nonmilk protein sources to counter the effect of their reduced digestibility.

Partly due to the high prices of milk by-products, many modern milk replacers are formulated using high-quality soy-based products (Heinrichs, 1995). Soy protein isolates, soy protein concentrates, and chemically treated soy flours are often used in certain lines of milk replacers and have acceptable results in the dairy calf with respect to growth and health of the animal, provided that the soybean has been processed properly, which includes altering the proteins to reduce or eliminate any allergic reactions. These soy protein products are quite high in protein with soy protein isolates at 96% protein, soy protein concentrate generally at 66% protein, and soy flour at 50%. It is interesting to note that whether a soy product or an all-milk origin products such as dried skim milk, whey protein concentrate, delactosed whey, and dried whey are used, the majority of the ingredients in some modern milk replacers are from milk-derived (primarily whey) products.

Milk replacers are often more convenient than the feeding of whole milk or waste milk and may be more appropriate for health reasons than other sources of liquid feeds. From a convenience perspective, calves are generally housed in different areas of the farm than the milking herd, thus making the movement of these products to the calf area of the farm difficult. Milk replacers are manufactured with a variety of ingredients and levels of nutrients to meet the needs of a variety of farmers. In addition, antibiotics, ionophores, and coccidiostats can be added to milk replacers, which allows for added convenience on farms where these are needed or desired.

The milk replacer industry's need to find alternative protein sources has led to a variety of replacers containing both plant and animal proteins (Fowler, 1992). These replacers exhibit little or no clot formation because of the absence of casein proteins normally found in cow's milk. This lack of clotting has precipitated numerous studies with results that support (Petit et al, 1987a,b) and oppose (Petit et al, 1988; Strudsholm, 1988; Petit et al, 1989; Cruywagen et al, 1990) the physiological need for curd formation in the young calf.

Current milk replacer studies indicate that although they lack casein proteins, some nonskim milk proteins, whey protein concentrate, and soybean derived products are acceptable for the young calf if they are processed properly (Babella et al, 1988; Mir et al, 1991). Early data found that the use of noncasein proteins was limited and often caused diarrhea, low growth rates, and poor performance (Akinyele and Harshberger, 1983). Factors other than the lack of clotting were found to be responsible for the poor performance when compared with milk-fed calves. Morphological abnormalities of the villi lining the small intestine caused insufficient absorption and digestion of nutrients followed by poor performance in calves fed replacers containing soy proteins (Seegraber and Morrill, 1986). Allergens and antitrypsin factors in soy proteins decreased the intraluminal concentrations of necessary pancreatic enzymes (Khorasani et al, 1989; Gardner et al, 1990). Improper or inadequate processing and reconstitution at high temperatures were also observed to alter the proteins (Mir et al, 1991). All of these factors apparently increased the incidence of diarrhea, causing lower digestibility, nutritional deficiencies, and reduced growth rates. These studies have encouraged the industry to formulate and evaluate milk replacers based on nutritional quality rather than their clotting ability, as defined by calf performance. A review of the importance and physiological role of curd formation in the abomasum of young calves is available (Longenbach and Heinrichs, 1998).

Calves receiving whey and nonmilk proteins such as soybean in milk replacers can perform comparably with those receiving skim milk proteins (Tomkins and Drackley, 1992; Tomkins and Sowinski, 1992). This evidence suggests that clotting is not needed during the entire milk-feeding period. Studies of whey proteins found satisfactory weight gains and feed utilization in the first 30 days of life (Babella et al, 1988; Lammers et al, 1996a). Up to 66% of the casein in milk replacer was replaced with whey protein in milk replacer without affecting calf performance (Babella et al, 1988).

Young calves fed milk replacers containing insufficiently processed soya products like steam-heated soya flour perform less well than calves fed skim milk powder. Predisposed individual calves also develop immune-mediated intestinal dysfunction, apparent by circulating anti-soya antibodies, and diarrhea and motility dysfunction (Lallès et al, 1995). Soy protein concentrate and full fat soy flour have been found to be more effective with older calves (greater than 3 weeks of age) compared with milk protein–based milk replacers. Data shows that calves 3 to 5 weeks of age fed a soybean protein milk replacer significantly retained more nitrogen per day than those calves up to 3 weeks of age (10.8 vs −1.24 g, respectively) (Akinyele and Harshbarger, 1983). Similar weight gains as for milk-fed calves were found for calves fed nonheated processed soybean milk replacers (extracted, fermented, and extruded) from 0 to 3 weeks of age. However, significantly more weight was gained by calves by the age of 30 and 180 days than those at 6 days of age (Mir et al, 1991).

Calves less than 3 weeks of age were found to be unable to digest soybean proteins because of lower levels of pancreatic and proteolytic activity in the intestine. These gastrointestinal problems occurred because of the immune response stimulated by the presence of larger quantities of undigested protein in the intestines. Calves chronically fed antigenic soya become sensitized and develop intestinal motility dysfunction, causing chronic diarrhea (Lallès et al, 1995, 1998).

Waste milk from cows infected with mastitis or treated with antibiotics supported similar weight gains and incidences of calfhood diarrhea as compared with whole milk. Feeding colostrum as compared with feeding a casein-based milk replacer showed a significant difference in average daily gain of 0.719 vs 0.493 kg/day for the period of 9 to 30 days of age (Broucek et al, 1989). However, from 30 days to 120 days of age, insignificant but higher weight gains were observed for the colostrum-fed calves. Minimal health problems occurred between the two treatments. In an earlier study calves fed colostrum from 0 to 3 weeks of age gained at a rate of 0.56 kg/day (Muller et al, 1973). These results were not statistically different, but the dramatic decline in growth response from 29% to 9% after the third week of age could have been due to the larger percentage of casein in the colostrum as compared with whole milk (5.2% vs 2.6% of

Downloaded From Vet-eBooks.com

the total proteins) (Bondi, 1987). The incidence of diarrhea in colostrum-fed calves was likely higher because of higher fat and mineral content (Muller et al, 1973).

Dilution Rates of Milk Replacers

Milk replacer powders are usually mixed with water at dilution rates that result in a product that is 12% to 15% dry matter and fed at a fluid intake of 8% to 10% of body weight per day (Hand et al, 1985). Higher or lower dry matter concentrations have sometimes been associated with diarrhea, but the cause-and-effect relationship has not been documented.

Acidified Milk Replacers

The concept of feeding acidified milk replacer for ad libitum intake has attracted the interest of dairy producers (Nocek and Braund, 1986). Organic acids such as citric and propionic acids have been used to reduce the pH of the liquid substitute to about 5.2, which acts to preserve the solution, regulate intake, and foster the ingestion of smaller and more frequent meals throughout the day. Calves offered acidified milk replacer free choice digest the ingredients with efficiencies equal to those of calves consuming conventional milk replacer. The pH of the abomasal contents and the feces is lowered, which may favor normal physiological function and decrease the incidence of diarrhea (Woodford et al, 1987). Superior weight gains of calves fed acidified milk replacer for ad libitum intake have been documented (Nocek and Braund, 1986). The increased weight gains are especially significant in calves less than 3 weeks of age. Total dry matter intake from the milk replacer is increased and significantly less from grain than calves fed a comparable quality of milk replacer (Nocek and Braund, 1986). Compared with normal milk replacer offered either warm (38° C [100° F]) or at ambient temperature (3° to 14° C [37° to 57° F]) acidified milk replacer increases calf weight gain (Fallon and Harte, 1988).

The reconstituted milk replacer can be stored for up to 3 days, increasing convenience and saving labor. With such cold-acidified milk replacer feeding systems, calves can be housed in groups with ad libitum access to the milk replacer. Calves housed in group pens consumed more milk replacer and were heavier than calves housed in individual pens to 5 weeks of age (Richard et al, 1988). However, the economics of ad libitum feeding of milk replacer must be considered. Calves fed ad libitum consume more replacer, which leads to a higher milk replacer cost. They also consume more total liquid and urinate more, leading to increased bedding costs. Labor costs in group housing situations should be reduced, but careful observation of individual calves is still necessary to ensure adequate milk intake and to assess the health status of each calf on a daily basis. The cost-benefit ratio of such feeding systems remains to be established (Hand et al, 1985).

WEANING CALVES

Calves should be weaned only when they are capable of thriving on a nonmilk diet. They should be eating at least 450 g of dry feed daily—primarily a high-protein calf starter and some good-quality hay. They should be ruminants before being weaned. Limited whole milk or milk replacer feeding systems with early weaning at 3 to 4 weeks of age may be successful under excellent management conditions. However, under most practical conditions, it is uneconomical to wean heifer replacement calves too early. They may not adjust to the dry feed quickly and effectively and may become unthrifty for several weeks.

The trend toward early weaning, rapid growth, and early breeding stresses the importance of good calf starter rations. Calf starters should be fresh daily and palatable, with the grains cracked or rolled, and a nutrient composition of 20% protein, 70% total digestible nutrients (TDNs), and added vitamins and minerals. At weaning time, the calf should be consuming approximately 0.5 to 0.7 kg/day of calf starter, which increases rapidly after weaning when offered free choice. The amount can be limited to 2 kg/calf/day and can be fed along with good-quality hay and free-choice water until the calf is 6 months of age. Feeding dairy calves 3.8 L of milk once daily, weaning at 28 days, feeding a calf starter from birth to 56 days, and feeding a total mixed diet from day 57 through day 180 allows calves to attain a body weight that exceeds acceptable reported means at 6 months of age (Hopkins, 1997).

Development of Rumen Function

At birth there are no microflora in the rumen of the calf. The rumen becomes inoculated with microflora from the environment, including the hair coat, feces, and saliva of other animals; bedding; and feeds consumed. The types of microflora that proliferate in the rumen are those that digest and use the feeds eaten. In addition to feed substrates, the microflora require water to proliferate and digest feedstuffs in the rumen. When the calf eats dry feed, the abomasal groove does not function, and therefore the feed directly enters the reticulum and rumen where it must be digested or chewed further through rumination or cud chewing. Calves may begin to ruminate by 2 weeks of age, depending on the diet. If water is not provided to the calf in early life, then rumen microbial growth will be limited. Water that is consumed does not bypass the rumen through the esophageal groove but becomes available for the calf's rumen microflora.

The development of the rumen and reticulum of the calf is highly dependent on the diet. The rumen of the newborn calf is relatively small and thin walled and has little papilli development. Fermentation in the rumen is limited, and absorption cannot occur efficiently. If calves are maintained on milk diets for periods of 4, 6, or 8 weeks, the rumen will remain smaller in size and underdeveloped. In contrast, calves that receive grain beginning at 3 days of age will have larger rumens at corresponding periods of time, and their rumen function is much more developed at 4, 6, and 8 weeks of age than in calves on a milk diet. Furthermore, calves at similar corresponding ages fed milk and hay have limited rumen development. Their rumens are not developed nearly as much as those of calves fed grain and milk. Some calves on diets of a high level of high hay or other forages will have larger rumens, but the papilli development is limited. The rumen papilli allow for a marked increased area for absorption of nutrients and digestion end products. These provide the calf with a large amount of energy for the calf to grow.

The increased concentration of energy in grains causes the production of microbial end products of butyric and propionic acids, which is the major reason grain and not hay is recommended before weaning. The butyric acid produced from grain primarily stimulates the development of the rumen. Much of the butyric acid produced in the rumen by the bacteria is absorbed through the rumen walls as a normal part of rumen metabolism. Butyric acid provides energy for the growth and development of rumen size and function.

Downloaded from Vet-e-Books.com

A small amount of grain along with water promotes ruminal fermentation and the production of butyric acid, which allows the rumen to become more functional and better able to digest grain. The process is self generating and allows the early grain-fed calf to have significant rumen development at a young age, 3 to 4 weeks of age. Thus it is recommended to feed grain to stimulate rumen development, which allows weaning to occur at a much earlier age than traditionally done.

DEVELOPMENT AND DELIVERY OF CALF HEALTH MANAGEMENT PROGRAMS

Dairy cattle practitioners have been providing planned health management and production programs as a veterinary service for many years. The emphasis in those programs has been on the maintenance and improvement of reproductive performance, mastitis control, and consultation on feeds and feeding systems, all of which are designed to produce high-quality milk at the lowest cost commensurate with the resources available. For a variety of reasons, calf health and production were not given the priority they deserved, but veterinarians have now begun to develop and deliver calf health management programs.

Insufficient attention has been given to monitoring the performance of calves on dairy farms. Ideally, calves should be weighed at birth and weekly thereafter until weaning. Body weight gain is usually minimal during the first week of life, but gains of 300 to 500 g/day, depending on the breed of the calf, should occur after the second week of life and until weaning. Decreased growth rates are associated with decreased whole milk intake, inferior milk replacers, and subclinical diseases, such as chronic diarrhea and enzootic calf pneumonia.

The cost of raising dairy replacement heifers is a substantial portion of the overall costs of milk production, perhaps second only to the cost of feed. Many producers are unaware that this enterprise can account for 15% to 20% of total milk production costs, and a computerized spreadsheet program is available to estimate the cost of raising dairy replacements (Goodger et al, 1989). The program allows the producer to calculate the costs of raising calves to calving for the particular conditions in the dairy using current calf populations and current facilities in the herd. Dairy producers have underestimated calf mortality rates and tended to rank calf disease low in economic importance. The dairy replacement heifer is a key asset for increasing milk production and profits in a dairy herd (Donovan and Braun, 1987).

The production potential of heifers is a result of all previous breeding and management decisions. Many dairy farms follow approved calf and heifer health management practices, but several aspects of management need improvement (Heinrichs et al, 1987a). The most important of these include the care and feeding of the newborn calf and the types and amounts of feeds fed to young calves, both of which have been shown to be related to high calf mortality. The role of the veterinarian is to educate the producer to understand the principles of calf health and production management and to adopt approved practices that lead to healthy calves that can grow at acceptable rates and become economical heifer replacements.

Surveys of management practices on dairy farms have revealed a lack of systematic understanding of the factors that are vital in calf health management (Heinrichs et al, 1987a; Goodger and Theodore, 1986). In spite of the long-known importance of colostrum, a significant percentage of producers do not appreciate the important factors that influence the passive transfer of colostral immunoglobulins in calves and what is required to ensure a high level of colostral immunity in the calves. Colostrum intake is often left to the calf, and most producers are unsure of the amount of colostrum obtained by the calf. Some producers vaccinate pregnant cows to prevent infectious diarrhea of calves but do not make the effort necessary to ensure that the calves ingest or are force-fed a sufficient amount of colostrum early enough after birth. The veterinarian must adequately inform producers about the importance of the entire sequence of events necessary to take maximum advantage of dry cow vaccination.

In large dairy herds, labor-intensive practices such as supplemental feeding of colostrum, close and frequent observation of the calving area, prompt removal of calves from the potentially infectious environment of the calving area, and separation of first-milking colostrum may not be practiced because of the labor required (Goodger and Theodore, 1986). Surveys have shown that calf mortality is lowest when a family member cares for the newborn calf, but calves in some herds, especially large herds, are often raised by hired labor, who frequently have other duties and do not have the same concern for health of the calves as would a family member. In the first 24 hours, calves need relatively intensive care, and this may conflict with hired labor schedules and other duties. In areas with herds that average less than 100 cows per dairy, family members usually feed and care for the calves.

There are four major goals in dairy calf management: (1) enhance the calf's immune system as soon as possible, (2) reduce stress and exposure to infectious disease pathogens, (3) provide adequate nutrition to ensure that the calf can resist disease, and (4) provide adequate treatment of calves with disease. There is substantial information available on how to achieve these goals, but the management efforts of dairy producers appear to be inconsistent and haphazard. Calf management practices and health management decisions on large dairies can be scored with a list of questions, which covers all aspects of young calf production (Goodger and Theodore, 1986).

The delivery of an effective calf health and production management program requires the establishment of a simple record-keeping system that records all pertinent calf health and production data as well as analysis and interpretation of this data by the veterinarian, who works with the producer or those caring for the calves to ensure that they understand the well-known risk factors that make calves susceptible to disease. In large dairy herds, epidemiological approaches can be used to investigate neonatal calf mortality with the objective of measuring risk factors (Thurmond, 1986). Some guidelines for the veterinarian are:

1. Work with the calf management personnel. All management success is conditional on the active participation of the producer.
2. Work within the conditions of the particular farm.
3. Determine the baseline of health and production when the program begins so that progress can be measured later.
4. Begin with the basics, such as colostrum and colostral immunity.
5. Introduce changes gradually and monitor changes in health and production.

REARING CALVES ON PASTURE

In many countries where grass is plentiful for several or more months of the year, young calves can be reared successfully on grass beginning shortly before or after being weaned from milk or milk replacer. In New Zealand, and to a lesser extent in Britain, most calves born in the spring are routinely placed on pasture soon after birth. Successful

Downloaded From Vet-e-Books.com

rearing of dairy calves on pasture can also be achieved in North America. Calf performance on pasture, with few exceptions, has equalled or surpassed indoor rearing and has produced healthier, thriftier calves.

Several factors are important for the successful rearing of young calves on pasture. The quantity and quality of grass available are of primary importance because of the highly selective nature of grazing calves. Young calves can starve on unsuitable pastures unless they receive a supplemental concentrate. Digestibility trials have found that calves from 3 to 5 weeks of age can digest approximately 75% of herbage dry matter. Compared with indoor feeding of hay and concentrates, pasture rearing has led to calves ruminating at an earlier age and developing greater rumen size and capacity. Pasture quality can also alter the response of calves to concentrate feeding. Calves on excellent pasture alone can make greater weight gains than calves on poorer pasture with supplementary grain feeding. Under conditions of poor pasture, low levels of nutrition, and adverse weather conditions, young calves are highly susceptible to parasitic gastroenteritis, which causes severe unthriftiness.

Dairy calves can be turned out to grass at 3 or 4 months of age under a leader-follower rotational grazing system during the summer months and can gain 0.55 to 0.74 g/day while receiving a daily grazing supplement of about 1.8 kg of concentrate. The followers can be yearling cattle and sheep.

The major problems in rearing young calves on pasture include insufficient good-quality grass to support optimum growth, mineral deficiencies (particularly of the trace minerals), parasitic gastroenteritis, and lungworm pneumonia.

Assessment of the nutritive value of pasture for young calves is a practical problem. Spring-born calves that have received cow's whole milk or a good-quality milk replacer until weaning at 6 to 8 weeks of age perform well on lush spring pasture. The performance of the calves must be monitored regularly by visual observation or, preferably, by monthly weighings. When grass is not plentiful or not of good quality, calves should be maintained on milk replacer for longer periods and supplemented with concentrate while on pasture.

A salt-mineral mixture must be provided for young calves on pasture. The composition of the mineral mixture depends on the mineral content of the forages and soil in the area. There are seven major minerals, or macrominerals (calcium, phosphorus, potassium, sodium, chlorine, magnesium, and sulfur), and eight trace minerals, or microminerals (iron, iodine, zinc, copper, manganese, cobalt, molybdenum, and selenium). The minerals that are commonly deficient in cattle grazing on native, unsupplemented pastures are phosphorus, copper, and cobalt. Mineral deficiencies are particularly common in cattle of all ages grazing in the tropics. Lack of good-quality pasture and multiple mineral deficiencies are major factors in the poor growth rates and prolonged delayed onset of puberty in calves grazing in tropical countries. It is not uncommon for dairy heifers in such areas to have their first calf at 3 to 4 years of age.

The control of parasitic gastroenteritis in calves that are pastured during the grazing seasons in countries with a temperate climate is now possible. Strategic chemotherapy involving the use of anthelmintics at selected times combined with various systems of grazing management have been successful. In the Northern Hemisphere, in the so-called Weybridge "dose and move" system, young cattle are dosed with an anthelmintic in late spring before the infection pressure is high and then moved to a pasture ungrazed by cattle since the previous autumn. Grazing management systems used to control bovine ostertagiasis have included rotational grazing of cattle, alternate grazing of cattle with different host species, or integrated rotational grazing of different age groups of cattle. Improved weight gains have also been reported when susceptible dairy calves were rotationally grazed on permanent pastures and followed by replacement heifers. The success of this system, known as the leader-follower system, depends on the careful management of the paddocks grazed by the calves and on the assumption that 2- to 3-year-old dairy heifers are immune to infection by *Ostertagia ostertagi*. Thus the calves are only permitted to graze the upper leafy part of the herbage before being moved onto the next paddock, thus avoiding the mass of third-stage larvae thought to be concentrated in the lower quartile of the herbage and subsequently ingested by the incoming immune heifers. In the Southern Hemisphere, the same principles have been used for the control of ostertagiasis, and the reservation of safe pasture at times of the year when levels of infestation are known to be increasing has been the method widely advocated in areas such as Australasia.

VEAL CALF PRODUCTION

Veal is made from dairy bull calves, largely of the Holstein breed, which unlike heifers are essentially surplus products of the dairy industry. The raising of dairy calves for veal production is profitable when the economic conditions are right. A readily available supply of inexpensive healthy male calves, good-quality milk replacers at an economical price, reliable labor, inexpensive housing, and market potential provide the opportunity to produce veal calves. Before the commercial veal industry developed about 30 years ago, such calves were killed or sold for slaughter within days after birth as bob veal or were grown as grass-fed veal calves, which were raised on grass pasture, sometimes supplemented with grain, for a few months to a year.

Classes of Veal

Four classes of veal are now recognized in the United States: (1) bob veal calves, which are 1 to 3 weeks of age and weigh up to 68 kg, (2) special-fed veal calves, which are more than 3 weeks of age, weigh 68 to 182 kg, and are fed a liquid milk-based diet, (3) non-special-fed veal fed a variety of diets, which are also more than 3 weeks of age and weigh 68 to 182 kg but are fed a solid diet, and (4) calves of more than 182 kg and fed no special diet; also called heavy or western veal calves, which are raised similarly but weigh more than 182 kg (Wilson et al, 1995).

Bob veal is obtained from young dairy-type calves and is primarily used for processed meat. Non-special-fed calves are fed a variety of diets including milk replacer, grain, and forages (hay, silage, or pasture). They may be of different ages at processing, and several cattle types may be utilized. Special-fed veal calves (also referred to as formula fed, fancy, or nature veal) are fed a liquid milk replacer diet in which the iron content decreases through the last half of the production cycle. The calves are raised in confinement for 16 to 20 weeks of age and are marketed at live weights of 160 to 210 kg.

According to the USDA (1991) approximately 33% of the male dairy calves marketed are used for bob veal production, 40% for special-fed veal production, and the remainder for a variety of subsequent feeding systems, including beef production. However, up to 95% of the male dairy calves in some areas may be used in veal or beef feeding systems. The numbers of calves used for bob veal, special-fed veal production, and other calf production declined 71%, 22%, and 73%, respectively, in the United States between 1986 and 1991. However, because of increased market weights of special-fed veal calves, total tonnage of veal

Downloaded from Vet-eBooks.com

produced has remained fairly constant in the last few years (Wilson et al, 1995).

Neither bob veal nor grass-fed veal is considered a high-quality product. Bob veal has pale muscle meat, which is a desirable characteristic, but it tends to have a soft and even slimy consistency; grass-fed veal is generally pink or red and can be tough or grainy, depending on the age at which the calf is slaughtered (Schwartz, 1990). Formula-fed veal calves—also known as milk-fed, prime, nature, special-fed, or fancy veal—are sustained on a low-iron, milk-based liquid diet until they are slaughtered at up to 20 weeks of age. This is done to produce pale, tender muscle meat, called white veal, which fills several cultural markets and an upscale specialty market, such as in restaurants and gourmet food stores.

The formula-fed veal industry developed in Europe and the United States in part because of the surplus of milk. In the United States, it now has become a billion-dollar industry that uses over $200 million in dairy feed products annually. Annually, in the United States, 1.2 million dairy bull calves are raised as formula-fed veal, which represents about 40% of the total veal market.

Targets of Performance

Consumers of veal prefer a well-fleshed calf of a "blocky" conformation, with only a small cover of white fat. The meat must be pale pink, an index of youth to the packer that is found only in an anemic calf. The North American market desires a live weight ranging from about 200 to 300 lb (90 to 135 kg). The calves should grow at a rate of over 2 lb (0.9 kg) daily with a feed conversion of 1.4 to 1.5 kg of milk replacer powder per kilogram of body weight gain. At the end of the feeding period, calves often gain in excess of 3 lb per day. A 100-lb calf should be ready for market in 12 to 16 weeks.

A survey of white veal calves in commercial farms in Ontario found a mean average daily gain for shipped calves over the entire production period to be 1.1 kg/day. The overall percentage of calves receiving at least one individual treatment was 59%, with an average number of treatment days per calf of 3.3 (Sargeant et al, 1994a). The mortality rate was 3.7%, and 5.1% of the calves were culled. Pneumonia was the single largest cause of death. Peak death and culling losses occurred during the sixth and seventh weeks of production. Calves shipped to slaughter averaged 130 days in production with a range of 64 to 189 days. Mean weight at time of entry was 45 kg with a range of 26 to 90 kg. Overall mean weight of calves at the time of marketing was 194 kg with an individual calf range of 106 to 269 kg. The mean farm level market weights ranged from 173 to 198 kg (Sargeant et al, 1994b).

There is a growing interest in raising calves on grain diets to produce a carcass that is lighter in weight than traditional beef, while circumventing some of the real or perceived problems of white veal production. A survey of red veal calf production practices and indices in commercial red veal farms found mean entry weight of 119 kg, mean individual calf marketing weight of 291 kg, 116 mean days in production, and average daily gains of 1.52 kg over the entire production period (Sargeant et al, 1994a). The percentage of calves receiving one or more treatment days was 55%, with an average number of individual treatment days per treated calf of 3.9. The population mortality during production was 5.4%, with 0.8% of calves culled (Sargeant et al, 1994a).

Welfare Aspects of Veal Calves

Formula-fed veal calves are usually raised under what has been termed by critics as "factory farming" conditions, in which calves are kept and fed twice daily in small, individual stalls or crates, with a minimal amount of bedding and without exercise, from less than 1 week of age until they are slaughtered. An emerging problem in veal calf production is the politics and welfare of the animals (Schwartz, 1990). Concerns have been expressed about confining calves in crates, feeding them liquid diets only, and limiting their iron intake to produce pale meat. Veal calves may be housed in individual raised floor stalls with no bedding, a restricted floor space for lying down, and no special contact with adjacent calves. These restrictions may encourage calves to reach each other at feeding times or to attempt to turn around in their stall to see each other. When veal calves are reared in groups, they may suck each other's navels and penises. If straw is provided in group pens, they eat the straw, which may exaggerate the incidence of abomasal ulcers. When they are housed in groups of 15 to 50, automatic milk replacer dispensers can be installed economically at the rate of one per 15 animals, which may overcome the sucking problem. It appears that a well-designed individual stall with a slatted front for visibility and a sufficiently wide floor that allows the calf to stretch out is satisfactory and humane. The Ministry of Agriculture, Fisheries, and Food of Britain (1985) has stated, "The use of veal crates or boxes is not an acceptable system and cannot be condoned."

Animal rights activists have focused on the conditions used to raise veal calves. An excellent publication on the politics of formula-fed veal calf production is available (Schwartz, 1990). Activists believe that such conditions are inhumane, alleging that they lead to anemia, behavioral deprivation, and more infectious disease and chemical residues, presumably because the calves are treated more often than calves raised under conventional conditions. There is evidence that the campaign of the activists has had a negative impact on the sales of veal. This is compatible with the results of a national survey, which found that the veal industry is perceived negatively by the meat-consuming public compared with the beef industry, which is still perceived positively. A congressional bill has been introduced that would make it unlawful to (1) keep a calf in an enclosure in which the smallest dimension is less than the length of the calf, measured from the tip of its nose to its tail, plus 6 inches; (2) prevent the calf from having an appropriate amount of physical contact with other calves; and (3) give the calf feed that does not meet standards to be established by the Secretary of Agriculture. It would also be unlawful to transport, sell, or purchase a calf that was known to have been kept or fed in violation of the act, and to fail or refuse to allow the secretary or any representative of the secretary to make inspections (Schwartz, 1990). The major issues are as follows:

1. Should calves be raised individually or in groups, and, if they are raised individually, should housing in small enclosures be stopped?
2. Is the raising of marginally anemic (low-normal hemoglobin/packed cell volume) calves inhumane?
3. Do residues of antibiotics, sulfonamides, and other chemical feed additives in veal need better control?
4. Should the federal government regulate the veal industry, mandate an industry-based method of regulation, or leave the industry to it own devices?

The above issues are being debated. However, before animal husbandry legislative changes are put into effect, it would seem prudent to perform the necessary research to obtain information to deal with these issues. New legislation intended to improve the health and well-being of veal calves should be based on sound science.

A recommended code of practice for the care and handling of specially fed veal calves is now available in Canada

Downloaded From Vet-eBooks.com

(Agriculture Canada, 1988) and was coordinated by the Canadian Federation of Humane Societies. It deals with housing, feed and water, delivery and postnatal care of veal calves, growing, attendants, supervision and protection of calves, transportation, processors, emergency procedures, space requirements, and wind chill factors. Other veal calf guides are also available.

The effects of different rearing systems on the development of calf behavior, health, cleanliness, and injuries have been examined (Webster et al. 1985a,b). Suckler cows with their calves at pasture, early-weaned calves bucket-fed in individual pens, early-weaned calves teat-fed and group-reared, veal calves bucket-fed in individual crates, and veal calves teat-fed and group-reared were compared. The major behavioral abnormalities of veal calves in individual crates were as follows:

1. Discomfort while standing on slats in the first few weeks of life. This could be improved by the use of wood shavings or similar bedding in the crates for the first few weeks after arrival and by ensuring that the gap between slats does not exceed 2 cm (Webster et al, 1985a).
2. The inability to adopt a comfortable sleeping posture above the age of about 10 weeks. This could be improved by prohibiting the use of crates less than 85 cm wide for calves weighing over 100 kg.
3. Veal calves deprived of access to solid food showed a much higher incidence of purposeless oral behavior than other groups. This did not reduce the time they spent resting relative to other calves, however, and the abnormal behavior did not last long enough to be described as an obsession.
4. Veal calves in individual crates were not alarmed abnormally by the presence of humans as long as they were exposed to the normal sights and sounds of farm activity.

The welfare of veal calves in commercial facilities has been examined using a multidisciplinary approach (Stull and McDonough, 1994). The low mortality rate, rapid growth rate, and absence of stress indicators demonstrate the ability of commercial agricultural systems to effectively manage and care for immunologically deficient calves. An important management advantage is the opportunity to individually feed and monitor a calf. The use of stalls in a controlled environment assists in the individual management of veal calves. Neither the constraints of individual stalls nor the diet of veal calves, which is formulated to decrease the iron content after 8 weeks of age in an effort to reduce the red color of the meat, are considered to have a deleterious effect on the calves. The total time spent lying down or the number of transitions from recumbency to standing are not different between calves housed in individual stalls and group-penned calves. The marginal clinical hemoglobin levels does not affect the growth or health status of the calf from 12 to 16 weeks of production. Veal calves with marginal anemia do not become anorexic, which is a clinical finding associated with anemia. The major factor that adversely affects the welfare of veal calves is an inadequate level of serum colostral immunoglobulins. This can be minimized by the ingestion of sufficient quantities of high quality colostrum in the first 24 hours after birth, preferably the first 12 hours.

The effects of the different systems of rearing on health, cleanliness, and injury revealed that veal calves in crates tended to be caked with feces around the legs and hindquarters, which they were unable to groom from about 8 weeks of age (Webster et al, 1985b). Veal calves in straw yards were generally dirtier overall than any other group. In general, calves were free from external injuries, but 20% of the veal calves in crates had abrasions and bruised or swollen knees. The system of rearing veal calves in groups in straw yards with ad libitum access to milk from an automatic dispenser appeared to present a greater risk for disease and mortality than housing veal calves in individual crates and bucket feeding controlled amounts of milk twice daily (Webster et al, 1985b). These results, along with the behavioral observations described above and the fact that production costs are higher when veal calves are fed ad libitum, indicate that free-choice feeding of veal calves in groups is not yet a satisfactory alternative to rearing veal calves in individual crates (Webster et al, 1985a).

Because they consume large quantities of fluids, formula-fed veal calves produce large quantities of urine. Therefore the building must be well drained and ventilated to remove the excess moisture. It is estimated that each calf will produce 1 to 2 gallons of manure and urine per day. Three gallons of wastewater are generated per calf per day in feed preparation and cleaning. Facilities should be planned with a total of 5 gallons of waste generated per calf per day.

Concern has also been expressed about the humaneness of producing veal calves that are marginally anemic. Quality veal is traditionally pale ("white") in color because the calves are fed an all-liquid, milk-based diet that is low in iron. The pallor of the meat is largely the result of low concentrations of myoglobin and other iron-containing compounds in muscle (Welchman et al, 1988). Formula-fed calves are not allowed to consume roughage, which would provide a source of iron and stimulate normal rumen development, rumen microbial production, and vitamin B_{12} synthesis (Schwartz, 1990).

Whether the low iron intake and marginal anemia affect the health and vigor of the veal calves is uncertain. The goal of veal calf producers is to deplete myoglobin but not to decrease the blood hemoglobin to below 8 g/dl, the low end of the normal range for cattle. The published literature on the possible effects of marginal anemia is not consistent and is open to discussion. There is no good evidence that feeding veal calves liquid diets low in iron that leads to low-normal or marginally anemic hemoglobin concentrations can cause increased susceptibility to disease or impaired productivity (Schwartz, 1990). Normal appetite and growth have been maintained in veal calves at hemoglobin concentrations greater than 7 g/dl and with a concentration of iron in the milk replacer of 25 to 30 mg/kg DM. The borderline of iron deficiency anemia at 16 to 20 weeks of age is defined as a hemoglobin concentration of 5 g/dl and a saturation of total iron binding capacity of 10% (Welchman et al, 1988). The addition of extra iron in a normal commercial milk replacer given from the end of week 6 until the end of week 16 of the fattening period influenced feed conversion positively, without a loss in meat quality (Wensing et al, 1986). The mortality, blood, and growth performance indexes measured in veal calf units suggest a generally acceptable level of well-being of special-fed veal calves housed in individual stalls (Wilson et al, 1994).

Health Management of Veal Calves

The major causes of economic loss resulting from disease in veal calf operations are the infectious disease enteritides and pneumonias. The enteritides are commonly associated with the low serum and intestinal levels of immunoglobulins in calves that are purchased from different, usually unknown, sources. Immunocompetence of the calves for veal production is a concern of the dairy and veal industries for both economic and animal welfare reasons. Calves have low levels of circulating IgG at birth, and consumption of

Downloaded from Vet-eBooks.com

colostrum by the calf within 24 hours after parturition provides passive immunity and reduces subsequent mortality. The percent of calves receiving adequate amounts of high-quality colostrum and thereby developing satisfactory passive immunity varies regionally. In a Pennsylvania study Wilson et al (1994) concluded that between 60% and 80% of calves entering veal production systems had received colostrum. Adequate immunity will enhance the health and well-being of the calf throughout the feeding cycle, thereby necessitating less use of antimicrobials and providing increased financial stability for veal farmers. In California, the leading milk-producing state in the United States, colostrum is collected at the dairies and sold to facilities specializing in raising dairy heifer calves.

Longitudinal surveys of veal calves have revealed that the usual enteric pathogens are present in calves within a few weeks after their arrival (De Visser et al, 1987). Veal calf hemorrhagic enteritis is a fatal syndrome of major concern to the veal calf industry (Mahdi-Saeed et al, 1993). Infection with *E. coli* strains that produce enterotoxins and cytotoxins may be causative agents. Calf pneumonia may also be associated with low levels of protective immunoglobulins, but inadequate ventilation of the calf barn probably has a greater influence on the health of veal calves raised under intensive conditions. Outbreaks of respiratory disease have occurred in veal units that used a high-pressure sprayer for the weekly cleaning of occupied calf rooms.

Bob veal is a class of veal defined as 1- to 3-week-old calves weighing up to 68 kg. Bob veal calves are predominantly bull dairy calves shipped to slaughter within a few days after birth. High rates of postmortem condemnation because of icterus have existed for a number of years in bob veal calves that appear normal at antemortem inspection. Icterus condemnations comprise a substantial proportion (41%) of total condemnations of bob veal (Gray et al, 1995). Normal and icteric bob veal calves have significant increases in total bilirubin concentration, and icterus bob veal calves is secondary to unconjugated hyperbilirubinemia. Lack of colostrum consumption is strongly associated with icterus in bob veal calves. Bob veal calves that had not consumed colostrum had significantly higher total bilirubin and creatine kinase levels (Gray et al, 1995).

Yellow discoloration in veal calves slaughtered at 26 weeks of age has been associated with chronic hepatitis of unknown etiology (Groot and Gruys, 1993).

Purchase of Calves

Ideally, all calves should weigh at least 45 kg (100 lb) and be at least 10 days old when delivered to the vealing unit. If possible, they should be purchased directly from dairy farms rather than from auction marts. This ensures obtaining calves of optimal physiological maturity and with adequate levels of serum immunoglobulins. In other words, a 100-lb calf that has survived for 10 days has a better chance of living for a few months than a smaller calf that is only a few days of age. In the absence of an economic and practical laboratory method of identifying calves that are a good risk, the probability is greater that the larger calf at 10 days of age possesses a greater degree of inherent or acquired resistance to infectious disease than the smaller calf at 2 days of age. An algorithm can be used to assist in deciding how to manage purchased calves with low serum levels of immunoglobulins and to determine what premium can be paid for calves with high immunoglobulin levels.

Within a few hours after arrival, all calves should be given a complete physical examination by the veterinarian. Calves with obvious abnormalities, such as navel infection, arthritis, diarrhea, or pneumonia should be isolated, treated if deemed necessary, or culled immediately. Each calf should be weighed on arrival and identified with a tag, and an individual calf card should be made out and clipped to its pen. All relevant information for that calf is recorded in chronological order: weight in and out, date in and out, diagnosis of illness, treatments, feed refusals, and nature and date of vaccination given. These cards are then analyzed when the calves are shipped to market.

The vealing unit should be filled with calves within the shortest time possible, and almost all calves should be marketed as soon as possible. This all-in, all-out system is essential for the control of infectious diseases. After the calves are marketed, the facilities are cleaned out, disinfected, and allowed to dry and remain vacant for several days or a few weeks before being restocked. The system of introducing new calves and selling a few on a continuous basis does not allow for effective disease control.

Feeding

Veal calves are usually fed solely on a reconstituted liquid milk replacer containing 16% to 24% fat (DM). The digestive problems associated with these milk replacers occur during the first few days, when the calves are adjusting to the ration, and later in the feeding period, when large amounts of the liquid are ingested at each feeding.

Nutritional diarrhea occurs in calves that consume too much milk replacer during the first few days. This can be controlled by feeding only 50% of the total daily allowance to new calves on the first day, increasing up to 75% on the second day, and finally giving a full allowance on the third to fifth day. The total daily allowance is increased each week as the calf grows older. The nutritional diarrhea associated with the feeding of milk replacers containing heat-denatured skim milk has been described (see "Milk Replacers" section). There is some evidence of an allergic hypersensitivity to milk replacers fed to veal calves (Flederus et al, 1988). Affected calves exhibit diarrhea and hyperemia of the conjunctivae and nose.

Abomasal bloat occurs during the finishing period in veal calves, which are by this time consuming large quantities (9 to 12 kg) of liquid milk replacer per feeding. The disease is highly fatal. Affected calves become bloated and die within 15 minutes after first being noticed. The cause and pathogenesis of the disease are unknown, but presumably it is related to the ingestion of large quantities of milk replacer, most of which enters directly into the abomasum. This sudden overloading of the abomasum may cause a reflex outpouring of fluids from the abomasal mucosa, which may further exaggerate the dilatation. Death results from peracute abdominal distention and acute heart failure caused by failure of venous return.

The method of feeding—once or twice daily, the temperature of the milk replacer when fed, and the use of buckets, nipple pails, or automatic dispensers—may affect the performance of the calves under certain management conditions. In general, however, almost any feeding system is successful if properly used with good care, management, and sanitation.

Feeding veal calves in groups with automatic milk replacer dispensers has some advantages over bucket feeding. The need for sucking is satisfied thus reducing the incidence of cross-sucking, including preputial sucking and urine drinking. Bucket-fed calves in group housing must be tied up during the first 6 to 8 weeks of the feeding period to control these problems. With automated feeding, the calves do not have to be tied up and the milk replacer can be provided more than twice daily, which saves labor (Maatje et al, 1993). However, the growth rate and feed intakes of calves fed automatically are lower than those of calves in individ-

Downloaded From Vet-eBooks.com

ual crates. In addition, sick calves fed automatically were not detected easily based on behavioral changes of reduced feed intake alone.

Some problems occur in veal calves that appear to be associated with feeding in the finishing system (Breukink et al, 1988). The failure of the esophageal groove reflex in some calves causes ruminal drinking. A large amount of milk is deposited in the rumen instead of the abomasum, causing fermentation of the milk in the rumen. This may be explained by the observations that affected calves seem to gulp their milk rather than suck it from the pail. Affected calves are chronically bloated with ventral abdominal distention, loss of appetite, unthriftiness, and loss of weight, and they have a long, dry hair coat. The feces are sticky and clay like. Large volumes of foul- or acid-smelling, grayish-white fluid can be siphoned off the rumen. Most calves become ill 2 to 3 weeks after the start of the finishing period, beginning with occasional feed refusal and chronic bloat. Extensive villous atrophy along the small intestine is characteristic. The pathogenesis is not well understood, but some calves may not maintain their reticular groove reflex into the fattening period. The experimental administration of milk into the rumen of calves has caused a similar syndrome (Van Weeren-Keverling Buisman et al, 1990). Ruminal drinking can be cured by the use of a rubber nipple floating on the surface of the milk, and it can be prevented by training calves to suck, using the attendant's fingers or a nipple, rather than gulp milk.

Lesions of the abomasum of veal calves are common. Approximately 60% to 75% of the abomasums of veal calves have lesions at slaughter (Wiepkema et al, 1987). The lesions consist of superficial erosions restricted to the mucosal layer, ulcers that may penetrate into the submucosa, and scars (the star-shaped remnants of ulcers). The lesions are predominantly in the pylorus. The possible relationship between stress or stereotypical behavior in veal calves and abomasal injury and disease has been examined. Biting and licking did not show a relationship, but tongue playing did (Wiepkema et al, 1987). Providing calves with roughage leads to a decrease of abnormal behavior, such as chewing the pen and tongue playing, and a reduction in hairballs. However, roughage enhances the occurrence of ulcers. The incidence and severity are greatest when calves are fed milk replacers ad libitum with access to roughage (Welchman, 1987). There is no evidence that the lesions affect the growth rate of calves. They are difficult to detect on clinical examination but are not considered to be significant on a welfare basis. The pathogenesis is uncertain, but local ischemia followed by focal necrosis or the stereotypic behavior and stress of veal calves in confinement may be factors (Breukink et al, 1989). The use of a beta-agonist such as clenbuterol has been examined as a prophylactic measure, but there are insufficient data to support a recommendation for its use.

Vaccination

Because veal calves commonly originate from many different sources, their immunological background also varies considerably and it is difficult to plan an effective, reliable immunization program. The control of acute undifferentiated diarrhea in veal calves depends on the purchase of healthy calves that have an adequate colostral status and on the minimization of the natural challenge by the calf's environment.

The use of modified live virus vaccines for the control of IBR and enzootic pneumonia caused by parainfluenza-3 virus infection may be considered in veal calves. Most veal calves are marketed by 16 weeks of age, and the use of viral vaccines at an early age, soon after the calves have arrived in the unit, is controversial. Colostral immunity begins to wane at 4 to 6 weeks of age, and vaccination with viral vaccines may be considered shortly after this time.

Housing

Veal calves are usually raised under intensified conditions in which many calves are housed in individual pens with raised floors.

The majority of North American veal farms use individual stalls or pens. Canadian and U.S. guidelines (Agriculture Canada, 1988; AVA, 1994) recommend stalls with a minimum width of 66 cm and length of 168 cm for calves weighing up to 202 kg. Most renovated individual stalls are 66 to 76 cm wide, with length of 168 cm; these dimensions are the current industry recommendations (AVA, 1994). Floors are constructed of either wood slats or plastic-coated expanded metal; fronts and sides are of wood slats. The stall sides between calves are usually 61 cm in length. The back of the stall is usually open; calves are tethered to the front of the stall with fiber or metal tethers 61 to 91 cm in length.

The use of individual stalls and the practice of tethering calves has been criticized because of limited social interaction between calves, lack of total body self-grooming, and restricted movement (Schwartz, 1990). The tethered calf can stand or lie in a natural, sternal position and take several steps either forward or backward (Albright et al, 1991; Stull and McMartin, 1992). Calves can reach and groom most parts of their bodies. Proponents of individual stall systems contend it allows regulation of air temperature and humidity through heating and ventilation, effective managing and handling of waste materials, limited cross contamination of pathogens between calves, individual observation and feeding, and, if necessary, examination and medical treatment with less stress from handling.

For lighting in veal calf housing facilities, American Veal Association (AVA, 1994) recommends that adequate levels of light be available for inspection while feeding or monitoring. In a recent study of 10 commercial veal facilities, all barns were equipped with adequate supplemental lighting; 6 of the 10 facilities had natural light sources through windows or doors, and none of the facilities incorporated darkness as a deliberate component of the production system (Stull and McMartin, 1992).

Because veal calves are fed large quantities of fluid, they give off large quantities of moisture in their urine and feces, and an effective ventilation system is necessary to remove excess moisture. Supplemental heat may be necessary during cold winter months to maintain a satisfactory minimum inside temperature of at least 50° F (10° C). In cold climates, the calf barn must be insulated with material having an R value of 15 in the walls and 20 to 25 in the ceiling. Continuous air exchange through the building at a minimum rate of four changes per hour is essential. In cold climates, for the winter months, the most satisfactory method is to bring in fresh air over the heating unit. During the summer months, 30 air exchanges per hour are desirable. Minimum ventilation requirements are to have 5 to 10 cu ft/min/100 lb body weight for winter and 50 cu ft/min/100 lb body weight for warm weather. With any system, careful management and common sense in operation are essential to its success, regardless of its design. Veterinarians should consult their local state or provincial agricultural engineering extension service for assistance in evaluating the ventilation system of calf barns. When in-

Downloaded From Vet-eBooks.com

vestigating a problem with respiratory tract disease in a group of housed calves, the ventilation system and its adequacy assume primary importance. Floor pen area should be 20 to 25 sq ft/calf. Ventilation systems for veal calf environments are currently being evaluated and correlated with calf health, behavior, growth, and carcass traits (Wheeler et al, 1997).

The flooring types used in special-fed Holstein veal calves have been compared for their effects on average daily gain, body weight, blood parameter, or carcass weight or grade. There were no differences between groups of calves kept on oak wood slats, rectangular vinyl-coated slats, and diamond-shaped, vinyl-coated slats (Wilson et al, 1998).

Surveillance System

Each calf should be examined twice daily for clinical evidence of disease. A nasal discharge, crusty nose, salivation, dyspnea, coughing, diarrhea, reluctance to get up, and refusal to feed are common clinical findings in sick veal calves. The diagnosis and treatment given should be recorded on the individual calf card; a summary of diseases and mortality should be prepared, analyzed, and interpreted; and the necessary control procedures instituted on a regular basis.

A decrease in appetite is one of the first and most reliable indicators of anemia in veal calves. A concentration of 25 to 30 mg of soluble iron/kg dietary dry matter provides sufficient hemoglobin for normal appetite, growth, and oxygen transport as well as provides carcasses light enough in color for the veal trade.

Because veal calves are slaughtered for meat, there is the potential for antimicrobial and other drug residues in calves that were treated for infectious disease or that received waste milk containing antimicrobials. Antimicrobial residues can be found in the urine of calves that consumed milk from mastitic cows that were treated with antibiotics. The live animal swab test is advocated for use on commercial dairy farms as a screening test for detecting antibiotic residues in the urine of calves and cull dairy cows. The swab test on premises (STOP) is used in the abattoir to test for the presence of residues in kidney and muscle.

Health Management of Replacement Dairy Heifers

The success of raising replacement heifers is of major importance to the viability and profitability of a dairy herd. An average of 25% to 35% of the cows in a dairy herd is culled annually. In addition, 10% to 12% of dairy calves born die within the first 2 years of life (NAHMS, 1992). This section describes health management programs for heifers from the time of weaning until calving and entry into first lactation. The alignment of this program with the producer's objectives for raising replacement heifers is essential. The principal components of a program for replacement heifers involve attention to nutrition, housing, reproductive performance, disease control, and genetic selection. The effect of a replacement heifer program is determined by the degree to which it completes the health management cycle. The use of record keeping and monitoring systems allows the continual assessment of heifer performance and provides the direction for changes in management. The resulting new levels of performance can be evaluated against industry standards or farm-level targets. After accounting for the effects of external factors, the continuous monitoring effort can lead to further management planning. The continuation of this cycle promotes improved health and performance (Fetrow et al, 1987).

OBJECTIVES OF RAISING DAIRY HERD REPLACEMENTS

Unlike many other food animal industries, dairy herds have tended to maintain systems to rear their own replacement animals. In some situations, economic conditions favor purchasing replacements from an outside source or contracting a third party to raise the farm's heifers. In the development of a system to raise replacement heifers, a dairy producer has five major objectives to achieve.

Maintenance or Expansion of Herd Size

The replacement program should provide an abundant, readily available supply of animals to replace cows culled from the milking herd. In addition, there should be a surplus of heifers available for sale or to allow for a progressive increase in lactating herd size.

Age at calving and herd turnover or culling rates of cows are two of the largest factors affecting herd replacement numbers that must be raised to maintain herd numbers (Table 9-3). Additional heifers on the farm would then be available to sell or improve the herd genetically.

Calving by 22 to 24 Months of Age

Calving and entry into first lactation by 22 to 24 months of age minimizes the total nonproductive days and maximizes lifetime profitability.

Sufficient Growth for Minimal Dystocia at First Calving

In order to be prepared for calving at the desired age, replacement heifers need to be large enough to calve without an increased rate of dystocia. This objective involves nutritional management to promote an optimum growth rate.

Maintenance of Health

The prevention of clinical and subclinical disease is a major factor in the ability of replacement heifers to meet the objective of 22 to 24 months of age at first calving. Survivability and lifetime productivity are also affected by the state of health during the replacement-raising period.

Genetic Progress

An important objective of the dairy herd replacement process is to produce replacement heifers with genetic merit superior to that of the current lactating herd. This genetic improvement may be expressed by increased productivity, improved efficiency of production, or enhanced resistance to disease. Genetic progress is dependent on the availability of sires of known genetic merit through artificial insemination (AI) and on the use of predictive indexes of the genetic potential of the replacement heifers.

COMPONENTS OF HEIFER HEALTH MANAGEMENT PROGRAMS

A successful health management program must be designed to assist the dairy producer to meet the objectives of raising replacement heifers. The program involves attention to five major health management disciplines (Box 9-1).

Each of these disciplines should be organized and performed to achieve completion of the health management cycle (Fig. 9-2). A prerequisite for effective incorporation of each of these disciplines into a replacement heifer health management pro-

gram is the implementation of a record keeping and monitoring system that allows the calculation of indexes of performance. With this monitoring system the current status of the replacement program can be assessed. The results of the assessment allow important management decisions to be made and a plan of action to be formulated and implemented. As monitoring of the replacement herd continues, the record of performance under the new management plan allows determination of the outcome of the program. It is important to account for the external factors and conditions that may have affected the outcome. Previously established goals and target values should be used to assess the performance outcome. In addition, the level of performance should be compared with standard values generated by monitoring a larger population of herds. These standard values may be available from regional dairy record processing centers or may need to be generated on a local basis from a number of herds participating in a replacement heifer health management program.

Each replacement heifer management discipline is presented here using this program format. The major indexes of performance, as well as currently suggested targets or performance standards, are described. An example of the use of this feedback cycle in the process of conducting a health management program for replacement heifers is given in Fig. 9-3.

Nutritional Management for Replacement Heifers

Completion of the anatomical and physiological changes that occur up to and at the time of weaning is a prerequisite for successful nutritional management of growing heifers. The majority of calves on an adequate feeding program, up to weaning, are ready to change from a milk or milk product-based diet to a dry feed ration at 8 weeks of age. The details of the preweaning feeding program have been described earlier in this chapter. In some management systems or with some individual heifers, the recommended age at weaning has to be altered.

Nutrient Intake and Feeding Programs

When the dairy calf is properly weaned at 4 or more weeks of age, the wall of the rumen, including the thickness of the wall and its papilli, is moderately well developed but not yet equivalent to that of a fully functioning adult ruminant. The diet of weaned calf should be formulated to maximize rumen development, which includes the rumen wall thickness and an increased number and surface area of the rumen papilli. The surface area of the rumen becomes more highly vascularized to allow for increased absorption of nutrients, including volatile fatty acids that are major end products of rumen bacteria. It has been estimated that the surface area of the rumen increases from less than 1 square foot in a newborn calf to a very large surface area in the adult ruminant. This transition occurs in a relatively short time, requiring a large amount of energy and protein for tissue growth. Complete rumen development usually requires 4 to 6 months and is heavily dependent on diet and feeding management. The higher the level of fermentable energy intake of these animals, the more rapid the rate of rumen development (Beharka et al, 1996). Thus calves fed high-level grain diets have more rapid rumen development than those fed high-level forage diets. In addition, high-quality, more digestible feeds and forages that contain more energy and more rapidly degradable energy for the rumen encourage faster rumen development. Propionic and especially butyric acids promote rumen development (Nocek et al, 1980).

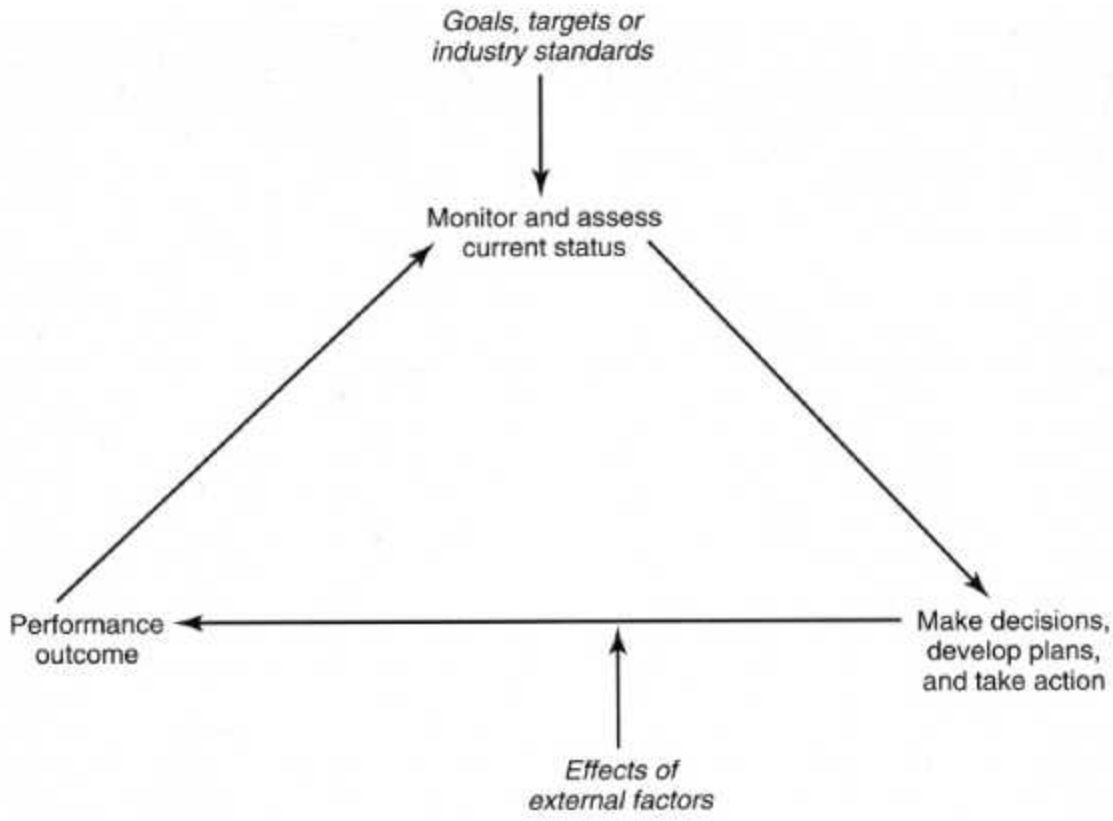

FIG. 9-2 Health management feedback cycle.

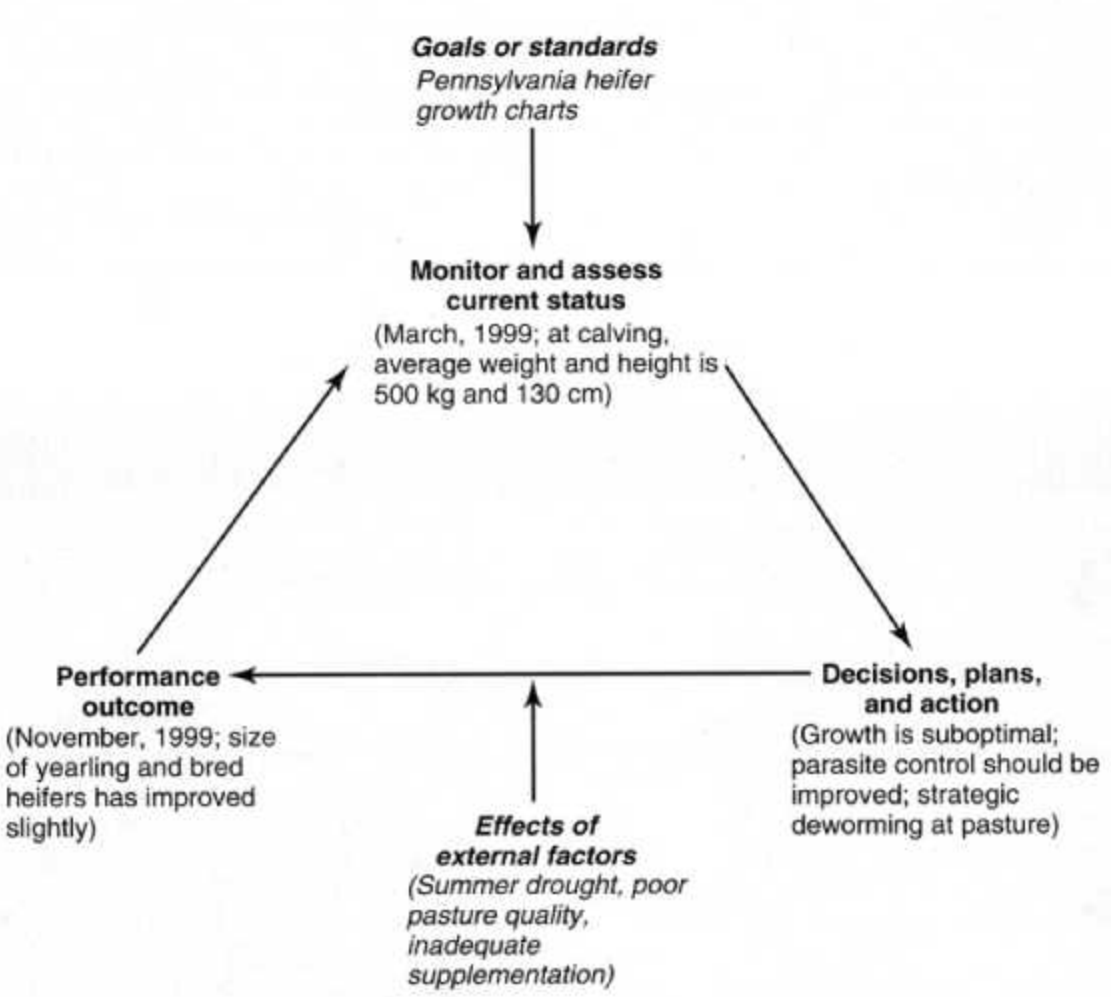

FIG. 9-3 Health management cycle in action. The current size of replacement heifers at calving is compared with industry standards. Growth is determined to be less than the desired rate. Parasite control is one option for improved performance, and a strategic deworming program is implemented. New levels of performance 7 months later show slight improvement. However, seasonal nutrition may have been a limiting factor. Continued monitoring can lead to new plans and actions.

Downloaded from Vet-eBooks.com

At weaning the liquid feed portion of the diet should be reduced and supplemented with a good free-choice grain mixture along with free-choice water. For heifers up to 6 months old, free-choice grain is recommended to a maximum rate of 5 to 6 lb/head/day. Young heifers consume much less forage than grain on a dry-matter basis. As the animals mature and grow larger, forages can make up a greater part of their diet.

The recommendations for nutrient intake and feeding program in the 2- to 6-month age range have undergone marked revision (National Research Council, 1989). Postweaning heifers up to 6 months of age are too young to depend on forages for the majority of their nutrient requirements. A 2- to 3-month-old heifer requires 75% of the nutrients from grain sources and 25% from forage. From 3 to 6 months, a diet with a 50:50 ratio of forage to grain provides the correct nutrient balance. In most feeding programs, grain is fed to support the appropriate dry matter intake; forage is fed free choice. For example, from 2 to 6 months of age, a heifer would be fed 1.4 to 1.8 kg of grain/day. With the provision of good-quality forage on a free-choice basis, this heifer gradually increases the forage:grain ratio of her total dry matter intake by increasing forage consumption. At 2 months of age, a heifer eating 1.6 kg of grain consumes only 0.6 kg of additional feed (forage), whereas a heifer at 6 months of age eats 4.5 kg of forage, or about 33% of the total feed consumed. Table 9-4 summarizes recommendations for suggested dry matter intake and forage:grain ratios for each age group of replacement heifer.

For the postweaning age group, the success of the nutritional program depends on two factors. First, adequate bunk space should be provided so that each calf has freedom of access to both grain and roughage without aggressive competition. This degree of access can be accomplished by housing replacement heifers in small groups (6 to 10) of relatively equal age and size in a facility with bunk space for each animal. The second important factor involves providing the opportunity for the change in amounts of forage consumed, as previously described. Forage quality should be monitored carefully for calves aged 2 to 6 months. Fine-stemmed, mold-free hay is preferred. Stemmy, moldy, or other poor-quality hay with lower digestibility, reduces forage intake and retards growth. If digestion of forage relies heavily on the young heifer to remasticate the material successive times in order to reduce the material to a particle size small enough to move through rumen undigested, dry matter intake will be reduced. The young calf is not as efficient as the adult cow at mastication.

A high-quality cool season grass, legume, or legume-grass hay from a second or third cutting should be fed. Such forages are normally lower in fiber, have greater leaf:stem ratios, and are normally more digestible than other feedstuffs on the farm. Forages that are less stemmy and fed dry are more palatable to young animals than forages that are coarse and stemmy. Fermented feeds such as haylage and corn silage can be fed to calves 4 to 6 months of age, provided that they also are high quality.

Fermented forages are most palatable when fresh. In the case of fermented feeds, normally within 8 to 12 hours (especially in the summertime) these feeds start to heat and become moldy. This is a process of refermenting by the yeast and molds found naturally on these feeds, which is a normal evolution of fermented feeds. Along with the growth of yeast and molds, heating of the forage causes the production of a variety of unfavorable end products, including ammonia and other nitrogenous compounds. Many of these are volatile and create a feed that is foul smelling and not as palatable for the calf, thus reducing intake. Mold growth will be very prevalent after 12 hours and will greatly reduce palatability. Thus, if silage is fed to calves, it must be replaced each day and preferably twice daily during warm summer months. This often does not happen on many farms because of time and labor constraints, and thus the recommendation is often made not to feed fermented forages to young calves. In reality, the nutrient content and digestibility are the primary factors that should dictate which forage is fed, yet the feeding management on a farm can alter these recommendations. The quality of forages fed to these young animals will determine how much protein and other nutrients are needed in the grain mixture. The types of forages commonly fed to heifers up to 6 months are shown in Table 9-5. Grain mixtures for heifers may be as simple as

corn, soybean meal, vitamins, and minerals, or may be as complex as desired. Sample grain mixtures for young heifers fed the example forages from Table 9-5 are shown in Table 9-6. In geographical areas where less palatable and less digestible warm season native grasses are grown, the grasses should not be fed in appreciable amounts to young calves if maximum growth rates are to be achieved.

From 6 months to breeding age, nutritional management principles similar to those for younger heifers should be applied. The housing system should allow for small groups of heifers (10 to 15) in order to achieve appropriate control of the feed and for adequate observation. Timid heifers, and those not reaching expected growth performance, should be separated for special attention. A 6-month-old heifer consuming 4.5 to 5.0 kg of dry matter per day and fed 1.3 to 1.8 kg of grain with free-choice forage is at a forage:grain ratio of 67:33. By 12 months of age, a heifer being fed 1.8 kg of grain consumes 7.3 to 8.2 kg of total dry matter for a forage:grain ratio of 75:25 (Table 9-4).

Information about the forage quality and nutrient content is essential in making these feeding recommendations. The forage quality affects the protein available from roughage sources. In turn, this determines the protein content required in the grain mix and the quantity of grain to be fed. A mixture of good-quality grass and legume hay, or a combination of legume hay with limited corn silage, creates a balanced ration with the previously suggested amounts of a 12% protein grain mix. However, a mixture of corn silage and grass hay has less protein content. In this case, the ration should be supplemented with a 16% to 18% protein grain mix. If the forage component of the ration were entirely good-quality legume hay, a grain mix of lower protein content (8% to 10%) would be adequate. Examples of the amounts of grain needed with varying levels of forage quality are given in Table 9-7.

Total mixed rations can be fed to growing heifers, but requires careful attention to providing the appropriate forage:grain ratios for each age group. This would require sev-

‡Two months before calving.

eral rations for the various age ranges, which only large dairy herds would have the economy of scale to implement.

After the heifers have been bred (14 to 15 months of age), good-quality forage provides an adequately balanced ration with no addition of grain. A complete ration consisting of half legume hay or hay silage and half corn silage is nutritionally adequate in protein and energy. However, a ration based on hay or hay silage of only average quality requires the addition of 0.9 to 1.4 kg/day of grain to provide the energy requirements. A ration consisting totally of corn silage is too high in energy and relatively low in protein and would cause suboptimum growth and excess fat.

As bred heifers approach calving, additional nutrients may be required to maintain body condition for their first lactation as well as for their growth and that of the fetus. A forage:grain ratio of 80:20 would be appropriate, depending on forage quality. Grain intake should be increased gradually to reach a level of 0.5% of body weight at calving. For example, a heifer weighing 570 kg would benefit from a gradual increase in grain intake to the level of 2.8 kg/day at calving.

The emphasis in nutritional management of replacement heifers is on balancing the ration for protein and energy requirements. However, the recommended levels for minerals, vitamins, and fresh water have been documented (National Research Council, 1989). Care must be taken to ensure that deficiencies in these nutrients do not exist.

Because replacement heifer rations are easy to formulate, the inclusion of low-cost feed additives as a means of supplementing lower quality forages may provide a great cost-benefit advantage over traditional grain sources (Rodenburg, 1989). For example, the application of nonprotein nitrogen to corn at the time of ensiling could represent a cost savings over feeding soybean meal. Ionophores such as monensin and lasalocid are approved for use in dairy heifer rations in some countries. Further research is needed on methods to reduce feed costs for raising replacement heifers.

Feed Bunks for Dairy Heifers

There is a large variation in the recommended feed bunk lengths for dairy heifers of all ages. Surveys of dairy farmers found that about 50% perceive that housing is the greatest problem of calf and heifer replacement management. No documented evidence has been available to define the minimum requirements for feed bunk length that would allow the optimum growth of dairy replacement heifers. Limited feed bunk length does not adversely affect group growth rates but significantly affects individual growth rates. This may be due to increased social tension within the group and the decrease in the opportunity to obtain adequate nutrients. The following feed bunk lengths per heifer are recommended for groups of Holstein heifers fed a total mixed diet at restricted intakes at accelerated rates of gain: 15 cm for 4- to 8-month-old heifers, 31 cm for 11.5- to 15.5-month-old heifers, and 47 cm for 17- to 21-month-old heifers (Longenbach et al, 1999). At these bunk lengths, the heifers are in a harmonious group housing environment that allows them to achieve the body weight gains and skeletal growth necessary to achieve calving at 22 to 24 months of age. A high level of management is necessary to achieve uniform growth at accelerated rates of gain under these housing requirements for feed bunk length.

Water Intake

A fresh, abundant, and clean supply of water should be available before, during, and after weaning. Old or unclean water and watering systems reduce an animal's water consumption and consequently its dry matter consumption (grain and forage). Water consumption depends on several factors, including age, body size, environmental temperatures, and forage intake (Table 9-8).

Nutrition and Mammary Development

The implementation of appropriate nutritional management during the growing period can have long-term effects on dairy cow performance. The success of feeding and management programs for replacement heifers must not only be measured in terms of efficiency of body growth but, more importantly, must be assessed by milk-yield potential of the heifer. Milk-yield capacity is largely influenced by the degree of mammary development. Nutritional status

*At air temperatures of 50° to 80° F intake depends on water content of forage ration. Higher levels apply to an all-hay ration. One gallon of water (U.S.) weighs 8.34 lb (3.785 kg) and contains 3.785 L. An Imperial gallon contains 4.546 L. One cubic foot of water weighs 62.4 lb.

is critical to mammary development, especially during hormone-sensitive developmental stages, including from before puberty through to early lactation. As the emphasis on decreasing input costs and improving productivity per economic unit increases, there is pressure to reduce the length of the nonproductive period by reducing the age at first calving. Efforts to achieve younger ages at first parturition require high planes of nutrition to support rapid body growth.

High levels of feeding before puberty can adversely affect the growth of the developing mammary gland. The result can be a decrease in the size of the functional gland and in milk production when lactation commences (Sejrsen, 1978; Sejrsen et al, 1983). An average daily gain of greater than 0.7 to 0.8 kg of body weight per day during the growing period (3 to 12 months) causes a subsequent progressively declining milk yield. Heifers grown at rates above or below the optimum range may produce 10% to 20% less milk.

The effect of hormone concentration on mammary growth has been examined (Sejrsen et al, 1983). Heifers were split into two groups for restricted and ad lib amounts of a ration, and gains for each of the feeding regimens were 513 and 1218 g/day, respectively. Growth hormone was elevated for the prepubertal heifers on the restricted feed, whereas there was no difference for postpubertal heifers. Concentrations of prolactin, insulin, and glucocorticoid were higher for heifers fed ad lib than for those restricted. Mammary tissue was not related to concentrations of insulin or glucocorticoids, mammary secretory tissue was correlated positively with blood serum concentrations of growth hormone, and extra parenchymal adipose tissue was correlated negatively with them. The negative influence of excess feeding on mammary development of prepubertal heifers appears to be associated with a decrease in concentrations of growth hormone in the blood. Thus mammary tissue growth and milk production capacity in heifers are unaffected by ration energy density when heifers are raised at a low feeding level. Pubertal mammary development and subsequent milk production capacity for heifers raised on a low level of feeding are unaffected by diet energy concentration, and mammary growth in relation to puberty was correlated with circulating levels of growth hormone within heifers.

From birth to puberty, mammary tissue undergoes relatively little development. Mammary growth rate is consistent with body growth rate (isometric growth) until the onset ovarian activity preceding puberty, and increase in mammary size is mainly due to an increase in connective tissue and fat. Beginning just before the first estrous cycle (puberty), mammary parenchyma (secretory alveolar tissues) begins to grow at a faster rate than whole-body growth (allometric growth). Rapid allometric mammary growth continues for several estrous cycles and then returns to an isometric pattern until conception (Park, 1998).

Allometric growth begins again at conception and continues after parturition for variable periods of time. The majority of mammary growth occurs during pregnancy, and the rate of growth remains exponential throughout gestation. In first-calf dairy heifers, the degree of mammary parenchyma tissue development around parturition is a major determinant of milk-yield capacity during the succeeding lactation cycles. Estimates of the correlation between milk yield and mammary alveolar epithelial cell numbers range between 0.50 and 0.85. Conversely, increased proportions of fibroblasts and adipocytes in the mammary gland are associated with reduced milk yield.

Changes in feeding level (mainly energy concentration) can alter the secretion of hormones such as somatotrophin and corticoids and affect mammary growth and differentiation during hormone-dependent stages of development as growth shifts from isometric to allometric. Careful control of energy allowance during peripuberty and gestation can significantly enhance mammary growth and succeeding lactation potential of heifers.

In growing heifers, restricting energy intake delays the normal rate of mammary gland development. However, a delay in mammary gland development, controlled by dietary energy, does not impair subsequent development and differentiation of parenchymal tissue during prelactational mammogenesis, provided energy requirements are met. Restricting the energy intake of growing animals brings about physiological adaptation, whereby energy flow is redirected to energy-conserving activities, mainly maintenance and repair functions. Energy restriction also reduces certain energy-wasteful metabolic systems, which may not be metabolically essential for growth and maintenance.

Realimentation following energy restriction induces compensatory growth, which is characterized by accelerated metabolism, reduced maintenance requirement by depression of the basic metabolic rate, activated endocrine status, and altered tissue composition of mammary gland.

A well-controlled nutrition regimen during the hormone-sensitive growth phase before first parturition can significantly affect mammary growth, differentiation, and performance at subsequent lactations. A time-dependent and nutritionally induced compensatory growth favorably alters the physiological development and differentiation of the mammary gland as well as the lactation potential. A stair-step nutrition regimen, proposed for developing dairy heifers, is a combination of both energy restriction and realimentation designed to induce compensatory mammary growth, which coincides with different developmental states (Park, 1998). A controlled stair-step compensatory nutrition model can enhance the growth potential of heifers. The controlled nutrition regimen encompassing both restriction and refeeding during the early peripubertal developmental stages has positive effects on mammary growth and milk yield potential. During the energy-restriction phase, the rate of growth lags behind the body weight of traditionally fed animals. During the energy realimentation phase following

Downloaded From Vet-e-Books.com

energy restriction, animals consume energy far in excess of that needed for maintenance, thereby redirecting the energy flow to the metabolic process of growth. Thus these animals exhibit an accelerated rate of growth that exceeds the normal growth curve. The extent of mammary hyperplasia and hypertrophy induced by a compensatory nutrition regimen is clearly reflected in the higher nucleic acid and protein content of the tissue (Park, 1998). A stair-step feeding program can be adapted to management practices of average to large sized farms.

An alternating *3-2-4-2-5-2-month stair-step nutrition model* for dairy heifers has been described (Park, 1998). Holstein heifer calves, weighing an average of 160 kg (at approximately 6 months of age), were compared with control heifers offered ad libitum access to a diet meeting the nutrient requirements recommended by the NRC (1989) and adjusted for an age at first calving of 24 months and liveweight gain of 0.78 kg/day. During the first stair-step, which lasted for 3 months (from 6 to 9 months of age) and encompassed the prepubertal period, the stair-step heifers were fed on a diet formulated to reduce the intake of metabolizable energy by 30%. Protein supply was maintained at levels recommended by the NRC (1989) by increasing the crude protein from 120 to 170 g/kg dry matter. Following 3 months of energy restriction, the heifers received a realimentation diet (1.3 times the metabolizable energy) for 2 months (from 9 to 11 months of age). Compensatory growth occurred during this allometric phase of mammary development. The second step (puberty and breeding) consisted of energy restriction for 4 months (11 to 15 months of age) followed by realimentation for 2 months (15 to 17 months of age). In the third and final step, energy was restricted for 5 months (17 to 22 months) followed by realimentation for 2 months (22 to 24 months of age). Overall, the stair-step heifers received an average of 0.9 of the energy allowance given to the control group. Both low-energy and realimentation diets were formulated to provide intakes of protein, vitamins, and minerals equal to the control diet, except energy intake that was varied. Heifers were bred during the second realimentation period (16 months of age) to calve at approximately 24 months of age.

Heifers raised on the stair-step feeding program responded with characteristic compensatory changes. They gained more body weight and consumed less feed than heifers fed conventionally. Live-weight gains were depressed during the period of energy restriction, but recovery occurred during the realimentation phase, causing significant improvements overall in feed, energy, and protein conversion ratios. In summary, a controlled stair-step compensatory nutrition program can enhance the growth potential of heifers. During the energy-restriction phase, the rate of growth lags behind the body weight of traditionally fed animals. During the energy realimentation phase following energy restriction, animals consume energy in excess of that needed for maintenance, thereby redirecting the energy flow to the metabolic process of growth. Thus these animals exhibit an accelerated rate of growth that exceeds the normal growth curve.

The compensatory nutrition feeding program causes mammary hyperplasia and hypertrophy and increased expression of the major milk protein genes, indicating increased mammary differentiation and functional activity in mammary tissues. Heifers on the compensatory program had 1.05 times the total protein and 1.15 times the casein in milk than the control heifers (Park, 1998). Lactation performance is significantly enhanced in cows reared on a stair-step feeding program compared with those fed according to the linear growth curve of the NRC (1989). Stair-step heifers produce 1.1 times the milk of conventionally-reared compared with control animals which increase represents about 900 kg milk over 250 days.

In summary, a controlled nutrition program, including both restriction and refeeding during early peripubertal developmental stages, has positive effects on mammary growth and milk yield potential. The dietary restriction consists of a reduction in energy (caloric intake) while providing an adequate supply of other essential nutrients (protein, vitamins and minerals). The fundamental concept of the stair-step compensatory nutrition program is to favorably exploit the nature of both dietary energy restriction and the compensatory growth phenomenon in concert with one or more hormone-dependent phases of mammary development.

The observation of differences among rates of mammary secretory tissue development has led to the concept of a "critical period" of mammary development (Sejrsen et al 1982). Ad lib feeding during prepuberty lowered mammary secretory tissue weights 23% and DNA content 32% compared with restricted feeding. In contrast, there was no difference in growth of mammary secretory tissue between postpubertal heifers fed restricted or ad libitum amounts. Composition of mammary parenchyma was not affected by plane of nutrition in prepubertal or postpubertal heifers. Because of this, a critical period was suggested for total mammary cell numbers in heifers during which mammary growth is affected adversely by a higher plane of nutrition. A heifer's capacity to produce milk is decreased when the plane of nutrition causes daily gains larger than 700 and 500 g in heifers of the large and small dairy breeds, respectively. In contrast, milk production is enhanced if the plane of nutrition after the critical period supported daily gain larger than 600 g in heifers of the large dairy breeds. Heifers that are reared on a high plane of nutrition during the critical period have a permanently-reduced content of parenchyma in the mammary gland. The positive effect of plane of nutrition after the critical period appears to be related to an increase in mammary size and feed intake that corresponds to the increase in body size and improved body condition. The decrease in milk production has also been shown to occur with overall increases in nutrient intakes and not solely increased energy intakes (Lammers et al, 1999). At the farm management level, careful attention to nutrition and growth from postweaning to puberty is crucial to maximizing the productive potential of replacement heifers. Lifetime productivity of dairy cows is affected by age at first calving, and this is closely related to the age at puberty onset.

Monitoring Replacement Heifer Nutritional Management

Charting Growth. On many dairy farms, heifer management is not the most critical part of the day-to-day activities, and chronic neglect of nutrition, feeding management, and health management can lead to suboptimal growth. This leads to heifers that calve much later than 24 months of age and that produce considerably less milk during their lifetime than those properly fed and well grown. Not only are undersized heifers smaller and less productive, but they also are prone to more problems at calving. On the other hand, accelerating the growth of heifers until they become fat also reduces their lifetime milk production and longevity. Overfeeding concentrates or high-quality forages such as corn silage can cause this condition.

An assessment of a replacement nutritional management program can be made by monitoring heifer growth (Donovan and Braun, 1987). Weight can be monitored by taking an actual calibrated scale measurement or an estimate from a heart girth tape and conversion chart. Skeletal growth is as-

Downloaded from Vet-eBooks.com

sessed by taking measurements of height at withers. These data can be plotted on prepared charts to evaluate the growth patterns of individual heifers or to assess growth in the replacement herd. In Pennsylvania, in one field trial, 5723 heifers on 163 farms were measured regularly to develop growth charts that represent the normal patterns of growth for Holstein heifers under commercial dairy management conditions (Heinrichs and Hargrove, 1987). Later data were collected from the National Dairy Heifer Evaluation Project that represents a U.S. population of Holstein heifers (Heinrichs and Losinger, 1998). Increased rolling herd average milk production is associated with greater growth among Holstein dairy heifers. The practice of feeding fresh or sour colostrum to heifers from 24 hours of age to weaning was also related to greater growth. Regionally, dairy heifer body weight was greatest in herds in the Midwest and least in the Southwest United States. It is suggested that differences in feeding strategies in various regions of the United States may explain the different growth rates.

The objective of a heifer-raising program is to achieve a relatively constant rate of growth. Holstein heifers should reach 750 to 800 lb (340 to 362 kg) and 48 to 50 in (122 to 127 cm) by the desired breeding age of 13 to 15 months. After calving, heifers should weigh 1137 to 1296 lb (515 to 587 kg) and measure 52 to 54 in (132 to 137 cm) tall at the withers. The recommended breeding heights and weights for all heifers are shown in Table 9-9.

Optimum Body Size of Heifer Replacements. There is a positive relationship between body weight at first calving and first lactation yield, which has been the basis for using live body weight to define body size of replacement heifers (Hoffman, 1997). However, live body weight is not the only available measurement to define body size. Skeletal measurements such as wither height, length, and pelvic area are related to first lactation performance or dystocia. Weight at calving is highly heritable but not correlated genetically with milk yield (Lee, 1997). Genetics determines the inherent potential of an embryo to grow into a highly profitable cow. Feeding and management determines the extent to which that potential will be realized. Heifers under one year of age should be fed to maximize growth without excess body condition. Better feeding of pregnant heifers can add body condition but cannot compensate for lack of early real growth in size.

Growth Charts. The summaries of measuring a large number of heifers of various breeds throughout the United States are illustrated in Figs. 9-4 to 9-10. The Holstein population was part of a nationwide USDA study conducted during 1991 and 1992 (Heinrichs and Losinger, 1998). Most of the data were collected from herds in which the average age at first calving was slightly greater than 24 months. As a result the heifers probably were smaller for any given age than those found on today's well-managed dairy farms that calve heifers at 22 to 24 months of age.

The Holstein heifer growth charts illustrate several percentiles of the U.S. population, allowing a producer to compare an individual heifer with all others and to set growth goals. Previous research has shown that heifers large enough to calve at 22 to 24 months old with acceptable levels of milk production must be near or above average in size (Figs. 9-4 and 9-5). Producers should remember that producing extremely large heifers may not cause increased levels of lifetime milk production and is expensive from a feeding perspective because of the larger animals' increased daily calorie requirements.

Age at calving is highly correlated to the profitability of the animal, and that body weight after calving (1250 lb [567 kg] for Holsteins) is highly correlated to first lactation milk production. An achievable goal for dairy producers or contract heifer raisers is to keep a majority of heifers near the 75th percentile and the entire herd ranging between the median and the 95th percentile. Under Dutch farming conditions, the optimum rearing strategy caused an average calving age of 22.6 months at a calving weight of 564 kg (Mourits et al, 1999)

For all breeds of heifers except Holsteins, the recommended growth ranges shown are between the average and the top 67th percentile of the population. To achieve early calving (24 months or less) and high production potential, individual heifers should fall near the top of or slightly above the shaded area. Readers can interpret from these graphs that the height at the withers is more variable for younger heifers and, in general, that the variability in weight increases as age increases. Breed standards developed from the measurements of Jersey, Ayrshire, Brown Swiss, Guernsey, and Milking Shorthorn were all done within the past 10 years (Figs. 9-6 to 9-10).

Evaluating Growth Charts. Growth charts can aid in the evaluation of the performance of a heifer management program and can alert the producer to problems such as entire groups of animals being undersized, underweight, or overweight. Low- or poor-quality forages (hay and silage) generally are responsible for inferior growth performance in young heifers, but lack of a balanced grain supplement and overcrowded housing can add to the problem. Underfed calves typically do not receive adequate energy and protein to meet their growth requirements. Inadequate housing and ventilation can contribute to poor growth by causing subclinical respiratory problems and can negate an adequate feeding program. The level of management and sanitation also can affect heifer growth.

Adequate weight but restricted skeletal growth may occur in a particular age group. This usually is caused by relying

TABLE 9-9

Suggested Weights and Heights for Breeding Age Heifers

Breed	Body Weight (lb)/(kg)	Wither Height (in)/(cm)	Hip Height (in)/(cm)
Holstein	750-800 (340-362)	48-50 (122-127)	50-52 (127-132)
Jersey	525-575 (238-260)	43-45 (109-114)	45-47 (114-119)
Ayrshire	700-750 (317-340)	46-48 (117-122)	48-50 (122-127)
Guernsey	700-750 (317-340)	46-49 (117-124)	48-51 (122-129)
Brown Swiss	750-800 (340-362)	48-51 (122-129)	50-53 (127-135)
Milking Shorthorn	750-800 (340-362)	46-48 (117-122)	48-50 (122-127)

on poor-quality hay and corn silage for all or most of the diet. Both of these forages typically have low protein, mineral, and vitamin levels. Feeding cereal grains with very little protein, mineral, and vitamin supplementation along with these forages may exacerbate the problem. Feeding 2 to 4 lb of grain per day and balancing the diet for protein, energy, minerals, and vitamins can solve a feeding problem, often within several months. Rations must be more nutrient dense if heifers are to compensate with increased growth rates.

Another common scenario involves overweight animals with fairly normal skeletal growth for a specific age group. Heifers as young as 6 to 8 months of age may appear fat, but the problem generally is more common in breeding-age heifers. This condition most often is caused by marginal to adequate dietary protein but excessive energy intake. This can result from free-choice corn silage feeding along with moderate levels of supplemental grain, and it arises on farms where good- to excellent-quality forages are produced and unrestricted amounts are fed to the heifers. Restricting the feed intake of these high-quality forages usually corrects the problem.

Computer spreadsheet and database programs are available for monitoring heifer growth. One such program analyzes individual heifer growth and herd averages as deviations from the expected growth patterns found in Pennsylvania (Ehrlich and Heinrichs, 1989). The computerized methods are recommended for maintaining an ongoing bank of information on replacement heifers in a herd and for making long-term management decisions. In summary, monitoring growth is the key step to starting the health management cycle for nutritional management of replacement heifers.

Monitoring Body Condition Score. Body condition scoring is an additional aid that can be used to evaluate the overall nutrition and management of a heifer program. Some limitations in conducting heifer body condition scoring include long winter hair coats (in colder climates) and the problem of assembling and restraining heifers to closely observe fat over the ribs and tail head.

The recommended range of body condition scores for heifers is illustrated in Fig. 9-11. Young calves generally are thin naturally (2.0 to 2.5 on the five-point scale), but their body condition score should increase to or near 3.0 by breeding age. A body condition score of 3.5 to 3.7 is considered ideal for heifers calving at age 22 to 24 months. This score allows a moderate amount of stored body fat to be used in early lactation when dietary energy is insufficient for milk output.

Housing for Replacement Dairy Heifers

Housing recommendations for dairy calves up to weaning were reviewed earlier in this chapter. This feature of calf management has been studied extensively, and its relationship to the morbidity, mortality, and growth of neonatal calves has been described. Data and conclusions regarding the housing of postweaning replacement heifers are not as abundant. A major step in heifer rearing is the process of weaning and the movement of calves from individual to

Ease of observation
Ease of cleaning and adding bedding as needed
Continuous water supply
Adequate ventilation

group housing. This transition step is especially important for calves moved from individual hutch housing systems to group pens for growing heifers. Housing for heifers from the weaning pen to calving must provide some rather simple yet important components (Box 9-2).

Current Status of Replacement Heifer Housing

In a survey of calf and heifer housing on Pennsylvania dairy farms, over 70% of farms moved newly weaned calves to loose-housing group pens or to superhutches for a group of calves (Heinrichs et al, 1987a). However, over 50% of the heifer housing facilities were located within direct contact with the milking herd. A large percentage of farms were mixing newly weaned calves with older heifers, and 13.7% of farms did not group heifers by age or size. Although the average group size was 6.3, the groups often contained too many heifers of a wide age range. In small dairy herds, it was common for heifers to be housed in stanchions. In summary, the recommendations for housing and grouping dairy replacement heifers were not often followed (Graves and Heinrichs, 1989). The most commonly cited reasons were insufficient housing space and uneven age distributions (Heinrichs et al, 1987a).

In the same study in Pennsylvania, the adequacy of ventilation systems was assessed. Air exchange was often not adequate, particularly for younger calves. The survey found that producers interpreted the term "natural ventilation" to mean a structure with no ventilation system. The major problems that farmers perceived with their own farms and those of their neighbors in relation to replacement heifer housing were *overcrowding* and *inadequate ventilation*.

Only 31% of the herds surveyed had some type of restraint facility for replacement heifers (Heinrichs et al, 1987a). The restraint systems in use included head gates, stanchions, and other approaches, such as behind a gate. A functional restraint system is an integral requirement for the adoption of AI and intensive health management programs for replacement heifers (Graves and Heinrichs, 1989).

A state-wide extension program on dairy replacements directed at dairy farmers, agribusiness, veterinarians, and others in frequent contact with dairy farmers found that 85% of

Downloaded from Vet-eBooks.com

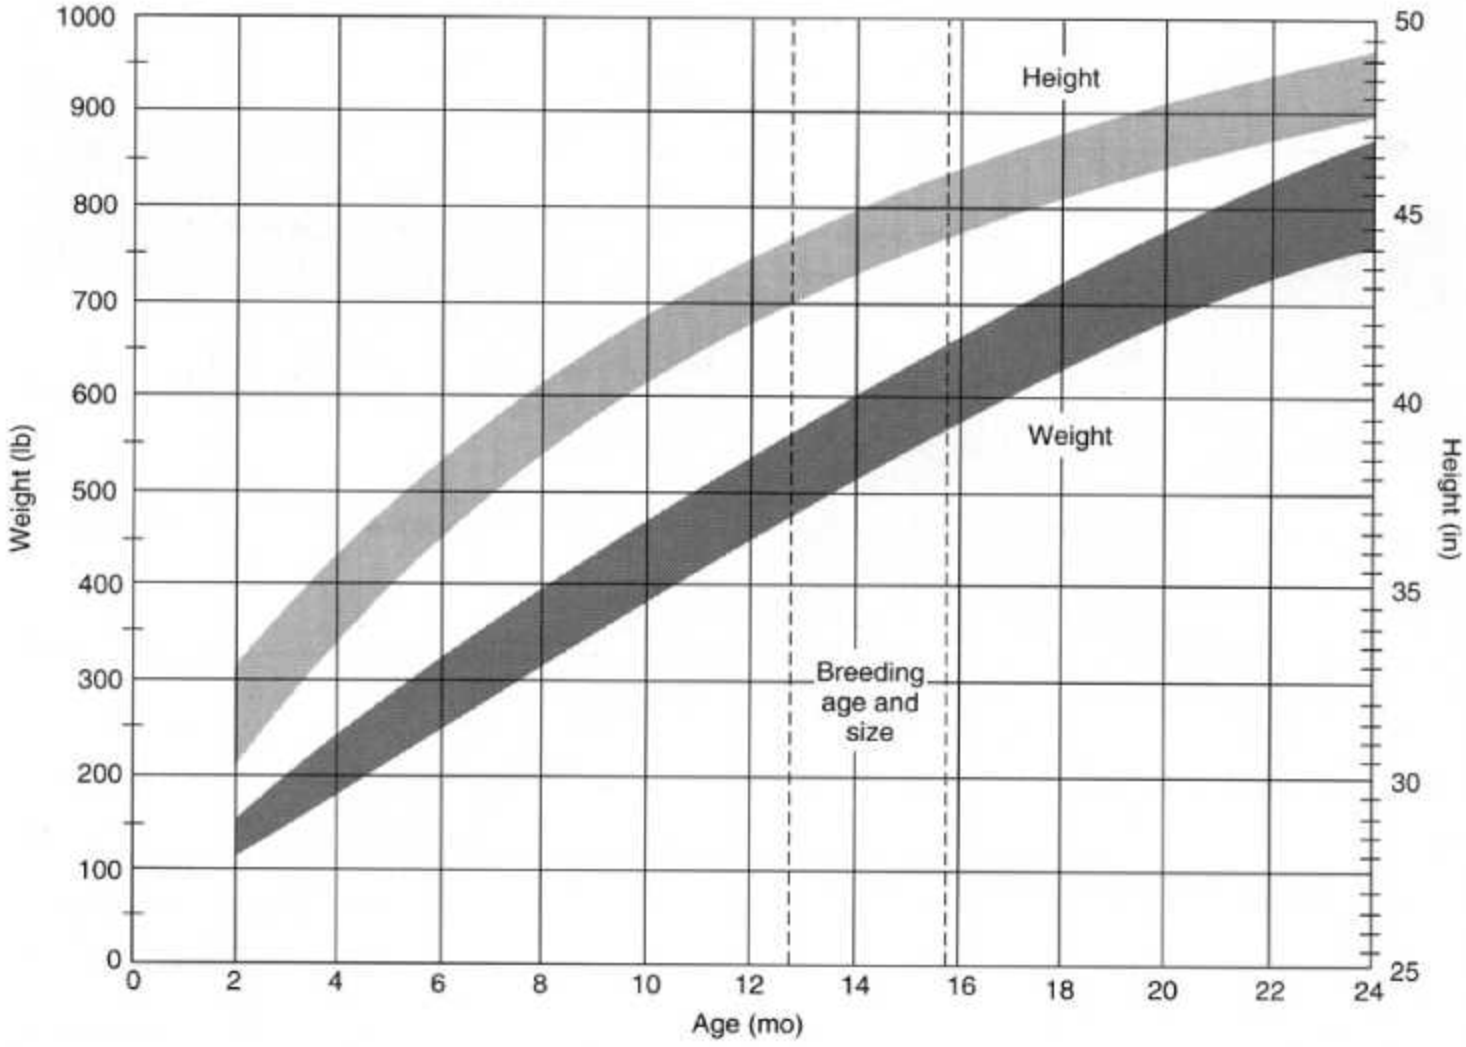

FIG. 9-6 Penn State calf and heifer growth chart: Jersey.

the farmers in the original random sample learned new information about calf and heifer management during the project, and 77% reported that they received all or part of this new information from extension (Heinrichs and Kiernan, 1994). Sources of information most often used by farmers in the study were dairy magazines, extension newsletters, and meetings organized through either extension or agribusiness. Adoption by farmers of many of the targeted practices specific to calving management, preweaned calves, and health management increased over the period of extension activity.

Surveys of dairy farms in Australia have found that there is much opportunity to improve the rearing of dairy heifer replacements (Hough and Sawyer, 1993; Moran et al, 1996).

In summary, current replacement heifer housing systems often do not create an environment conducive to optimum health and performance. Although the recommended approaches to housing heifers are well known, the adoption of these practices is not widespread and more focused extension efforts are needed. Veterinarians may overestimate their services in providing advice about heifer rearing compared with what the herd owners perceive (Giger et al, 1994). There are many opportunities for veterinarians who are providing a health management service to dairy producer to provide advice on housing and ventilation systems for heifer replacement rearing.

Principles and Recommendations for Housing Calves After Weaning

A special effort should be made to reduce the stress on calves before, during, and immediately after the weaning process. The facility should be clean, dry, and draft-free and should ensure isolation from the milking herd or older replacement heifers. A small group housing system to accommodate three to five calves per group should be used for at least 1 month after weaning. Because hutch housing systems are commonly recommended for young calves, a structure termed a "super-hutch" is a desirable system (Graves and Heinrichs, 1989). These small buildings accommodate three to five calves, are movable, and require minimal normal labor to manage.

The location of the postweaning housing is important for frequent observation of the recently moved calves so that animals not adapting well to the new situation can be detected early. Submissive calves that are easily pushed away may need extra attention to ensure adequate feed and water intake. The rates of clinical disease in a herd may affect the frequency of calves not adapting well (Waltner-Toews et al, 1986f).

The process of weaning should take place 2 to 4 weeks before changing locations. The types of forage and grain should remain constant throughout this period. The availability of a continuous supply of frost-free water is important. At least 0.45-m bunk space, with stanchions, head gates, or dividers to define eating positions, promotes optimum feed intake. The group pen should allow for approximately 3 m^2/calf for adequate comfort. In Danish commercial dairy farms, both welfare and production were improved in heifers with access to 2.7 to 3.6 m^2 compared with 1.8 m^2 resting area per heifer (Morgensen et al, 1997). Increasing the resting area from 1.8 m^2 to 2.7 or 3.6 m^2/heifer improves the welfare of group housed dairy heifers (Nielsen et al, 1997).

Free-stall housing is not recommended for calves up to 4 months of age. The requirements for minimum area per animal, minimum feed bunk space per animal, suggested free-stall size, and appropriate watering methods are given in Table 9-10), as are the recommended maximum number of

Downloaded from Vet-eBooks.com

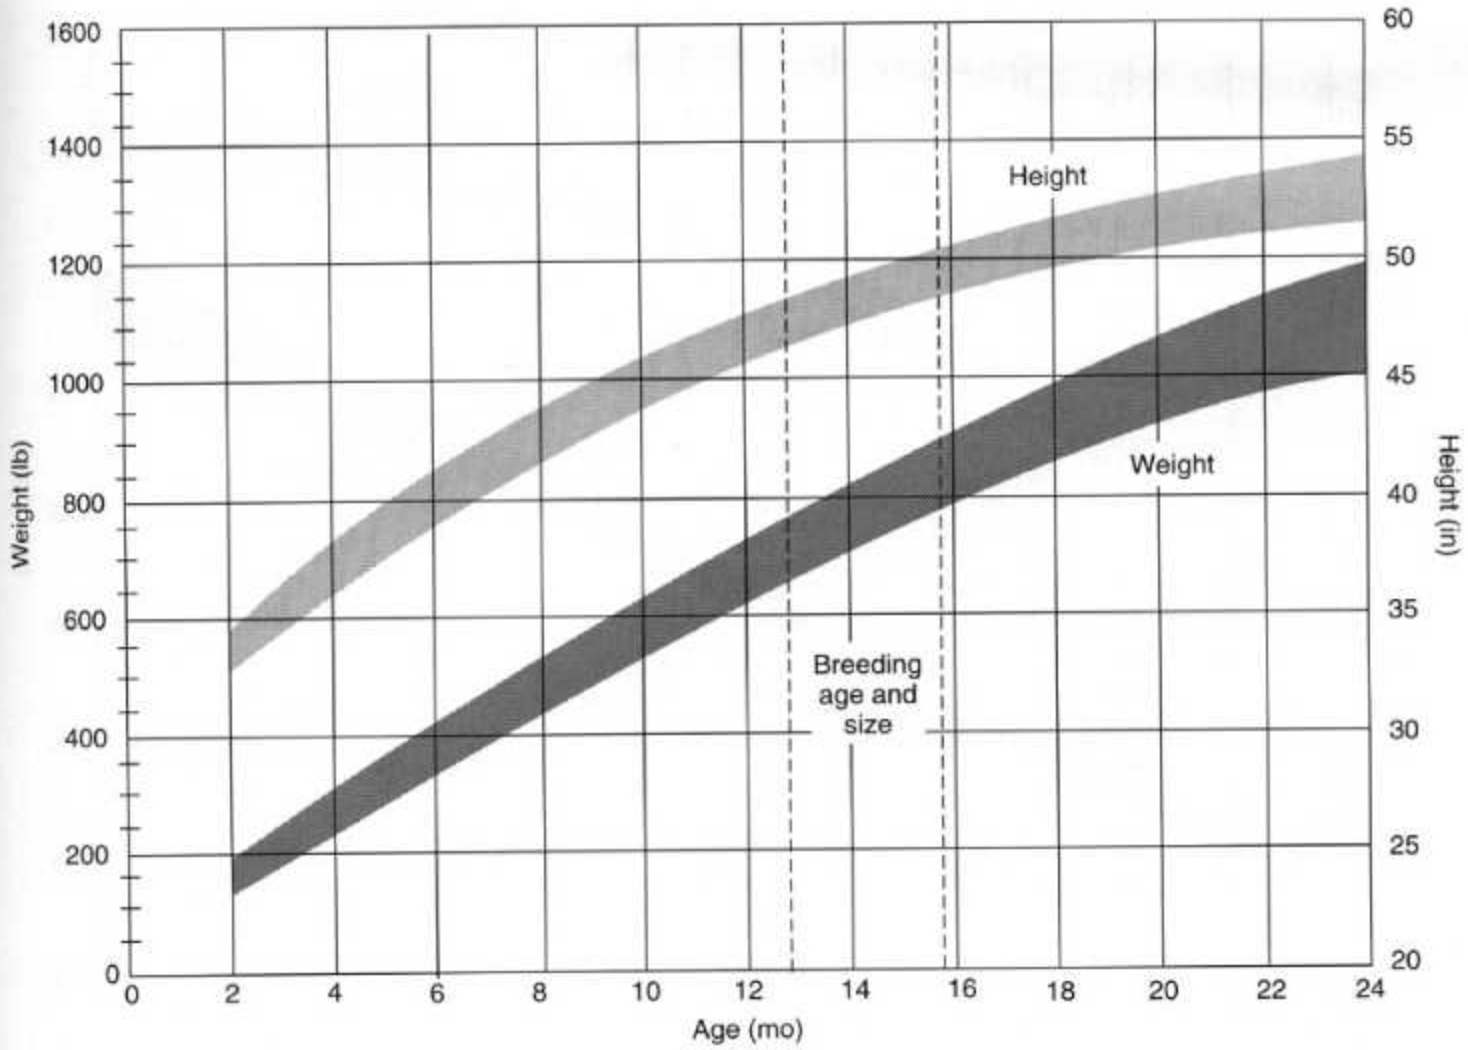

FIG. 9-7 Penn State calf and heifer growth chart: Guernsey.

animals, maximum age spread, and maximum weight variation per group (Heinrichs et al, 1987a). Compliance with these recommendations can promote environmental conditions that lead to desirable levels of health and performance in dairy replacement herds.

Air quality is a critical issue for indoor housing systems. The health and performance of postweaned calves raised in conventional indoor group pens have not been compared with those raised in naturally ventilated units in controlled experiments. Natural ventilation offers considerable advantages in energy efficiency and operator comfort. Although improvements in animal health and performance are expected with the use of natural ventilation systems, further documentation is necessary.

The Missouri system of dairy heifer production consists of four phases of development: birth to 2 months, during which calves are housed in individual hutches; 2 to 4 months, when raised in free-stall barns; and 6 to 12 and 12 to 24 months, when calves are on rotational pasture systems with supplemental feeding (Randle et al, 1998). Guidelines are available for site selection, animal flow, breeding, health management, and husbandry and feeding management.

Principles and Recommendations for Housing Growing and Bred Heifers

The key to the health and performance of growing and bred replacement heifers lies in the ability to change the forage:grain ratios in the ration according to age and size. Housing is crucial in allowing for the appropriate grouping of heifers. The housing system should permit easy, uneventful movement from group to group according to growth. Small groups of 6 to 12 heifers are most desirable. The facility should allow frequent observation, minimal labor for manure removal and addition of bedding, continually available frost-free water, and natural ventilation.

Several designs of yearling heifer facilities allow for the implementation of appropriate health management principles (Graves and Heinrichs, 1989). If a new facility is to be constructed, a commonly recommended design is an open front or gated bedded pack heifer barn (Graves and Heinrichs, 1989; Stone, 1987). This barn type has distinct advantages for convenience of observation, ease of movement from group to group, and ability to install adjustable, self-locking head gates to accommodate each heifer in the pen. The effectiveness of AI and health management program options improve dramatically with the installation of automatic restraint devices (Heinrichs et al, 1987a).

Good-quality pasture represents an excellent, cost-efficient system of nutrition for replacement heifers, particularly after pregnancy has been confirmed. In most climatic regions a three-sided open front barn or some other adequate type of shelter is necessary for protection from precipitation and wind. In addition, provisions must be made for supplemental feeding, depending on the pasture quality. Portable hay racks, silage wagons, or round bale feeders are some options available to provide additional feed. The use of pasture systems may affect health management requirements, such as appropriate parasite control and vaccination programs.

Monitoring Effectiveness of Replacement Heifer Housing Systems

The adequacy and effectiveness of replacement heifer housing systems can be monitored reliably with indexes of health and performance. The charting of growth, as previously described, is a good indicator of housing suitability. The calculation of age-specific and disease-specific morbidity and

Downloaded from Vet-e-Books.com

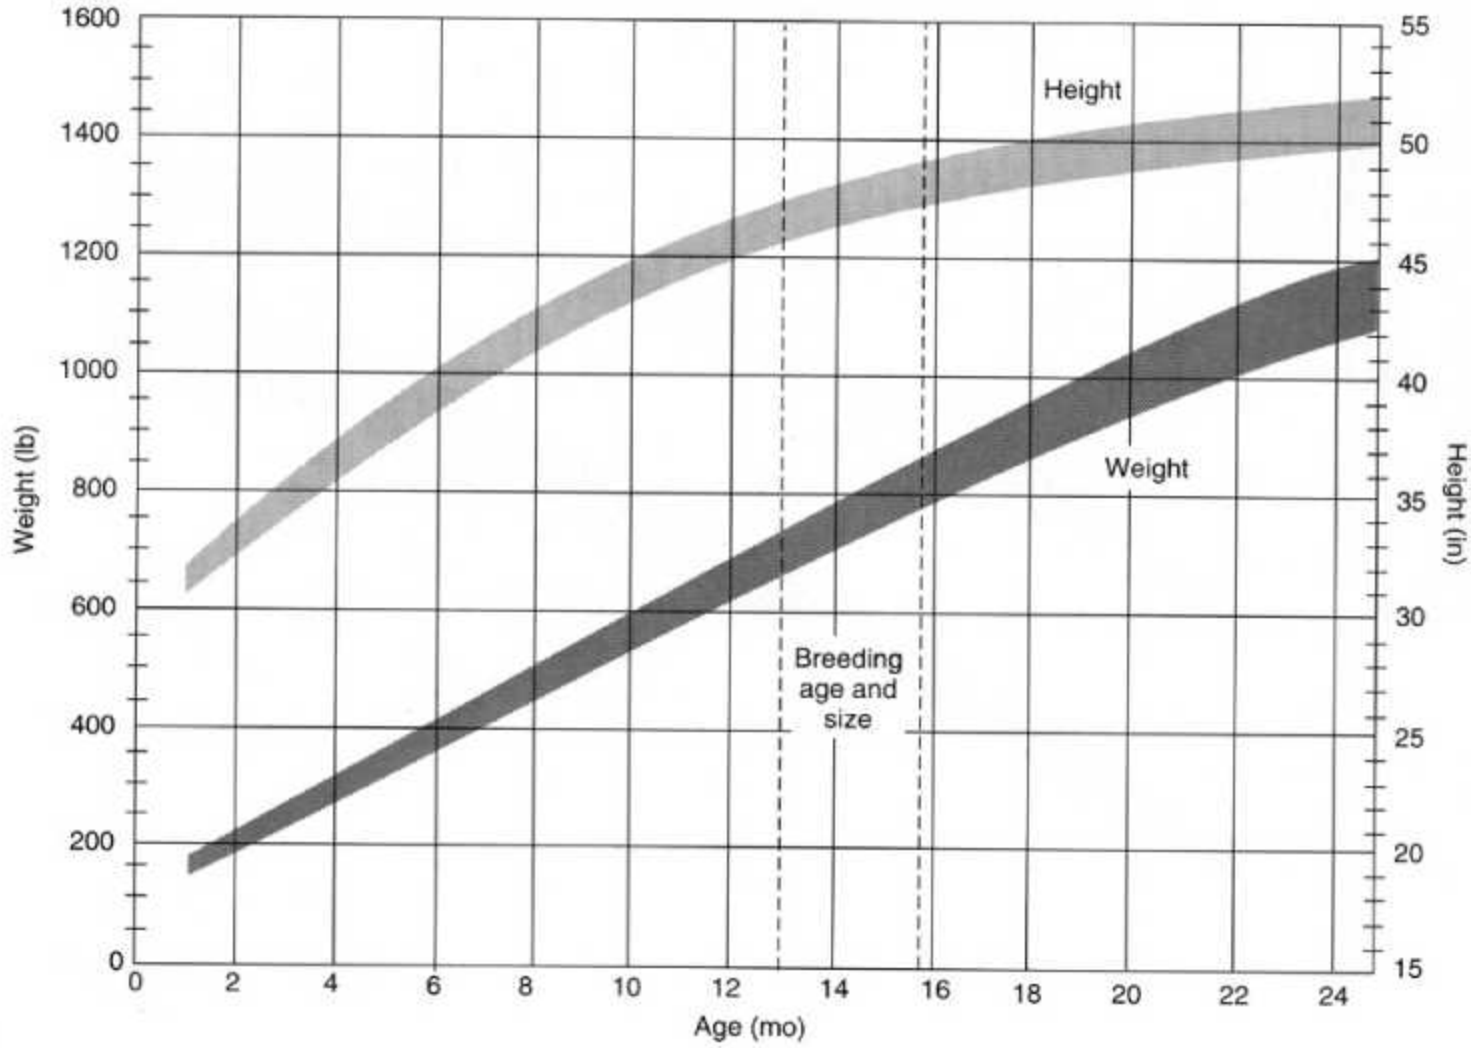

FIG. 9-8 Penn State calf and heifer growth chart: Ayrshire.

mortality rates can effectively monitor the adequacy of a housing system to provide an environment that reduces the risk of clinical and subclinical disease. The specific methods of calculation and interpretation of these indexes have been covered in previous chapters and are reemphasized in disease control for replacement heifers.

Reproductive Performance in Replacement Dairy Heifers

The major objectives of the reproductive performance program of replacement dairy heifers is to achieve an economically appropriate age at first calving and to have a minimum rate of dystocia at first parturition.

Age at First Calving

The current status and trends over time in age at first calving of dairy heifers have been examined (Nieuwhof et al, 1989; Powell, 1985). For each of the six major dairy breeds, the average age at first calving did not change appreciably between 1960 and 1982 (Powell, 1985). For example, in 1960, the mean age at first calving of 54,444 Holstein heifers was 27.2 months. In 1982, 485,200 Holstein heifers averaged 27.3 months of age at first parturition. The frequency distribution was skewed to the left. For unexplained reasons, all breeds had their highest mean age at first calving in 1976. Also, there was a seasonal association with age at first calving. Heifers born in the period from January to March of each year averaged 0.5 months older at first calving than those born in August and September. There were consistent differences among breeds. Jersey heifers had an overall average age at first parturition of 26.2 months for the 22-year period studied as compared with an average of 28.6 months for Ayrshire heifers. The average ages for Holstein, Guernsey, Brown Swiss, and milking shorthorns were intermediate.

The important issue is the relationship of age at first calving to productivity and profitability. This relationship has been studied in two ways. Observational studies of field data involving large populations of dairy heifers have been reported (Little and Kay, 1979). As age at first calving increased, lifetime production and herd life span decreased. Heifers that calved at a younger age had lower production in first lactation. However, their production per day of herd life and lifetime total yields ended up to be significantly higher than heifers that calved at an older age.

The decision to begin breeding heifers is often based on weight, body size, and age, or on a combination of these factors. Thus the use of observational studies from DHIA field data to assess the effects of breeding age may be confounded by growth rate and reproductive performance. To validate the observational studies, experiments have been designed specifically to compare two groups of heifers prospectively that were randomly assigned for breeding to calve at different ages. In these studies the late calving group had slightly better first-lactation performance than the early calving group (Lin et al, 1986). These differences did not carry over to the second and third lactations. The early calving group had more productive days, produced greater total yield, and yielded more per day of herd life (Lin et al, 1986, 1988). In addition, calving ease, reproductive performance, and health data were not different among the groups.

Downloaded From Vet-eBooks.com

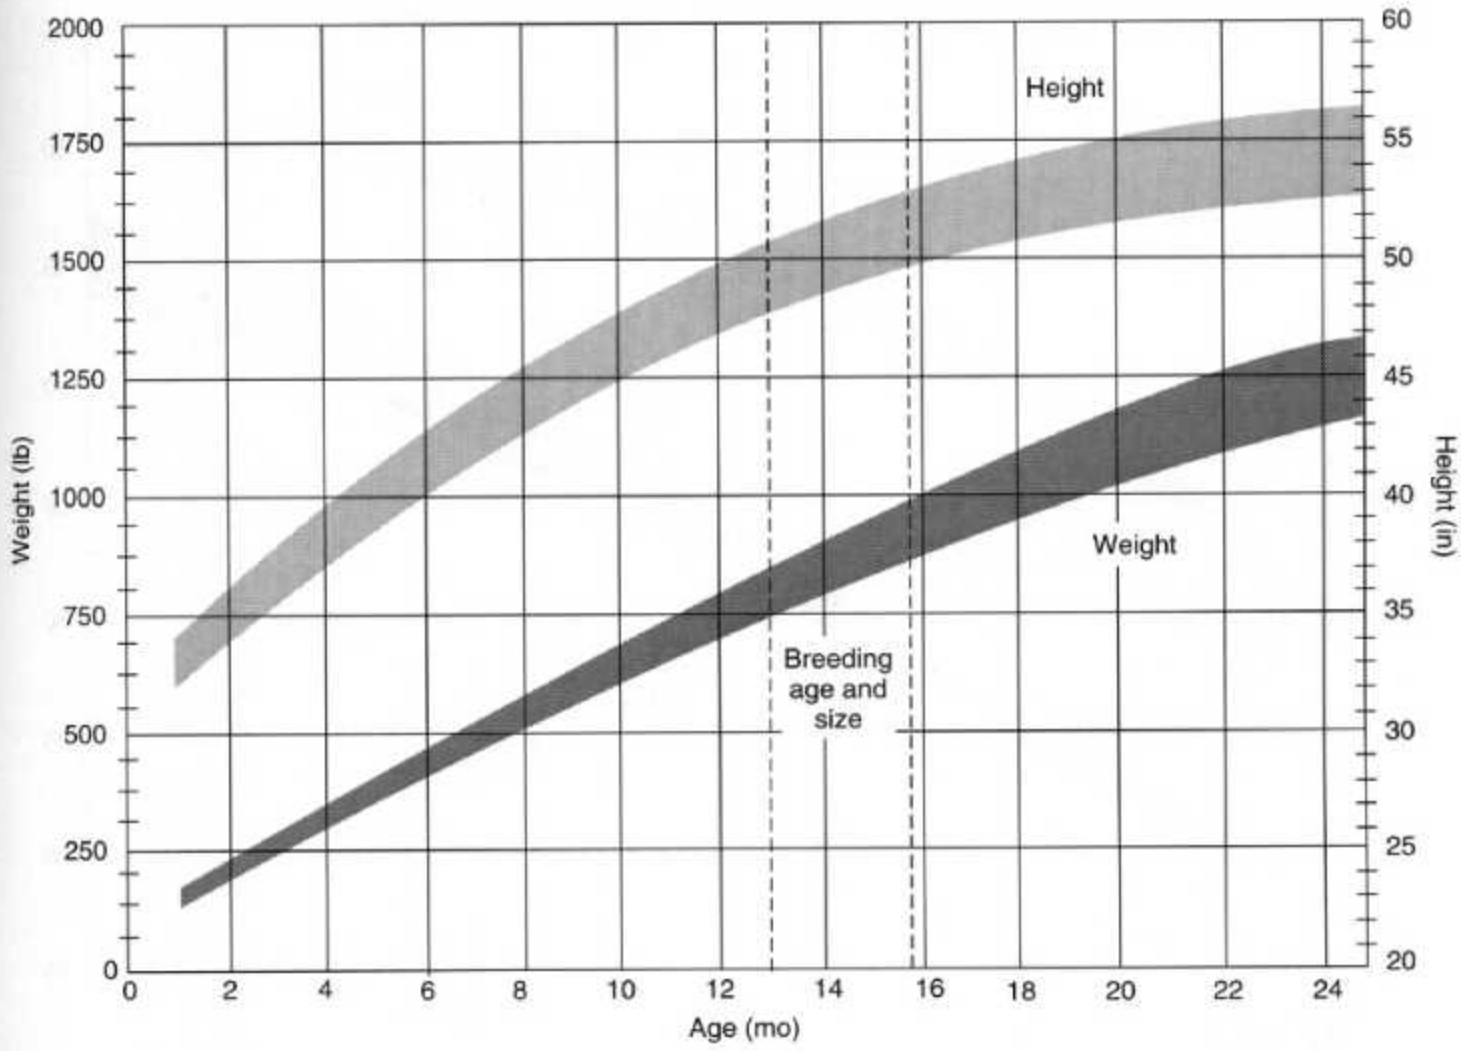

FIG. 9-9 Penn State calf and heifer growth chart: Brown Swiss.

The results of these observational studies and prospective field trials have led to the conclusion that there would be substantial economic benefit for the dairy industry in reducing the age at first calving. Only 50% of 948 Holstein replacement heifers from 21 herds in New York State had calved by 30 months of age (Correa et al, 1988), even though the objectives of their replacement management program had stated goals that were much younger than this age (Curtis, 1986).

Effects of calfhood morbidity on age at first calving have been documented (Correa et al, 1988). Heifers without respiratory illness were twice as likely to enter first lactation compared with heifers treated for respiratory disease as calves. In addition, average age at first calving was 6 months younger for calves without respiratory illness. Heifers with nonspecific illness characterized by dullness were 1.6 times more likely to calve and calved 2 months earlier than calves that did not have dullness. Waltner-Toews et al (1986f) studied survival to maturity and age at first calving in heifer calves from 34 Holstein dairy farms in southwestern Ontario. Heifers treated for diarrhea as calves were found to be 2.9 times more likely to calve after 900 days of age than were nonaffected calves.

In a study of 1161 Holstein-Friesian heifers from 22 Michigan dairy herds, age at first calving was not related significantly to either milk production or reproductive efficiency. However, heifers calving at an older age (>750 days of age) had greater problems with dystocia and ketosis. It was concluded that the managers of these Michigan herds should attempt to lower the age at first calving (Van Dam et al, 1988).

Dairy replacement heifer programs should strive to achieve a target of 24 months for average age at first calving for their herds (Donovan and Braun, 1987). It is clear from previous research that this objective is difficult to achieve with suboptimal health management practices and that proactive strategies may have to be implemented. Most DHIA record processing centers provide this index. Otherwise, age at first calving can be calculated easily from manual records.

Under grazing conditions in New Zealand, it is suggested that dairy heifers should reach 60% mature weight by 15 months of age for optimum fertility at first breeding, and 90% mature weight by 22 months for optimum milk solids production in the first lactation (Penno et al, 1994, 1997).

Calving Ease

Being able to get dairy heifers into production in their first lactation, without a significant problem at parturition such as dystocia, is a major goal of replacement rearing programs. Dystocia, defined as delayed and difficult parturition, has a major economic impact on the dairy cattle industry (Berger, 1994). In addition, the significant economic loss from calf stillbirth associated because of a high incidence of dystocia is undesirable.

An additional 14 days open and a decrease of 654 kg in milk production was found in cows with extreme calving difficulty compared with no calving difficulty (Djemali et al, 1987b). A decreased milk yield in first lactation following a difficult birth, at an estimated minimum cost for each assisted delivery in heifers of $50 to $60 (U.S.) has also been reported (McDaniel, 1981).

Dystocia rates for first-lactation Holstein heifers have been reported to be approximately 10% to 11% (Van Dam et al, 1988; Cue and Hayes, 1985). Calving difficulty, stillbirth, and associated factors have been studied extensively in Swedish (Phillipsson, 1976a,b,c) and in U.S. dairy cattle breeds (Pollak and Freeman, 1976). Dystocia is affected by several nongenetic factors, such as age and parity of the dam, sex of calf, year and season, size of the calf, and management intervention. Cows with shorter wither height and shorter pelvises tend to require more calving assistance. Heavier calves, winter calvings, earlier parity, and male calves were all related to an increase in dystocia rates.

Stillbirth is a substantial problem in the dairy industry, particularly at first calving. It is predominantly associated with dystocia. Cady and Burnside (1982) reported that 9.7% of approximately 29,000 calvings resulted in stillbirth. This stillbirth rate was 5.5% for animals with unassisted or easy calvings and 40.8% for those with dystocia. Because 23.6% of the heifers at first calving had dystocia, stillbirth was a major problem in this group (Cady and Burnside, 1982). Other reports have described stillbirth rates of 5.0% of calvings in 329 Pennsylvania herds (Heinrichs et al, 1987b) and 5.4% of calvings of 250,000 Israeli Holstein cattle (Weller et al, 1988). Although milk is the primary source of revenue in the dairy industry, calves provide income from direct sales and as replacements. The annual loss from stillbirth has been estimated at $5.2 million in Ontario (Cady and Burnside, 1982). This represents a $520 loss per farm annually. Strategies to reduce the stillbirth rates need to be evaluated and adapted.

In the beef cow-calf industry, attempts have been made to reduce the rates of dystocia and stillbirth prospectively by selection of heifers with larger pelvic openings as replacements for the breeding herd. In one controlled study, however, the predictive value of the pelvic area for the occurrence of dystocia in beef heifers was low (Van Donkersgoed et al, 1990). The usefulness of this technique in dairy heifers has not been reported.

In general, the heritability of calving difficulty is low (approximately 10%). If dystocia is measured as a direct effect of the sire, differences among dairy bulls have been reported (Berger and Freeman, 1978). The AI industry has evaluated Holstein sires for the tendency of their calves to have dystocia. Originally, a linear procedure was used to calculate this index, and this system is still in use in Canada. In 1988, the U.S. evaluation system was modified to a categoric method (Djemali et al, 1987a). The overall goal of these programs is to identify sires that might be preferred for mating to heifers and small cows, because less assistance is needed during the birth of the progeny of these sires.

Dystocia is not an all-or-none trait. Variations exist within sire progeny groups. Easy calving sires may have some progeny that are born with difficulty, and difficult calving sires can have some progeny that are born without assistance. Sires are evaluated for calving ease based on a standardized threshold model at Iowa State University in a program supported by the National Association of Animal Breeders. The model includes effects of herd-year, sex of calf, parity of dam, season of birth, birth-year group of sire, and sire of calf (Berger, 1994). Unlike other genetic traits that are expressed on a continuous scale of measurement, the expected progeny differences (EPD) for calving ease are in standard deviation units which are difficult to interpret, particularly when the original data are in scores of 1 to 5 (Berger, 1994). The method of reporting each sire's evaluation helps dairy producers understand the expected risk of using a sire chosen for easy or difficult calving and addresses their needs in planned matings to minimize calving difficulty of future progeny. The evaluation of each sire is reported to dairy producers as the expected percentage of difficult births (EDB) in primiparous cows. The EDB is calculated by transforming a linear function of the solutions from the threshold model to a scale of probabilities. The analysis is based on direct comparisons among sires with progeny in the same herd years. Sires in herd years without progeny of other sires in the same herd-years contribute little information to the analysis. Thus it is important to have as much information as possible from all sires in the same herd-years.

Dystocia evaluations are intended to increase the use of AI for heifers. Bulls can be selected so that the likelihood of a difficult calving is reduced. When bulls chosen for easy calving are selected for mating to heifers, this selection should follow or be within groups of bulls of comparable genetic merit for traits with higher economic value than that for dystocia. The sire evaluations for calving ease can be used to improve the economic efficiency of herd breeding programs without giving up genetic improvement for traits that are part of the selection objective.

There may be limited progeny information for young sires, and their evaluation for calving ease is subject to change as more progeny information becomes available for later evaluations. The reliability of each sire's evaluation for calving ease indicates the amount of information available to determine the predicted merit for calving ease.

Dairy producers are encouraged to select a bull with a higher reliability if the choice is between two bulls with the same EDB for calving ease.

The calving ease ratings reported for proven sires by the AI units are often underused for mating selections in replacement heifer management programs. It is essential that data concerning the difficulty of first calving be recorded. This information is integral to make a knowledgeable decision regarding the need for proactive selection. A system of scoring calving should allow for easy classification into broad categories. An example of one system is shown in Table 9-11 (Cue and Hayes, 1985). Using this system, calving ease is categorized into four groups, from unassisted or unobserved (category 1) to cesarean surgery (category 4). It is possible to adapt a numerical score to this system. The data can be recorded in any easily retrievable manual or computerized record system with the associated stillbirth information. The dystocia and stillbirth rates should be calculated and reviewed regularly.

Breeding organizations do not select bulls for calving ease, which is confirmed by the relatively constant under-

TABLE 9-11

Calving Ease Classification and Scoring System

Category	Description	Score
1	Unassisted or unobserved	100
2	Easy pull	100
3	Hard pull	50
4	Surgery	0

Downloaded From Vet-eBooks.com

weighted mean EDB. Because the weighted mean EDB is lower than the unweighted mean, bulls chosen for easy calving are used more frequently than their contemporaries with higher EDB. Therefore the opportunity to reduce calving difficulty has been an effective incentive for producers to mate more heifers to AI bulls. National in scope and international in implication, the NAAB Calving Ease Sire Evaluation program benefits AI organizations, dairy producers in North America, and dairy producers in other countries who routinely import semen, embryos, and animals.

Monitoring Reproductive Performance in Dairy Heifers

Programs for the monitoring and management of reproductive performance in lactating dairy herds have been common for many years (Williamson, 1987). However, the regular assessment of replacement heifer reproductive performance is rare, even though the general categories of information needed are the same as for the milking herd. In order to assess reproductive performance in dairy replacement heifers properly, there is a need for indexes of overall reproductive performance and for indicators of heat detection efficiency and the success of inseminations. For example, the age at first service and the age at first calving are indicators of overall reproductive performance. The age at first detected estrus and the interservice interval provide a reasonable measure of heat detection efficiency. The pregnancy rate over all services can be used to evaluate the success of insemination. Calculation of these few important indexes produces a useful assessment of replacement heifer reproductive performance.

As with many other aspects of replacement heifer health management, it may be difficult to obtain reproductive performance information on a routine basis. Many DHI record processing centers do not provide any measure of heifer performance other than age at first calving. Other centers provide a considerable amount of detail about the replacement heifer herd. The sections on maintaining record systems described in Chapter 3 are appropriate in this context. Many dairy herd management microcomputer software systems provide extensive information on individual heifers as well as averages for the replacement herd. The use of these programs on farms, or as a bureau system based in veterinary practices, has been reviewed (Lissemore, 1989). However, the usefulness of computer herd management programs for improving replacement heifer performance has not been reported. The use of these systems can take time to gain widespread acceptance, but manual record systems can be adapted easily to calculate the desired reproductive performance parameters for replacement heifers. An example of one manual system that can be adapted for heifers is shown in Chapter 3.

The optimum organization of a reproductive health management program for dairy replacement heifers is not well documented. Williamson (1987) proposed that heifers should be examined if (1) no heat is seen by 15 months of age, (2) interestrus intervals have exceeded 35 days, or (3) breeding occurred 35 days or more ago, without observed heat since. Based on the diagnoses and recommendations from rectal palpation findings of individuals in these categories, it is suggested that target reproductive performance indexes can be achieved. The size of the replacement heifer group, the seasonality of heifer management, and the availability of adequate restraint facilities determine the frequency of heifer reproductive examinations. Continual monitoring of heifer reproductive performance allows implementation of the health management cycle (Fig. 9-12).

Health and Disease Management

The future productivity of the dairy herd is largely based on its ability to replace culled animals with superior individuals. Thus a major objective of replacement management programs is to ensure that replacement animals entering the milking herd are of excellent health status and are prepared to deal with new stresses that present themselves. For example, it has been shown that there are detrimental effects of respiratory disease on survivability and on age at first calving (Correa et al, 1988). Calves with respiratory disease were twice as likely to leave the herd and to calve 6 months later than calves without respiratory disease. Based on data collected in the United Kingdom, the total cost of respiratory disease per 100 calves in a herd was $3584, which is a major cause of economic loss that must be minimized (Esslemont and Kossaibati, 1999). Calves treated for diarrhea are 2.9 times more likely to calve at 900 days of age or greater (Waltner-Toews et al, 1986b). Detailed studies that quantify milk and component production in replacement heifers of varied health status have not been reported.

The major areas of management of health in dairy heifers involve the control of parasites, coccidiosis, certain bacterial and viral diseases of the respiratory and alimentary tracts, keratoconjunctivitis, pododermatitis, and udder health management.

Parasite Control

There is considerable influence of geography and environment on the need for intensive parasite control programs (Reinemeyer, 1990). Strategic anthelmintic treatment programs are the methods of choice for replacement heifer parasite control. The major objective is to break the cycle of parasite transmission by halting the development of the parasite and by reducing the risk of infection and reinfection. This can be accomplished with sustained-release therapy (Gibbs and Kitsos, 1985) or with two strategic anthelmintic treatments at 3 and 6 weeks after turnout to pasture (Herd et al, 1987). The factors that should be considered in determining the most efficient approach to internal parasite control are the availability of labor and restraint facilities, the pasture stocking density and rotation rate, the climatic and pasture drainage conditions, and the costs of anthelmintic preparations.

The seasonal control of external parasites, such as warbles and lice, can be economically important in many dairy herds (Berkenkamp and Drummond, 1990). The use of ivermectin in the fall months has been effective in limiting the effects of these parasites and in minimizing the need for more extensive control programs. However, in some herds, the control of lice throughout the winter may require the implementation of additional measures, such as the use of pour-on organophosphate preparations.

Coccidiosis is a self-limiting disease and control can be achieved through the development of immunity (Schillhorn van Veen, 1986; Ernst and Benz, 1986). However, the effects of transient, naturally occurring coccidial infection on growth, reproductive performance, and future productivity have not been defined. It is difficult to relate the prevalence of infection with coccidiosis or the proportion of cases with clinical disease to replacement heifer performance. It has been suggested that clinical signs, severity, and losses resulting from coccidiosis are variable and are often related to stress factors such as weather, weaning, and crowding (Schillhorn van Veen, 1986). Several compounds can be fed to calves to control or reduce the severity of the coccidiosis, including lasalocid (Bovatec, Hoffmann-LaRoche) and decoquinate (Deccox, Rhne-Poulenc-Rorer).

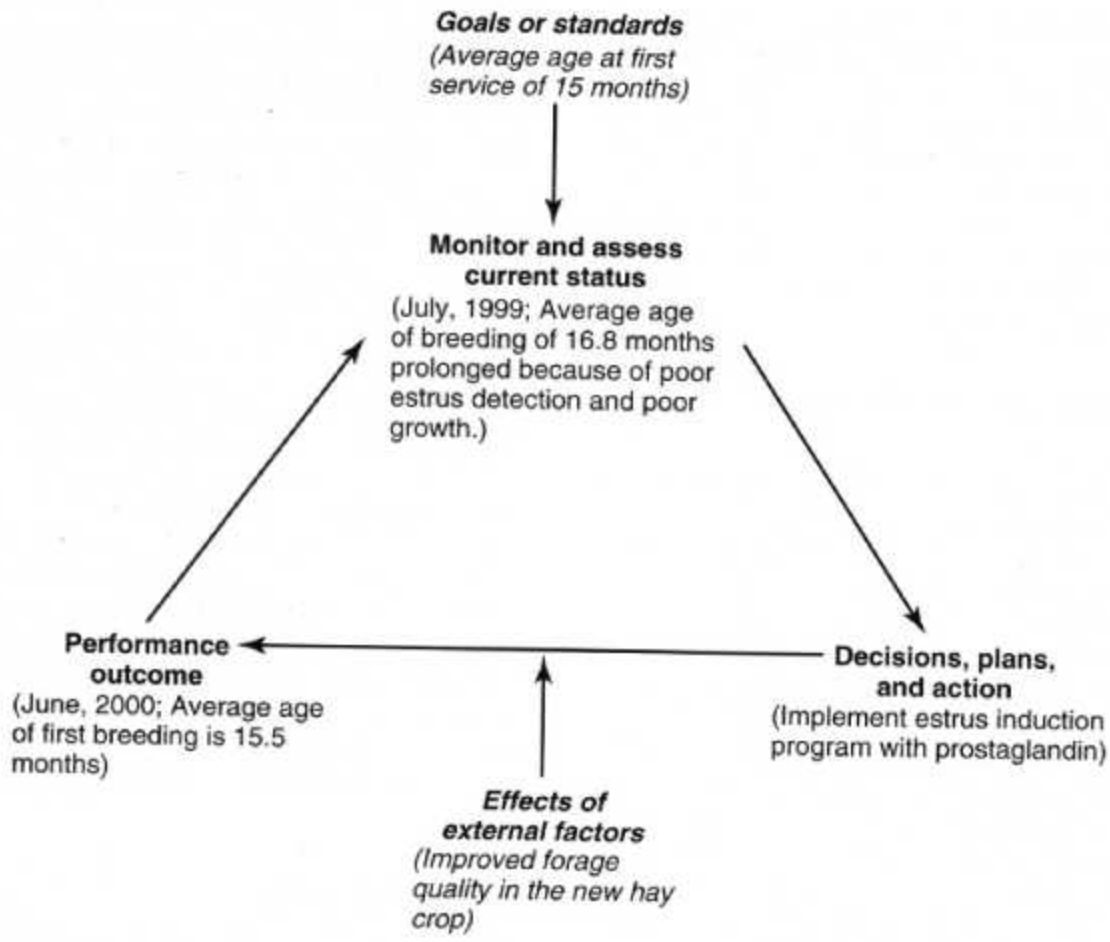

FIG. 9-12 Using the health management cycle in a heifer reproductive program. The herd has age monitored at first breeding and is above the target level. A prostaglandin estrus induction program is implemented. Over the next 11 months, average age at first breeding has improved. Improved nutrition resulting from higher quality forage may have been an important factor in the performance outcome. Monitoring is to continue, and new plans can be formulated.

Although some studies have demonstrated improved weight gains in experimentally infected calves (Conlogue et al, 1984), there is concern about the similarity between experimental infection and natural exposure. The pattern of oocyst shedding, in the absence of clinical signs, may provide little indication as to the need for medication or the prediction of long-term effects of the disease. One study found that lasalocid and decoquinate were effective in reducing coccidia in young calves under conditions of low naturally occurring exposure and good management (Hoblet et al, 1989). These findings were the same as in other studies after experimental inoculation (Foreyt et al, 1986; Stromberg et al, 1982) in that reductions in oocyst shedding were not accompanied by a significant improvement in weight gain. Subjective evaluations of medicated calves reported glossier hair coats and healthier appearance than nonmedicated controls. Perhaps these visual changes are responsible for the widespread inclusion of decoquinate in commercial calf starters in some regions, such as Ontario (Rodenburg, 1989). For recently weaned calves, estimated costs are 2 to 3 cents/head/day. Waltner-Toews et al (1986a) have reported that over 80% of Ontario producers start feeding calf starter grains at less than 2 weeks of age and that over 60% use commercial preparations. The cost-effectiveness of this use of coccidiostats for improved performance in dairy replacement programs needs further study.

Replacement heifers reared on pastures are commonly affected with gastrointestinal parasites. Continuous ivermectin treatment from birth to puberty in dairy heifers grown on nematode-infested pastures can increase growth rate, advance the onset of ovarian activity, and positively affect yearling pelvic area (Mejia et al, 1999).

Infectious Disease Control: Vaccines and Immunization Schedules

The principles of the control of infectious diseases are presented in Chapter 4. A health management program for dairy replacement heifers must emphasize the reduction of the degree of exposure to infectious agents. Appropriate nutrition and attention to the genetic aspects of disease resistance are important for immunocompetence and the prevention of infectious disease. However, a replacement heifer health management program offers the ideal opportunity to immunize heifers selectively against the major infectious agents.

A wide range of bacterial and viral vaccines is available in North America against the major infectious diseases of dairy cattle. Most vaccines are multivalent preparations containing inactivated or live antigens (Bowland and Shewen, 2000). The selection of the specific diseases against which dairy replacement heifers are vaccinated depends on several factors. The risk of exposure to a particular disease, the efficacy of the available vaccines, and the costs involved in carrying out a recommended program are important variables (Radostits and Tremblay, 1994). In addition, the regulatory requirements in each particular region and the restrictions imposed by the domestic or foreign markets targeted by the herd for sale of surplus heifers are other important points to consider. An immunization program for dairy replacement heifers in North America includes the use of vaccines against IBR, parainfluenza-3, bovine virus diarrhea, BRSV, and a bacterin containing five strains of *Leptospira* sp. Vaccination of dairy heifers against BRSV before parturition—twice at 2-week intervals, with the second vaccine administered at 2 to 3 weeks before calving—may increase milk production and first insemination conception rates (Ferguson et al, 1997).

Downloaded from Vet-eBooks.com

The need for vaccination against *Brucella abortus,* rabies virus, and clostridial agents depends on the region and characteristics of the individual farm.

To be effective, a vaccination program must be planned according to the age of heifer and season of the year. The strategy is to induce protective immunity as early as possible after the decline of maternal antibody levels. Revaccination before breeding age serves to maximize protection during the vulnerable stages of pregnancy against some of the major pathogens. One approach that meets these outlined objectives and criteria is to organize an annual immunization program for replacement heifers on a quarterly basis. Heifers are vaccinated between 5 and 8 months of age, and revaccinated 6 months later between 11 and 14 months of age, to booster immunity before breeding. This schedule ensures that all heifers are vaccinated twice before first lactation and before becoming part of the health management program for the milking herd. The seasonal risk for some problems, suchs as leptospirosis, may dictate early fal vaccination for this disease.

The recommended vaccination schedule for dairy heifer replacements is shown in Box 9-3.

The final components and organization of a replacement heifer vaccination program for a specific farm are derived after consultation and deliberation regarding the risks of disease, efficacy of available vaccines, and specific economic factors important on that farm. A high percentage of dairy herds are not adequately vaccinated against bovine virus diarrhea (Rauff et al, 1996), and veterinarians are not taking full advantage of their pivotal role in dairy vaccination and herd biosecurity programs. According to the National Dairy Heifer Evaluation Project of 1991-1992, in the United States, only 33% to 46% of dairy cattle producers vaccinated dairy heifers between weaning and first breeding for IBR, bovine viral diarrhea, BRSV, and parainfluenza-3 virus. From 32% to 44% of producers vaccinated for those diseases between breeding and calving. Only 19% vaccinate for clostridial diseases, whereas 65% vaccinated for brucellosis. In a survey of dairy herds in Saskatchewan only 25% of dairy producers appear to follow the label directions for administering killed virus vaccines (Carruthers and Petrie, 1996).

BOX 9-3

Recommended Vaccination Schedule for Dairy Heifer Replacements

CALVES AT 6 TO 8 MONTHS OF AGE
Clostridial bacterin (eight-way antigen)
Infectious bovine rhinotracheitis-parainfluenza-3
Bovine virus diarrhea
Bovine respiratory syncytial virus
Leptospira pentavalent

HEIFER REPLACEMENTS AT 13 TO 15 MONTHS OF AGE (AT LEAST 3 WEEKS BEFORE BREEDING)
Infectious bovine rhinotracheitis-parainfluenza-3
Bovine virus diarrhea
Leptospira pentavalent

Udder Health in Replacement Heifers

Several studies have reported the prevalence of intramammary infections in nulliparous dairy replacement heifers (Bray et al, 1989; Oliver and Mitchel, 1983; Trinidad et al, 1989; White et al, 1989). Although there is considerable variability in the reported infection rates, mastitis is undoubtedly more frequent than would be expected in heifers before entering the lactating herd. The majority of these infections are caused by coagulase-negative *Staphylococcus* sp. Bacteria, which are eliminated spontaneously or with antibiotic therapy during early lactation (Myllys, 1995). However, high rates of *Staphylococcus aureus* have also been reported in bred heifers (Trinidad et al, 1989). In this particular situation, with such a high prevalence of an important intramammary pathogen, it was shown that antibiotic therapy of heifers before their first parturition had a beneficial effect by reducing the prevalence of infection and by increasing first-lactation milk production (Trinidad et al, 1990). Another study, with lower prevalence of *S. aureus* infection, did not confirm this improvement (Bray et al, 1989). Prepartum intramammary therapy of primigravida heifers with commercial dry cow antibiotics (penicillin-novobiocin or cephapirin) caused cure rates of 94% to 100% for *S. aureus* (Owens and Ray, 1996). Recommendations concerning the maintenance of udder health status in replacement heifers require information on the prevalence of infection and the types of organisms involved.

Mastitis in heifers can occur in well managed, productive herds with low somatic cell counts and a high frequency of mastitis treatments administered by the veterinarian (Myllys and Rautala, 1995). Recovery from clinical mastitis is good, but mastitis in heifers is a cause of culling.

The sources of intramammary infection of heifers with *S. aureus* at parturition are milk from other infected mammary glands and heifer body sites (Roberson et al, 1998). Contact among heifers may be an important mode of transmission of *S. aureus,* leading to intramammary infection in heifers at parturition. Horn flies (*Haematobia irritans*) are able to transmit *S. aureus*-induced intramammary infection to heifers, and scabs on teats are a potential source of the organism (Owens et al, 1998). Fly control on dairy cows in herds with known *S. aureus* mastitis problems is recommended as a method to control infection.

Elective Procedures

Dehorning and removal of supernumerary teats are most easily done before weaning but should be completed by at least 4 and 8 months of age, respectively. During the growing period, heifers should be examined to confirm that these procedures have been completed appropriately. The removal of the medial dewclaws of young calves for the prevention of teat injuries in later life as stabled lactating cattle was recommended for many years, but there has been no evidence from formal field trials or observational studies that this procedure is necessary. Reticular magnets can be administered at 15 months of age or at the time of first breeding for the control of traumatic reticuloperitonitis. This recommendation depends on the occurrence of potential risk factors for this condition in the population in question.

Biosecurity in Dairy Heifer Replacements

Several diseases of cattle may be introduced into dairy herds by the importation of heifer replacements that may be infected unknowingly with pathogens. These include enzootic bovine leukosis, Johne's disease, bovine virus diarrhea, brucellosis, *N. caninum,* papillomatous digital dermatitis, and contagious mastitis pathogens. Serological tests can be done for enzootic bovine leukosis, Johne's disease, and brucellosis. Blood can be cultured to detect animals persistently infected

Downloaded from Vet-e-Books.com

with the bovine virus diarrhea virus. Imported animals should be tested and found to be seronegative before entry into the herd or kept in quarantine in the herd of entry until the test results are available. A high percentage of dairy herds with digital dermatitis could be prevented using management strategies related to biosecurity (Wells et al, 1999). Congenitally acquired *N. caninum* infection in calves can cause a substantial number of abortions during the initial pregnancy of heifers, and subsequent abortions can be expected in congenitally infected cows that have aborted previously (Thurmond and Hietala, 1997). Seropositive heifers commonly give birth to calves with high *Neospora* titers, and congenitally acquired *Neospora* sp. infections can persist in healthy heifers and can be transmitted transplacentally to the next generation (Anderson et al, 1997). Thus seropositive heifers should be culled, but there is no assurance that all seronegative animals are free of infection. Feed biosecurity and water contamination are also considerations in preventing the introduction of pathogens into dairy herds. Animal by-products such as meat and bone meal may be contaminated with salmonella, which may be introduced into a dairy herd (Bender et al, 1997).

Monitoring Disease Control in Replacement Heifers

The efficiency of disease control programs in dairy replacement heifers can be monitored by calculating morbidity and mortality rates, in addition to charting growth. Disease-specific morbidity rates for conditions such as pneumonia or abortion are useful to assess the efficacy of vaccination programs. Care must be taken to ensure that the appropriate numerator and denominator are used in the calculations, as described earlier. With the determination of such rates and with the measurement of growth, it is possible to complete the health management cycle for disease control. An example of this process is depicted in Fig. 9-13.

Details of a monitoring system for replacement heifer rearing are available (Quigley et al, 1996). The headings of a calf-rearing chart, which can be customized to meet the needs of individual farms, are shown in Box 9-4 (Quigley et al, 1996).

Genetic Selection and Numbers of Replacements

The replacement heifer herd is the major source of additions to the milking herd. Thus it is important that the number of heifers available and their genetic potential be greater than the potential and number of cows being removed from the herd (Rodenburg, 1989). To ensure that this potential for progress is realized, several requirements of a replacement heifer management program should be met (Box 9-5).

Artificial Insemination of Replacement Heifers

A survey in Pennsylvania found that only 59.5% of herds used exclusively AI breeding programs for their replacement heifers (Heinrichs et al, 1987b). The use of AI offers the availability of sires with proven genetic merit. Selection can be based on the maximum genetic improvement in desired production and conformation traits while being cognizant of calving ease.

The use of a beef breed bull on dairy replacement heifers in an attempt to reduce dystocia rates is common. This practice, however, is neither without risk of dystocia or venereal disease, nor a substitute for better replacement management to raise well-grown heifers. In addition, a large number of potential replacement heifers are not produced. Assuming that animals of different parity have equal probabilities of having a heifer calf and of calf survivability, first-calf heifers produce approximately 30% of the heifers born, as compared with 25% and 20% from second-lactation and third-lactation cows, respectively.

The use of an AI breeding program in replacement heifers offers several other advantages over natural service. The

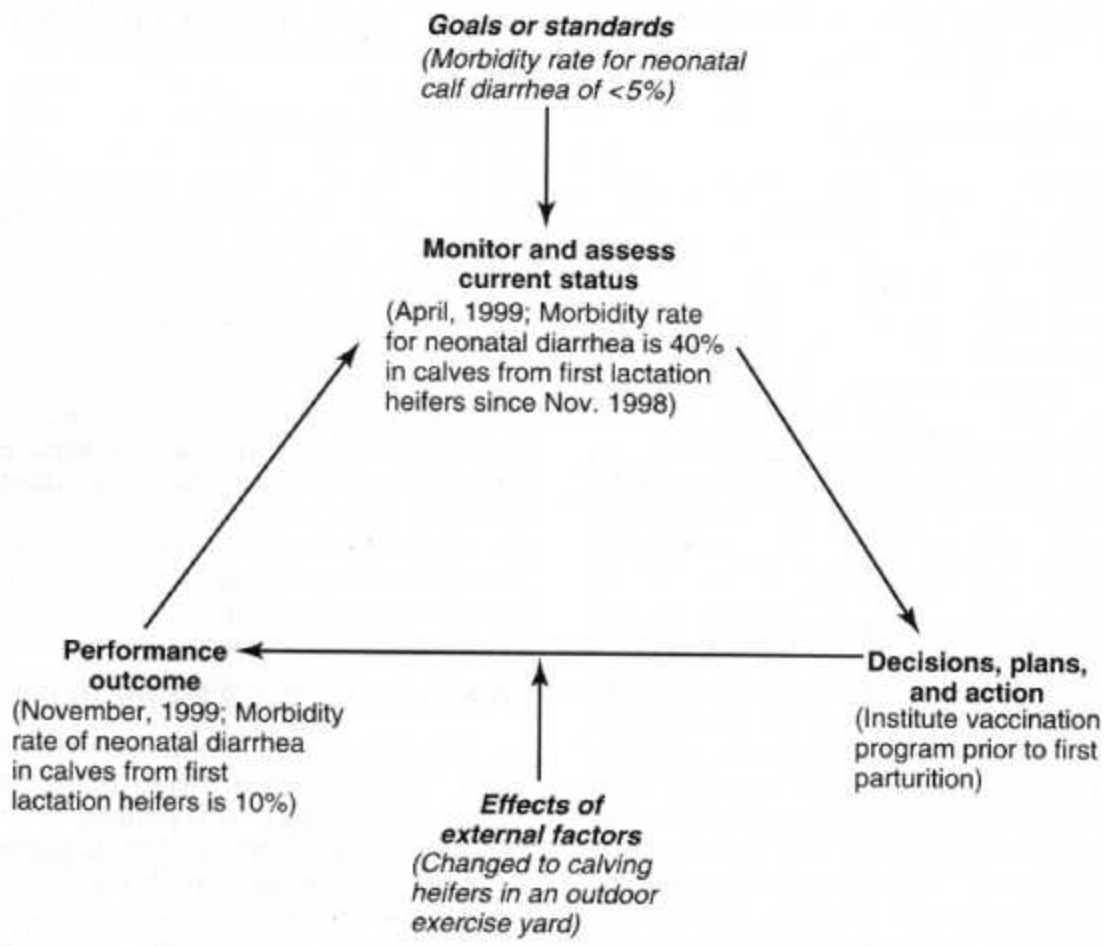

FIG. 9-13 Using the health management cycle in a replacement heifer disease control program.

Downloaded from Vet-e-Books.com

record keeping necessary for an AI program benefits animal identification and observation. The facilities required for an AI program, such as smaller group sizes and self-locking head gates, enhance the ability to deliver better nutritional management. An AI program offers more opportunity to restrict the times when heifers calve, if this is a management advantage.

In summary, the use of AI in dairy replacement heifers can lead to excellent reproductive performance and offers the greatest potential for genetic progress within a herd.

Monitoring Genetic Progress

The accurate identification of heifer calves is essential to ensure genetic progress. Advances in electronic animal identification can assist with this aspect in the future. The reproductive and health records are also helpful in making decisions about the replacement potential and mating selections of individual heifers. An estimate of the genetic merit can be calculated for all replacement heifers with known parentage. The details of genetic indexes are discussed in Chapter 7. Animals with inferior performance potential can be removed preferentially.

Herd Reproductive Performance

Poor reproductive performance adversely affects the opportunities for selection from replacement heifers. The potential number of calves available declines as the calving interval increases. The effects of herd calving interval on the number of replacement heifers available (Table 9-12). As the calving interval increases by 1 month, approximately 8% fewer calves are born each year. Thus a herd with a 14-month calving interval has 84 calvings per 100 cows annually. Reasonable assumptions are that 50% of calves are females and that 25% of heifer calves leave the herd before 24 months of age because of various factors, ranging from illness and poor growth rate to infertility as a yearling heifer. With these assumptions, an increase in the calving interval from 12 to 15 months can decrease the number of heifers available for selection, because replacements decrease from 38 to 29 heifers per 100 cows annually. Age at first calving also affects the number of heifers available for selection as replacements. The effect of an increase in age at first calving on the inventory of replacement heifers needed as herd replacements at various culling rate levels, assuming a 10% heifer culling rate, is summarized in Table 9-3. A herd of 100 dairy

BOX 9-5

Requirements of a Replacement Heifer Management Program

Sires of superior genetic merit should be used on heifers through artificial insemination.
Genetic progress in the replacement herd should be monitored through accurate animal identification, detailed record systems, and accessing predicted genetic indices for the replacement herd.
The reproductive performance of the herd must be maintained, because it directly affects the number of replacement heifers available.
The losses of calves and heifers must be minimal to enhance the number of quality replacements available.

TABLE 9-12

Effect of Herd Calving Interval on Replacement Heifers Produced Annually

Calving Interval (mo)	Average Calves Born Annually (per 100 Cows)	Bred Heifers Available (per year)*
12	100	38
13	92	35
14	84	32
15	76	29

*Assumes that 50% of calves born are females and that 75% of female calves survive and are available to freshen as first-calf heifers.

Downloaded from Vet-eBooks.com

cows with a 24% culling rate needs an inventory of 54 heifers of all ages if a 24-month age at first calving is maintained, compared with an inventory of 62 heifers if age at first calving is 28 months.

In summary, the herd reproductive performance and the age of first calving directly affect the number of heifers available as herd replacements. In turn, the ability to apply some selection pressure on both milking cows with a poor record of performance and on heifers with poor genetic potential to produce relies on having an abundant supply of replacement heifers.

Successful replacement heifer raising programs have lower death losses and provide a greater opportunity to cull cows and heifers with less genetic potential. If calf morbidity and mortality have been high, it is possible that the entire remaining group of replacements is needed. Genetic gain is limited because of the necessity to keep inferior cows and replacements in the herd. It is desirable to have a sufficient replacement inventory to allow for a 10% culling rate among heifers.

Under grazing conditions in New Zealand, it is suggested that dairy heifers should reach 60% mature weight by 15 months of age for optimum fertility at first breeding, and 90% mature weight by 22 months for optimum milk solids production in the first lactation (Penno et al, 1997).

ECONOMICS OF REPLACEMENT HEIFER HEALTH MANAGEMENT

The investment in raising replacement heifers is the second largest financial input into a dairy enterprise (Donovan and Braun, 1987; Goodger et al, 1989). Feed costs for the lactating herd represent the largest dollar input. However, raising dairy replacement heifers can account for 15% to 20% of total dairy enterprise costs (Annexstad, 1986). Some of the costs associated with raising replacement heifers have been studied extensively. Estimates of the costs to raise a calf to 24 months of age range from $1080 to $1353 (U.S. dollars) (Annexstad, 1986). These estimates probably included major differences in management, environmental conditions, housing needs, feed sources, measurement of weight gain, and general market conditions at the time of the study. Any change in feed, labor, and energy inputs would dramatically affect the cost estimates.

Age at calving and herd turnover or cull rates are two of the largest factors affecting herd replacement costs as it affects the numbers of heifers that must be raised to maintain herd numbers. When age at calving increases, so does the need for heifer housing, feed, and labor. This increase can be as much as 50% or more in extreme situations. An example of this magnitude of increase would be comparing a farm with a 26% herd turnover and 22-month calving age with another having a 38% herd turnover and a 30-month age at calving. The first farm needs 53 heifers in the replacement herd while the second requires 106, or twice as many heifers just to maintain a constant 100-cow herd size. The costs to raise the extra heifers can be tremendous and make a major difference on the profit potential of each farm.

It is important for farmers to understand the overall costs involved in raising dairy heifers for both farms wanting to raise their own heifers and for those seeking contract growers. In either case, in order to do a better job or to let someone else raise them, veterinarians must know the current costs in order to do better in the future.

Heifer-raising costs are generally separated into two major categories. *Fixed costs* include buildings, equipment, property, machinery, depreciation, interest on investment, repairs, taxes, and insurance. Some of these costs are of the type that are often overlooked by those not accustomed to a rigid accounting system, but they are all real and can add a significant portion to the cost of raising a heifer. *Variable costs* include feed, labor, bedding, utilities, veterinary care, breeding, and supplies. These vary nearly proportional to the number of heifers raised at one time. Most variable costs are easily understood and calculated. Fixed costs are often hard to calculate and easy to overlook for the heifer enterprise on the dairy farm (Table 9-13).

With the current state of dairy replacement programs, the greatest immediate potential for economic improvement is in the reduction in age at first calving. Reduction in the age at first calving, to a goal of 24 months of age, would reduce the total nonproductive days and allow for a one-time surplus in replacement heifers. A spreadsheet program has been developed to calculate the losses caused by a delay in age at first calving (Fetrow et al, 1987). An example of a printout from this program is shown in Table 9-14. By reducing the average age at first calving of the 45 replacement heifers that calve each year in this sample herd from 28.3 months to a goal of 24 months, over $12,000 in input costs could be avoided. In addition, a one-time income of over $19,000 is available from the sale of 16 extra heifers. Because the age at first calving has shown little improvement in the last two decades (Powell, 1985), this type of spreadsheet could be useful as an extension tool to discuss the benefits of health management programs for improving age at first calving with producers.

Raising Heifer Replacements by Contract

A nationwide interest in raising dairy heifer replacements by contract is growing. On farms where facilities, labor, feed,

TABLE 9-13

Dairy Heifer Replacement Rearing Budget Summary

Cost Summary	Age Interval (mo)			
	0-3	3-12	12-24	0-24
Feed costs	$45. 26	$143.20	$328.56	$516.56
Total variable costs	$73.27	$197.65	$434.28	$705.20
Total fixed costs	$33.69	$91.88	$124.75	$250.31
Average cost/mo	$77.32	$37.17	$50.75	$48.98
Average cost/day	$2.54	$1.22	$1.67	$1.61

management, or any number of circumstances are limited, contracting with someone else to raise the heifers for all or part of the growing period up to calving can make sense. Contracting heifers offers a number of advantages for the dairy farmer and may be a logical alternative to traditional methods of raising heifers. Since replacement raising costs typically account for 15% to 20% of total milk production cost, selecting the most beneficial and commercial method of raising heifers is a major one.

The National Dairy Heifer Evaluation Project conducted from 1991 to 1992 found that 1.7% of U.S. farmers have someone else raise their heifers on a contractual basis (Heinrichs et al, 1994). In the Northeast 2.4% of farmers contract their heifers to another heifer raiser. Similarly 2.1% of farmers in the Southeast contract heifers. Contract raising is less often used in the Midwest (0.5%); however it is quite common in the West (7.8%). It is likely that the numbers are growing each year as farms become larger and more specialized. Interest in this area is definitely growing. The National Dairy Heifer Project did show that herds that use contract raising are generally much larger than average (more than 230 cows) and that this trend is increasing also. This study showed that 41% of producers who use contract raising send calves out between 12 hours and 4 months of age, 47% send heifers out between 4 months and breeding, and a smaller number (12%) contract out heifers from breeding to precalving time only. A large percentage of heifers are contracted out until 2 to 6 weeks before calving, regardless of age when they were first sent to the contract grower.

Changing the way a dairy farmer allocates farm resources is the largest benefit of contract heifers. As a result of someone else raising heifers, dairy farmers should free up a variety of limited resources such as labor, management time, buildings, equipment, land, and operating capital. In addition to freeing up homegrown forages or grain for use by animals other than heifers can be considered a good reason to look at contract raising heifers. It is important that the farm use these limited resources for something more profitable once the heifers are no longer being raised at home. In addition, the alternative use of resources, in terms of profitability, must be equal or better than their use in raising heifers. If this is not the case, then one of the major benefits attributed to contract raising will be lost.

In situations in which a major farm expansion is being considered, the alternative of adding milking cows to use the resources previously occupied by the heifers may be advantageous. Eliminating the heifer-raising enterprise on the farm should allow labor and management to specialize on the milking herd. The possibility exists that the lactating herd performance could improve because of this specialization, whether or not the actual herd numbers grow. In a sense, removing the heifers from a farm operation and adding milking cows can lead to an improved cash flow for either a limited or long-term period.

Once the decision has been made to not raise heifers in a traditional manner, contract raising heifers could be considered much better than buying heifers on the open market. The herd genetics, breeding, and, most importantly, herd health programs can be controlled by the dairy farmers using contract raising. A final point is that if the farmer's actual cost of raising heifers is greater than the alternative of contracting, then the economic benefits will be important. The effectiveness of specializing in heifer raising can often result in reduced costs and perhaps better grown, healthy heifers. Contract raising heifers can provide a full- or perhaps part-time employment for someone who does not want to milk cows or whose milking facilities are not adequate to milk cows. For smaller sized operations it can provide a part-time income that has flexible hours for the part-time farmer.

TABLE 9-14

Sample Printout From a Spreadsheet Program to Calculate Losses Resulting From Delay in Age at First Calving

Parameter	Goals	Actual	Average Parameter	Costs	
				Goals	Actual
Age at calving (mo)	24	28.3	Average heifer feed/mo	$35	$38
Weight at weaning (lb)	150	150	Overhead/mo	$540	$540
Age at weaning (mo)	2	2	Overhead/head/mo	$12	$12
Weight at calving (lb)	1200	1164	Total cost/heifer/day	$1.55	$1.63
Rate of gain (lb/day)	1.59	1.29			

Price of springing heifer	$1,200
Number of heifers calving/year	45

Analysis: loss avoidable per head	Feed: $221	Total loss avoidable per year: $12,278
	Overhead: $52	
	Total per head: $273	

Income available from transition to goal by selling 16 extra heifers because of calve: $19,350

The facilities to be used for the heifer raising, including the ventilation, water system, and grouping systems, must be sufficient to be used for heifers. Contract raising heifers allows the full- or part-time replacement grower to feed available grain and forages. Again, these must be adequate in quality, or one of the benefits of contract raising heifers is lost. One common problem is that facilities, feeds, or management not sufficient for milking cows is often not of sufficient quality to raise heifers.

Contracts for heifers may contain an option-to-purchase (owner sells the calf but reserves the right to buy the resulting spring at market price), or they may be limited to a direct contract (the dairy farmer retains ownership and pay the grower a fee). Contracts should be drawn up to protect both the heifer owner and the heifer grower. Some items to consider are the length of the contract term, a provision for termination, and a method of arbitration. A renewal clause should be negotiated after the heifers raisers' abilities have been evaluated thoroughly and one or more groups of heifers have been raised. Health requirements such as calf-hood vaccinations need to be taken care of as well as how death losses are handled and who assumes the necessary veterinary costs. The person who assumes the responsibility for breeding the heifers and paying the cost of breeding must be determined. The responsibility for transportation to and from the heifer grower must also be decided.

Contracts drawn on a year-to-year basis provide flexibility in establishing fees and other cost figures that parallel the general farm economy. Contracts should be written to permit the addition and deletion of animals as conditions dictate. The method of payment should also be determined in the contract. Monthly charges, fees based on body weight gain, or a one-time fee similar to purchasing are often the options.

Accounting records and animal identification are absolutely important for contract raising. These will aid both the owner and grower. Both the owner and the grower should retain copies of all records. In addition, preestablishing performance guidelines are absolutely necessary. Heifer owners may wish to dictate ration components and dry matter intakes or may want to establish minimum and maximum guideline on growth, both weight and height at a given age. If growth is an established criterion for assessing a benchmark of performance or establishing a fee structure, height at withers or some other measure of skeletal structure should be used in addition to body weight. Ranges of acceptable growth should be used to account for individual and genetic variation between animals. In addition, the subjectivity of body condition scoring of heifers may not make it the best alternative for monitoring performance.

Costs of raising heifers may be dictated by the age that heifers are received. Labor and feed costs of very young calves may be much higher per day than for older heifers. The contract raiser must determine these costs in relation to the time period that they will have the heifer in order to determine the appropriate charges to make. Since the objective and resources are so different from farm to farm, an analysis of benefits and active cost must be calculated on a farm-by-farm basis.

CHAPTER 10

Mastitis Control in Dairy Herds

RON J. ERSKINE

The production of high-quality milk is a realistic and meaningful goal for all aspects of the dairy industry and the primary motivator for establishing a mastitis control program in a dairy herd. The thrust of these efforts has been the implementation and use of management techniques to limit the spread of major mastitis pathogens, thereby reducing the quarter infection rate. Detailed mastitis control strategies have been outlined and promoted by the National Institute for Research in Dairying (NIRD) and by the National Mastitis Council (NMC). With proper implementation, these programs cause a dramatic decrease in the prevalence of common contagious mastitis pathogens (Jackson, 1980; Dodd, 1983; Smith, 1983). Herds that have successfully implemented a comprehensive mastitis control program also need to develop strategies to control infection with environmental organisms and need to use an effective monitoring system for new infections (Smith et al, 1985b). However, the adoption of effective mastitis control programs has often been less than desirable (Gill et al, 1990; Godkin, 1990; Hueston, 1987), despite extensive research validation of the recommended control practices and major extension efforts at both national and local levels. The reasons for this slow adoption of mastitis control strategies have not been documented. Research in Minnesota has shown that producers look to the veterinary profession for information on mastitis and its control (Burton et al, 1988). If significant progress is to be made toward a general improvement in udder health status, veterinarians must remain active in organizing, conducting, and monitoring comprehensive mastitis control programs. Box 10-1 lists the 10 fundamental elements of a mastitis control program as recommended by the NMC. Emphasis and details of each point may vary from herd to herd; however, if practiced with consistency, mastitis should be minimized as an economic loss for a dairy.

DEFINITIONS AND TERMINOLOGY

Mastitis is an inflammation of the mammary gland and primarily results from invasion of pathogenic microorganisms through the teat canal. An *intramammary infection (IMI)* has occurred if the invading pathogen causes an inflammatory response and loss of potential milk production in the affected quarter of the gland. Mastitis can occur with a wide range of clinical signs, from subclinical to severe, which is dependent on the virulence of the pathogen and the extent of the response of the host immune system. *Subclinical mastitis* is defined as the presence of pathogenic organisms in the milk, and an inflammatory response that can only be detected by screening tests or laboratory procedures. Thus signs of inflammation that are detected by visual observation or palpation such as swelling, heat, redness, pain, or systemic responses such as fever, are not observed. The causative agent(s) can only be identified reliably from bacteriologic culture of milk. *Somatic cell counts (SCCs)* of milk, which are essentially measurements of the concentration of leukocytes in the gland, are the most frequently employed method to detect inflammation. The correlation between IMI and elevation of SCCs is not perfect, but it is a very strong relationship in predicting both infection status of individual cows and prevalence of chronic IMI in a herd. More than one quarter may be infected simultaneously, which also tends to increase composite (commingled samples from all four quarters) SCC. Cows with a linear SCC less than 4 ($\leq$141,000 cells/ml) are usually not infected. Likewise, bulk tank SCCs below 150,000 cells/ml are usually associated with a low prevalence of IMI in a herd.

Clinical mastitis results when the cow's immune system responds with enough intensity to an IMI to elicit signs of inflammation that are physically observable. The nearly universal observation of clinical mastitis is abnormal color or texture of milk. As the degree of local inflammation increases, swelling, discoloration, and pain in the udder may become evident. Typically, clinical manifestations of the inflammatory response are seen in only one quarter at a time, although multiple quarters can exhibit clinical signs, especially for *Mycoplasma bovis*. In mild clinical mastitis, clinical signs are generally restricted to local involvement of the udder. In severe clinical mastitis, systemic involvement is apparent, with varying responses such as fever, anorexia, depression, shock, and recumbency. Especially in the severe form, milk production can be decreased profoundly, the affected quarter may become agalactic, eventual culling may be needed, or in a small proportion of cases, death may result.

IMIs can be described as *chronic* if the duration of infection, with or without clinical signs, is greater than 2 months. Likewise, clinical cases can be described as chronic if affected quarters either frequently recur with clinical signs after apparent cures or frequently maintain a clinically abnormal status for extended periods of time. *Acute* mastitis generally refers to clinical mastitis cases, and more properly describes the rapid onset of clinical signs rather than the severity. Superimposed on this terminology are the categories of *contagious* and *environmental* mastitis. These refer to the reservoirs of particular bacterial infections. Contagious mastitis occurs with organisms that spread from cow to cow. Environmental infections occur from ubiquitous organisms commonly found in the housing environment. In studies of the herd prevalence of microorganisms in milk, two of the most common bacteria isolated are *Corynebacterium bovis* and coagulase-negative *Staphylococcus* sp. These organisms are occasionally associated with clinical changes and often induce only a moderate SCC response (Brooks et al, 1982; Erskine et al, 1987b). There is considerable debate as to the significance of these organisms for the mammary gland and for cow productivity. For this reason, these organisms are classified as *minor pathogens*. Minor pathogens have been credited

BOX 10-1

Ten Guidelines for a Mastitis Control Program

1. Establish goals for udder health
2. Use proper milking procedures
3. Maintain a clean and comfortable environment for cows
4. Properly maintain and use milking equipment
5. Use appropriate treatment of clinical mastitis during lactation
6. Provide effective dry cow management
7. Maintain biosecurity for contagious pathogens and cull chronically infected cows
8. Keep good records
9. Regularly monitor udder health status
10. Periodically review the mastitis control program

with maintaining a higher than normal SCC and with increasing the resistance of the colonized quarter to invasion by a major pathogen (Rainard and Poutrel, 1988). There is evidence that long-term intensive programs of teat dipping and dry cow therapy can markedly reduce the prevalence of *C. bovis*, however, responses with the staphylococci are more variable.

It is necessary to be able to communicate the extent of a mastitis problem in a herd to a dairy producer. Most importantly, a *case definition* of a mastitis case must be used, particularly for clinical mastitis cases. Once a clinical case or IMI has been defined, it is then possible to determine the extent of the problem. The *prevalence* of mastitis in a herd is defined as the number of cows (or quarters) that are diagnosed as infected divided by the total number of cows (or quarters) currently at risk of infection. Prevalence yields a proportion of the herd that is infected at one point in time. Bacteriologic culture of milk samples collected from a herd is the preferred method to determine the prevalence of infection. Interpretation of the calculated prevalence of mastitis depends on three important factors: (1) the incidence of new intramammary infections, (2) the duration of intramammary infections after they have occurred, and (3) the rate that infections are removed from the herd by treatment, spontaneous cure, culling, or death.

Determination of prevalence can offer reliable insight for contagious pathogens such as *Streptococcus agalactiae* and *Staphylococcus aureus*. Herd bacteriologic cultures are sensitive and specific indicators of IMI caused by these and other organisms that have a long duration and relatively low rate of spontaneous cure. The magnitude of infection caused by coliform (lactose fermenting, gram-negative rods of the family Enterobacteriaceae) organisms is often poorly described by herd culture of cows at one point in time, because infections are more transient and most IMI spontaneously cure in less than 30 days. In addition, clinical signs of mastitis that develop as a consequence of coliform IMI usually persist for less than 7 days. Thus routine culture of suspect cows with high SCC following monthly testing by Dairy Herd Improvement (DHI) organizations would be timed poorly to identify the dynamics of clinical mastitis in a dairy herd if a high proportion of the causative agents are coliforms.

Prevalence studies of IMI in dairy herds have been reported (Brooks, 1982; Gonzalez et al, 1988; Erskine et al, 1987b). A review of this information requires particular attention to the method used to select study herds, the criteria for inclusion in the study, the sampling methodology used, and the techniques used for bacteriologic culture. There are undoubtedly broad variations among different countries, regions, and individual herds for the prevalence of contagious pathogens. Numerous studies have identified that herds with low SCC have low prevalence of IMI caused by contagious pathogens (Eberhart et al, 1982; Hogan et al, 1989b; Schukken et al, 1989a; Erskine et al, 1987b). In a Pennsylvania study (Erskine et al, 1987b) the herd management characteristics and prevalence of mastitis in a group of dairy herds with a high mean herd SCC (>700,000 cells/ml) was compared with a group of herds with a low mean SCC (<150,000 cells/ml). In the low SCC group, 0.2% of the cows were infected with *Str. agalactiae* compared with 50.9% in the high SCC group. Similarly, the *S. aureus* prevalence was 1.8% versus 22.2% in the low and high SCC herds, respectively. It was clear from this study that implementation of the NMC-recommended mastitis control practices drastically reduced prevalence of the major contagious mastitis pathogens. The prevalence data for minor pathogens, such as *C. bovis* and *Staphylococcus* sp., vary among herds, but a high proportion of cows may be infected with staphylococci even in herds with relatively low SCC.

The mastitis *incidence* is the number of new cases of IMI or clinical mastitis in the population at risk during a given period. Mastitis incidence relates to how much the udder health status is changing, and always involves time in the denominator. A commonly used mastitis incidence parameter is the number of new cases of mastitis in the milking cows per month. For descriptions of mastitis cases that have a high percentage of spontaneous cure, or for types that have a high removal rate from the herd by culling or death, incidence is a better measure than prevalence. For example, herds that experience cases of environmental mastitis caused by coliform agents should monitor udder health status using incidence rather than prevalence of infection. Measuring mastitis incidence using a whole herd culture approach typical of prevalence determination requires the laborious and expensive task of repeated culturing of individual cows in the herd at regular intervals. Thus it is far more practical and more common to sample cases of clinical mastitis when they occur to estimate mastitis incidence. Monitoring the occurrence of clinical cases of mastitis can be an effective method of determining the changes in udder health status over time, particularly in herds with low bulk milk SCC (Schukken et al, 1989a). The usefulness of calculating incidence for cows that change from under to over a SCC threshold value has been studied (Dohoo and Leslie, 1991). It was found that this method was not a particularly sensitive test on an individual cow basis. However, on a herd basis, it could be useful for the detection of changes in udder health status.

The incidence of clinical mastitis has been compared between high and low SCC herds (Erskine et al, 1988). The incidence was considerably higher in the low SCC herds. Over 50% of bacteriologic isolations from the clinical cases in these herds were caused by either coliform or environmental streptococcal organisms. In the high SCC herds, over 60% of the clinical cases yielded bacteriologic isolation of *Str. agalactiae* or *S. aureus*. It is also noteworthy that over three times as many clinical cases were found to have negative bacteriology in the low SCC herd group. These results support the general conclusion that dairy herd managers should not expect a decrease in the incidence of clinical mastitis as the general herd udder health status and bulk milk SCC improve. In other studies of clinical mastitis in herds with low bulk milk SCC, a similar wide variability in incidence has been reported (Hogan et al, 1989b; Schukken et al, 1989a; Gonzalez et al, 1990). In the Dutch survey the mean incidence was less than the surveys reported from

Downloaded from Vet-e-Books.com

North America (Schukken et al, 1989a). Also, the proportion of clinical cases caused by *S. aureus* was substantial at 13.0% (Schukken et al, 1989a), although a case study of one herd in Ohio reported a high incidence of clinical mastitis caused by *S. aureus* in a herd with low bulk milk SCC (Hoblet et al, 1988). Thus there is a great need to implement systems to record and analyze the herd data on clinical mastitis incidence. This information may prove to be extremely useful in making refinements in the mastitis control efforts of the herd.

WHY MASTITIS CONTROL SHOULD BE PART OF A DAIRY HERD HEALTH PROGRAM

The goal of mastitis control is the production of quality milk. Dairy farms are economic enterprises, and thus veterinary practitioners need to engage in areas of dairy cattle health that not only ameliorate animal suffering but also promote economic viability of the dairy as a business. Aspects of the dairy enterprise related to cow health that offer the greatest opportunity for financial and production efficiency should be surveyed. Mastitis causes greater economic losses to the North American dairy industry than any other infectious disease. Much of these losses relate to lost production from inflammation in the infected quarters. Losses, especially with chronic IMI, accrue on a daily basis, and although they are not as dramatic as those resulting from severe clinical cases for the short term, they can be substantial over an entire lactation. SCCs are positively correlated to infection prevalence and thus lost milk production. Conversion of SCC to linear scores provides a direct linear relationship between SCC and potential milk yield losses (Table 10-1).

Although the most substantial loss associated with chronic mammary inflammation is lost production, there are other potential areas of concern for the dairy producer. Many regulatory bodies use SCC as a measure of milk quality and thus establish limits that either serve as criteria for the ability to market milk or initiate monetary penalties for continued marketing of milk over the limit. There are often regulatory limits for raw bacteria counts as well, and in some instances, elevated raw bacteria counts can be caused by a high prevalence of mastitis. In the United States the price that dairy producers receive per pound of protein marketed (multicomponent pricing) is progressively higher for each 50,000 cells/ml increment below 300,000 cells/ml, and progressively lower for each 50,000 cells/ml increment above 400,000 cells/ml (Table 10-2). Many milk cooperatives and processors also pay direct monetary bonuses for quality milk that includes maintaining low SCC and raw bacteria counts in marketed milk (Table 10-2). In addition, some milk marketing cooperatives pay volume bonuses based on the amount of milk marketed by a dairy, but only if the producer maintains the bulk tank SCC below a certain level, usually in the range of 300 to 350,000 cells/ml. Although this varies with marketing cooperatives and local regulatory agencies, incentives that promote the production of quality milk well below that considered adequate for regulatory limits reflect milk buyers' concerns over the lower cheese yield, shelf-life, and higher rancidity associated with higher SCC as well as consumer desire for milk to be a wholesome food product.

As previously noted, death of the cow can occur in more severe cases of clinical mastitis. This generally occurs in a small minority of cases and leaves a lasting, and often exaggerated, impression with dairy farm managers as to the cause of mastitis losses from clinical mastitis. Likewise, dairies that suffer few, if any, deaths from severe clinical mastitis or that have a low incidence of severe clinical mastitis may have the mistaken impression that losses from clinical mastitis in their herd are not important enough to monitor. The two predominant economic losses resulting from clinical mastitis are lost production, which can be difficult to estimate unless daily milk weight technology is used in a herd, and, perhaps more importantly, discarded milk following treatment with antimicrobials. Combined with other expenses such as drugs, labor, and veterinary care, average costs of clinical mastitis cases can range from $100 to

*Current regulatory limit for permit to market grade A milk in the United States is 750,000 cells/ml.
†Varies with milk order (region) and price of cheese.
‡Additional premiums include $0.05/cwt for both a raw bacteria count (standard plate count) of ≤10,000 cfu/ml and a preliminary incubation count (PI) of ≤20,000 cfu/ml. To qualify for premiums, producers may not have during the month: (1) positive drug residues, (2) abnormal freezing point, and (3) rejected load shipment.

$200/case and $40 to $100/cow in herd per year (Hoblet et al, 1991; Bartlett, 1991; Erskine, 1995).

Further losses from mastitis occur from premature culling of cows. This can arise following unsatisfactory convalescence after a severe clinical case, cows that are culled because of recurring clinical cases, or chronically infected cows that contribute high SCC to the herd average. Particularly with respect to contagious pathogens, culling is an important method of decreasing the reservoir of new infections. Lost genetic potential of culled cows and their offspring is possible but is predicated on many unknowns, not the least of which is the ability for the culled cow to propagate viable heifer calves on a regular basis. Other concurrent diseases that may decrease production would enhance the rationale for culling a cow with mastitis. More direct losses are incurred if culling forces the producer to maintain low-producing cows in the herd that preferentially would have been culled, or entering heifers into the milking herd that may have generated income from sale as replacement stock. If expansion is part of the herd plan, culling from mastitis may decrease the ability for a farm to realize cow numbers that fully utilize the physical plant of the dairy or force additional purchases of cows to maintain cash flow.

Finally, mastitis is the most critical disease on dairy farms that affects the incidence of antimicrobial residues in marketed milk. Mastitis is the primary cause of antimicrobial therapy in adult dairy cattle and thus is the primary cause of antimicrobial residues in marketed milk. It is essential for practitioners to integrate mastitis therapy protocols into a health program for dairy herds. Involvement from dairy producers is obtained because of rigorous regulatory monitoring of marketed milk and substantial financial losses for milk that is marketed with violative residues.

Practitioners who convey the economic principles of the benefits of a mastitis control program to dairy clients will more likely secure the monetary investment and time and labor commitment to successfully achieve the production and marketing of quality milk. Herds should attempt to apply universal management practices such as those suggested in Box 10-1. However, in order to design a mastitis control program that will offer the best economic benefits to the dairy farm, practitioners need to develop a program that is best suited to the herd on an individual herd basis, preferably with use of comprehensive herd records. The steps that a practitioner should follow to design a mastitis control program are: (1) to establish goals with the herd managers, (2) to assess if the current mastitis control program is meeting the goals, (3) to implement mastitis control practices that are likely to reduce losses from mastitis, and (4) to establish a monitoring program to evaluate the success of the management changes.

EPIDEMIOLOGY OF MASTITIS

The causation of mastitis involves a complex relationship of three major factors: host resistance, microbial agents, and the environment. Host defense mechanisms are critical in affecting the susceptibility of the dairy cow to udder infection (Nickerson, 1987). However, the characteristics of specific microbial agents and the influence of the environment can also affect development of the disease. The environment of the cow should allow them to be clean, dry, and comfortable. Bedding or other housing conditions that pro-

Downloaded from Vet-eBooks.com

vide nutrients to bacteria (organic bedding such as sawdust) or are damp or wet will promote greater exposure of pathogens to the cow's teat end and thus promote a higher incidence of mastitis. Therefore a herd mastitis plan should include provisions to house cows adequately in all stages of the lactation cycle, including the dry period and the maternity pen, and to provide the best possible support to enhance host resistance.

Host Factors

Host characteristics are important risk determinants in the pathogenesis of mastitis (Grommers, 1988). These factors are associated with the development of specific immunity and with nonspecific host defense mechanisms (general resistance). This general resistance by the host relates to genetic predisposition, anatomical characteristics, nutritional status, stage of lactation, parity, and use of management procedures to enhance resistance.

Genetic Resistance

There is ample genetic evidence that the heritability of SCC allows for selection against susceptibility to mastitis (Shook, 1989). There is also evidence of the genetic correlation between milk production and mastitis (Kennedy et al, 1982; Syvajarvi et al, 1986). Selection for milk yield has been accompanied by increased susceptibility to disease (Shook, 1989). It is speculated that long-term selection pressure for milk production may have had a negative effect on the polymorphism of the immune response genes linked to the major histocompatibility complex (BoLA) in the dairy breeds (Lewin, 1989).

Physical Characteristics, Teat Lesions, and Leaking Milk

Anatomical characteristics of the teat and udder affect general resistance to mastitis. Specifically, teat shape is associated with increased risk of clinical mastitis (Van de Geer et al, 1988). Similarly, the integrity of the teat streak canal is important (Jones, 1986). Leaking of milk between milkings has been associated with an increased risk of clinical mastitis (Schukken et al, 1989c; Van de Geer et al, 1988). The presence of continuous milk flow provides a route for invasion from the environment into the teat cistern. Teat-end lesions operate on a similar principle as an important risk factor for mastitis (Dohoo et al, 1984a).

Stage of Lactation

Stage of lactation is a determinant of both subclinical and clinical mastitis. Mastitis caused by environmental organisms, such as clinical coliform infection, is most common in the first few days after calving and occurs less as lactation progresses (Erb et al, 1984; Erskine et al, 1988; Hogan et al, 1989b; Schukken et al, 1989a). General immune function and the mammary influx of leukocytes both markedly decrease shortly after calving (Kehrli et al, 1989). In addition, humoral defense mechanisms that have increased in the dry period suddenly decrease after calving (Nickerson, 1989a). Increased serum cortisol concentrations at calving are also associated with decreased glucocorticoid receptor expression, which results in decreased L-selectin expression in neutrophils (Preisler et al, 2000). L-selectin is a critical membrane protein necessary for neutrophil margination and diapedesis into a site of inflammation, such as a mastitic quarter. This offers a molecular rationale for increased susceptibility of cows to mastitis in the periparturient period and supports earlier research that noted the decreased ability of recently calved cows to recruit neutrophils into the mammary gland during severe coliform mastitis (Hill et al, 1979). On the other hand, the prevalence of subclinical infections increases as the stage of lactation progresses. These infections are generally the result of contagious mastitis pathogens, such as *S. aureus*. This is caused by an inability of mastitis control efforts to limit cow-to-cow transmission of organisms rather than by a physiological effect.

Parity

Increasing parity is a risk factor for increased incidence of clinical mastitis as well as for an increased prevalence of subclinical infections (Dohoo et al, 1984b; Schukken, 1989c). Although heifers are often subjected to different management practices than older cows before calving, they should have equal exposure to pathogenic microorganisms as milking animals. Younger cows may have a decreased susceptibility to mastitis because they may have a more effective host defense mechanism. They have significantly better polymorphonuclear leukocyte function than multiparous cows (Dulin et al, 1988). On the other hand, Hogan et al (1989b) found the highest incidence of clinical mastitis in first-lactation animals.

Nutrition and Periparturient Diseases

Proper feeding of the peripartuient cow affects the incidence of numerous metabolic diseases. Periparturient diseases, such as dystocia, parturient paresis, retained placenta, and ketosis have all been identified as risk factors for the subsequent development of mastitis. In a study of 137,000 calvings, cows experiencing dystocia had a 1.5 times increased risk of clinical mastitis (Bendixen, 1988). Multiparous cows with parturient paresis had a fivefold higher risk of developing clinical mastitis compared with multiparous cows without parturient paresis (Curtis et al, 1983, 1985). Animals that retained the placenta were two to three times more likely to develop mastitis (Bendixen, 1988; Schukken et al, 1989c). In studies by Dohoo and Martin (1984a) and Syvajarvi et al (1986), animals with a history of ketosis were at increased risk of mastitis. The biological explanations for these associations but have not been explained definitively.

Colonization with Minor Pathogens

There may be broad effects of management intervention and mastitis control practices on host resistance. For example, the long-term use of postmilking teat disinfection has been hypothesized as a risk factor for clinical mastitis in low SCC herds. The increased risk is thought to result from a reduction in the prevalence of minor pathogens (Hogan et al, 1987; Robinson et al, 1983; Schukken et al, 1989a). Studies have been designed to decrease the infection opportunity by major mastitis pathogens through colonization of the glands with minor pathogens, such as *C. bovis*. These experiments have shown both decreased (Brooks and Barnum, 1984; Matthews et al, 1989) and increased incidence (Hogan et al, 1988b) of infections by major organisms. A field trial involving four herds with moderate levels of infection demonstrated that premilking teat disinfection in combination with a postmilking teat dipping program decreased the incidence of infection with environmental pathogens (Pankey et al, 1987). The whole subject of infections with minor pathogens providing a protective effect against the development of infection with a major organism still requires considerable elucidation.

Downloaded from Vet-e-Books.com

Immune Modulation

Immune modulation has been attempted in order to enhance mastitis resistance. In a field study of 13 farms using recommended mastitis control programs, cows with the physical immunostimulation provided by an intramammary device were observed to have a 4.6 times lower incidence of clinical mastitis than cows without the device (Paape et al, 1988). Other attempts at nonspecific immunostimulation to prevent mastitis have been described for levamisole (Anderson, 1984); concanavalin A (Oliver and Sordillo, 1989), interleukin-2 (Nickerson, 1989a), and thymosine (Kehrli et al, 1989). Most methods of nonspecific immunostimulation have only been tested under experimental conditions. Field trials for many prospective immune modulators have not been described or have proved to have less than desirable results (Hogan et al, 1995; Erskine et al, 1998a).

Vaccination

A great deal of research has been aimed at improving the specific resistance of dairy cows to mastitis by vaccination to produce immunity against the major mastitis organisms (Colditz and Watson, 1985). Most of this research has focused on the prevention of *S. aureus* and *Escherichia coli*. Vaccines against *S. aureus* mastitis have been developed in Australia (Colditz and Watson, 1985; Frost and Mattila, 1988) and have shown some promise against experimental challenge. A field trial was conducted to evaluate the efficacy of *S. aureus* mastitis vaccine developed against pseudocapsular components of the pathogen in commercial dairy herds in Australia (Watson and Schwartzkoff, 1990). Even with considerable herd-to-herd variation, there was an overall reduction in *S. aureus* clinical cases and in the levels of subclinical mastitis. This represents a considerable improvement over previous staphylococcal mastitis vaccines. However, longer-term studies are necessary for the validation of these findings and for the support of cumulative improvement with several years of vaccination in a herd.

Field trials using a mutant *E. coli* J5 (core-antigen) vaccine have shown a decrease in the incidence of coliform mastitis (Gonzalez et al, 1989; Cullor, 1991). Both of these trials used an untreated group for the control. Further studies with experimental *E. coli* infections have supported the belief that vaccination with core-antigen vaccines decreases severity of infections. Commercial products that use this technology have become available and will be discussed in greater detail in the section regarding environmental mastitis.

SCREENING TESTS FOR DETECTING MASTITIS

In order to select an appropriate screening test and to interpret the results of the test properly, it is important that the test be evaluated with epidemiologically sound criteria. The sensitivity, specificity, predictive value, and efficiency of a test are helpful in determining the appropriate situations for its use. In the context of a mastitis screening test, sensitivity is the ability of the test to yield a positive result when the cow actually has mastitis. The specificity of a test is its ability to discern that an animal is actually negative for mastitis.

It is essential that an excellent method of determining true mastitis status be used in order to have a meaningful evaluation of the sensitivity and specificity of the screening test. For most evaluations of mastitis screening tests, milk bacteriology has been the gold standard. However, there are situations in which culture results may not provide the best assessment of the true status. Some of these situations are described later in this chapter.

For tests with a continuous numerical result, such as SCC, a threshold value is used to classify the result as positive or negative. Selection of the threshold level can greatly affect the sensitivity and specificity of the test. A mastitis screening test with a high sensitivity can reduce the number of cows incorrectly classified as negative (false-negatives). A highly specific test reduces the false-positive rate (those animals incorrectly classified as having mastitis). The choice of the threshold value depends on the purpose of the test. For example, the use of SCC data to select cows for dry period therapy would favor a high sensitivity, with minimal false-negative results. Thus the threshold would be lowered to enhance the test sensitivity. This would ensure that as many infected cows as possible would be dry treated, even at the expense of treating some false-positive (uninfected) cows. On the other hand, the use of SCC in culling decisions would favor a highly specific test with a low false-positive rate. In this situation a higher threshold would be used to improve the reliability that a high SCC cow truly had mastitis. A schematic representation of the relationship of sensitivity to specificity and the importance of the threshold value is shown in Fig. 10-1.

The sensitivity and specificity provide information about a mastitis screening test while assuming a known rate of mastitis in the population. However, it is much more common to have the test result and to desire information about the state of the disease in the population. In other words, what is the predictive value of the test? The predictive value of a test depends on its sensitivity, specificity, and prevalence of the disease in the herd. The positive predictive value (PV+) is the probability that a cow with an SCC over the selected threshold is infected. The negative predictive value (PV−) is the probability that a cow with an SCC under the threshold is not infected. The proportion of cows in the herd that have mastitis greatly affects these values. As the prevalence of infection in the herd increases, the positive predictive value increases and the negative predictive value decreases. In other words, in a herd with a high prevalence of mastitis, the likelihood of a cow over the 250,000 SCC threshold value being infected is greater.

The efficiency of a screening test is the total percentage of all cows that are correctly classified as to infection status with the test result. The overall efficiency of a test, such as SCC, is not particularly meaningful, because it is unaffected by changes in prevalence and is relatively constant.

In summary, appropriate implementation of a mastitis screening test into an udder health management program depends on an understanding of the characteristics of the test. In a particular herd situation, the usefulness of a specific test depends on its sensitivity, specificity, and predictive value. Care must be taken that the "gold standard" used to determine screening test performance is the best estimate of true mastitis status in each particular situation.

Milk Bacteriology

Incubation of a standard volume of aseptically collected milk that has been streaked on an agar culture medium has been the standard diagnostic method for bovine mastitis for many years. The resulting bacterial growth is observed, quantified, and tested. Standard microbiological procedures for use in the diagnosis of bovine mastitis have been widely adopted. In fact, the use of milk culture is widespread as a means to determine udder health status. It is the definitive, standard diagnostic test for determining if an infection exists as well as the causative agent.

Many countries have developed a regional system of diagnostic laboratories dedicated to the bacteriologic culture of milk. The standard methodology used in most of these laboratories involves an individual milk sample being streaked

Downloaded from Vet-e-Books.com

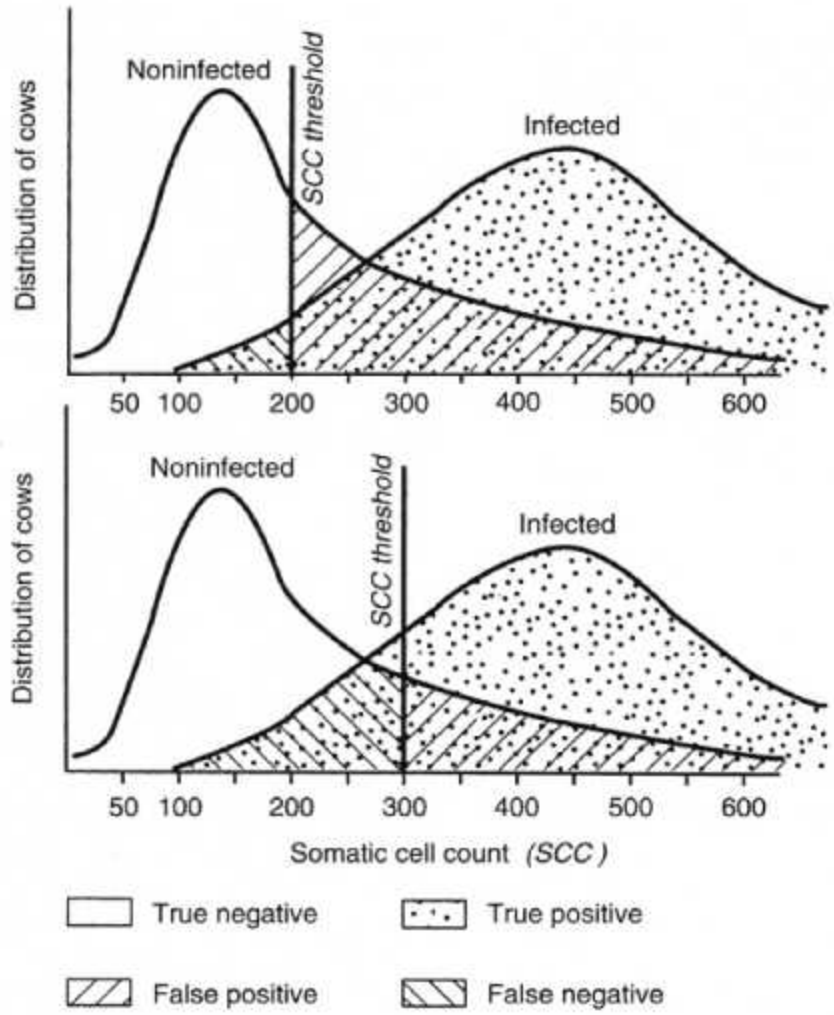

FIG. 10-1 Schematic representation of the effect of changing the somatic cell count threshold value for the classification of cows as positive or negative.

onto one of four quadrants of a blood agar plate with the use of a sterile cotton swab or flamed loop. The plates are incubated at 37° C for 18 to 24 hours and longer for slow-growing organisms. Identification of organisms is done by colony morphology, microscopic examination, and further laboratory tests. Effective use of these culture results can play a major role in the improvement of udder health status at the individual cow and herd levels.

Although the microbiological culture of milk has become the undisputed standard diagnostic procedure in mastitis control, there are several key points to be considered. Relative to other tests, such as SCC, bacteriology is labor intensive and expensive to conduct. Furthermore, even though milk culture is assumed to be the standard test, it has seldom been subjected to formal epidemiological methods of test evaluation. The sensitivity, specificity, and predictive value of bacteriologic tests for diagnosing subclinical contagious mastitis has been reviewed (Jensen and Knudsen, 1990; Buelow and Nordlund, 1999). Diagnostic procedures that are based on the bacteriologic examination of single foremilk samples have a low positive predictive value for the diagnosis of infectious subclinical mastitis, especially *S. aureus*. Even in combination with a fixed SCC threshold value to determine positive cows, milk bacteriology has a low sensitivity for minor pathogens.

Isolations of bacteria from milk samples can be difficult to interpret. The isolation may be a result of teat streak canal colonization or of overt contamination in the sampling process. The least amount of errors occur when a diagnosis is categorically based on bacteriology alone (Neave, 1975). However, a completely objective reference method was not used to evaluate bacteriologic tests. The quantification of the number of colonies recovered cannot be strictly interpreted as a measure of diagnostic sensitivity. For example, a milk sample yielding 400 colonies of *Str. agalactiae* can be equivalent to a sample with a culture result of only a few colonies (Villanueva et al, 1991).

For contagious mastitis pathogens, identification of all infected cows, and on some occasions infected quarters within a cow, is important in the overall control effort. The standard definition of an IMI is the isolation of a pathogen from two of three consecutive milk samples collected from a quarter on from three separate collection dates. Particularly for environmental pathogens, the probability for contamination of one sample is great enough to warrant concern over false-positive results unless the isolation is repeated on a subsequent culture. However, false-positive results occur infrequently enough with contagious pathogens that one positive isolation is considered indicative of an IMI. Repeated sampling of quarters can be labor intensive, thus one alternative is to use the collection of duplicate milk samples collected at the same time and isolation of the pathogen in both samples as being indicative of an IMI. Alternatively, composite samples collected and mixed from all four quarters of a cow are easier to collect and cause less cultural needs. The chance of contamination is higher however, and this method should really only be used to identify potentially infected cows with contagious pathogens (low false-positive rate) and perhaps as a screening test for IMI caused by more chronic pathogens such as *Streptococcus uberis*, although follow-up sampling would be suggested to confirm the presence of IMI caused by environmental pathogens. Because *Str. agalactiae* tend to be shed in high concentrations in milk from infected quarters, the sensitivity of a single

Downloaded from Vet-e-Books.com

composite milk sample to detect an IMI is greater than 95% (Dinsmore et al, 1991). However, chronic *S. aureus* infections have been shown to have a periodic shedding pattern, and if negative results are obtained after culture, serial samples should be collected at least two more times in order to detect a positive quarter (Sears et al, 1990b; Daley, 1991a). Freezing of milk samples before bacteriologic testing has been shown to increase the isolation rate of contagious pathogens (Villanueva et al, 1991; Schukken et al, 1989b), which reflects the release of intracellular pathogens following lysis of phagocytes.

To have a profile of the organisms causing clinical mastitis in a herd, it is recommended that milk samples be collected aseptically from each clinical case before treatment and that the samples be stored by freezing. At a convenient time, such as a scheduled health management visit, the frozen samples should be gathered and cultured. The incubation of mastitic milk samples before bacteriologic culturing can be used to decrease the negative culture rate from clinical cases (Schukken et al, 1989b). In cases of clinical mastitis caused by environmental organisms, negative bacteriologic culture findings are common.

Bacteriologic culture of bulk tank milk can be a useful indicator of udder health status at the herd level. Regular, repeated cultures of a standard volume of bulk milk on selective media can be useful for determining the presence of *Str. agalactiae, S. aureus,* and *M. bovis* (Godkin, 1990). The value of bulk tank cultures for determining the presence of environmental pathogens is limited because of potential contamination, and almost all herds have cows infected with streptococci and staphylococci at any point in time. Likewise, care should be taken in trying to assess the prevalence of IMI in a herd based on bacteria counts from bulk tank culture. Sampling of individual cows and monitoring the proportion of cows with elevated SCC is more accurate.

In summary, milk bacteriology continues to be recognized as the definitive test for determining infection status in mastitis research and udder health management programs. This widespread use of bacteriology is perfectly acceptable as long as its epidemiological characteristics and limitations are considered. Contagious pathogens are not frequently associated with false-negative results; however, negative isolations from suspected infected cows may warrant repeat culture to increase the sensitivity. Pure isolations of any pathogen collected from quarters of clinical mastitis cases can be used as an identification of etiological agent. However, routine culture of environmental pathogens, especially from subclinical cows or quarters, and those with low linear SCC should be suspected as contaminants, and follow-up samples or duplicate samples collected at the initial sampling should be cultured to improve specificity.

Somatic Cell Counts

The counting of somatic cells excreted in the milk has become a widely used indirect measure of mammary gland inflammation. Somatic cells (predominantly neutrophils, as well as other leukocytes and epithelial cells) enter the mammary gland as a result of damage to the alveolar lining by infection or chemical irritation. The cells can be counted by a laborious direct microscopic method on stained milk smears. The cell numbers can also be estimated by indirect chemical tests. However, the electronic enumeration of cell numbers in either preserved or fresh milk samples has revolutionized the potential for monitoring udder health status (Meek and Barnum, 1982). The most commonly used automated device for rapid determination of the SCC in milk samples is the Fossomatic milk cell counter (Foss Electric, Hillerod, Denmark). This instrument stains cells with a fluorescent dye and then counts the number of fluorescing particles. This electronic technology is capable of the rapid, inexpensive determination of SCC in large numbers of samples. The instrumentation can be linked electronically to large computer data files. This has allowed DHI organizations to develop programs for the routine screening of preserved composite milk samples from individual cows. Bulk tank milk samples are routinely tested for SCC by regional regulatory laboratories and milk cooperative facilities.

Factors Affecting Somatic Cell Counts

The correct interpretation of SCC data depends on an understanding of the factors that influence the number of cells in milk at the quarter, cow, or herd level (Dohoo and Meek, 1982). The factor with the greatest effect on SCC is intramammary infection. In comparison, all the other factors that affect SCC are of only minor importance. There are considerable differences in mean SCC levels from composite milk samples of individual cows, according to their infection status. Cows that are free of infection have significantly different mean SCC levels than those with major or minor mastitis pathogens. However, within each of these groups the SCC is widely variable (Dohoo et al, 1981). There is even some variation in SCC response elicited by various major pathogens, yet it is not possible to distinguish among the pathogens on the basis of SCC alone. The SCC of an individual cow composite sample depends on the number of quarters infected, the severity of infection in each quarter, and the respective milk production of each quarter. The dilution of high SCC milk from infected quarters with low SCC milk from uninfected quarters is an important consideration in the interpretation of a composite sample cell count.

The practical use of SCC data to determine cow infection status requires the selection of a threshold level. The importance of threshold selection has been described previously. If the aim of monitoring SCC is to detect cows that may only have subclinical mastitis in one quarter, then the use of an SCC threshold value of 200,000 cell/ml appears to be reasonable (Dohoo and Meek, 1982). Fig. 10-1 illustrates the effect of selection of a threshold value on the occurrence of false-positive and false-negative classifications.

Factors other than infection can cause a substantial SCC increase. Chemical irritants, such as antibiotic therapy, can cause raised SCC. Trauma to the udder can also cause higher than normal SCC levels. Experimentally induced stress on individual cows has resulted in higher SCC. The time and method of sampling may affect the resulting SCC value. For example, counts are lowest immediately before routine milking and are highest in stripping samples. Samples at evening milkings are somewhat higher than in the morning. There is considerable variation in SCC of an individual cow from day to day. The reasons for this diurnal variation include fluctuations in production, spontaneous elimination of new infections, unobserved udder injury, stress, and inherent biological variation of individual cows. Therefore it is prudent to draw conclusions from a series of SCC values rather than to base an interpretation on one mildly elevated count.

On a regional basis, bulk milk SCC monitoring programs have shown some seasonal variation, with cell counts higher in summer and early fall than in winter or early spring (Dohoo and Meek, 1982). This seasonal variation is not large, and has been attributed to the increased stress of cow movement on the udder resulting from the pasture and loose housing systems used in the summer months, and to

Downloaded From Vet-eBooks.com

greater numbers of environmental bacteria in the bedding of cows (Smith et al, 1985c).

Two of the more substantial factors affecting the SCC of individual cows are age and stage of lactation (Dohoo and Meek, 1982). As cows become older, the SCC is generally higher. This SCC elevation results from an increased prevalence of subclinical infections with age, a greater cellular response to infections in older cows, and an increased amount of residual damage from previous infections. In cows that have never had an intramammary infection, however, there is no increase in SCC with age. Considerable variation in SCC occurs relative to the stage of lactation. Greatly elevated counts are observed immediately after calving. The SCC returns to normal at approximately 8 to 14 days postpartum. Counts also rise just before drying off, as milk production decreases markedly. The observed increase in SCC that tends to occur as the stage of lactation progresses is probably caused by an increased prevalence of subclinical infections in later lactation. There is no evidence that SCC changes throughout lactation, provided IMI does not occur. In other words, in herds that have a low prevalence of infection by having controlled contagious pathogens, there should be little evidence of change in the SCC distribution with stage of lactation.

Some technical factors, such as method of transportation, use of milk preservatives, time in storage, and type of cell counting instrument can affect SCC values. However, these technical factors are unlikely to be important in any routine SCC monitoring program.

The interpretation of SCC data as a measure of infection status for problem solving and decision making in udder health management programs require consideration of all factors affecting the SCC.

Epidemiological Evaluation of SCC

The SCC has been epidemiologically as a screening test for subclinical mastitis in individual cows, using bacteriology as the standard test (McDermott et al, 1982; Dohoo et al, 1981). At a threshold value of 200,000 cells/ml, the sensitivity of the SCC for determining infection is approximately 80%. In other words, roughly 20% of infected cows have SCC levels of less than 200,000 cells/ml. The specificity of SCC at this threshold is approximately 75% to 80%. That is, 20% to 25% of noninfected cows have SCC levels greater than 200,000 cells/ml. As described earlier, the SCC threshold can be changed to improve specific decision-making purposes, such as selection of cows for dry cow treatment or for culling. Using a threshold of 200,000 cells/ml, the sensitivity and specificity values discussed show that SCC is a helpful screening test. The prevalence of mastitis (cow infection rate), however, changes the predictive values. As the prevalence of infection in the herd goes up, the positive predictive value of SCC also goes up. In other words, a cow over 200,000 cells/ml is more likely to be infected. However, the negative predictive value is reduced because cows under 200,000 cells/ml are less likely to be free of infection. Over a range of cow infection rates from 5% to 50%, the efficiency of SCC as a screening test changes little (75% to 78%, respectively). Efficiency is the total percentage of all cows tested that are correctly classified as to infection status at the chosen threshold (Dohoo et al, 1981). Eberhart et al (1982) emphasized that additional insight into the probability of a cow being infected was gained by knowing the actual SCC magnitude, as opposed to knowing only the status relative to the chosen threshold. As the SCC increases over the threshold, the probability of infection with a major pathogen also increases.

Somatic Cell Counts Converted to Linear Scores

Somatic cells are measured as thousands of cells per milliliter of milk and can range from tens of thousands to many millions. Converting the actual SCC to a natural logarithmic scale (linear score) can improve the usefulness of SCC for herd management purposes. Linear scores (LS) reduce the SCC to a scale ranging from 0 to 9. The corresponding values for SCC and LS are shown in Table 10-1. An increase of one unit in LS corresponds to a doubling of SCC. For example, the midpoint for LS3 is equal to a 100,000 SCC, LS4 to a 200,000 SCC, and LS5 to a 400,000 SCC. Any individual SCC can be converted to an LS value.

There are two major advantages for using LS rather than raw SCC values. First, there is a consistent, linear relationship between an increase in LS and milk production losses (Raubertas and Shook, 1982). The estimates of milk loss with each unit increase in LS are presented in Table 10-1. Second, the major advantage of using LS is in the averaging of counts. An average of several SCC values is more useful for analysis and interpretation than a single value. However, one extremely large SCC value can have a great effect on the average. An average of LS more accurately represents the lactation average of an individual cow or the average of a particular management group. Thus average LS values are more effective for mastitis management purposes. This advantage is particularly important in small herds. A worksheet that provides a method to calculate potential production losses from mammary inflammation based on individual cow LS is presented in Chapter Appendix A (p. 432).

Fig. 10-2 is an example SCC report provided by the Dairy Records Management Systems for a dairy herd in Michigan.* Fig. 10-2, *A* (SCC Profile DHI-520) provides a herd average SCC and a summary of individual cows in the herd. The owner may choose actual or linear SCC for the individual cows. Actual scores are provided in this report, and data are presented for the last six test dates. If a cow was one of the 26 cows in the herd with an SCC above 200,000 cells/ml (LS >4.0) in the current test month, she was classified as having a new or chronic (two or more consecutive test dates ≥200,000 cells/ml) IMI. Chronic cows based on this report are likely to be infected and would make excellent candidates for sampling for culture. Cows are ranked from those with the highest contribution to the bulk tank SCC on the top (cow no. 31; 19%) to the lowest SCC contributors on the bottom (Sally; <1%). This ranking is a function of SCC and milk production so that culling decisions based on SCC alone would be tenuous; however, a within herd classification on 305-day mature equivalent production is also provided for each cow. Cows with an "A" ranking are superior cows within the herd, the "E" cows the most inferior. Thus, from a standpoint of SCC, cow no. 45 and Connie would be good candidates to be on the cull list. Cow no. 31 is contributing 19% of the bulk tank SCC, but she is a better-than-average cow for production and had a marked elevation in SCC since the last test. A history of this cow regarding possible clinical mastitis, and a culture of a milk sample to identify the causative agent would be helpful. Cow no. 85 has only one test and has not yet displayed a chronic IMI. However, this cow is a second-lactation animal, and previous lactation records should be examined to determine if the current IMI was continued through the dry period, in which case this cow would also be a good candidate to be on the cull list. Additional information regarding causative pathogen, breeding history, and other health problems would also need to be weighed into the decision. Fig. 10-2, *B* (SCC summary DHI-521) provides a distribution of LS, a

profile of LS by days in milk and lactation number, and an estimate on milk loss per day for each cow and the entire herd. Fig. 10-2, *C* (SCC graphs DHI-522) provides graphic comparisons of the test herd to the best 25% of the herds in the state and SCC for the last 14 months.

Summary: Interpretation and Use of Individual Cow Somatic Cell Count

It is important to choose a threshold SCC value to suit the management purposes of the mastitis control program. In most herds, 200,000 cells/ml detects approximately 80% of infections and correctly classifies 75% to 80% of noninfected cows. At any threshold, infected cows can be missed and negative cows can be classified incorrectly as infected. The probability that a cow is infected goes up with the magnitude of the cell count. For any given SCC, the probability that the cow is infected varies according to the prevalence of subclinical mastitis in the herd. The interpretation of a series of SCC values over time is more effective than the evaluation of a single count. Regardless of the infection status, the SCC is an excellent indicator of udder health status. The natural logarithmic conversion of SCC to a linear score is useful for herd management purposes. Linear scores are directly related to milk production losses. An average of LS removes the problem of the adverse effect of one or two extreme SCC values on the raw SCC average. The reporting by DHI organizations of SCC and LS data on individual cows, and in a variety of herd summary graphs and tables, has become an important tool in describing the extent of subclinical mastitis and in serving as a selection criteria for determining which cows should be sampled for culture.

Other Diagnostic Tests

Several other diagnostic tests have been developed to detect intramammary inflammation. This is accomplished by measuring milk somatic cells indirectly or by determining the concentration of various by-products of the inflammatory response. Many of these tests have been compared formally for detecting mastitis (Emanuelson et al, 1987). Some of the tests may have a role in mastitis control programs, either as rapid cowside methods to determine which quarter is infected or as automated in-line detection methods for milking parlors.

California Mastitis Test

The California Mastitis Test (CMT) involves mixing and swirling equal parts of bromcresol violet reagent and milk in a plastic paddle with a compartment for each quarter. This test is inexpensive and extremely portable. The test results are interpreted subjectively as either a negative, trace, 1+, 2+, or 3+ inflammatory response based on the viscosity of the gel formed by mixing the reagent with the milk. The CMT can be a useful adjunct to laboratory screening tests performed on composite milk. For example, individual cows that are positive on composite sample DHI SCC results can be checked with a CMT. This determines whether the cow has remained positive in the lag time since the DHI laboratory SCC test was conducted. In addition, the CMT is also useful to determine which quarters are positive. Cows with mild clinical changes in a mammary gland, but with no abnormalities in the milk, can be evaluated readily using the CMT.

N-Acetyl-β-D-Glucosaminidase (NAGase)

The milk *N*-acetyl-β-D-glucosaminidase (NAGase) test is a simple and rapid microplate assay intended for the mass screening of milk samples. The amount of NAGase enzyme in milk is measured fluorometrically in the reaction between a substrate and milk (Kitchen et al, 1984). The NAGase activities of the milk samples being tested are compared with those of a milk standard. Interquarter differences are used to minimize the physiological variation among cows. The NAGase test may be more specific than some other tests because it detects the cellular damage during inflammation. Infection leads to the release of lysosome enzymes into the surroundings of the damaged cells. The procedures and equipment used to conduct the milk NAGase test are relatively simple and inexpensive. However, it has not received widespread adoption in North America.

Electrical Conductivity

Mastitic milk has a higher electrical conductivity (EC) than normal milk because of its higher electrolytic content, especially sodium and chloride ions. As a method of monitoring mastitis status, measuring EC is attractive. A conductivity sensor can be installed in the milk line to measure the EC of the milk from each quarter of each cow at every milking (Linzell and Peaker, 1975). A shift in electrolyte content in the milk is one of the earliest changes to occur with the development of mastitis. Therefore the automatic measurement of EC could be a useful early warning system.

Computerized milk EC monitoring systems are now available commercially for installation in milking parlors. Some difficulties have been encountered with the implementation of these system. Variations in the sensitivity and specificity of EC among herds have been reported as a considerable problem (Sheldrake, 1981). The use of a predetermined threshold of EC, without consideration of the differential conductivity between quarters, has led to diagnostic errors. It is important that the EC analysis be done on foremilk or stripping samples rather than during the main milk flow. Air bubbles in the milk can cause variations in EC results, and the electrodes can foul up because of milk and solids. However, with the development of protected in-line electrodes, and with the implementation of computerized data retrieval and analysis systems, the measurement of EC holds great potential for the automated monitoring of udder health. A summary of EC studies has been published (Nielen et al, 1992).

Hand-held conductivity meters, suitable for checking individual quarters, are now available. These devices give a digital readout of the EC result. This system represents an alternative to the CMT as a cowside diagnostic screening test.

Specific Antibody Test

Other than milk bacteriology, the diagnostic screening tests used in udder health management programs provide no indication of the causative bacterial agent. The recommendations for dealing with infected individual cows and for the specific components of an udder health management program depend somewhat on the predominant pathogen involved. Therefore it is important to have some method of specific bacterial identification. There is a great need for rapid, sensitive, and specific tests to identify microbial agents in milk samples directly. It is important that these tests can be conducted on preserved milk samples that have been collected for routine analytic purposes, such as DHI test day samples.

An enzyme-linked immunosorbent assay (ELISA) has been developed to detect the binding of *S. aureus* antibodies in milk to a purified antigen preparation (Adams, 1989). It has been shown that the shedding pattern of organisms in *S. aureus* infected quarters may be cyclic and, thus, periodically undetectable. A reported advantage of the *S. aureus* milk anti-

Downloaded from Vet-eBooks.com

body test is its ability to identify antibodies, even when the organisms may not be shed into the milk. The *S. aureus* antibody test and bacterial culture results have been compared (Gay and Fox, 1993; El-Rashidy et al, 1992). There were many false-positive results. The sensitivity and specificity of the test ranged from 59% to 93% and 89% to 100%, respectively. However, the use of milk bacteriology as a reference standard in this comparison may be inappropriate. Several DHIA laboratories have made this test available on samples already submitted for SCC and component testing. Systems need to be developed to use these results, in combination with SCC and milk bacteriology, for udder health management programs. Use of this technology has been outlined (Gay and Fox, 1993); in general, cows within 30 days of calving or with less than 30 lb of daily milk production should not be tested. If this system is to be used for identification of individually infected cows, then all cows should be tested at regular intervals. If a cow is test positive and is to be culled based on having an IMI caused by *S. aureus*, then confirmation of infection status should be done by bacterial culture of milk.

There is considerable difference in the cure rate of cows infected with different major mastitis organisms. It would be extremely useful to have rapid cowside screening tests to differentiate among these microorganisms. With rapid advancements being made in diagnostic methods through the use of biotechnology, such tests could be available in the near future.

Other Laboratory Tests

There are three other laboratory screening tests that have been evaluated for detecting mastitis (Emanuelson et al, 1987). Adenosine triphosphate can be extracted from milk and measured by light emission. Bovine serum albumin in milk can be determined by the radial immunodiffusion assay and measured by the diameter of a precipitation zone after 24 hours of incubation. The antitrypsin concentration in milk can be determined by a colorimetric procedure. All these tests can be used to determine the presence of udder infection. However, the potential for the large-scale use of these tests is most likely in combination with currently available screening procedures to increase the predictive value of the diagnostic process.

Summary

Because the vast majority of mastitis is subclinical, there is a great need for diagnostic screening tests to monitor the prevalence and incidence of IMI in an udder health management program. Many screening tests have been developed and tested. Milk bacteriologic tests are used as standard criteria. As new screening tests are developed and refined, individuals involved in dairy health management programs should be aware of the test performance characteristics and how they were evaluated.

CONTAGIOUS MASTITIS: GOALS, ASSESSMENT, AND CONTROL

Etiology

The contagious pathogens of primary concern in most dairies are *Str. agalactiae* and *S. aureus*, which are usually the predominant intramammary pathogens in herds with identified subclinical mastitis problems (bulk tank SCC routinely >500,000 cells/ml). SCCs average 900,000 to 2,240,000 cells/ml for quarters infected with *Str. agalactiae* and 1,500,000 to 1,820,000 cells/ml for quarters infected with *S. aureus* (Erskine et al, 1987b; Schultz, 1977). As a result, there is a strong correlation between herd SCCs and the number of infected cows in a herd. In herds with SCC ≥700,000 cells/ml, it is not unusual for at least 50% of the cows to be infected with these pathogens. Other pathogens, such as *C. bovis*, *Str. dysgalactia*, and *Arcanobacter pyogenes* are believed to have, at least in part, the infected udder as a reservoir for new infections. In addition, the contagious nature of *M. bovis* mastitis has been well described, and this pathogen has caused devastating mastitis outbreaks in some herds, particularly those that have expanded by addition of new animals into the herd. However, much of this section of the chapter will consider the identification and control of *Str. agalactiae* and *S. aureus* as the prototypical contagious pathogens.

Str. agalactiae is essentially an obligate udder pathogen (McDonald, 1977a). It spreads from cow to cow during milking, and it is typical for more than one quarter of an affected cow to be infected. Infections become chronic and remain for the most part in a subclinical state, with occasional, although rarely severe, clinical episodes. Colonization of the teat canal before invasion of the duct system of the gland is thought to be an important step in the initiation of infection. The best method to detect the presence of IMI caused by these organisms is by SCC screening and culture of milk samples from suspected quarters. Prevention of new infections must focus on procedures on the farm that are employed during milking of the cows. Elimination can often be achieved with treatment. Anecdotally, dairy managers who have experienced problems and subsequent resolution with *Str. agalactiae* mastitis note that cured quarters are softer and milk out quicker than when infected.

S. aureus also has a contagious reservoir of infection, and, as with *Str. agalactiae*, prevention focuses on milking procedures. *S. aureus* can colonize other tissues, particularly skin, thus there is more potential for other fomites of contamination than just milking equipment, such as milker's hands, or at times when teat skin is compromised after such trauma as cold-related chapping. *S. aureus* infections often result in deep-seated abscesses (McDonald, 1977a). Therapy is difficult, especially as resistance to antimicrobial drugs (particularly β-lactams) is more common as compared with streptococci (McDonald et al, 1976), and *S. aureus* may survive intracellularly following phagocytosis where antimicrobial concentrations are reduced. In addition, *S. aureus* has numerous extracellular substances that impart an ability to survive in the presence of a hostile host immune system. Consequently, elimination of infections by antimicrobial treatment is often not successful.

Goals

The goals of a contagious mastitis control program for a dairy are to produce and market the optimum amount of quality milk. Regulatory limits provide the framework for milk quality, but these limits do not promote optimum production of the cow and, as previously described, optimum profitability for the farm. Table 10-3 outlines reasonable goals for most dairy farms, realizing that because of differences among farm personnel and physical plant herd expectations can vary. In addition, it can be less profitable for the farm to blindly attempt to attain mastitis control goals at the expense of other aspects of the farm. An example would be the culling of genetically superior cows that produce a high volume of milk and detrimentally affect the cash flow of the farm. Culling to help reduce the prevalence of IMI in a herd is often used, but it should be done judiciously.

Assessment of Contagious Mastitis

The primary tools that determine the extent of contagious mastitis in a herd are SCC and bacteriology of milk samples.

Downloaded from Vet-e-Books.com

TABLE 10-3

Quality Milk Goals for Monitoring Contagious/Subclinical Mastitis

Goal	Level	Frequency of Monitoring
Bulk tank SCC*	<200,000 cells/ml	Monthly
Linear SCC distribution	<15% of the total herd: (1) ≥2nd lactation cows with linear ≥5 (2) 1st lactation cows withlinear SCC ≥4	Monthly
Standard plate count† (raw bacteria count)	<10,000 cfu/ml	Monthly
Preliminary incubation count‡	<20,000 cfu/ml	Monthly
Cows infected with *Streptococcus agalactiae* or *Staphylococcus aureus*	<1%	Quarterly if SCC goals are met, otherwise monthly
Residue violations	None	Every day

SCC, Somatic cell count.
*Bulk tank SCC can be misleadingly low if a high proportion of cows in a herd are out of the tank because of treatment-mastitis, or elevated if a few cows are contributing a disproportional level of somatic cells to the tank because of high SCC and production.
†May be caused by mastitis, poor udder preparation, improper cleaning, or inadequate refrigeration.
‡Not regulated by Pasteurized Milk Ordinance in United States; generally indicative of improper cleaning.

As indicators of inflammation in the mammary gland, individual cow SCCs serve as markers of potentially infected cows. They cannot be used to determine cause of infection but can help delineate cows to be cultured and thus promote more efficient time and money spent on bacteriology. In many herds, if herd bulk tank SCCs are meeting the goals of the farm and the percentage of cows with elevated SCC is low, little more action regarding the contagious mastitis program is required, except continued monitoring of monthly SCC. Occasional culture of milk samples from high SCC cows or the bulk tank may be warranted to monitor the presence of contagious IMI in a herd. If the quality milk goals are not being met for a herd, a logical place to start the investigation is to determine if contagious mastitis is part of the problem, and if so, the extent of the contribution that these pathogens have on the problem. It is best to first use SCC data to determine a plan of action for collecting milk samples for culture and provide information regarding risk factors associated with infection, such as lactation number, stage of lactation, and if examined retrospectively, the duration of the problem in the herd. Subsequent culture is then used to confirm or deny the presence of contagious pathogens in the herd and the prevalence of IMI. Typically, an SCC threshold of linear score 4 or 5 is used as the criterion for culture. If the focus of the plan is to identify cows infected with the contagious pathogens, veterinarians should collect composite samples, freeze them for at least 24 hours, and then culture. Follow-up sampling is indicated for negative isolation results and to confirm IMI caused by other chronic pathogens such as the environmental streptococci. For the example herd in Fig. 10-2, the herd average SCC is 782,000, and 19/41 cows (46%) have LS ≥5. It is apparent that the goals as suggested in Table 10-3 are not being achieved, and thus either the 19 cows with LS ≥5, or the 30 cows with chronic LS ≥4, could be selected for composite sampling for culture. Cow samples yielding no isolate in the laboratory should probably be cultured again.

Contagious Mastitis Control Programs

If it is determined from SCC information and subsequent culture that contagious pathogens are present in undesirable levels in the herd, the next step is to propose management protocols on the farm that will reduce the problem. To begin this process, a review and preferably direct observation of milking preparation and actual milking techniques is required. Particularly in herds with multiple personnel, and especially in herds with hired labor, it is important to understand that farm management protocol and actual milking time practices may not be the same. Review of critical areas such as udder preparation before milking, time of preparation and attachment of milking units, actual milking time, postmilking teat dipping, and dry cow treatment programs are essential. In herds with multiple milkers, the compliance of herd protocol must be established. This is also a good opportunity to review and/or perform an analysis of the operation of the milking equipment, including the ability to maintain a stable vacuum (effective reserve) and milk cows efficiently (pulsators, automatic take-off units, and replacement of liners and hoses). If marked behavioral changes or problems are noted in the cows during milking, stray voltage or harsh treatment of the animals should be considered. It is possible that the existing mastitis control program is sound, but because of unforeseen events such as

Downloaded from Vet-e-Books.com

addition of infected animals to the herd, or adverse changes in weather, the prevalence of IMI has increased to unacceptable levels. Nonetheless, to reduce the prevalence of infection in a herd we need to achieve three fundamental goals: **(1) prevent new infections, (2) eliminate existing infections, and (3) monitor progress after implementation, and if progress is not being made, seek alternative approaches in farm management.**

Prevention of New Infections

Postmilking Teat Dipping. Teat dipping with a germicidal solution immediately after every milking has proved to be an effective milking management practice to reduce the rate of new intramammary infections. Substantial evidence supports postmilking teat antisepsis as the single most effective practice in the prevention of new contagious IMI in lactating dairy cows. Teat dipping is a simple, effective, and economical means to reduce bacterial populations on teat skin. There is general agreement that the numbers and types of bacteria on teat skin have a direct relationship to the incidence and types of intramammary infections that develop in a herd. An effective teat dip, correctly used, can reduce the incidence of new udder infections by 50% to 90% (Pankey, 1984). Postmilking teat dipping must be done correctly and consistently. Proper teat dipping requires that teats are dipped with a clean solution immediately after milking and that teat ends and lateral surfaces are well covered. Sprayers are used in some milking parlors as an alternative to dipping in cups; however, there is a potential for improper coverage of teats with these devices, especially where labor is pressed to maintain cow flow through the parlor. If done properly, two to four L of dip are used for each cow in the herd each year. Herds with a high prevalence of infection despite an appropriate postmilking program may benefit from a change in teat dip germicides. Studies in Kentucky, Pennsylvania, and Michigan reported that the consistent use of some germicidal classes of teat dips may increase the prevalence of infection with contagious mastitis pathogens (Harmon et al, 1988; Erskine and Eberhart, 1991b; Erskine et al, 1998b).

The background information, regulations, classes of available products, proper storage and handling guidelines, application methods, and published efficacy data have been reviewed (Pankey, 1984). An updated listing of available postmilking and premilking products that have efficacy data published in peer-reviewed journals, is presented each year in the appendix of the Proceedings of the NMC. There are several major classes of postmilking teat germicides and many products available within each class. The products vary widely in composition, formulation, and mode of action. Each product should be evaluated for its safety, efficacy, advantages, and disadvantages. Caution should be exercised in selecting teat dips, and changes are not warranted in herds already achieving quality milk goals. Likewise, efficacy is best demonstrated in the prevention of naturally occurring IMI under field conditions, and the accepted protocol to evaluate this outcome is also presented in the NMC Proceedings. Because of wide variability in study design, practitioners are advised to carefully evaluate the validity of published studies to the approved protocol.

Teat dipping may promote healing of chapped skin. In one study, chapped teats dipped with a 1% iodophor—10% glycerin dip reduced *S. aureus* skin colonization and promoted faster healing than did undipped teats (Fox et al, 1991). In extreme cold, dipping should be practiced, but teats should be blot dried with paper towels before cows are exposed to the elements. Teat dips should be stored in a cool, dry place and not allowed to freeze. Contamination should be prevented and expiration dates observed. For economic reasons, producers are tempted to dilute commercially available products. However, their effectiveness and safety may not be maintained. At the end of milking, unused teat dip solution should not be poured back into the original container. Dipping devices should be cleaned regularly.

In summary, postmilking teat sanitization is an extremely important component of good milking management. The objectives are to kill mastitis pathogens residing on teat skin and reduce the rate of new intramammary infections. Teat dipping or spraying immediately after every milking should completely cover at least the lower half of each teat with a product of proven efficacy.

Premilking Hygiene and Udder Preparation. The effect of various approaches to premilking udder hygiene on the incidence of mastitis has been reviewed (Pankey, 1989). The major objective of premilking udder preparation and teat sanitation is to reduce the microbial population at the teat end. The aim is to minimize the probability of new IMI and have good milking performance (Galton et al, 1986b; Merrill et al, 1987). Milking time hygiene is extremely important because of the potential interaction between milking machine function and the microflora of teat skin. The incidence of IMI is highly correlated to the number of mastitis pathogens on the teat end at milking (Galton et al, 1988). however the effect on the prevention of new IMI with contagious pathogens is minimal compared with postmilking teat dipping.

There is considerable variation in premilking cow preparation, both in theory and practice. Alternative recommended procedures for premilking udder preparation include water hose washing and manual drying of teats, washing teats with a paper towel wetted in warm sanitized solution plus drying with a single-service paper towel, and using premilking teat dipping in germicide plus paper towel drying. It is argued that manual teat washing improves stimulation and the release of oxytocin for milk letdown in addition to cleaning debris from the teats and teat ends. In milking parlors in which hand-held spray washers are used, it is important to avoid wetting the udder. Excessive water use can lead to bacterial contamination of the teat cups. In addition, drop hoses in parlors have been cited in several case studies as sources of contamination and subsequent mastitis outbreaks caused by *Pseudomonas aeruginosa* (Erskine et al, 1987c). It is recommended that, unless cows are exceptionally dirty, water be avoided in the preparation of udders and teats for milking. In addition to individual paper or cloth towels, latex gloves should be used. Use of gloves may be particularly useful if the skin of milkers' hands is thought to play a role in herds with a high prevalence of *S. aureus* (culture of skin swabs compared with isolates from cows), or to protect milkers' hands from effects of germicides while milking.

Premilking teat disinfection with iodine-based teat dip preparations has become an increasingly common management procedure in North America. A survey of Ontario DHI producers reported that 12% used iodine predip (Gill et al, 1990). The use of predipping is expected to increase as mastitis problems shift from contagious pathogens to a predominance of infections caused by environmental organisms. There are only two controlled studies that have reported on the effectiveness of predipping (Galton et al, 1988; Pankey et al, 1987). In both these studies, there was significant merit in the use of iodine predipping for the reduction of udder infections caused by environmental pathogens but not contagious pathogens. Additional evidence is needed to evaluate predipping in a variety of management situations, in particular for the control of contagious pathogens.

Although premilking teat dipping with iodine-based germicides may play a role in reducing new intramammary in-

Downloaded From Vet-e-Books.com

fections, there are some precautions that should be taken. The major concern is the potential for increased iodine residues in milk. Galton et al (1986a) demonstrated that predipping with either 0.5% or 1% iodophor does not significantly increase milk iodine residues as long as a paper towel is used to dry the teats. Without drying, iodine residues were significantly increased. In addition, predipping in combination with postmilking teat disinfection may increase the potential for residue problems (Galton et al, 1984). There is a continuing search for germicidal products with naturally occurring ingredients and a wide margin of safety.

The overall objective of premilking sanitation is to have clean and dry teats ready for attachment of the milking equipment. Nonetheless, compared with a hygiene program that included postmilking teat dipping and total dry therapy only, Kingwill et al (1970) found no difference in decreasing prevalence of IMI as compared with a program that included (1) milkers wearing and sanitizing rubber gloves before milking of each cow, (2) use of a hypochlorite sanitizer in the udder wash water, and (3) use of individual udder wash cloths in addition to postmilking teat dipping and dry cow therapy. Concurrently, similar results were obtained in a study of 27 New York herds (Natzke, 1974). In 32 Pennsylvania herds, washing and drying of udders and the use of separate paper towels before milking were as frequently practiced in herds with high prevalence of contagious pathogens as those with low prevalence (Erskine et al, 1987b).

Thus substantial support exists for the combined use of postmilking teat dipping and total cow dry cow therapy (see later) as the most critical means of controlling contagious mastitis pathogens. Other hygienic practices, although possibly important in preventing infections caused by environmental, and to a lesser extent contagious, pathogens, or in achieving lower bacterial contamination of milk, have not been demonstrated to be as critical. Consequently, practitioners should emphasize to their clients the importance of postmilking teat dipping in the prevention of new contagious IMI.

Milking Equipment Attachment and Use. Oxytocin stimulation of mammary myoepithelial cells that surround the milk secreting alveolus is the primary mechanism of milk letdown, although teat stimulation on sympathetic tone in the mammary gland augments the oxytocin mechanism. Thus proper stimulation of the teats and udder to activate milk letdown is critical for achieving effective milk ejection during milking. Late lactation cows typically require more stimulus than early lactation cows (Reneau et al, 1995). Preparation of teats by cleaning and drying should take a minimum of 10 seconds, followed by a lag time before milking equipment attachment. Optimum prep-lag time (time between the beginning of teat preparation to the application of the milking machine) is accepted as 1 to 1.5 minutes in order to best use oxytocin-induced letdown (Rasmussen et al, 1992; Reneau et al, 1995). Prep-lag times greater than 3 minutes increase residual milk and decrease milk yields (Rasmussen et al, 1992). Implementing proper prep-lag times improves milk yield as well as decreases time of milking equipment attachment during milking (Reneau et al, 1995).

When attaching the teat cups, it is imperative to minimize the amount of air drawn into the system. Too large an air inlet could cause vacuum fluctuations that might generate milk aerosol impacts of the teat end and machine-induced infections. The machine position and support should be adjusted as necessary during milking. This ensures that the quarters milk out properly. The milking unit should hang on the cow as straight and level as possible. An improperly adjusted support could contribute to uneven milk out and to an unbalanced udder on some cows. In addition, there is an increased probability of liner slips (inadvertent air admitted into the system between the teat and liner) and squawking, which in turn increases the risk of new IMIs.

In a tie-stall barn, it is recommended that a maximum of three units per person be used. It is unlikely that milking with more than three units per person in a tie-stall barn is accompanied by the use of appropriate cow preparation and milking machine attachment methods. In more automated parlor systems the number of milkers needed per cow is highly variable, and cow throughput of the parlor is an overriding concern on many large dairies. The same care needs to be followed in preparing udders hygienically and efficiently in relation to the oxytocin "let-down"; however, cows are often prepared in shifts of five to ten cows at a time. Units are attached, and then the next group of cows is prepared.

A majority of milking machine-induced intramammary infections occur near the end of milking (Spencer, 1989). Liner slips occur with greater frequency near the end of milking. During a liner slip, small droplets of contaminated milk may be propelled back against the end of the other teats. Over a sustained period of time, liner slips and milk impacts may cause intramammary infection. Machine stripping is the act of putting hand pressure on the milker unit at the end of milking for the purpose of removing extra milk. It has been shown that machine stripping is habit-forming and eventually leads to increased milking time. In addition, there is a greatly increased risk of squawking, liner slips, and milk impacts during machine stripping.

As soon as a cow is milked out, the vacuum to the milker unit should be shut off and the teat cups removed (Griffin et al, 1982). The milker unit should gently fall off the teats, causing no irritation (Natzke et al, 1982). Removing the unit under vacuum causes milk and air to impact onto the teat ends (Spencer, 1989). Overmilking should be avoided to prevent teat end irritation. It is recommended that the unit be removed as soon as the first quarter is milked out. The risk of liner slip is also increased during overmilking. However, there is little evidence that overmilking causes an increased rate of IMI unless liner slips and teat end impacts occur. The practice of removing teat cups individually is also discouraged.

Establish Milking Order and Segregation Programs. In herds with a significant prevalence of contagious pathogens, such as *S. aureus*, establishing a specific milking order may be helpful to limit the rate of new infections. In general, first-lactation heifers and fresh cows should be milked first. Cows with a high SCC, chronic clinical mastitis, and current clinical cases should be milked last. The maintenance and management of both SCC and clinical mastitis records become important to make milking order programs work. This may be difficult to arrange in herds milking in parlors. In free stall housing, cows are usually grouped according to stage of lactation and production level. For nutritional management reasons, it is often suggested to have high-, medium-, and low-production groups. Fox and Hancock (1989) have compared the change in prevalence of coagulase-positive staphylococci in unsegregated herds to herds using a segregation program. The segregated herds did not control *S. aureus* any better than nonsegregated control herds. A more significant decrease in the prevalence of *S. aureus* mastitis was found in herds that gave priority to a full milking hygiene program in combination with dry cow therapy and culling. Segregation is not a simple, single solution to contagious mastitis problems.

Sanitize Teat Liners. Disinfection of the milking machine teat cup liners between cows has the potential of lim-

Downloaded From Vet-eBooks.com

iting the spread of contagious organisms from cow to cow. There is ample evidence that bacterial populations in liners can be greatly reduced by sanitization (Smith et al, 1985b). However, there is considerably less documentation that flushing liners causes a major reduction in contagious mastitis problems (Spencer, 1989).

In tie-stall milking barns, liner sanitization is a laborious process that involves dipping the claw in a series of solutions. Liners must be put through a rinse, a disinfectant, and another rinse to remove the germicide. The solutions should be kept hot and replaced when they become overly contaminated. Only two liners can be dipped at one time in order to avoid an air lock in the claw, which can reduce the effectiveness of the disinfection process. In large milking parlor operations, automatic backflushing of milking units between cows is commercially available. In conjunction with automatic takeoffs, the claw is flushed with rinse water, then disinfectant, then rinsed again, immediately after the unit detaches from the cow. Massive numbers of microorganisms can be removed from teat cups by this backflushing process (Smith et al, 1985b). However, documented reductions in new infection rates are limited. Further studies on the usefulness of backflushing are warranted.

Other Reservoirs of Infection. Conventional wisdom for *S. aureus* IMI states that the major source of new infections is the lactating cow, and that heifers should calve "clean" of contagious IMI because of lack of any exposure. However, reports have indicated that this should not be accepted as dogma for all herds. Although highly variable among geographic regions, reports indicate that as many as 2% to 50% of heifers may be infected with *S. aureus*, as well as other staphylococci, at calving before the first milking (Nickerson et al, 1995; Oliver et al, 1992; Pankey et al, 1991). "Summer mastitis," caused by *A. pyogenes*, has been reported in Europe as a significant mastitis problem related to fly bite dermatitis of the teats and ensuing infections (Madsen et al, 1991). Research from Louisiana has suggested that a similar mechanism may contribute to IMI caused by staphylococci, including *S. aureus* in heifers (Nickerson et al, 1995). In particular, the horn fly *Haematobia irritans* may serve as a vector in the transmission of *S. aureus*. Herds using some form of fly control had fewer cases of heifer mastitis caused by *S. aureus* and streptococci than did herds without fly control (Nickerson et al, 1995). In an elegant use of DNA fingerprinting, all of the *S. aureus* isolates collected from horn flies belonged to two subtypes identified in heifers with infections caused by the same pathogen (Gillespie et al, 1999). Thus, in herds with significant fly problems, the potential for primigravid or nulligravid heifers as a source of new infections should be considered. Treatment of quarters with an intramammary infusion before parturition decreased the prevalence of infection in heifers at calving (Oliver et al, 1992; Nickerson et al, 1995). Caution should be exercised before embarking on this protocol in most herds unless increased incidence of clinical mastitis, elevated SCC in early lactation, or preferably positive cultures of recently calved heifers is evident. The labor, risk of residues in milk, uncertainty of exact dates of calving, and the risk of IMI by breaching the teat end barrier demands careful herd record assessment before using this protocol.

In addition to insect sources, total eradication of *S. aureus* from a herd can also be limited by the potential exposure of cows from numerous other sources, including housing, feedstuffs, air, equipment, bedding, farm animals, workers, water, and skin (Roberson et al, 1994). Thus, although the primary source of infection for *S. aureus* is the udder of the cow, a careful understanding of the risk factors associated with new of IMI should be considered to alert investigators to other potential reservoirs of infection.

Vaccination. Development of vaccines for streptococcal mastitis has been slow to develop. However, there has been considerable effort to develop a vaccine against *S. aureus*. A good review of the subject is presented by Nickerson (Nickerson, 1999). Previous attempts to develop vaccines against cell wall components (protein A) and bacterial adhesion proteins (fibronectin-binding) have met with mixed results. However, new technology has developed a vaccine against the pseudocapsule that surrounds the bacterial cell wall when *S. aureus* grows in milk (Watson, 1990). The vaccine enhances antipseudocapsular antibodies that aid in opsonization of bacteria for phagocytosis by neutrophils. This approach, combined with α- and β-toxin antigens has demonstrated positive results in the prevention of subclinical IMI and clinical mastitis cases caused by this organism (Watson et al, 1996; Sears, 1990a; Nickerson et al, 1993). Commercial development has not as yet been provided, and eventual large scale efficacy trials would be needed to demonstrate long-term efficacy as well as economic feasibility. However, this concept is deserving of being pursued as a sound scientific method to prevent new *S. aureus* IMI.

Proper Installation, Function, Use, and Maintenance of Milking Equipment. The milking machine plays an integral role in the efficiency of the operation of a dairy farm, and it has direct contact with teat tissue. It must perform properly and consistently every day, year after year. For these reasons, it is important that the installation of the milking system be done according to approved guidelines. Regularly scheduled maintenance should be carried out and machine function evaluated by periodic analysis of the system. Each person involved in the milking management process should thoroughly understand the basic components, function, and operation of the milking equipment. They should also be aware of the significance of regular equipment maintenance and of the importance of good milking techniques.

In order to carry out the basic functions and achieve the objective of efficient removal of the milk with minimal opportunity for intramammary infection, milking and milk handling equipment requires three basic components: (1) a vacuum system, (2) a milk pipeline system, and (3) a bulk milk tank for milk cooling and storage. Fig. 10-3 shows a simplified schematic diagram of these three milking system components. A great deal of engineering expertise goes into the proper design, installation, and function of milking equipment. For the purposes of understanding the basic principles of machine milking, these three components are briefly described.

The proper functioning of milking equipment depends on the creation of a partial vacuum. A vacuum pump is used for this purpose. It continuously removes some of the air from the various lines in the milking system. The amount of air removed determines the system vacuum level, which is important for proper function. The vacuum level is monitored using a gauge that is read in kilopascals (kPa), millimeters of mercury (mm Hg), or inches of mercury (in Hg). If half of the air is removed from the system, the vacuum gauge would read 50 kPa (15 in Hg) vacuum. Vacuum pumps are rated on the basis of the volume of air they can move when the intake vacuum is at 50.7 kPa (15.0 in Hg). Cubic feet per minute (cfm) is the standard air flow measurement used. The cfm rating of a vacuum pump determines the number of milking units that can be used on the system. For example, in order to operate six units, the minimum vacuum pump capacity is 52 cfm.

Because the vacuum pump continuously removes a constant amount of air from the system, a vacuum reserve tank is placed between the pump and the vacuum supply line. The purpose of this tank is to provide a common site for connecting the vacuum header lines and to provide a reserve

Downloaded from Vet-eBooks.com

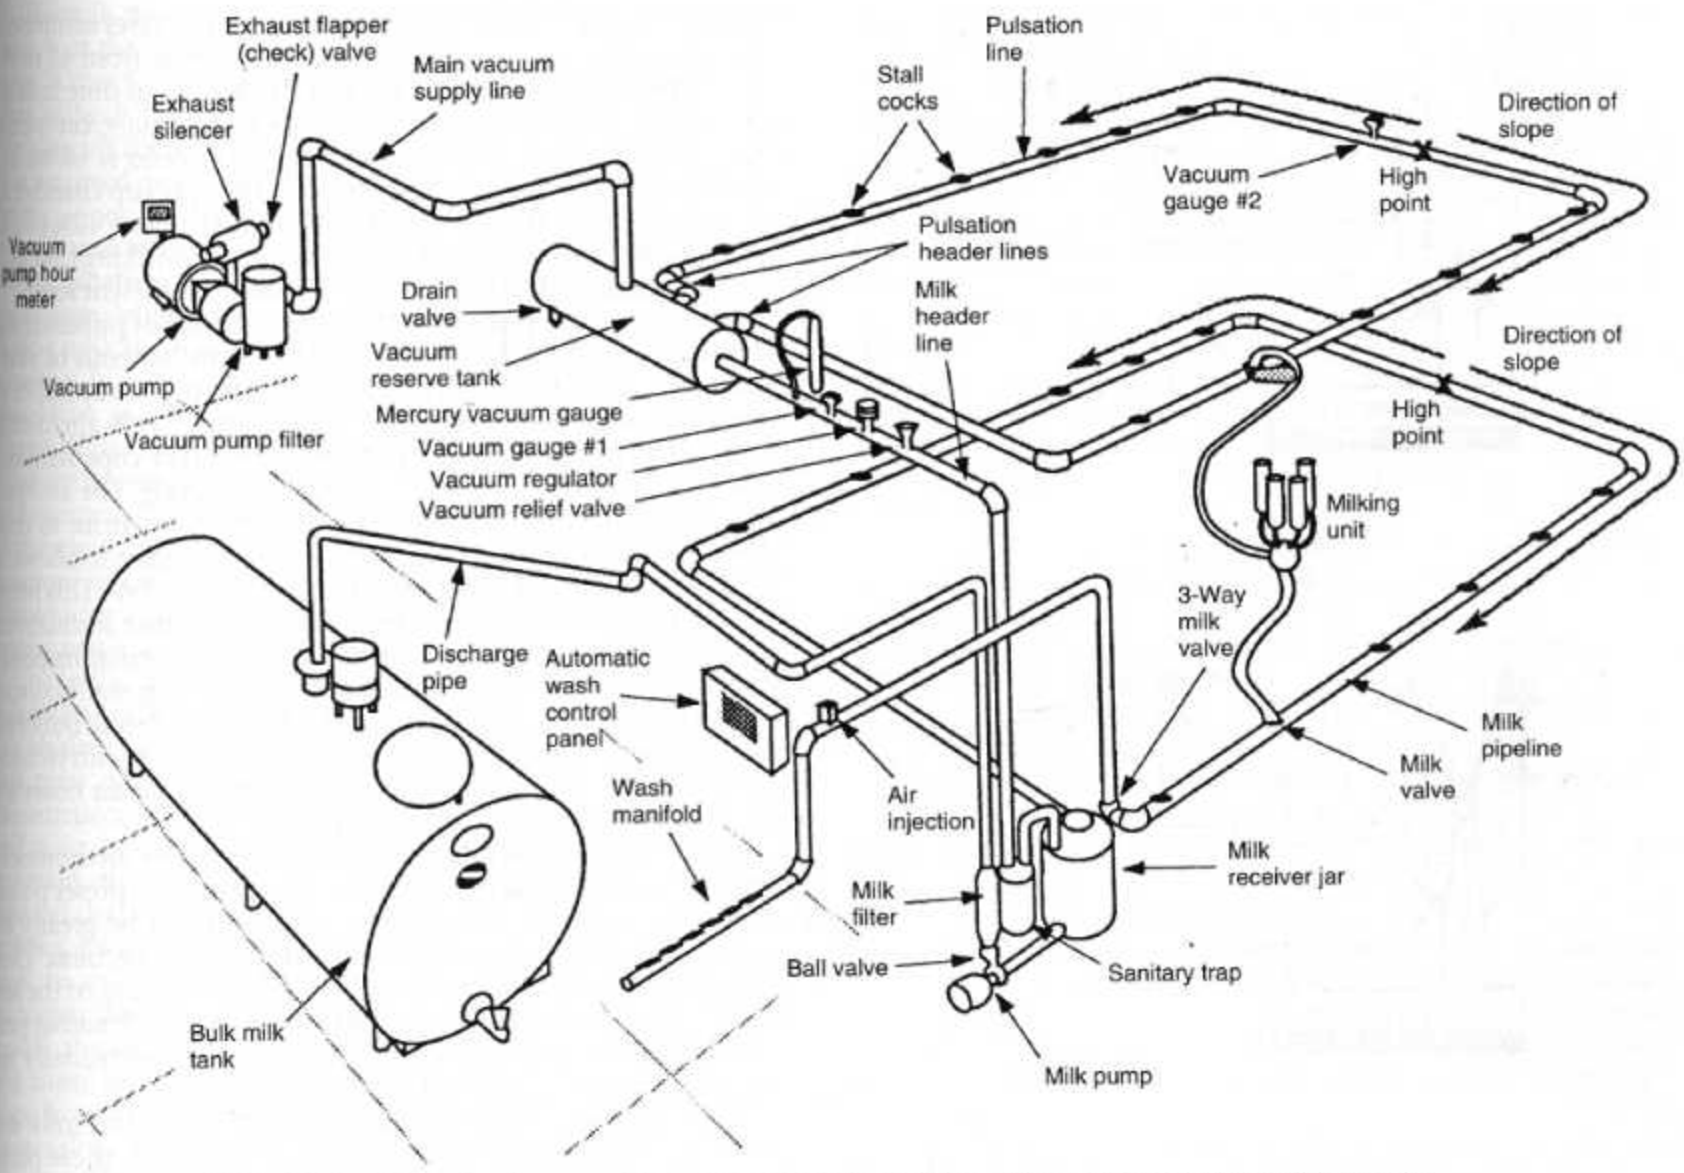

FIG. 10-3 Schematic diagram of the components of a milking system: the vacuum supply, the milk pipeline, and the bulk tank for milk storage.

of vacuum to help buffer the sudden admission of air into the system. For example, when a milking unit falls off a cow, there should be enough reserve vacuum to maintain system function. The amount of reserve vacuum needed in a system is a function of pump capacity, pump performance, regulator operation, and degree of system leakage. Vacuum reserve tanks are usually constructed of PVC plastic and should not be smaller than 75-L capacity. These provide a common site for connecting the vacuum header lines.

A vacuum regulator or controller is an important component of the vacuum system. The function of the regulator is to keep the vacuum of the milking system at a preset level by responding to changing air admissions into the system. The regulator should be located on the vacuum line between the sanitary trap and the vacuum reserve tank. The regulator should provide a rapid response to changes in vacuum. Servodiaphragm regulators are the most sensitive style available and are highly recommended. An increase in vacuum pump capacity cannot compensate for poor regulator function. Similarly, a sensitive regulator cannot compensate for a deficiency in pump capacity. The two components must work well together.

It is recommended that two vacuum gauges be installed in the system for the purpose of monitoring the system vacuum. One gauge should be located on the milking vacuum supply line, near the regulator. A second gauge is best situated at the far end of the vacuum pulsation line. A portable mercury monometer should be used on a regular basis to calibrate the accuracy of the system vacuum gauges and to make adjustments to the vacuum regulator. The preferred vacuum system installation consists of two header lines from the vacuum reserve tank that continue to form a completely looped pulsation line. The recommended vacuum lines are 76-mm (3-in) PVC pipe, adequately supported, slightly sloped in the direction of air flow, and with automatic drain valves. This line allows for attachment of the milking unit pulsators.

A properly functioning pulsation system is critical to teat and udder health. In addition, it should ensure fast, complete milk out. The pulsator causes the chamber between the teat cup shell and the liner to alternate regularly from vacuum to air source. Pulsators are electromagnetic or pneumatic. In an electromagnetic system, all pulsators function together off an electrical signal. An electronic control circuit turns the current to the electromagnet on and off. Pneumatic pulsators run off the vacuum system and use air to move a plunger or slide valve to cover and uncover the air passage, producing the pulsating action.

Understanding the dynamics within the teat cup and the characteristics of pulsation is crucial to ensuring that the objectives of mechanical milking are achieved. The chamber between the teat cup shell and the liner is regularly subjected to a vacuum source, whereas the inside of the liner is under a stable milking vacuum at all times. The dynamics of these changes are illustrated in Fig. 10-4. The pulsation cycle involves a milk phase and a rest or massage phase. When air is admitted between the shell and the liner, the liner collapses around the cow's teat. The collapsed liner has a massaging action on the teat and is called the *rest* or *massage phase*. Milk does not flow from the teat during this phase.

Downloaded from Vet-e-Books.com

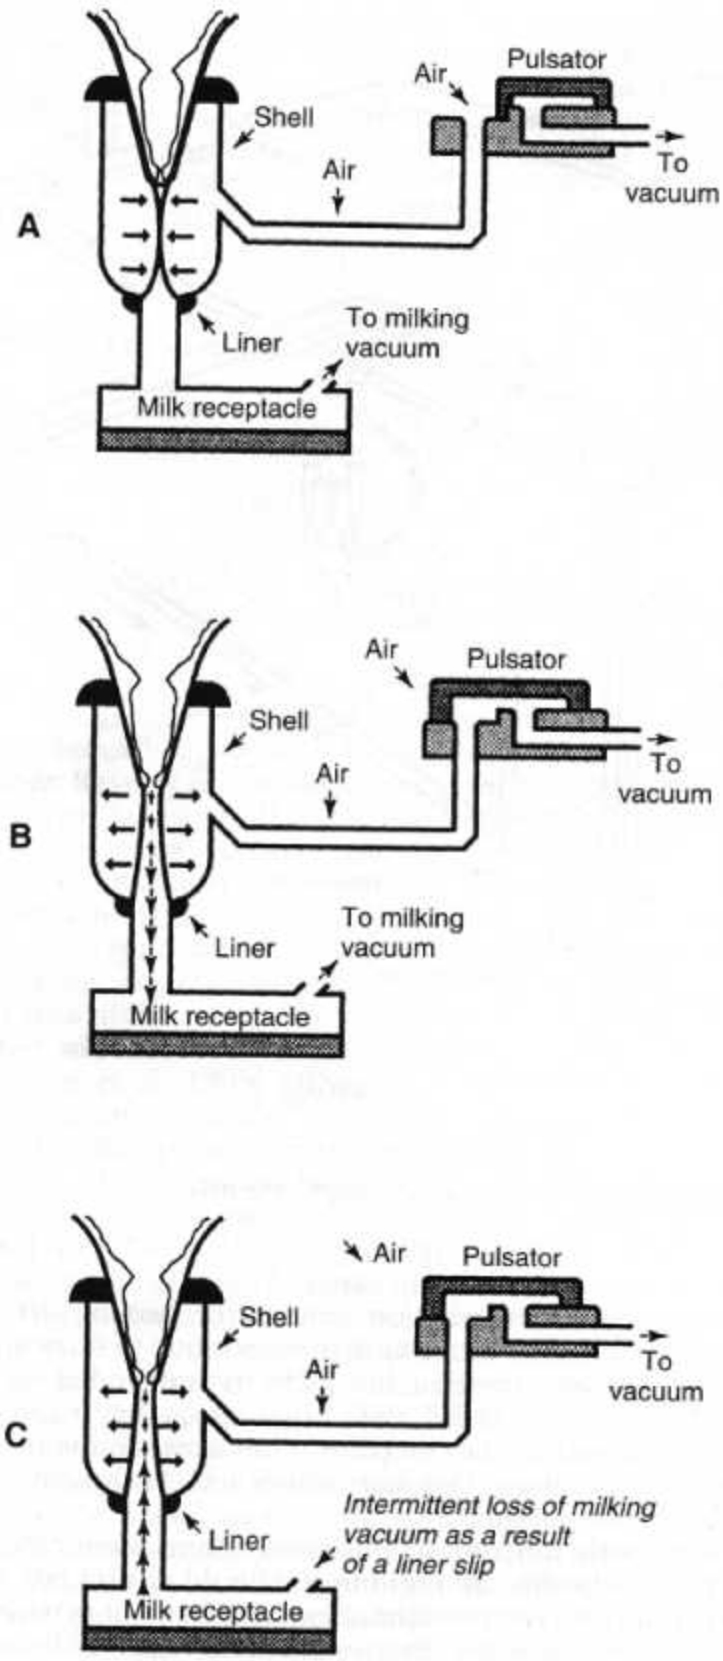

FIG. 10-4 Schematic diagram of the dynamics of pulsation and the changes within the teat cup of a milking unit during the rest phase and the milking phase, and in the event of a liner slip. **A**, Rest (massage) phase. **B**, Milk phase. **C**, Milk impact.

When the pulsator opens, the space between the liner and the shell is exposed to the system vacuum. This creates equal pressure on both sides of the liner, causing it to open. The cow's teat end is now exposed to the milking vacuum. This vacuum, in combination with the internal pressure of milk letdown within the cow's udder, causes milk to be drawn out through the teat streak canal. This component of pulsation is called the *milk phase*. The process of milking involves repeatedly opening (milk phase) and closing (rest phase) the teat cup liner.

The pulsation cycle is measured by the time, in seconds, for the completion of one milk phase and one rest phase. The pulsation rate refers to the number of cycles completed by a pulsator in 1 min. Pulsation rates range from 45 to 60 cycles/min. The pulsation ratio is the length of time in each cycle that the pulsator is in the milking phase compared with its rest phase. A common pulsation ratio is 60:40, indicating that in each pulsation cycle the teat cup chamber is milking 60% of the time and massaging the teat 40% of the time. Wide pulsation ratios can speed up milking time but can put undue stress on the teats from insufficient rest.

The pulsation phase refers to the method of pulsation for the whole milking unit, and is either simultaneous or alternating. In simultaneous pulsation, all four teat cups milk at the same time and rest at the same time. With alternating pulsation, two teat cups milk while two teat cups rest, and then alternate to complete the pulsation cycle. The alternating action may be from side to side or from front to rear. Alternating pulsation has several advantages. It allows a more uniform milk flow into and out of the claw. This helps minimize flooding of the claw, which can cause fluctuations in teat end vacuum. In addition, front-rear alternating pulsation allows for a wider pulsation ratio on the rear quarters, which encourages a more uniform and timely milk out of all four quarters. For alternating pulsation systems with two different ratios, care must be taken to ensure that air hoses are not reversed when attached to the claw.

Electromagnetic pulsators are unaffected by environmental temperature and can function at a constant preset pulsation rate and ratio. Pneumatic pulsators can be greatly affected by changes in temperature and system vacuum. They require more maintenance and constant checking of the settings. Thus electromagnetic pulsators using alternating pulsation are most commonly recommended, particularly for high-producing cows with fast milk letdown.

The problems of liner squawks, liner slips, and milk impacts were discussed. The dynamics involved in these problems are illustrated in Fig. 10-4. If a teat cup is not positioned properly on a teat, the liner may slip down the teat and produce a "squawking" sound. As this is happening, air is entering around the teat into the liner. The entrance of this air changes the system of stable milking vacuum within the claw and the other teat cups. These changes lead to droplets of milk being driven in a reverse direction back at the teat ends of the other teats, and these are referred to as "milk impacts." Repeated milk impacts, particularly with milk contaminated by mastitis pathogens, can cause new intramammary infections.

Milking parlors and stanchion barn pipelines have similar systems for transporting milk from the cow to the bulk tank. The components of the transport system are described in the direction of milk flow. The rubber or silicone insert in each teat cup is referred to as a liner, or inflation. The liner should milk cows safely, with a minimum number of squawks from downward slippage and without the teat cup crawl action of riding up on the teats to the base of the udder. Liner performance depends on many interrelated characteristics of the milking system. Narrow-bore liners are recommended. Liners must be compatible with the teat cup shell. The most important management consideration with respect to teat cup liners is to ensure regular replacement, as recommended by the manufacturer. As a general guideline, natural rubber liners last from 500 to 700 cow milkings, synthetic rubber liners from 1000 to 1200 cow milkings, and silicone liners from 5000 to 10,000 cow milkings. Other rubber parts of the unit, such as the short air tubes on the claw, should be checked constantly for cracks or signs of wear. These problems could seriously affect air flow and liner pulsation. Proper storage in dark, cool conditions, as well as the correct use of cleaners and sanitizers, can affect the life of rubber parts.

The milk claw is an important component of the milking unit. It is the collection point for milk from the four teat cups. It should have adequate capacity to handle peak milk flow without flooding. Each claw should have a means of shutting off the vacuum to the teat end, so that the unit is not removed under vacuum. Most claws have an air vent in the upper half to allow a predetermined quantity of air into the unit to facilitate milk flow away from the cow and into the pipeline. Claws should be inspected routinely for cleanliness, plugged air vents, and dented liner connectors. A long milk hose is used to carry milk from the claw to the pipeline. It can be made of plastic, rubber, or silicone. It should be as short as possible, with an appropriate hose hanger. If the milk hose is crimped or allowed to loop, milk flows are interrupted and lead to irregular fluctuations in teat end vacuum. The milk hose should attach to an inlet located in the top third of the milk pipeline, at the 11 or 12 o'clock position. Inlets should be self draining and self closing and should not cause milk flow restrictions that would lead to irregular teat end vacuum fluctuations.

The milk pipeline serves two important functions. It transports milk from the cow to the receiver jar, and it carries air flow to provide milking vacuum to the teat end. Either glass or stainless steel can be used for milk pipeline construction. The milk line should form a complete circuit and must be supported rigidly from the floor in order to maintain the appropriate slope. It is generally recommended that milk lines be installed as low as is practical. In milking parlors, low pipelines are installed below udder level. In stall barns high pipelines are used but should be no higher than 2 m above the cow platform. Milk moves by gravity through the pipeline to the receiver jar. The milk line must be self-draining and should have a continuous slope from the high point toward the milk receiver jar. The correct slope is important for the movement of milk and air during milking as well as for proper cleaning of the system. In the construction of new tie-stall barns, it is recommended that the foundation, floor, and gutter be sloped toward the milk house end. This helps minimize pipeline height and ensures that the line slope facilitates drainage during milking and washing.

Line diameter is another important feature of milk pipeline design. In addition to line slope and the level of herd production, pipeline diameter determines the number of milking units that a system can handle. Too many units lead to milk line flooding and a reduction in air flow rate. Slugs of milk moving through the line is an obvious sign of milk line flooding. This problem has a negative impact on milking time, herd production, and udder health. The recommended minimum pipeline size (in inches) is the square root of the number of units milking into each slope. For example, for a 2-inch line, high-producing herds should not use more than four milking units per slope. Thus larger pipeline sizes are often recommended for new installations. Pipeline couplers or welds must prevent air leakage into the system.

Milk should flow into the receiver jar in a continuous, unimpeded fashion. When sufficient milk has accumulated, an electronic probe triggers the milk pump to transfer milk from the receiver jar to the bulk tank. A milk filter is inserted into the transfer system as a mechanism for removing coarse impurities that may have entered the line. The receiver jar is connected to the main vacuum supply. A device called a sanitary trap is used to separate the "air only" portion of the milking system from the "milk handling" side of the system. The sanitary trap is designed to protect the vacuum supply from potential damage caused by the chemical cleaning and sanitizing solutions used to clean milk pipelines.

A milking system should have the capability of measuring the amount of milk from each cow. In older milking parlor systems, weigh jars were often used for this purpose. They allowed for a quick, visual means of monitoring individual cow production at each milking, as well as providing vacuum stability to the cow. However, they were expensive and represented a challenge to clean. More recently, milk metering systems have been developed that give an electronic digital readout of the milk volume produced at each parlor station. These systems can often be adapted to automatic data recording in an on-farm computer system. In stall barn pipeline installations, several types of mechanical milk meters are in use. It is important that any metering system not be restrictive to the flow of air and milk. These restrictions can cause a drop in teat end vacuum and irregular, teat end vacuum fluctuations. Increased milking time, incomplete milk out, and new intramammary infections can result.

The bulk milk tank is the vessel used to cool and store raw milk until it is picked up by the bulk milk transport truck. All tanks must be of an approved sanitary design and construction. The cooling capabilities of bulk milk tanks are clearly specified. Appropriate cleaning and sanitizing procedures for bulk tanks are critical in order to prevent bacterial growth and contamination of raw milk.

Relationship of Milking Equipment to Udder Health. The milking machine can influence new IMI rates in several ways: (1) it may be a carrier of mastitis pathogens from one cow to the next, (2) it may serve as a pathway of cross infection within cows, (3) malfunctioning or improperly used equipment may fail to relieve congestion in teat tissue, with eventual teat end damage and IMI occurring, and (4) abrupt loss of milking vacuum may create changes in air movement of sufficient force to move pathogens past the streak canal defenses. This phenomenon is known as the *impact mechanism*.

The pathogenesis of new infections related to machine milking probably involves all four of these factors (Spencer, 1989). However, even though the milking system becomes the focus of many herd udder health investigations, there is little evidence that machine factors are of primary importance in most problem herds. It has been difficult to link milking machine factors and prevalence of herd infection (O'Shea et al, 1979). Mastitis has been difficult to produce experimentally by altering machine function (Olney and Mitchell, 1983). In a study of several problem herds with pipeline milking systems, only 6.6% of the infections could be attributed to the milking machine (Schmidt-Madsen and Klastrup, 1980). In a Pennsylvania study, operation or maintenance of milking equipment did not differ between herds with a high or low prevalence of contagious mastitis (Erskine et al, 1987b).

A great deal of research has been directed toward the identification of machine factors related to mastitis. Although many problems have been identified, the only factors consistently associated with udder health problems are pulsation failure and the impact mechanism related to the inability to maintain a stable vacuum level at the teat end. Appropriate pulsation is important for sufficient teat end massage. Although a continuous vacuum removes milk from cows' teats, it eventually causes excessive congestion, edema, and teat end damage. An adequate compressive load by the liner on the teat tissue is necessary to relieve the congestion. Mechanical failure of the pulsator, shortness of the liner barrel, or a liner rest phase that is too short are the most common examples of pulsation problems. The impact mechanism results from an abrupt loss of milking vacuum. Poor liner design, inadvertent air leaked into the system such as when a unit is kicked off an udder or leaks in the pipelines, or inadequate effective reserve air flow of the system (the amount of air that can be admitted without a drop in vac-

Downloaded from Vet-eBooks.com

uum) from improper pump or regulator function, can all contribute to vacuum fluctuations.

Summary of New IMI Prevention. The prevention of new IMI caused by contagious pathogens often focuses on lactating cows, and the events that occur immediately before, after, and during milking. Postmilking teat dipping is the most critical event that occurs during this part of a cow's daily routine. On an individual herd basis, other problems such as contamination on milkers' hands, teat end trauma, careless preparation, and potential machine problems can contribute; however, these are not usually major risk factors in the prevention of new IMI caused by contagious pathogens, and it is important to maintain a perspective of any management practice of mastitis prevention in relation to all others.

Elimination of Contagious Intramammary Infection

Elimination of IMI During Lactation. Subclinical mastitis does not present an urgent potential loss of gland function or life to the cow. Therefore therapy is administered on the premise that treatment costs will be outweighed by compensatory production gains after elimination of infection. In the case of contagious pathogens, elimination of infection may also cause decreased risk of new infections in previously noninfected cows. Although host immune defenses play a critical role, the degree of therapeutic success in treating subclinical mastitis relies predominantly on the type of causative pathogen, and often not on the drug regimen selected. Most often the predominant pathogens causing subclinical mastitis are streptococci and staphylococci. In particular the contagious pathogens *Str. agalactiae* and *S. aureus* offer a study in opposites with respect to therapeutic success.

Prevalence of *Str. agalactiae* IMI can be reduced rapidly by "blitz" treatment. With this method an entire herd, or more economically, all the culture-positive cows in a herd, are treated with antimicrobials. The most efficacious and cost-effective regimen is to use intramammary β-lactam therapy, although use of erythromycin has been successful. All four quarters of infected cows should be treated to ensure elimination of the pathogen from the cow and prevent possible within cow cross-infection of a noninfected quarter by an infected quarter. Cure rates can often be from 75% to 90% and are economically beneficial (Weaver et al, 1986; Erskine and Eberhart, 1990; Erskine et al, 1996). Commercial intramammary products are as efficacious as procaine penicillin G infusions, and thus these products are preferred because of higher quality control for sterility and better reliability for predicting withholding periods for milk and meat discard after treatment (Weaver et al, 1986). Much of this success relies on the high degree of antimicrobial susceptibility of *S. agalactiae,* as well as it being essentially an obligate udder pathogen. It is necessary to monitor treated herds by SCC and bacteriology to further identify and treat cows that were not identified as being infected initially. Usually, 30-day monitoring intervals after each treatment are adequate. A small percentage of cows will not respond to therapy and are best segregated or culled. In addition, failure to use postmilking teat dipping and total dry cow treatment to prevent new IMI while eliminating existing IMI from blitz treatment will ultimately cause considerable expense and frustration on the part of the producer because of subsequent reinfection of treated cows. Parenteral therapy is not likely to offer any benefit over intramammary therapy, and in one study, 90% cure rates were achieved with intramammary penicillin-novobiocin therapy as opposed to 9% with intramuscular ceftiofur, an elegant demonstration as to the importance of pharmacokinetics for parenteral drug selection (Erskine et al, 1996).

Other common streptococci causing IMI are *Streptococcus dysgalactiae, Str. bovis,* and *Str. uberis*. As with *Str. agalactiae,* most of these streptococci are very sensitive in vitro to antibiotics, especially penicillin. In one study, virtually 100% of *Str. uberis, Str. dysgalactiae, Str. bovis,* and group G isolates were sensitive to penicillin, although only 63% of the enterococci were sensitive to penicillin (McDonald et al, 1976). Despite this apparent sensitivity however, these streptococcal infections are not as easily cured as those caused by *Str. agalactiae.* Controlled clinical data on the therapy of streptococcal infections is not extensive. Intramammary administration of β-lactams is considered to be effective therapy. However, efficacy and cost-effectiveness of this therapeutic regimen is difficult to assess. In strains with in vitro susceptibility to a combination of penicillin and novobiocin, intramammary therapy has obtained cure rates of 90% or more for subclinical IMI caused by *Str. agalactiae, Str. uberis,* and *Str. dysgalactiae,* and 77% for other streptococci (Owens, 1997)

Studies of treatment efficacy of *S. aureus* mastitis have found cure rates of 25% to 55% of infected quarters in experimental infections that were evaluated for 21 to 60 days after infection (Newbould, 1974; Owens et al, 1988). However, natural infections are usually of longer duration before therapeutic intervention is used and thus more refractile to therapy. Intramammary cefoperazone for the treatment of clinical *S. aureus* mastitis led to bacteriologic cures for only 39% of the cases, as measured 14 days after treatment (Wilson et al, 1986). These results may be optimistic since assessment of bacteriologic cures depends on the time period the infection is monitored after therapy; apparent cures often relapse as time after treatment increases, especially if assessed before 30 days (Newbould, 1974).

Consequently, novel combinations of drugs, including parenteral treatment regimens, may be needed to eliminate a higher proportion of infections. In experimental infections in lactating cows, the combined use of intramuscular procaine penicillin G and intramammary amoxicillin achieved a better cure rate (18/35 infected quarters) than did intramammary amoxicillin alone (10/40 infected quarters (Owens et al, 1988). Parenteral administration as an adjunct to intramammary therapy has been further supported by an additional study that determined improved cure rates for lactating cows with *S. aureus* IMI when they received 10 mg/kg body weight of oxytetracycline in addition to intramammary antimicrobials as compared with cows administered intramammary infusions only (Sol et al, 1990). In addition, therapy that is administered for longer periods than those typical for labeled intramammary regimens (4 as opposed to 2 days) maintains MIC in the gland for more effective time periods and causes better efficacy (Ziv et al, 1981).

Therefore therapy of chronic, subclinical IMI may have the best probability of success by including parenteral, in addition to intramammary, therapy; preferentially it should be administered for periods long enough to insure drug levels above MIC to allow effective killing of the pathogen. However, cure rates attained may not be much better than those attained from spontaneous cure. In addition, definitions of cure must be made critically, and affected quarters monitored bacteriologically for at least 30 days to encompass the refractory period when IMI is present but bacteria may not be isolated.

With the exception of *Str. agalactiae,* antimicrobial therapy is not recommended for subclinical IMI in lactating cows. Exemptions exist, but other alternatives should be explored first. The most attractive alternatives are therapy of dry cows and culling.

Elimination of IMI During the Dry Period. The dry period offers a valuable opportunity to eliminate IMI while cows are not lactating. Thus the expense of discarded milk

Downloaded From Vet-e-Books.com

after therapy can be avoided, and with proper identification and segregation of dry cows out of the lactating herd, residues in marketed milk can be averted. In addition, once involution occurs 1 to 2 weeks after dryoff, the host defenses of the mammary gland become markedly more effective in eliminating IMI. This is in part due to increased phagocyte efficiency; increased involvement of lymphocytes and macrophages; elevated concentrations of lactoferrin, complement, and immunoglobulin; and the presence of a keratin barrier in the streak canal of the teat (Nickerson, 1989a). Furthermore, the beginning and the end of the dry period represent times of increased risk of infection (Eberhart, 1986). The greatest increase in susceptibility is during the first 3 weeks of the dry period. In this period the new infection rate is many times higher than during the preceding lactation as a whole. A second period of heightened susceptibility occurs just before parturition (Fig. 10-5). The average rate of new infections in untreated dry cows is expected to be between 8% and 12% of quarters (Eberhart, 1986). The objective of udder health management during the dry period is to have as few infected quarters as possible at calving. Thus infections present at the time of drying off should be eliminated, and the rate of new intramammary infections during the dry period must be minimized.

Although the focus of mastitis control schemes for the dry period is often on contagious pathogens, environmental bacteria need to be considered. Exposure to environmental pathogens is likely to continue throughout the dry period. Thus the prevention of new dry period infection with environmental agents represents a considerably greater challenge (Eberhart, 1986). Herds that have implemented a basic mastitis control program still need to be aware of the importance of preventing environmental infections in the dry period. There are different rates of infection by the various environmental agents as the dry period progresses (Smith, 1985b,c). For example, infections with environmental streptococcal species, *Klebsiella* sp., and *Enterobacter* sp. occur more frequently early in the dry period. *E. coli* infections tend to occur immediately before calving. Dry cow management strategies need to account for the risk of infection during the entire period from last milking until the next calving. In addition, the cessation of milking time hygienic practices, such as teat dipping, allows bacterial subpopulations on teat skin to increase. It has been shown that *S. aureus* numbers are high immediately after drying off.

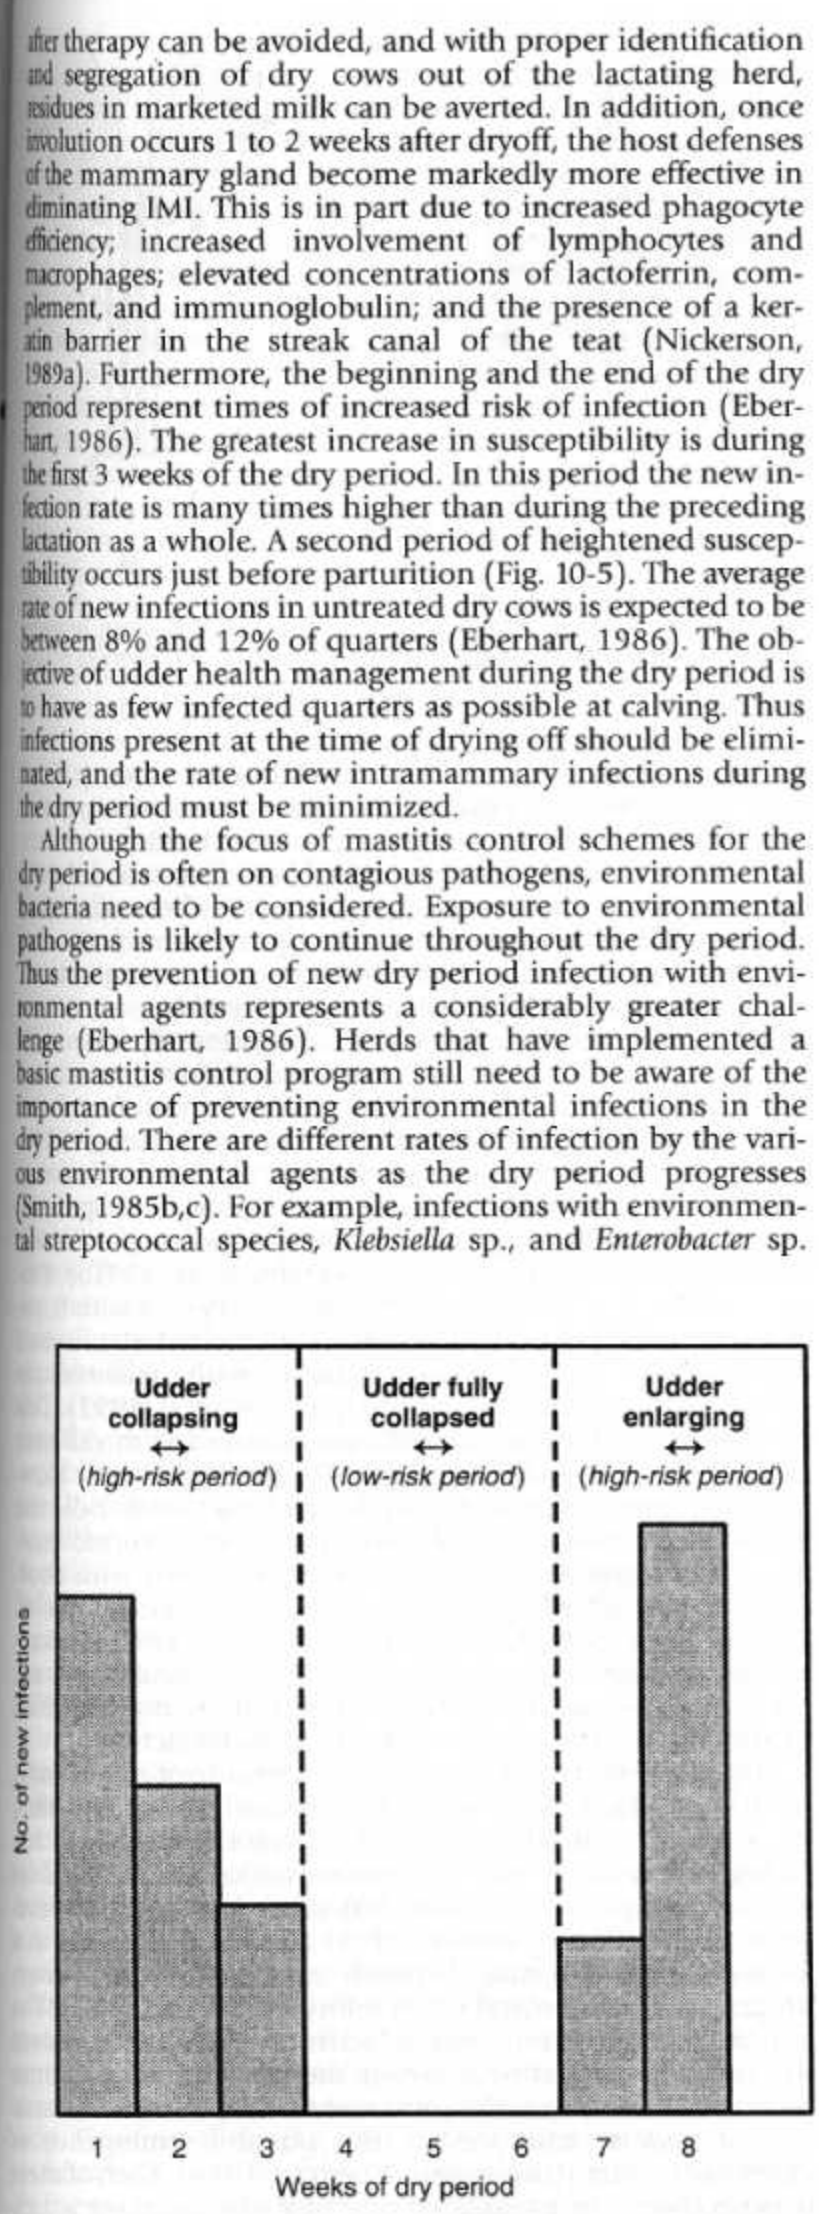

FIG. 10-5 Graphic representation of the frequency distribution of new intramammary infections in dry cows showing the periods of high and low risk.

Early research in 14 herds in England (Dodd et al, 1969) determined that although teat dipping reduced the new infection rate by 50% over a period of 12 months, the prevalence of all IMI decreased by only 14%. Antimicrobial therapy of all dry cows at the end of lactation was proposed to eliminate existing infections; such therapy was proved to be an effective complement to postmilking teat dipping. Subsequently, many studies have supported the combined use of postmilking teat dipping and total dry cow therapy (therapy of all quarters of all cows at the start of the dry period) as an effective management practice for controlling contagious mastitis (Erskine et al, 1987b; Oliver, 1984). Dry cow therapy has become the most effective and widely used mastitis control method for dry cows. Its efficacy and advantages are well known (Eberhart, 1986). Particularly for streptococcal IMI and coagulase-negative staphylococcal IMI, cure rates are often near 90%. However, the elimination of chronic IMI such as that caused by *S. aureus* or *Str. uberis* is less successful. Dry cow therapy also reduces the incidence of new intramammary infections by 50% to 75%.

Long-acting antibiotic preparations have been formulated specifically to treat subclinical mastitis and to prevent new infections in dry cows. These preparations include drugs that target the therapy of gram-positive pathogens such as benzathine cephapirin, benzathine cloxacillin, and sustained-release formulations of erythromycin, novobiocin, and penicillin. The withholding period for milk from animals treated with these dry cow formulations ranges from 30 to 42 days after treatment. The label directions must be followed carefully for the recommended dosage level, required withdrawal period, storage guidelines, and expiration dates. A general recommendation is that dry cow treatment should never be administered within 1 month of the expected calving date, and if therapy in this time period is necessary, products designed for lactating cows are recommended. Single-dose syringe preparations of dry cow antibiotic treatment are recommended. The risk of contamination by environmental bacteria and yeast is much higher for multiple-dose bottles than for single-dose syringes.

Intramammary infusion is a highly used and widely recommended procedure for mastitis therapy. However, there is a potential for the introduction of organisms during the infusion process. Unsanitary infusion practices can introduce antibiotic-resistant environmental organisms into the udder. Infection with opportunistic microorganisms, such as yeast or *Nocardia* sp., may cause more extensive udder damage than the original organism for which treatment was being administered. Adequate teat end preparation and careful dry cow treatment procedures can reduce this risk. Dry cow treatment procedures should be carried out as follows: (1) milk out the udder completely, (2) immediately after teat cup removal, dip all teats in an effective teat dip, (3) allow the teat dip to dry (if necessary, remove excess dip from teat ends with a clean, single-service paper towel), (4) disinfect each teat end by scrubbing for a few seconds with a separate alcohol-soaked cotton swab (start with the teats on the far side of the udder and work to the near side, allowing the alcohol to dry), (5) infuse each quarter with a single-dose syringe of a recommended dry cow treatment, starting with the teats on the near side of the udder, and (6) dip all teats in an effective teat dip immediately after treatment.

Downloaded from Vet-eBooks.com

The necessity of using appropriate dry cow treatment procedures cannot be overemphasized. The importance of these procedures has been demonstrated vividly with reports of udder health problems across Canada. From 1987 to 1989, a dramatic increase in the rate of isolation of *Nocardia* sp. from milk samples submitted to diagnostic laboratories was documented (Dohoo and Leslie, 1991). Three separate case-control studies were conducted to determine risk factors associated with this increase in *Nocardia* mastitis (Stark and Anderson, 1990; Ollis et al, 1991; Ferns et al, 1991). Each of these studies reported that blanket dry cow therapy, especially with neomycin-containing products, was an important risk factor for the occurrence of *Nocardia* mastitis. However, *Nocardia* organisms were not found as a contaminant of the suspected products. In one study, teat end preparation by scrubbing with an alcohol-soaked cotton swab protected against the occurrence of *Nocardia* infection when teats were contaminated experimentally with organisms immediately before drying off (Leslie et al, 1992). Most commercial dry cow treatment products provide individually wrapped alcohol-soaked cotton swabs for use with each syringe. The use of good teat end preparation before intramammary infusion needs to be emphasized continually to clients, and periodic comparisons of the number of alcohol pads in a box of mastitis infusion tubes with the number of tubes may offer insight as to teat end preparation compliance.

The problem of new dry period infections associated with the method of treatment has been the subject of some investigation. Partial insertion of the infusion cannula (up to 4 mm) has caused fewer new intramammary infections and improved cure rates (Boddie and Nickerson, 1986). The improvement with a short cannula is attributed to fewer organisms being delivered beyond the streak canal. In addition, antibiotic that is deposited within the streak canal should control local infections. Major pharmaceutical companies have developed modified infusion cannulas for the convenient use of a partial insertion method of administration. These devices are now widely available on commercial dry cow products. The difference between full and partial insertion of the infusion cannula is illustrated in Fig. 10-6.

Thus dry cow therapy is a critical part of a contagious mastitis control program. The major benefits are prevention of new IMI during the dry period and elimination of existing IMI. As a result of enhanced host defenses in the mammary gland, success of therapy is more likely for many pathogens during the dry period than during lactation. Nonetheless, infections caused by *S. aureus* can be the prototypical therapeutic problem in the elimination of IMI in many dairy herds. Bramley and Dodd (1984) stated that "one of the major limitations to effectiveness of mastitis therapy was the poor response of staphylococcal infections." In a retrospective study, new infection rate during the dry period of *S. aureus* in quarters was 11% when treated with one of three commercially available intramammary infusion products containing (1) cloxacillin, (2) neomycin and cloxacillin, or (3) a combination of nafcillin, procaine penicillin, and dihydrostreptomycin as compared with 4.9% in nontreated control quarters (Ziv et al, 1990). Dry cows administered intramammary cephapirin benzathine had a cure rate of 30.8%, and a new IMI rate of 51.7%, as compared with 33.3% and 29.3% in untreated quarters (Soback et al, 1990). However, subcutaneous norfloxacin nicotinate administered at the start of the dry period achieved a better cure rate (66.6%) and lower new infection rate over the dry period (17.1%).

The studies just mentioned provide evidence that herds with *S. aureus* IMI that are difficult to eliminate may want to consider including systemic drug regimens, preferably antimicrobials that distribute well in mammary tissue and abscesses

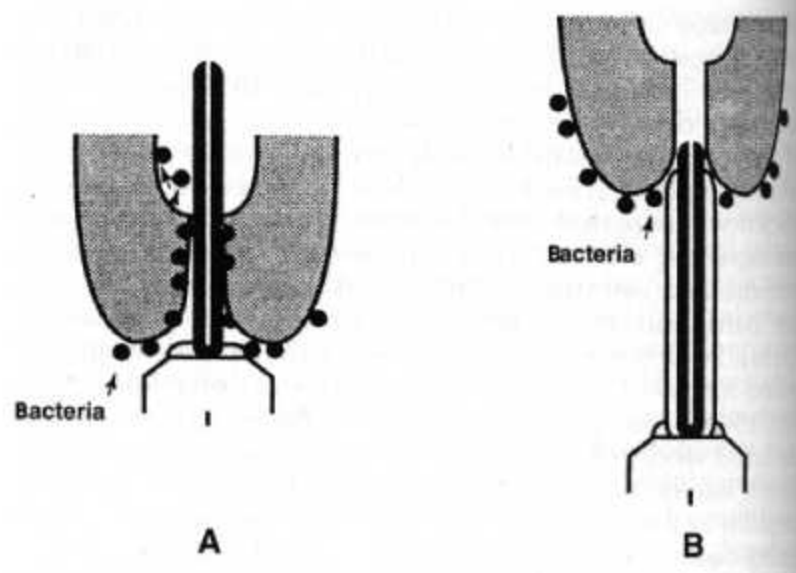

FIG. 10-6 Diagrammatic representation of the difference between **A,** full insertion and, **B,** partial insertion of the infusion cannula during intramammary therapy.

(e.g., tetracyclines, macrolides, and fluoroquinolones). Alternatively, the most effective therapy of chronic, nonresponsive *S. aureus* IMI may be to cull the cow from the herd.

Numerous cytokines, which regulate cell function during immune and inflammatory processes, have been identified and purified from cattle. With subsequent identification of the genes responsible for cytokine synthesis, recombinant production has been made possible. Cytokines that have demonstrated promise for use in the prevention or treatment of bovine mastitis are interleukin-1 (IL-1) and interleukin-2 (IL-2), interferons, and colony stimulating factor (Sordillo et al, 1991; Daley et al, 1992, Nickerson, 1989b, Oliver et al, 1990b). Intramammary IL-1β and IL-2 increase mammary gland polymorphonuclear leukocyte diapedesis. In addition, IL-2 activates inducible superoxide production and phagocytosis in neutrophils (Daley et al, 1991b). Preliminary trials with cows experimentally infected with *S. aureus* determined that 38% and 42% of infected glands were cured when treated intracisternally with recombinant bovine IL-1β and IL-2, respectively (Daley et al, 1992). This compared similarly with cure rates achieved with different intramammary formulations of sodium cephapirin. However, two subsequent field trials determined that IL-2 did not markedly improve cure rates among *S. aureus* infected quarters, and in one trial use of IL-2 was associated with abortions in treated cows (Hogan et al, 1995; Erskine et al, 1998a). Thus cytokines modulate and even enhance nonspecific cellular defenses, although clinical availability is not yet a reality; as yet, we do not understand the repercussions of altering the many mechanisms of cytokine activity.

Although dry cow therapy is a cornerstone of any mastitis control program, there is continuing controversy regarding the need to treat all quarters of all cows. This debate has gained momentum as the implementation of basic udder health management practices has caused a reduced prevalence of infection (Schultze, 1983) and an association in a large observational study between selective dry cow therapy programs and improved profitability (Gill et al, 1990). The major reasons for pursuing selective therapy are to reduce the expense of treatment, avoid the elimination of minor pathogens that may make cows more susceptible to environmental agents, and prevent the possible emergence of antibiotic-resistant organisms (Eberhart, 1986). Each of these reasons should be considered carefully when making a decision between selective and total dry cow therapy.

An important prerequisite for the large-scale implementation of selective dry cow therapy would be the develop-

Downloaded from Vet-e-Books.com

ment of a cheap, practical, sensitive, and specific test to identify infected cows. The positive and negative predictive values of any of the available screening tests are unacceptable as a basis for decisions concerning selective therapy. The history of clinical mastitis, CMT, individual cow SCC, and even bacteriologic culture all leave some infected cows untreated. In addition, many uninfected cows are treated. To compensate for the inadequate predictive values, repeated cultures would be necessary to enhance detection of infected cows. This would offset the benefit of decreased labor and product cost gained by selective therapy. It also must be considered that the prevention of new intramammary infections is effectively lost with the selective approach. Natzke (1981) has estimated that total dry cow therapy reduces new infection rates from approximately 14% to 7% of quarters. The increase in milk production from preventing these infections is sufficient by itself to offset the cost of antibiotic treatment for all cows. Currently, it is clear that the replacement of complete dry cow therapy with a selective program cannot be justified economically.

Total dry cow therapy can reduce the prevalence of infection with both major and minor udder pathogens. It has been suggested that the reduction of these minor infections is associated with an increase in clinical mastitis. One large epidemiological study did not support this hypothesis (Schukken et al, 1989a). The study followed 125 farms with low bulk milk SCC. Dry cow treatment had neither a beneficial nor a detrimental effect on the rate of clinical mastitis during lactation. Environmental conditions and individual cow factors were the most important risk factors. It would appear far more useful to develop meaningful programs to prevent environmental infections than to debate the risk of having a low herd SCC.

Despite blanket dry cow therapy, some cows calve with infected quarters and some with clinical mastitis. Several risk factors affecting the results of dry cow treatment of *S. aureus* IMI have been evaluated (Newbould, 1974; Sol et al, 1990). Probably the single most important factor in predicting the success of therapy is the duration of infection. Infections that have been present for greater than 2 to 3 months are less likely to be treated successfully than more recent IMI. Quarters of cows that have three or four quarters infected have a poor cure rate; this may reflect an inherent susceptibility of the affected cow to infection. As the age of the cow increases, the probability of *S. aureus* infections being cured by dry cow therapy decreases; this also could reflect duration of infection. In addition, the cure rate of *S. aureus*–infected quarters diminishes as the SCC before treatment increases. Controlling for age and number of quarters infected, there was a significantly lower cure rate in quarters with a SCC of greater than 1×10^6 cell/ml (Sol et al, 1990). There is a distinct herd effect on the success of dry cow therapy. The cure rate of *S. aureus* has been shown to be higher in herds with good hygiene and with a low prevalence of *S. aureus* infections at drying off (Sol et al, 1990).

Thus there is considerable potential in using individual cow and herd-level information to predict the likelihood of a *S. aureus* IMI cure. For example, an older cow with three infected quarters and a persistently high SCC has a low probability of a cure. Remember that antimicrobials only help the immune system in clearing IMI, and that signs of immune compromise such as multiple quarters infected should be used as signals that individual cows are poor therapeutic risks. Continued development of information management systems to assist with therapy and culling decisions can clarify the expectations of dry cow treatment.

Persistent *S. aureus* infections represent only one of the shortcomings of antibiotic treatment for dry cows. Most dry cow products are formulated for efficacy against gram-positive cocci. These antibiotics are of limited usefulness against gram-negative bacteria. In other words, new coliform infections would not be prevented by this therapy. Even though dry cow products are formulated for sustained activity, the provision of adequate protection during the critical prepartum period is questionable (Smith, 1985c). The persistence of effective levels of antibiotic has been evaluated for various dry cow treatments (Oliver et al, 1990a). Few products have persistent activity until the time of calving. One potential solution for protection through the critical periparturient period is the infusion of a lactating cow product 1 to 3 days prepartum (Pankey et al, 1982a,b). This approach merits investigation. However, there are concerns about the predictability of calving, accuracy of predicted calving dates, and the potential for antibiotic residues in milk of cows that calve early.

Appropriate dry cow management is extremely important for the maintenance of optimum udder health. Antibiotic therapy at the end of lactation is the most effective method of eliminating existing infections. Dry cow therapy also significantly reduces the rate of new infections during the dry period. Until better diagnostic tests and data management methods are available, the preferred approach is a blanket dry cow therapy program. This involves the treatment of all quarters of all cows immediately after the last milking. In addition, provision of a clean, dry environment and a properly balanced ration assists in the prevention of new dry period infections. Better methods of enhancing mammary involution and protecting the teat end need to be developed. Special attention is required in the precalving period.

Elimination of Infections by Culling. Culling may be the most effective method of decreasing the prevalence of chronically infected cows. The ability to cull infected cows is often limited by the need to maintain ample marketed milk for farm cash flow. Culling must be done judiciously with respect to production, breeding performance, genetic potential, and other health problems. Excessive culling to achieve quality milk premiums might have a negative net financial impact on herds. An alternative to culling chronic cows is to chemically dry off an infected quarter. Two to three doses of 60 ml of Novalsan solution (2% chlorhexidine acetate) has been reported to enhance fibrosis and involution of the treated gland (Boddie and Nickerson, 1994). The success of achieving fibrosis is variable and, if effective, permanent. This may allow the continued milking of a genetically superior cow, and compensatory milk production with the noninfected quarters is likely to maintain near normal; production levels. This would not be a good choice for cows with multiple infected quarters.

Frequently, dairy producers want to determine if culling a cow or multiple animals from a herd to lower the herd average SCC is a beneficial economic decision. As discussed with the example of the DHI reports (Fig. 10-2), there are many factors that enter into this decision. However, one of the incentives that is often discussed is the potential benefit from bonuses that are applied to lower herd SCC levels. A worksheet that reviews potential scenarios regarding this process is presented in Chapter Appendix B.

Mycoplasma Mastitis. Mastitis caused by *Mycoplasma bovis* and closely related pathogens has been increasing in importance throughout the dairy industry. Greater risk is associated with increasing herd size, especially if expansion involves purchase of cattle from varied sources. Explosive herd outbreaks of clinical mastitis may occur, or sporadic episodes in a few cattle at any point in time. As with other contagious pathogens, the primary reservoir of infection is believed to be other infected cows and subsequent exposure in the milking equipment. However, unlike the other typical contagious pathogens, *M. bovis* is believed to be able to

Downloaded from Vet-e-Books.com

cause an IMI from a hematogenous route following a respiratory infection (Jasper, 1982). Arthritis is also a common result of cows with bacteremia. Calves in affected herds may display respiratory symptoms and head tilts associated with inner ear infections. It has been suggested that milk from infected cows may be a source of infection for young calves, which in turn may display respiratory signs or become asymptomatic carriers (Walz et al, 1997). Reports from New York and Ohio determined that 2% to 3% of herds had *Mycoplasma* spp. in the bulk tank, although a California study isolated this organism from nearly 50% of the herds surveyed (Gonzalez et al, 1992; Hoblet and Muzammil, 1996).

Clinically, cows with IMI caused by *M. bovis* can be latent carriers or display clinical mastitis, although SCCs are usually consistently elevated. Initial episodes of clinical mastitis for an individual cow are often acute; systemic involvement can occur and often affect multiple quarters, which is unusual for other pathogens. Affected quarters often have serous secretions, and may go agalactic within a matter of days. Because of the more stringent culture requirements of these organisms compared with more common aerobic pathogens, it is best to involve diagnostic laboratory assistance to isolate this organism from milk samples of suspect cows. One of the more important methods of control is to identify and segregate infected cows. Affected cows, especially those that chronically display systemic signs or do not recover milk production, should probably be culled. A report from Florida suggested that many cows will return to adequate productivity, and thus culling should be made on an individual basis (Brown et al, 1990). Because of the potential for a long-term carrier state with intermittent shedding of bacteria in milk, segregation should be continued indefinitely for affected cows if possible. Other than clinical testimonials, no reports of successful antimicrobial therapy for mastitis caused by *M. bovis* have been reported. It is thus suggested that therapy should not be a major component of control for this problem.

Practitioners should be aware of the problem just described, especially in herds with a history of recent additions. Clinical episodes of mastitis that consistently do not yield pathogens on culture of milk, or that involve multiple quarters per cow, should be investigated thoroughly. Routine culture of bulk tank milk samples is useful for determining if *Mycoplasma* spp. are present in the herd, although culture of clinical mastitis cases probably offer the best probability to identify infected cows. Consideration should be given to not feed calves with milk from known infected cows to help prevent reintroduction of carriers into the herd once calves mature into first lactation cows.

ENVIRONMENTAL MASTITIS: GOALS, ASSESSMENT, AND CONTROL

In a Pennsylvania study (Erskine et al, 1988), clinical mastitis incidence did not differ in low SCC herds that were essentially free of contagious mastitis, as compared with high SCC herds with a high prevalence of contagious mastitis. As may be expected, the predominant cause of clinical mastitis in the high SCC herds was *Str. agalactiae* and *S. aureus*. The predominant causes of clinical mastitis cases in the low SCC herds were coliforms and streptococcal pathogens other than *agalactiae*. Thus, despite successful implementation of a contagious mastitis control program that is founded on postmilking teat dipping and total dry cow treatment, well-managed herds could continue to have significant mastitis problems. Other reports from Ohio, California, and Michigan have confirmed the importance of clinical mastitis caused by environmental pathogens in well-managed herds that have controlled contagious mastitis, with incidence of clinical cases ranging from 25 to 50 cases/100 cows/year (Hoblet et al, 1991; Gonzalez et al, 1990; Judge et al, 1997).

This section outlines a health management program for herds that have controlled contagious mastitis to a point at which environmental pathogens have become the predominant cause of mastitis. Chronic, subclinical manifestations of IMI caused by environmental pathogens occur, although some pathogens in this group, most notably the coliforms, tend to have transient infections with varied intensity of clinical signs. In addition, because the reservoir of new infection is the environment of the cow and not the parlor or barn where milked, management practices that focus on the prevention of transmission of pathogens during milking would be expected to have little effect on exposure of the teat in the housing of the cow. Thus a management plan for identifying and controlling clinical mastitis caused by environmental pathogens must offer a different perspective from that used to control contagious pathogens.

Goals

Because of the dynamic, rather than static, nature of many environmental IMIs, standard tools that identify prevalence or describe the extent of the problem on any given day are inadequate. Particularly, routine herd culture and monthly SCC reports are poorly correlated both at a herd and an individual cow level with identification and prediction of a clinical mastitis problem. In the Pennsylvania study, whole herd culture yielded low prevalences of IMI for all pathogens, including environmental pathogens. Nonetheless, in the ensuing 6 months many cows were affected with a case of clinical mastitis despite previous negative cultures or low DHI SCC (Erskine et al, 1988). Likewise, it can be more difficult to assess monetary losses from environmental mastitis as compared with contagious mastitis. Chronic IMI caused by pathogens such as *Str. uberis* can be monitored and lost production calculated from LS. However, lost production from transient episodes of clinical mastitis, and treatment costs, especially the cost of discarded milk following treatment, cannot be discerned from DHI SCC records. Thus goals should reflect an understanding of these principles and describe the extent of the environmental problem in a herd in relation to potential economic opportunities (Table 10-4).

Assessment

The NMC Mastitis Control Program emphasizes good record keeping and monitoring of udder health. To assess clinical mastitis incidence and losses, observations and recording of case information must be made daily. This is the most critical opportunity and greatest potential failure for many herd managers in an environmental mastitis control program. Unlike the "automatic" appearance of a DHIA tester at regular intervals to sample the cows, or herd culture of suspect cows that can be done on a convenient basis such as during a herd health visit, recording of clinical mastitis data must be done everyday and on the manager's initiative. With all the other time commitments that demand a dairy producer's attention, this can be a difficult task. It does not matter if information is recorded on computer or written records, as long as it is as complete as possible. Excellent examples of data sheets that can be used for maintaining herd data are presented (Fig. 10-7). Thus the first critical element of assessing clinical mastitis is a record of clinical cases. By simply recording cow, quarter, and date, and subsequently researching the personal data of the affected cow, these records can be vital to determine important risk factors for a herd problem such as days in milk, season, and age. The

Discarded milk from mastitis therapy	<0.5% of total production/year or <$15/cow in herd/year	Monthly

*Clinical outcome death, agalactia, or culling within 30 days as a direct result of mastitis case.

number of days that milk was discarded for each case should be recorded. This will allow an economic tracking system of the clinical mastitis problem. In herds that utilize daily milk weight technology, economic losses from lost production for each case can be calculated elegantly by comparing milk production after the clinical mastitis case with predicted performance.

The second important focus needed to monitor clinical mastitis in a dairy herd is the bacteriologic culture of milk samples from clinically affected quarters. It is unrealistic to assume that all cases will be sampled. However, if a representative number of cases are sampled (representative not just in number, but in terms of season, age, severity, etc.), bacteriologic data can augment the recorded data in offering a powerful database from which management decisions can be made. Herd personnel will bear the primary responsibility to collect samples, and thus emphasis on aseptic collection technique and collection, before any treatment should be made. Collected samples may be frozen and stored on the farm until collection by the practitioner during a routine visit. Freezing of milk samples for greater than four weeks may decrease the ability to isolate *E. coli* from samples, although not affect isolation of gram-positive cocci (Schukken et al, 1989b). Nonetheless, it is typical to have 25% to 35% of samples not yield isolates; some of this apparent failure is likely due to the short duration of many IMIs that cause clinical mastitis. In addition to epidemiological information, culturing of clinical cases also serves to safeguard a herd from clinical mastitis from unusual pathogens. Between 85% and 95% of bacterial isolates from clinical cases in low SCC herds are coliforms, streptococci, and staphylococci. Consequently, when a high proportion of cultured pathogens other than the three major groups is isolated, an usual mastitis problem should be suspected. Notably, if one type of organism is predominantly isolated, a point source of infection in the environment of the cow, such as contaminated teat dips, water hoses, or intramammary infusions, should be suspected. Accurate records coupled with bacteriology can also positively influence therapeutic decisions regarding clinical mastitis, especially in designing herd level protocol.

Control of Environmental Mastitis

Epidemiology

Coliform is a general term that refers to lactose-fermenting rods of the family Enterobacteriaceae. This group includes the genera *Escherichia, Klebsiella,* and *Enterobacter*. Among herds and cows within herds, a variety of species and serotypes may cause mastitis. Serologically identical strains are rarely found in IMI of different cows within a herd. This suggests a noncontagious nature of coliform mastitis, and the failure of herd management practices that successfully control contagious pathogens to control the incidence of coliform mastitis is well documented. Field studies in herds with low SCCs from Pennsylvania, Ohio, and California have reported average herd incidence of clinical mastitis to be 40 to 50 cases/100 cows annually (Erskine et al, 1988; Hogan et al, 1989b; Gonzalez et al, 1990). Coliform organisms were the single most common group of pathogens isolated from culture in these studies, accounting for 30% to 40% of the clinical cases, and as much as 61% of the cases in which a causative agent was isolated. Although only 10% to 30% of clinical coliform cases are severe (systemic signs), coliform organisms are often the single most important cause of severe clinical mastitis, accounting for 35% of the cases in an Illinois study, and nearly 60% in an Ohio study , but only 15% in a more recent Michigan study (Hogan et al, 1989b; Bezek, 1998). As many as 10% to 15% of cows with severe cases die or have to be culled.

The other major groups of pathogens that frequently cause clinical mastitis are the streptococci, excluding *Str. agalactiae,* and staphylococci. *Str. uberis* and *Str. dysgalactiae* are the two most common streptococcal isolates, although numerous other streptococci and closely related enterococci have been identified as causative agents. Streptococci may account for 20% to 25% of the clinical cases (Bezek, 1998; Erskine et al, 1988; Judge et al, 1997). Incidence of clinical mastitis caused by staphylococci can be more variable but usually accounts for less than 20% of the cases in herds that have controlled contagious mastitis (Erskine et al, 1988; Judge et al, 1997). As with the coliforms, control measures that are successful for contagious pathogens are less successful with the streptococci. However, modest decrease in the prevalence of streptococcal IMI with postmilking teat dipping and dry cow therapy has been reported (Eberhart and Buckalew, 1972), suggesting at least in part a contagious reservoir of infection. Particularly, the dry period is believed to be a critical part of the cow's lactation cycle for new IMI caused by streptococci, and as much as 50% of clinical mastitis cases that occur in the first 60 days of lactation are manifestations of IMI that started in the dry period (Smith, 1985c).

There is considerable variation in the incidence of clinical mastitis between herds. Among 12 herds with low SCC in Pennsylvania, the incidence of clinical mastitis over 6 months ranged from 5 cases/100 cows/year to 123 cases/100 cows/year (Erskine et al, 1988). Thus some herds are able to control contagious mastitis and have a low incidence of clinical mastitis.

Environmental pathogens are ubiquitous but are particularly numerous in bedding and manure. Sawdust bedding

has been incriminated as a factor in increased incidence of coliform mastitis, and straw bedding as a factor for streptococci (Hogan, 1989a). Coliform counts in sawdust bedding have been determined to be higher than counts in sand, fresh cattle manure, and unused sawdust, and *Klebsiella* organisms readily multiply in sawdust (Bramley, 1985). Any bedding material can harbor potential pathogens, particularly those with higher organic content or fecal contamination. Thus a clean dry environment for dairy cattle is probably the most critical factor in the prevention of coliform mastitis. Other factors such as improved understanding of periparturient nutrition, climatic conditions, and use of core-antigen vaccines may also account for decreased incidence of environmental mastitis. In this author's opinion, realistic goals of one to two cases of clinical mastitis per 100 cows per month are obtainable when cows are clean, dry, and comfortable.

In a Pennsylvania study, cows were four to five times more likely to be affected with clinical coliform mastitis in warm, humid periods of the year than in cooler, drier months (Erskine et al, 1988). This seasonal variation in incidence may, in part, be explained by a higher degree of environmental exposure to coliform organisms during the summer months. Considerably higher numbers of coliforms and streptococcal bacteria are isolated from organic bedding sources in summer than in other seasons of the year (Smith, 1985c). Conversely, bacterial numbers isolated from bedding material during winter were lower than those isolated during all other seasons. These findings were consistent with higher rates of new infections in nonlactating cows during spring and summer (Smith, 1985c).

Recently calved cows are at greater risk for being affected with clinical mastitis, especially those in the first month of lactation. In a New York study the incidence of clinical mastitis was four times higher during the first 21 days after parturition than any other 21-day period of lactation (Erb et al, 1984). In Pennsylvania herds, nearly 50% of clinical mastitis cases occurred in the first month of lactation, and 7% of all cows had an episode of clinical mastitis in this 30-day period (Erskine et al, 1988). The increased risk of coliform mastitis for postpartum cows may be associated with a decreased ability of neutrophils to migrate into the gland during infection (Hill et al, 1979). The mechanism may be associated with the cortisol surge that occurs during calving, which in turn decreases neutrophil L-selectin expression (Preisler, 2000). L-selectin is a membrane protein necessary for neutrophils to marginate and initiate diapedesis into a site of infection. A higher incidence of infection also has been reported among older cows as compared with first lactation cows. In addition, despite the near hysterical claims that the use of bovine somatotropin is detrimental for udder health, use of this production enhancement technology by proper label use does not cause increased incidence of clinical mastitis, rate of culling because of mastitis, or discarded milk following therapy of mastitis with antimicrobials (Judge et al, 1997).

A summary of the epidemiology of environmental mastitis includes some key points. The reservoir of infection is the environment of the cow, which causes a wide variety of organisms as causative agents. Mastitis management practices that are successful in controlling contagious pathogens have little success in controlling environmental mastitis. As a result, many of the herds most severely affected with clinical mastitis caused by environmental pathogens have above average production and below average SCC. The periparturient period, warm humid seasons, and increasing age have all been identified as potential risk factors for increased incidence. Consequently, if herd records indicate a clinical mastitis problem and herd SCC are meeting quality milk goals, the control program will likely need to focus on the environment of calving cows, their first 30 days of lactation, and possibly the dry period if streptococci are a problem.

Reduce Exposure

With respect to environmental mastitis, the goal of every dairy farm should be to expose the teat of a cow to as few bacteria as possible. This concept of prevention is simple; the execution can be very difficult. Trends towards increased size of dairy herds, more confinement housing, greater milk production (with subsequent increases in dry matter intake and manure production!), and genetic selection toward production and away from disease resistance are all modern dairy management realities that work against practitioners in the control of environmental mastitis. The demands on producers to manage labor to maintain a clean, dry environment for cattle housing competes with other needs of the dairy enterprise. Housing should account for all climatic possibilities in a given region, not just good weather conditions. Pastures can also pose problems, especially after periods of extensive rainfall. Dairy producers should provide adequate shade to prevent crowding in warm periods of the year, and if portable shading is used, frequent movement about the pasture is recommended. Dry cow housing and particularly maternity areas should receive attention as well. Particularly, for lactating cows, adequate free stall space should be provided for the number of cows in each housing group.

Sand bedding used in well-designed free stalls should be considered as the standard for housing. In some dairy operations this may not be practical because of manure handling and storage facilities or lack of cost-effective regional supply. Sawdust, if frequently changed, such as on a cow mattress system, may offer an alternative. However, in one study, cows maintained on sawdust bedding had an incidence of clinical coliform mastitis 4.5 times higher than herdmates bedded on sand (Bramley, 1985). An Ohio study suggested that addition of lime at 1 part to 10 parts sawdust will raise the pH of the bedding and reduce coliform counts (Hogan, 1995). However, this must be done daily to attain the desired effect.

Other methods to reduce teat exposure to the barnyard environment may offer marginal success. However, no management practice will be successful if the general environment of the cows is otherwise unhygienic. A minimum amount of water should be used in udder preparation before milking. Although research substantiating this practice as a means to reduce incidence of clinical mastitis is lacking, copious amounts of water used to wash udders will eventually cause wash water on the teat end. This and other less-than-desirable practices such as failure to clip udders can eventually lead to greater numbers of bacteria on the skin of the teat and, if nothing else, contribute to higher bacteria counts in milk. As previously stated, drop hoses in parlors that carry wash water for udder preparation have been incriminated as sources of *Pseudomonas* IMI (Erskine et al, 1987c).

As an alternative to wash water for teat preparation, premilking teat dips have been advocated as part of a preparation routine. Premilking teat dipping was reported to reduce the incidence of new IMI infections by 61% in a four herd Vermont study (Pankey, 1989). However, a Pennsylvania study found no benefit of predipping in reducing new infection rate (Unflat, 1985). Due to a lack of published data correlating premilking teat dipping with incidence of clinical mastitis caused by environmental pathogens, a blanket endorsement of this practice as a means to decrease environmental mastitis for all herds cannot be made. It is most likely to be advantageous for herds with demonstrated ability to maintain adequate clean housing for cows. Because of poten-

Downloaded From Vet-e-Books.com

tial residues following premilking teat dipping, care should be exercised to thoroughly clean the teats before milking equipment attachment. Acrylic latex and other materials have been added to teat dips to serve as a barrier to the environment. Results have not been consistent. Farnsworth et al (1980) reported a significant reduction in the rate of new coliform IMI in lactating cows when a barrier dip was used as a postmilking teat dip. However, another study did not attain a reduction in new coliform IMI rate (McArthur et al, 1984). In addition, dipping teats once daily for 14 days before parturition did not reduce new infections at calving. While these products are promising in theory, further development is needed. These products should be used in lactating cows in conjunction with monitoring IMI status of contagious pathogens as routine use of some barrier dips, since a postmilking teat dip may not effectively prevent new IMI caused by contagious organisms (Erskine and Eberhart, 1991b).

Enhanced Resistance

The teat sphincter is the primary barrier to infection. Once this defense is breached, secondary and less effective immune mechanisms are mobilized. Key to the secondary line of defense is the neutrophil. Quarters with elevated SCC are more resistant to experimental *E. coli* infection than quarters with low SCC (Carroll et al, 1973). This may explain, in part, why cows in herds with high SCC have greater incidence of coliform mastitis than cows in high SCC herds.

Increased incidence of diseases such as hypocalcemia, ketosis, and displaced abomasums are associated with increased incidences of clinical mastitis. Thus poorly managed nutrition of dry cows, prepartum cows, and cows in the first 30 days of lactation can adversely affect udder health. Antioxidant supplementation also plays a critical role in mammary immune resistance. Selenium and vitamin E supplementation enhances neutrophil killing of phagocytized bacteria. Cows supplemented during the dry period with vitamin E and administered a single injection of selenium before calving had decreased incidence of clinical mastitis (37% reduction) and shorter duration of infection (62% reduction) than unsupplemented controls (Smith et al, 1984). A decrease in clinical mastitis (57%) and duration of infection (40%) during first lactation was observed in selenium and vitamin E–supplemented heifers as compared with unsupplemented controls (Smith, 1985a). First-lactation Holstein cows supplemented with 0.14 ppm dietary selenium had peak bacterial concentrations in milk during experimental *E. coli* mastitis 100 times lower than selenium deficient cows (Erskine et al, 1989). Consequently, selenium deficient cows exhibited diarrhea, dehydration, quarter agalactia, and residual quarter atrophy more frequently than selenium supplemented cows.

One of the more promising methods of enhancing mammary resistance for coliform (and all gram-negative) IMI is by the use of core antigen vaccination. Historically, attempts to immunize cows against coliform infections met with little success. Much of this failure resulted from the diversity of surface ("O" or capsular) antigens presented on invading pathogens. Among herds and cows within herds, a variety of species and serotypes may cause mastitis. Serologically identical strains are rarely found in intramammary infections of different cows within a herd (Eberhart, 1979). However, development of a bacterin derived from the J5 mutant of *E. coli*, a strain that lacks the capsular antigens but retains the lipopolysaccharide core of the cell wall, has proven effective in reducing the severity of coliform mastitis. The lipopolysaccharide core is highly conserved genetically and is phenotypically expressed throughout most gram-negative bacteria. Thus exposure and presentation of the endotoxin antigens in the bacterin to the immune system should lead to nearly universal recognition, and hopefully a response to any gram-negative bacterial pathogen. California studies demonstrated that cows receiving two vaccine doses during the dry period and one dose after calving had an incidence of clinical coliform mastitis of 2.6%, as compared with 12.8% in unvaccinated controls (Gonzalez et al, 1989). A second field trial determined that vaccinated cows had a threefold decrease in clinical coliform mastitis (Cullor, 1991). Subsequent field studies from Ohio have confirmed the benefits of this technology (Hogan et al, 1992b). Titers among cows for naturally occurring serum antibody specific for the J5 strain of *E. coli* were negatively correlated to risk of clinical coliform mastitis in a California dairy herd (Tyler et al, 1988). Similarly, titers in response to immunization were negatively correlated with severity of clinical outcome after experimental challenge of *E. coli* (Hogan et al, 1992a). Experimental challenge models of *E. coli* mastitis have indicated that vaccination with J5 bacterins (1) decreases clinical severity but does not prevent infection, (2) reduces the concentration of bacteria in milk, and (3) is beneficial for multiparous cows as well as primigravid heifers (Hogan et al, 1992a; Hogan et al, 1999). Commercial availability of this vaccine technology has allowed widespread use in many herd mastitis control programs. Despite the potential benefits, these vaccines cannot overcome poor environmental conditions for housing or be expected to affect clinical mastitis caused by non–gram-negative pathogens. However, development of this vaccine has been the single biggest advance in active transfer of immunity against mastitis for dairy cattle and, depending on the incidence of clinical mastitis caused by gram-negative bacteria in a herd, should be considered for a complete mastitis control program.

Therapy of Clinical Mastitis

Guideline 5 of the NMC guidelines for mastitis control promotes appropriate therapy of clinical mastitis. This is a topic that offers considerable variability in clinical interpretation of efficacy, debate as to preferred therapeutic regimens, and frequent testimonials of apparent success. Between 30% and 35% of bacteriologic cultures of milk samples collected from cows with clinical mastitis do not yield any microorganism. Unlike severe clinical mastitis cases, treatment of mild cases (abnormal milk with or without local inflammation of the affected quarter, no systemic signs) is a more voluntary therapeutic decision. Many mild mastitis cases are coliform IMI that are resolved before treatment is necessary. Numerous mild clinical mastitis cases are temporary setbacks in the balance between pathogens and host defenses during the course of chronic IMI. A high proportion of clinical cases observed in cows during the first 60 days after calving, particularly those caused by gram-positive cocci, are manifestations of infections that started during the dry period. In addition, chronic IMI often displays recurring episodes of clinical mastitis at regular intervals, and a small proportion of cows (lactations) often accounts for a disproportionate number of cases (Morse et al, 1987). This poses the major dilemma for treatment of mild clinical cases: Does antimicrobial therapy enhance cure rate over that attained by no treatment (spontaneous cure)? Therapeutic and spontaneous cure rates for clinical mastitis cases caused by coliforms and staphylococci are similar. However, streptococcal IMI, at least if not chronic, may be advantageous to treat.

Information on the therapy of streptococcal clinical mastitis infections is not extensive. Wilson et al (1986) reported 74% of clinical cases caused by *Str. uberis*, and 84% of cases caused by *Str. dysgalactiae* resolved after a single intramammary infusion of cefoperazone. However, bacteri-

Downloaded From Vet-eBooks.com

ologic cure was achieved in only 60% to 65% of the cases, and a comparison of cure rate in treated versus untreated cows was not reported. In a study of three California dairies, bacteriologic cure assessed at 4 and 20 days after treatment with amoxicillin, cephapirin, or oxytocin (no antimicrobial) did not differ for mild clinical mastitis cases caused for all pathogens, although antimicrobial treatment led to better clinical cure rates for cases caused by pathogens other than streptococci and coliforms (Guterbock et al, 1993). Thus a "no antibiotic" approach to mild clinical mastitis cases promotes a convenient regimen to avoid costs of discarded milk and residue risks that are inherent in antimicrobial therapy. However, an economic analysis of the California data determined that, although milk production and survival in the herd did not differ between antimicrobial- and nonantimicrobial-treated cows, the rate of both relapses and recurring cases was higher in nonantimicrobial treated cows, especially among streptococcal cases (Van Eenennaam, 1995). A case report from a Colorado dairy also reported an acute increase in incidence of clinical mastitis, prevalence of IMI, and subsequent increase in herd SCC associated with streptococcal IMI following adoption of a no antibiotic approach to clinical mastitis (Cattell, 1996). Administration of supportive care, intravenous oxytetracycline and intramammary cephapirin to cows with varying degrees of clinical mastitis severity caused a higher frequency of normal udder appearance at 10 days (clinical cure), and bacteriologic cure 14 days for streptococcal IMI, and clinical cure for coliform IMI compared with cows administered supportive care only (Morin et al, 1998).

Nonetheless, many herds report success with minimal antimicrobial therapy of clinical mastitis cases. The decision to pursue this option on any dairy must be made on an individual basis, and records of clinical mastitis incidence, SCC, and bacteriologic identification of causative agents should be monitored carefully. However, no matter what the overall herd approach is to new clinical cases in cows, it is rarely efficacious or profitable to administer therapy to milder clinical cases that are chronic and recur repeatedly.

The therapeutic management of severe coliform mastitis is an important concern for veterinary practitioners. Reviews of the therapy of severe coliform mastitis have suggested various treatments, including antimicrobials, supportive fluids, stripping of infected quarters, antiinflammatory agents, glucose, bicarbonate, and calcium (Anderson, 1989; Eberhart, 1979). However, efficacy has not been proven for most of the drugs recommended as therapy for coliform mastitis. In addition, the antimicrobials selected for treatment are usually based on in vitro sensitivity patterns, and because of a high degree of resistance to labeled mastitis therapeutic regimens, typically therapy resorts to extra-label use (Anderson, 1989; McDonald et al, 1977b). These facts, as well as new information regarding the pathophysiology of coliform mastitis, indicate that the traditional approach to therapy should be reconsidered.

After infection, bacterial concentrations in milk increase rapidly. Peak bacterial concentrations in milk often occur within 5 to 16 hours. Subsequently, there is a massive migration of neutrophils into the gland, followed by a rapid decline in bacterial numbers. The inflammatory and systemic changes observed during the course of acute coliform mastitis result from the release of lipopolysaccharide endotoxin as bacteria are destroyed. Endotoxins cause the subsequent activation of numerous endogenous inflammatory mediators, including arachidonic acid metabolites, macrophage-derived monokines, and phagocyte-derived oxygen free radicals (Erskine, 1991a). The severity of acute coliform mastitis appears to be related to the magnitude of the bacterial growth phase and the subsequent cascade of inflammatory events. In order to reduce the severity of these cases, either bacterial growth must be inhibited to prevent high peak concentrations or the effects of endotoxin release must be neutralized.

From a practical standpoint, therapy of acute coliform infections cannot begin until clinical signs appear. Clinical recognition of coliform cases usually occurs well after peak bacterial numbers in the gland have come and gone (Erskine, 1991b). Thus, by the time antibiotic therapy is initiated, the coliform bacteria are in decline and the maximum release of endotoxin has already occurred, which raises questions as to the benefits of antibiotic therapy. Thus early recognition of acute coliform mastitis is extremely important. Limiting the peak of bacterial growth is highly correlated with a successful clinical outcome. Careful examination of the udders and milk at the time of milking, as well as new methods of automatic in-line detection of inflammatory changes, may represent the most meaningful herd-level approach to minimize the effects of clinical coliform mastitis. Therapeutic intervention in coliform mastitis cases should be targeted at reducing the effects of inflammation rather than antimicrobial action. In other words, administration of fluids and effective antiinflammatory agents are more important than antibiotic therapy.

Although antimicrobial therapy may be of secondary importance relative to supportive treatment of endotoxic shock, it remains a practical part of a therapeutic regimen for severe mastitis. Much of our understanding of the pathogenesis of coliform IMI arises from experimental challenge models. However, these cannot be considered as universally applicable for all cases. Occasionally, coliform infections do cause chronic mastitis. Septicemia can occur and has been reported in 15% to 45% of severe cases of coliform mastitis and systemic antimicrobial therapy would be indicated (Powers et al, 1986; Wenz et al, 1998). In addition, numerous other pathogens cause acute clinical mastitis, which can be difficult to distinguish from cases caused by coliforms at initial presentation. Chronic IMI caused by pathogens such as *S. aureus* can become acute or even gangrenous at times of neutropenic dysfunction such as parturition. Severe overwhelming IMI that lead to sepsis can occur during IMI caused by pathogens such as *P. aeruginosa* and *Bacillus cereus*, although antimicrobial therapy for these pathogens may offer little amelioration of clinical outcome. The need for antimicrobial therapy in cows with grossly abnormal milk but with improved appetite, attitude, and milk production, should be evaluated critically. Unnecessary extension of therapy in these instances causes increased discarded milk expense for the dairy producer and risk of antimicrobials in marketed milk. The rational use of approved antibiotics is still indicated, pending confirmation that the infection was actually caused by coliform organisms and that they have been reduced in numbers.

Thus a treatment protocol for clinical mastitis should be established for herds on an individual basis. Records of clinical cases including recurrences, clinical outcome of each case including days of discarded milk and culling, bacterial culture of milk collected from affected quarters, and sound use of pharmacokinetic principles, particularly for drugs selected for parenteral administration, are all needed to ensure the most cost-effective plan.

SUMMARY

Control of mastitis on a farm cannot overshadow the need to balance other aspects of the dairy enterprise, and thus mastitis control programs cannot be initiated without an understanding of the nutritional, reproductive, replacement, and other infectious disease programs that also dictate the

Downloaded from Vet-e-Books.com

use of labor and physical facilities on a dairy farm. Nonetheless, information that allows effective mastitis decision making is available in the form of bacterial cultures, SCC, and records of clinical mastitis. Practitioners should use this to some extent on every dairy, although goals may vary. Familiarity of DHIA reports used in the region, potential quality incentives offered by local milk cooperatives, and penalty programs for less than optimum quality milk should be a prerequisite for a mastitis control program. It is also imperative to fully understand and establish a client's drug use protocol and residue avoidance plan.

It is highly recommended that any practitioner who wants to maintain a current understanding of mastitis control participate in organizations such as the American Association of Bovine Practitioners and the NMC. In particular, the NMC has recently released a reference manual for bacteriologic culture of milk samples, which can be considered as the standard guidebook, and should be in the possession of any practice that participates in mastitis control of dairies and particularly if bacteriologic culture of milk is performed.* Mastitis cannot be eradicated from a dairy farm, but it can be reduced to an acceptable level of economic losses to instill pride in a farm's ability to market a quality product.

APPENDIX A

WORKSHEET TO ESTIMATE MILK LOSS FROM LINEAR SCC

Linear somatic cell count (LS)	Milk Loss (lb/day)*	No. of Cows	Milk Loss
3	1.5	U	1.5 × U
4	3.0	V	3.0 × V
5 (284,000-565,000)	4.5	W	4.5 × W
6	6.0	X	6.0 × X
7	7.5	Y	7.5 × Y
8	9.0	Z	9.0 × Z
9	10.5	ZZ	10.5 × ZZ
Total Milk Loss/Day/Herd	=	Σ of milk loss column products	

Losses are estimates of second and greater lactation cows. Losses for each LS category are one-half that of older animals. Multiply the number of cows in each category by the milk/loss/day factor. Sum total all the products for the milk loss /day/herd. Multiply this total by the market value of milk to determine the economic loss per day.

Example Herd

Linear SCC (LS)	Milk Loss (lb)/Day*	Number of Cows ≥2 lactation(1st lactation)	Milk Loss (lb/day)
3	1.5	5	7.5
4	3.0 (1.5)	10 (4)	30 (6)
5 (284,000-565,000)	4.5	4	18
6	6.0	6	36
7	7.5 (3.75)	2 (2)	15 (7.5)
8	9.0	4	36
9	10.5	0	0

Total milk loss/day/herd = 142.5 lb/day + 13.5 lb/day for 1st lactation
= 156 lb/day relative to linear score of >3.0

DHI SCC summary (see Fig. 10-2, *B*) calculates loss on average LS for herd on test date. This was 5.3; this LS = 4.5 lb/day assessed on all cows in herd, 41 cows in herd = 184.5 lb/day. summa

*Milk loss = 1.5 lb/day for cows ≥2 lactations; 0.78 lb/day for lactation = 1 (from Raubertas and Shook, 1982).

Downloaded From Vet-eBooks.com

APPENDIX B

CULLING COWS TO ATTAIN A SOMATIC CELL COUNT

1. **PARTIAL BUDGET FOR CULL COWS** (75 lb/day/cow; 305-day lactation)

Increased revenue	\$0.35/lb × 1,400 lb − auction fees	\$455
Decreased costs	\$6/day × 305 days	\$1830
Decreased revenue	75 lb/day × \$ 0.13/lb × 305 days	\$2975
Increased costs		\$0
TOTAL (loss from culling cow)		−\$690

This assumes a 75 lb/day average for the herd and projects potential losses-gains for an ensuing 305-day lactation. It is difficult to assess potential gains from removing a cow with contagious mastitis from the herd (removal of a reservoir for new IMI) and potential gains for culling of cow with other potential health problems). Use of potential replacement heifers is not in model.

2. **POTENTIAL GAIN AT HERD SCC LEVEL** (refer to Table 10-2)

= Co-op bonus + FMO Bonus
= [Value of milk (\$/cwt) × cwt milk marketed/year] + [\$/lb protein × (lbs milk/yr × mean % protein of marketed milk)

Other bonuses may apply, such as volume bonus for larger herds if a specific SCC is attained

Example Herds (refer to Table 10-2 for bonus information)

Example 1: Removal of 5 cows results in bulk tank somatic cell count (BTSCC) decrease from 310,000 to 260,000
100 cow dairy; 75 lb DM; 3.2% protein
Cull Cow Loss + Herd Bonus
−\$ 3450 + 0.05/cwt × 27,375 cwt + 0.01/lb protein × 87,600 lb protein
−\$ 3450 + \$ 1370 + \$876
−\$ 1204 loss from culling 5 cows

Example 2: Removal of 5 cows results in BTSCC decrease from 220,000 to 190,000
100 cow dairy; 75 lb DM; 3.2% protein
Cull cow loss + Herd Bonus
−\$ 3450 + 0.10/cwt × 27,375 cwt + 0.02/lb protein × 87,600 lb protein
−\$ 3450 + \$ 2737 + \$ 1752
+\$ 1039 gain from culling 5 cows

Example 3: Example herd (recorded in Fig. 10-2, A); 41 cows milking, 31 lb of milk/day average, 3.2% protein; Cull cow # 31, cow # 45, Carol, and Connie to lower herd SCC to 381,000 (projected from DHI-520) and no longer pay penalty for protein price (Milk Order 40). Culled cows producing a total of 175 lb/day: potential lost revenue for 305 days is 53,375 × \$ 0.13 = \$ 6940 (for all four cows); potential increased revenue and decreased costs are \$2285/cow × 4 cows = \$ 9140; total from culling cows \$2200 gain

Cull cow loss + Herd Bonus
\$ 2200 [SCC bonus = 0] + [0.11/lb protein × 14,845 lb protein]
\$ 2200 + \$ 1633
\$ 3833 gain from culling 4 cows

This model is based on U.S. pricing system in which milk quotas are not involved in the marketing. Gains/losses are projected for 1 year after culling of cows to attain a SCC level. Results will vary depending on price of milk, protein, cull cows, and daily milk production per cow/day. However, the assumption for potential gain relies on the ability for the farm to maintain the lower SCC level, and thus attain the improved price bonus for milk, for 1 year. This implies that IMI will be prevented effectively and any new IMI in the herd will not cause elevated SCC, or additional cows will need to be culled to maintain the SCC bonus.

CHAPTER 11

Dairy Cattle Nutrition

BRIAN J. GERLOFF

There is probably no aspect of a dairy enterprise that has wider impact than the feeding program. Dairy farm feeding programs have direct effects on production and growth and set the stage for future productive potentials. Many health problems on a dairy relate in some way to the feeding program. Feed costs on the average dairy account for more than 60% of total operating expenses in the United States (USDA, 1988). A significant part of the average dairy's labor force devotes its time to planting, growing, harvesting, mixing, and feeding rations to a variety of animals. Investments in equipment used in feeding programs are an important part of the dairy's debt load. Small changes in feeding programs may bring about large changes in productivity, health, income, feed costs, labor allocation, and debt load. The total savings from small changes can be substantial. Without considering improved production or health effects, one study has shown that routine nutritional consultation by veterinarians can save 14% of total feed costs on dairies (Ferguson et al, 1987).

For all these reasons, veterinarians who intend to serve their dairy clients on a herd basis must become actively involved in the herd's feeding program (Gerloff, 1991). Dairy herds are commonly fed unbalanced, expensive rations (Ferguson et al, 1987). By serving as independent consultants, veterinarians can provide unbiased advice to their clients. Those veterinarians who wish to serve their clients at a herd level constantly find their attention focused on the feeding program. The next recumbent, hypocalcemic cow raises questions about dry cow feeding. The next anestrous, thin cow with smooth ovaries raises questions about early lactation energy levels in the ration and dry matter intake (DMI). The next time the herd average mature equivalent milk production falls by 500 lb, the problem generates the same sense of urgency as a cow with a prolapsed uterus. As a profession, dairy veterinary medicine must come to grips with the fact that it cannot truly serve client needs by practicing therapeutic medicine separately from nutritional consulting. Veterinarians must train themselves to deal with nutrition directly, consistently, and knowledgeably.

In recent years, as herd size has increased, many dairies have come to rely on a team of advisors rather than only one or two. A nutritional consultant, local veterinarian, and outside consultant may all be providing advice to a dairy. In these circumstances, communication about the feeding program and resulting performance is critical. It is imperative that the veterinarian be knowledgeable about dairy nutrition and involved in ration formulation. The veterinarian needs to maintain their involvement as part of the advisory team.

LEVELS OF NUTRITIONAL SERVICE

Having decided to be involved in a dairy's feeding program, the veterinarian and client should first agree on the level of nutrition service that is to be provided. The level varies from herd to herd, depending on the veterinarian's expertise, the client's ability and interest, and the role being played by other consultants to the farm. There are essentially four levels of service that might be provided:

Level 1: Problem Identification and Analysis

At level 1 the veterinarian takes on the task of monitoring the dairy herd for indicators that there might be nutrition-related problems. Many areas need to be monitored: production, milk components, DMI, body scores, disease rates, growth rates, and feed costs. Based on these monitored areas, the veterinarian can call attention to problems as they arise, form and test hypotheses about likely causes, and interact with other farm service personnel as the problems are addressed.

Level 2: Ration Analysis

At level 2 the veterinarian evaluates the nutritional adequacy of diets as they are fed to the cows. If problems of balance or economics are identified, they are referred to the appropriate person for reformulation. This level is difficult to sustain over time because, after a while, the person formulating the ration is likely to resent being "second-guessed." It can work well if the "team approach" is part of the procedure on the dairy.

Level 3: Ration Formulation

At level 3 the veterinarian takes on the responsibility of formulating the ration. To operate responsibly at this level, veterinarians need several additional skills beyond those traditionally taught at veterinary colleges. The veterinarian must know how to use a computer to formulate a balanced, deliverable, cost-effective ration. The veterinarian should have experience in the daily mechanics of how feeds are handled and how cows are fed. It requires an intimate knowledge of the farm and its personnel. The veterinarian must maintain daily contact with the feed industry so that feed prices and availability can be factored into the farm's overall feeding program.

If not managed carefully, this level of service has several pitfalls. It lacks the on-farm follow-up, supervision of implementation, and monitoring of results that are included in level 4. There is a truism about feeding dairy cows that every cow has three rations: the one **formulated,** the one **delivered,** and the one **actually eaten.** The best feeding programs minimize the difference among these three rations. If the veterinarian's role stops at formulation, then mistakes can occur in delivery and feed bunk management that can doom the program to failure. If the program fails, the veterinarian's formulation is likely to be blamed.

Downloaded From Vet-e-Books.com

Level 4: Total Program Consulting

Level 4 of nutritional service includes those aspects missing in level 3. The veterinarian plays an active role in implementing the feeding recommendations. Attention is paid to areas such as bunk management, cow comfort, feeding frequency and scheduling, quality control, and consistency of feeding management. Working closely with the producer, plans for future forage production can be generated, including attention to factors such as timing the harvest for maximum feed value. The monitoring described in level 1 is sustained, and timely adjustments and feedback are provided to ensure that the rations are accomplishing the desired ends. In the long term, this is the level of service that is most desirable for both the veterinarian and the client. The producer benefits from the added supervision and support, and the veterinarian can assure the client that the program is carried out as designed. If the program is not working, it can be modified. Total program consulting can be accomplished with the veterinarian as a part of the team that would include the nutritionist, as well as by the veterinarian alone. With many larger herds, particularly, multiple outside consultants are used, and a team approach provides the owner with the best opportunity for expert advice. In many herds the veterinarian is best suited to be the "team leader."

DIGESTIVE PHYSIOLOGY OF THE DAIRY COW

The fate of feeds eaten by the dairy cow is more complex than in monogastric species. The cow's rumen contains a complex ecosystem of microbes that is necessary if the cow is to break down fiber that would otherwise be indigestible (Hoover and Miller, 1991). The rumen florae are also able to use nonprotein nitrogen sources for microbial protein synthesis. This microbial protein is then available for digestion by the cow. Rumen motility, regurgitation, cud chewing, and salivation serve to mix the contents, reduce particle sizes, and provide a stable environment for optimum microbial activity. Any consideration of dairy cattle nutrition must begin with the rumen. Maintaining the efficient performance of this complex fermentation vat is necessary to optimize both production and health of the dairy cow.

The rumen is a complex ecosystem. Fermentation of dietary components in the rumen causes the growth of microbes (primarily bacteria) and the production of volatile fatty acids (VFAs). VFAs are responsible for approximately 70% of the energetic needs of a high producing dairy cow, and microbial mass is responsible for supplying approximately 65% to 70% of the protein requirements. Bacterial species comprise the largest number of organisms and the greatest mass. Bacterial concentrations can be 10^{10} cells/g of rumen contents and have been classified according to shape, size, or substrate fermented. Box 11-1 shows one classification of rumen bacteria. The balance between these species populations will be affected primarily by the substrate available for fermentation. Protozoa are typically present in large numbers and are present at a greater relative percentage on high forage diets, approximately 10^5 to 10^6 cells/g. Protozoa actively ingest bacteria, and their net effect on fermentation efficiency is debatable. Their presence, however, is generally regarded as suggestive of a healthy rumen ecosystem. Fungi are also present, as are phages or virus-like organisms whose involvement in rumen dynamics is little understood (Penn State Extension Service, 1999). A macroscopic view of the rumen would show a compartment with four strata. The topmost would be a gas layer, filled with the gases produced from fermentation, including carbon dioxide and methane. The next layer would be a floating fiber mat, comprised of longer pieces of buoyant plant material floating on the liquid layer, which could be considered to be the third stratum. The liquid layer also contains small, saturated food particles suspended within it. The fourth layer would include dense particles on the floor of the rumen and reticulum. This may include food particles as well as stones, sand, and gravel.

The rumen microbes are sometimes described according to their location in the various rumen environments. These include the liquid phase, where bacteria and protozoa exist and metabolize soluble carbohydrate and protein. These microbes in the liquid phase are removed from the rumen relatively quickly—as liquid leaves. They are relatively fast growing. A small number of bacteria are attached directly to the rumen epithelium. In the third, or solid phase, microbes attach directly to the food particles. This is where digestion and metabolism of most of the less readily available carbohydrate and protein fractions of feedstuff particles occurs. Attachment, digestion, and fermentation must happen before the fibrous feed particles leave the rumen, or they will remain undigested. Slower growing bacteria (as are most cellulolytic and other fiber-digesting bacteria) require an adequate length of time attached to particles in the solid phase to prevent their depletion and removal from the rumen. It should be apparent that there is a complex interaction between rumen microbial species, substrate, rumen retention time, and passage rate that will affect the efficiency of digestion, VFA production, rumen microbial production, and, subsequently, whole animal performance and health. A large influence on this ecosystem is the floating fiber mat. The mat retains smaller particles, keeping them in the rumen longer, and allows more complete fermentation.

Carbohydrates account for a majority of the dry matter in a cow's diet. Most of these sugars, starches, pectins, and fiber (cellulose and hemicellulose) in the cow's ration are broken down in the cow's rumen. When the rumen microbes break down these carbohydrates, they produce the VFAs acetate, propionate, and butyrate. The rumen wall can absorb these metabolites (Linn et al, 1989). Feeds leave the rumen based on density (specific gravity) and particle size (Welch, 1986). The density of the mat of floating long fiber also affects the passage of feedstuffs from the rumen (Van Soest, 1982). Fiber with small particle size may escape the rumen before there is enough time for the cellulolytic microbes to digest it (Ruckebusch et al, 1991). Smaller particles are rapidly saturated and fall to the bottom of the rumen. From there they move forward to the reticulum and out through the reticuloomasal orifice (Swenson, 1984).

Longer fiber length also serves to encourage eructation, cud chewing, and salivation. The rumen is most efficient as a fermentation vat if conditions within it are held stable. The bicarbonate and phosphate ions secreted in the saliva during cud chewing are a major source of buffering capacity for the rumen, and the saliva provides 70% of the water present in the rumen (Bartley, 1976). A cow may produce 100 to 200 L of saliva per day. Total saliva production is fairly constant for total mixed rations (TMRs) that use differing silages (corn silage versus haylage) (Cassida and Stokes, 1986), but can vary widely if more disparate feedstuffs are fed (Bailey, 1961).

Depending on the nature of the ration, cows chew their cud between 20% and 40% of the day (Beauchemin, 1991; Shaver et al, 1988). Total chewing time (both eating and cud chewing) should be between 10 and 11 hours per day or longer (Beauchemin, 1991; Sniffen, 1988). Cows tend to chew their cud while resting. In a comfortable environment most cows should be lying down while chewing their cud. Between 60% and 70% of resting cows should be chewing their cud. Cud chewing serves to reduce fiber particle size, making those particles more accessible to the cellulolytic microbes in the rumen.

Micrococcus sp.

HEMICELLULOLYTIC SPECIES
Butyrivibrio fibrosolvens
Bacteroides ruminicola
Ruminococcus sp.

AMYLOLYTIC SPECIES
Bacteroides amylophilus
Succinimonas amylolytica
Bacteroides ruminicola

*Adapted from Penn State Extension Circular 422, From feed to milk: understanding rumen function, Table 5.

Rumen pH has a profound influence on rumen efficiency, VFA production, and overall animal health. The pH (concentration of free hydrogen) is influenced by many factors, including rate of acid production, rate of acid absorption and removal, which specific acids are produced (lactate versus butyrate versus acetate versus propionate), saliva and bicarbonate secretion, and buffering capacity of the feed. The physical form and constituents of the diet, as well as the total amount and proportion of concentrate, also influence the pH (Allen, 1995). Cellulolytic bacteria and methanogenic bacteria are favored at a pH of 6.0 to 6.8. As the pH drops, starch and sugar digesters are favored, with their preferred range being 5.2 to 6.0. As pH drops from 7.0 to 5.2, the proportion of acetate produced declines and propionate increases. As pH drops further, lactate production increases and all others decline. The "optimum" rumen pH is dependent on diet. It involves production of a maximal amount of VFAs without significantly inhibiting cellulose digestion. Rumen pH below 5.5 to 5.6 has been associated with health problems such as laminitis, ketosis, and LDA (Nordlund, 1995). These diseases have commonly been grouped together and referred to as subclinical acidosis. In most dairy cattle diets, then, the optimum pH should probably be between 5.8 and 6.3. This range balances the desire for rapid microbial growth and VFA production with the need to maintain an active cellulolytic population and avoid negative health effects on the whole animal.

Rumen microbial growth, then, is affected by such factors as the composition of the feed (substrate); particle size (affecting where and in which layer the particles end up); feeding pattern; salivation (fluid and mineral flow); intake (affecting passage rate and how long the particles stay in the rumen); rate of carbohydrate fermentation; and availability of adequate nitrogenous substrate (ammonia, peptides, and amino acids) for microbial growth. Attempts by computer models to predict bacterial growth rates should theoretically account for all of these effects. Rudimentary efforts, including those of the National Research Council (NRC) (1989, 2001), predicted rumen microbial protein production based only on energy and crude protein content of the diet. Successive computer programs refined this to make predictions based on energy—discounted for the fat content—and degradable or available protein (Spartan Ration Evaluator, 1992). More recent attempts at mechanistic model development have further increased the sophistication of these predictions (Russell et al, 1992; Sniffen et al, 1992; Fox et al, 1992; O'Connor et al, 1993).

A truly accurate model of the rumen would predict the fermentation rates of each component of each feed. It would predict the end products of fermentation (or which specific VFAs) are produced; the microbial mass produced by the fermentation; the rate of passage of both unfermented feed and the microbial mass out of the rumen; the chemical composition of these substances; and their digestive fate in the lower gastrointestinal tract. To accomplish this would require not only knowledge of the bacteriological processes in the rumen but also a means of predicting the physical movement of each feedstuff particle in the rumen milieu. Both the knowledge and mathematical computing power are inadequate to develop this complex a model. Yet many

Downloaded From Vet-e-Books.com

observations and measurements have been made, which allow more and more precision in predictions of rate of feedstuff fermentation and bacterial production. These observations include both in vitro and in vivo systems. Drawing on this literature has caused preliminary attempts to more accurately model rumen dynamics and formulate rations using those models.

Models currently in use attempt to characterize the rate of carbohydrate digestion of a feed—including neutral detergent fiber (NDF), starch, sugars, other nonfiber carbohydrates, and lignin—and predict the feed's rate of passage from the rumen, based primarily on the level of DMI. These factors are combined to mathematically estimate the amount of carbohydrate available for microbial fermentation and to predict energy availability and bacterial yield. Similar calculations are developed to predict protein, peptide, and ammonia availability in the rumen based on estimates of the rate of digestion of the protein component of the feed and its passage rate through the rumen. These concepts then allow an estimate of the bacterial production and feed (especially protein) bypassing the rumen with more accuracy and precision. The models provide opportunities for significant improvement in practical and conceptual applications in dairy nutrition (CPM Dairy, 1998; NRC, 2001).

Once past the rumen, the digestive process in the cow proceeds similarly to that of monogastrics, except that the cow digests both the ingested nutrients that have bypassed ruminal degradation and the microbial population that has been washed out of the rumen.

FACTORS AFFECTING NUTRIENT REQUIREMENTS

The high-producing dairy cow does a prodigious amount of metabolic work. She may consume 25 kg or more of dry matter, expend 40 Mcal of net energy, and use 4 kg or more of protein per day. Nutrient needs vary, depending on breed, body size, stage of lactation, milk production, fat content of the milk, gestation, environment, and feed digestibility. The nutrient requirements of lactating cows have been published by the National Research Council (NRC, 2001). The 2001 guidelines represent a comprehensive summary and review of the literature over the last 12 years, and can be considered a necessary reference for professionals involved in offering advice and consultation on the topic of dairy nutrition. Specific changes include: a more detailed rumen model of carbohydrate and protein utilization; an attempt to quantitate specific bypass amino acid requirements for milk production; and expected changes in dry cow nutrition requirements.

Lactation Cycle

There are five phases in the cycle of lactation from one calving to the next. The first phase is from calving through peak milk production, about the first 10 to 12 weeks of lactation. During this phase, the cow's level of milk production increases rapidly to peak near the end of the phase (Fig. 11-1). The butterfat content of the milk starts high and decreases. Both of these are natural adaptations to the needs of a nursing calf, augmented by generations of genetic selection. Feed intake (DMI) increases too but lags behind the demands of the rapidly increasing milk production. The cow calls on body fat reserves to fill the difference between energy intake and energy needs. The cow loses weight during phase 1. Protein in the ration must be high during this phase because the cow's ability to mobilize body protein for milk synthesis is limited. If protein intake is too constrained, the cow does not reach her genetic potential for milk production.

Phase 1 is the most difficult phase for feeding. The cow must adjust from eating a high-fiber, low-energy-density, dry cow ration to a high-energy, constrained-fiber, lactating cow ration. She must compensate for dramatic increases in mineral turnover. Cows are in negative energy balance and have limited DMI capacity. Phase 1 is the phase during which almost all metabolic diseases occur. Phase 1 cows often have infections of the uterus and/or mammary gland. These infections are another metabolic demand and may further reduce appetite and DMI.

In phase 2 (weeks 12 to 24 of lactation), the cow's DMI gradually rises until her nutrient intake matches her level of production. The cow should no longer be losing weight; in fact, she may begin to regain some of the weight lost in phase 1. The feeding challenge in phase 2 is to sustain peak production as high as possible while supporting the cow as she is bred and begins the next gestation. If BST is used, it is usually started during phase 2. This may increase the nutrient requirements of this cow but should not alter the basic relationships.

Phase 3 (approximately weeks 24 to dry off) completes the lactation and is the longest phase of the cycle. Milk production gradually declines and butterfat content rises slightly during phase 3. DMI also falls off in response to the cow's decreasing nutrient needs with declining production. During this phase the cow can consume enough dry matter to more than support her production. The weight lost in phase 1 should be restored and gestation of the next calf supported. If cows are fed only to support their current milk production in phase 3, then the reserves of fat are not restored and peak production in the next lactation suffers.

Phase 4 is the early dry period, The entire dry period should last for 6 to 8 weeks before the next calving. Phase 4 includes all except the last 3 weeks. Dry cows should be fed a separate ration tailored to their needs. Rations should be based dominantly on forages and should be supplemented adequately with vitamins and minerals to support the advancing pregnancy and approaching lactation. The mineral balance should be monitored to avoid metabolic diseases at calving. Although the dry cow should gain some weight because of the growing conceptus and fluids, under ideal conditions the cow's body condition should not change during the dry period.

Phase 5 is the late dry period, sometimes called the transition period, that occurs in the last 3 weeks before calving. The feeding program during this period is critical as a period for adaptation to the lactating cow diet and for meeting the nutrient needs of a cow in dramatic metabolic transition as she prepares for calving and milk production (but within the constraints of a significant drop in DMI). Most metabolic disease problems are triggered by an inadequate phase 5 diet, and a more detailed discussion of this phase occurs in the section on feeding the dry cow and metabolic disease.

First-lactation heifers present an additional challenge during all phases of the cycle. They must not only respond to the challenges of lactation but must also continue to grow to maturity. DMIs are lower in heifers than cows producing the same amount of milk. This is partly the result of body size, but on many farms it is also a function of competition and feeding strategies.

Environment

The cow's environment can have a profound effect on feed intake and nutrient metabolism (NRC, 1981). The thermoneutral zone for cows is from approximately 0° to 16° C

Downloaded From Vet-eBooks.com

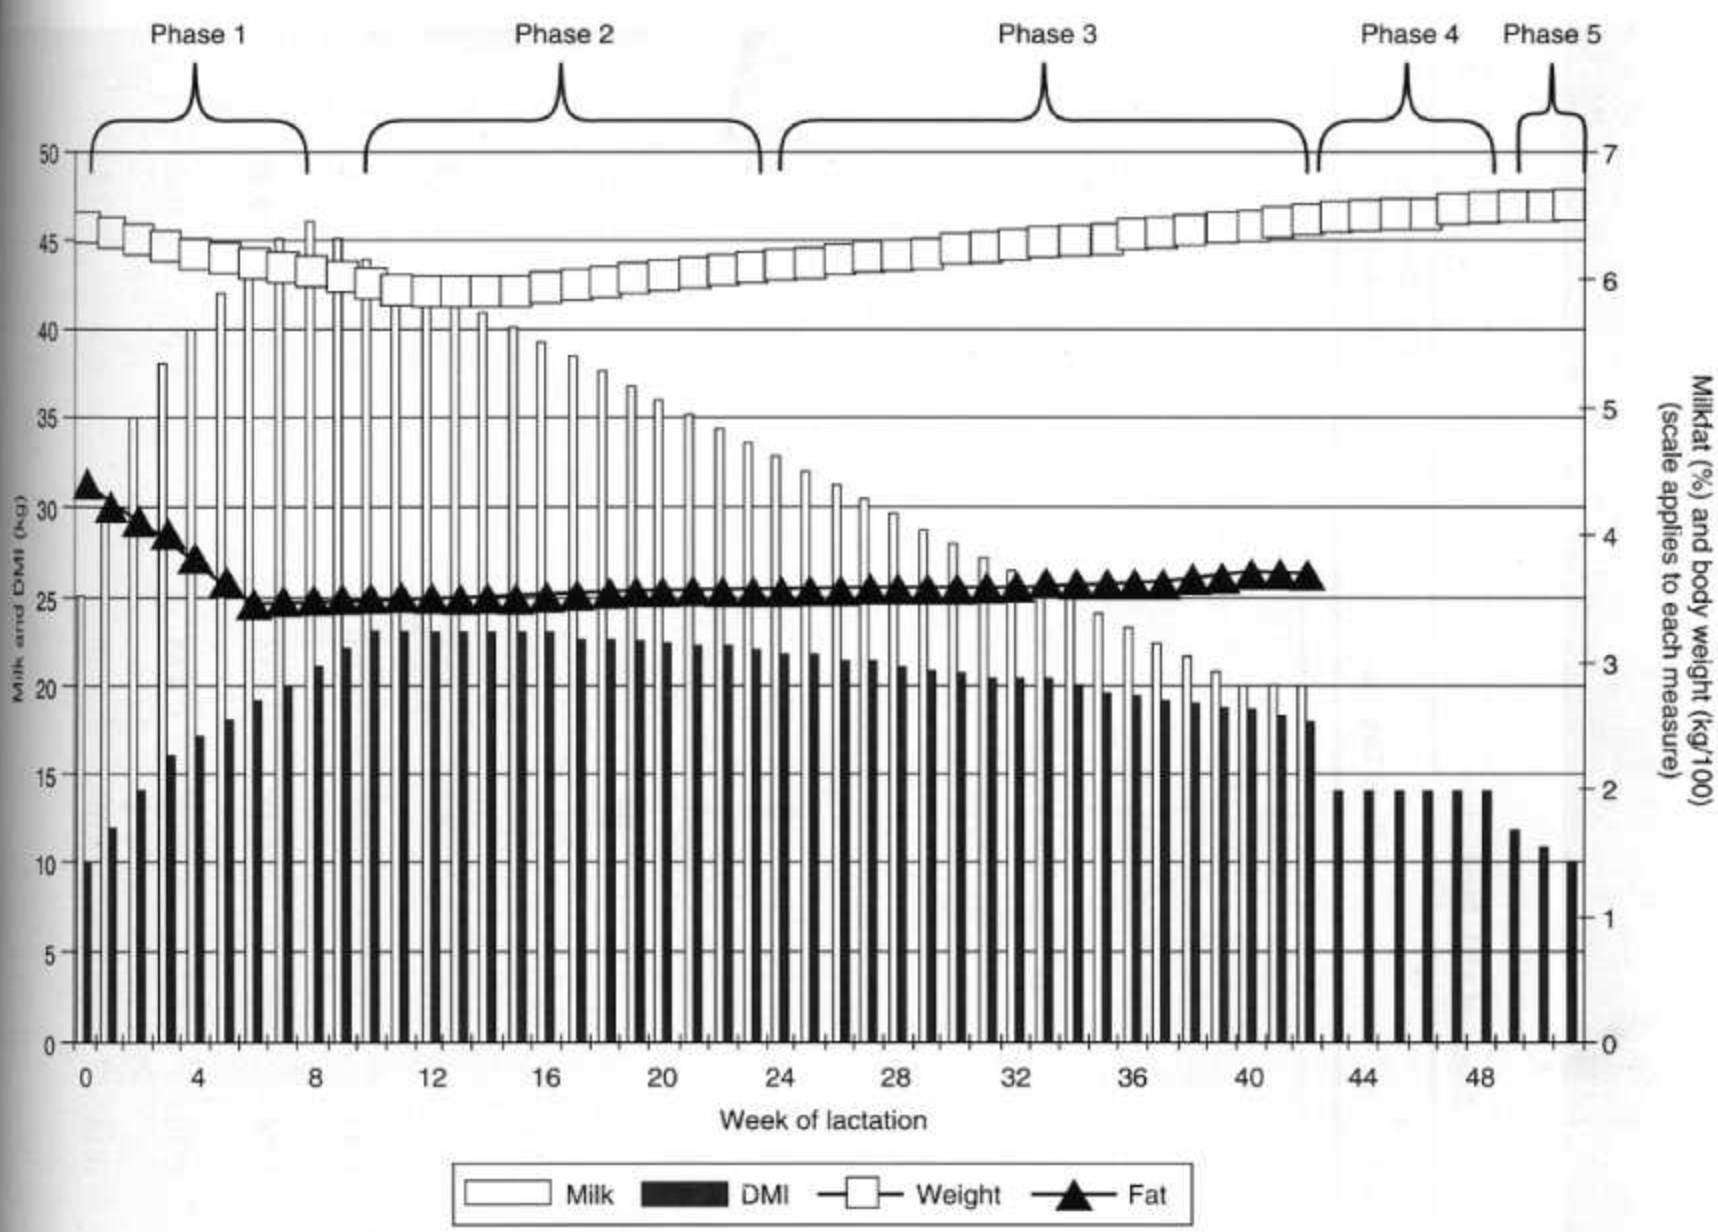

FIG. 11-1 Dairy cow lactation cycle. *DMI*, Dry matter intake.

(32° to 61° F), although some acclimation can occur (NRC, 1981). Cows in cold environments (lower than −20° C, or −4° F) may consume as much a 35% more dry matter than cows at a more thermoneutral temperature (10° to 20° C, or 50° to 68° F) in order to compensate for their increased energy requirements. Intakes begin to decline with heat stress above 25° C (77° F) and show a significant decline above 30° C (86° F). At 40° C (104° F) intake may be only half the intake at 20° C (68° F). To compound these problems, maintenance energy requirements actually increase in cows exposed to more than a few hours per day of temperatures greater than 30° C (86° F). The effects of heat are less if the cow has access to shade or moving air or is in a climate with lower humidity. Access to water is also important. Water intake may double as the temperature rises from 15° to 30° C (59° to 86° F). The amount of exercise also affects the cow's requirements. Most published requirements assume minimal exercise. Pasture systems may increase the energy requirement by 20% or more (NRC, 2001).

Cow Comfort and Competition

In addition to ambient temperature, humidity, and wind, the physical and social environment of the cow have an effect on feed intake. Heifers are particularly susceptible to reduced intake because of competition, proximity of "boss cows," and limited access to feed bunks. In open access feed bunks, there should be a minimum of 60 cm of bunk space per animal, and for optimum intake 75 cm may be better (Sniffen, 1991). If feed is available at all times, cows eat as many as 12 "meals" per day. Restricted access to feed reduces this number and decreases total intake. Cows spend a large amount of time per day ruminating, and conditions should encourage them to lie down while chewing their cud. Cows perform better if housed and managed in a clean, quiet environment and handled in a gentle, consistent manner.

NUTRIENT REQUIREMENTS OF DAIRY COWS

Table 11-1 provides the general nutrient requirements of mature dairy cows at moderately high and middle ranges of milk production and as dry cows (NRC, 1989, 2001; Penn State Extension Service, 1995). The NRC supplies a microcomputer program on disk that can calculate nutrient requirements for various classes of cattle and provides a concise summary of recommended levels of nutrients for each class of animal, including required and maximum tolerable levels of nutrients. It is important to remember that the NRC values are not absolutes. Experienced nutrition consultants almost always modify NRC requirements in keeping with their own particular experience and to match the particular

herd's needs, feed ingredients, and production levels. The NRC values should be used as guidelines, not absolutes. The text of the NRC and other nutrition references should be consulted for detailed information. The revised NRC guidelines (NRC, 2001) have suggested some adjustments in calculating energy, protein, and mineral concentrations of diets. Many of these adjustments are based on a more dynamic model of rumen function, dependent on DMI. The NRC provides a CD-ROM with the reference text that incorporates these changes.

The NRC uses a "factorial" method for calculating requirements. Whether the nutrient in question is energy, protein, or a mineral, the total requirement is arrived at by estimating requirements for maintenance, growth, reproduction, and production, and then summing these individual factors. The amount supplied is estimated by discounting the gross amount in the diet by factors for digestion and absorption, metabolism, and tissue utilization efficiency. It should be appreciated that calculations of both requirements and amounts supplied are dynamic values, changing under various circumstances. This is especially true when estimating amounts supplied, because of the complexity of interactions within the rumen.

It is important to remember that the recommended proportions of nutrients such as those in Table 11-2 are based on the assumption that the animal being fed is eating "normal" amounts of total ration—that is, its DMI is normal. This is a critical point. When considering feeding programs, nutritional consultants commonly communicate in a complex subdialect of numbers. Usually, these numbers are some proportion of the ration. For example, they might refer to 1.65 Mcal/kg, or 17% protein, or 40 ppm of manganese. Each of these numbers is a proportion, usually of DMI. Ratios are also commonly used—for example, a 60:40 ratio of forages to concentrates or 3:1 ratio of vitamin A to vitamin D. Proportions and ratios are useful shorthand for communication, but keep in mind that the cow's requirements are not satisfied by balanced ratios. The cow requires absolute amounts of each nutrient. She requires total megacalories of energy, kilograms of protein, and milligrams of manganese. Proper proportions in a diet satisfy the cow's requirements only if her total dry matter intake is adequate. If she eats too little of a "balanced" ration, her requirements remain unfilled.

Dry Matter Intake

When veterinarians formulate rations for high-producing dairy cows, DMI should be the first consideration. In maximizing milk production, DMI is the single most constraining factor in feeding lactating cows. Numerous factors influence DMI: body weight, forage quality and digestibility, stage of lactation, milk production levels, butterfat content of the milk, exercise, environment, management, cow comfort, social interactions, body condition, ration balance, and feeding frequency and schedule (NRC, 1987). Prediction equations have been developed that provide an estimate of intake for lactating dairy cows. NRC equations have been reported to significantly underestimate DMI at peak and later and to significantly overestimate early lactation DMI (Roseler et al, 1997). The best approach in practical on-farm circumstances is to always measure DMI directly. Table 11-2 provides a brief selection of DMIs for two body weights and various milk production levels.

Cows in early lactation consume less dry matter than cows at the same milk production level later in lactation. Table 11-2 thus overestimates the DMI of a cow in early lactation. This reduced DMI makes it difficult for an early-lactation cow to consume enough nutrients to support her rapidly rising production, and she loses weight (Fig. 11-1). DMI usually peaks 10 to 14 weeks postpartum, several weeks after milk production has peaked (NRC, 2001).

DMI is affected by the digestibility of the ration, particularly of the forages fed. If forages are too mature when harvested or grazed, their digestibility is reduced. These slowly digested forages are retained longer in the rumen, taking up space and inhibiting further consumption. Reduced fiber digestibility can also result if the ration contains too little rumen-degradable protein, starving the rumen cellulolytic microbes of the peptides and nitrogen they need to grow and ferment fiber. As the digestibility of the ration increases (commonly by increasing the proportion of grain fed), the DMI increases but only up to a point. Depending on the cow's milk production, there is a point at which enhanced digestibility actually reduces DMI. This point is reached when the cow can consume all her energy needs and intake begins to be regulated by energy needs, rather than by the cow's rumen fill and turnover capacity (NRC, 2001).

Feeding conditions and environment will affect intake. Hot, humid conditions (>27° C [80° F] and >80% relative humidity) will depress DMI. Mold, originating either during storage or in the bunk, decreases DMI. Important strategies to maximize DMI include maintaining adequate feeding rate from the surface of ensiled feed, avoiding spoiled feed accumulating in the bunk, and avoiding poor quality, moldy feeds.

Water

Water is an essential nutrient, although it is commonly overlooked as such (Beede, 1991). Cows consume more water than any other nutrient. A 600-kg cow eating a corn silage–based diet in a thermoneutral environment and producing 45 kg of milk per day drinks at least 140 L of water/day (NRC, 2001). On most farms, water is supplied free choice and is available most of the time. If access to water is limited, milk production falls (Little et al, 1984). Restriction of water intake has a more rapid and profound effect on milk production than restrictions on any other nutrient. Cows with uninterrupted access to fresh water drink more water than cows that have access only at certain times of the day. Along with increased water consumption, cows with unlimited access to water consume more feed dry matter and produce more milk (NRC, 1981). Cattle grazing on pasture drink two to five times per day if they have easy access to water. If water is more distant, they drink less often and consume less dry matter. Water consumption is influenced by milk production, access and competition, diet DMI, diet moisture content, environmental temperature, and the content of various minerals in the ration, particularly sodium. Water consumption increases rapidly when the ambient temperature rises above 27° to 30° C (81° to 86° F). Herd performance problems can sometimes be due to insufficient water consumption. Flow meters can be installed and used to monitor water consumption. Expected water intakes have been published (Penn State Dairy Reference Manual, 1995) and can be expected to vary between 20 and 35 gal/cow/day. Lactating cows can tolerate water of varying pH, hardness, and water temperature. Extremes of any of these factors can create problems.

The simplest and most effective approach to satisfying the cow's water needs is to provide easy, noncompetitive, free-choice access to clean, fresh water all the time. There should be at least one watering space per 20 head. A watering space is either one drinking cup or 2 linear feet of accessible trough perimeter. There should be a minimum of two separate drinking locations per group of cows to minimize the bullying effect of boss cows (Midwest Plan Service, 1985). Water flow should be designed to prevent back

siphoning of water into the plumbing system. Whatever system is used, it must be protected from freezing.

Energy

The most important aspect of any ration is to provide enough energy to meet the animal's needs. Determining the energy available in a particular feed or ration is complicated. Except under expensive research conditions, the energy content of a feed cannot be measured directly. In practice, the energy content of feed is calculated from measurements of the chemical constituents of the feed—fiber, protein, fat, and ash. The energy available from a particular feed is different depending on whether it is being used for growth or maintenance, or by a lactating cow. These differences require attention when balancing rations for growing heifers or for bulls. Fortunately, the energy metabolism for a lactating cow is similar enough for maintenance, weight gain, and lactation that one measure of a feed's energy content works for all three. That measure is net energy for lactation (NE_L) (NRC, 2001). This value discounts the energy in a feed for the digestive, absorptive and metabolic efficiencies, which are assumed to occur in its utilization. Another way to measure the energy content of feeds is to determine the total digestible nutrients (TDNs). This older system has the disadvantage in that it tends to underestimate the energy available from grains. An estimate of NE_L can be derived from TDN by this equation: NE_L (Mcal/kg) = [TDN (% of dry matter) × (0.01114) − 0.054] × 2.204 (Linn, 1989).

The lactating cow needs energy for lactation, maintenance, and growth (both for herself and for her fetus). The energy required for lactation is the energy contained in the milk produced. The cow's maintenance energy requirement depends on her level of activity and the ambient temperature. The recommended levels of energy given in Table 11-1 have been adjusted to allow for "average" activity levels. Cows forced to walk long distances or that graze on poor pastures might need as much as 20% more maintenance energy to account for the extra effort expended in "harvesting" their ration. Similarly, extremely cold weather may increase energy needs as much as 8% of a cow's total energy requirement or more. The energy needed for growth in a mature cow is the same as the energy lost during the period of weight loss in early lactation. Weight loss during early lactation contributes approximately 5 Mcal of NE_L/kg body weight loss (Moe et al, 1971). This energy must be replaced as the cow regains that weight in later lactation. Because of the increased efficiency of metabolism in lactating cows, weight gain is usually more economical when gained in late lactation rather than in the dry period. This practice also reduces the incidence of metabolic disorders in the early postpartum period that can result from overfeeding dry cows (Morrow, 1976).

The energy in the diet is derived from several sources. Carbohydrates account for between 50% and 80% of the dry matter in a cow's diet, and most are fermented to a degree in the cow's rumen. When the rumen microbes break down these carbohydrates, they produce the VFAs acetate, propionate, and butyrate. The rumen wall can absorb these metabolites. VFAs provide 50% to 70% of the cow's total energy intake. The relative proportion of these VFAS is dependent on substrate and rumen pH. When large amounts of fiber are fed, and rumen pH >6.0, acetate is the predominant volatile fatty acid produced, accounting for 60% to 70% of the total VFAs. In addition to serving the gen-

Downloaded from Vet-eBooks.com

eral energy needs of the cow, acetate is the major precursor of butterfat in milk. When higher quantities of sugars and starches are consumed, relatively more propionate is produced. Under these conditions, the milk fat content may be reduced (Linn et al, 1989).

The degree of rumen fermentation of carbohydrates depends on the material, its physical form, and the other feeds being fed. Simple sugars are almost completely metabolized, and 60% or more of starches are broken down in the rumen. Starches and sugars are more available and more fully digested if they have been processed (e.g., ground, heated, extruded) than if they are eaten as whole grains. Of the cellulose and hemicellulose in plant fiber, 30% to 50% are digested in the rumen. Fiber may be less fully used if particle size is reduced because it may escape from the rumen before the microbes have had the chance to digest it (Allen and Mertens, 1988).

Fats can make up an important part of the energy in a cow's diet. Fats have a significant advantage over carbohydrates as an energy source because they have 2.25 times as much energy per unit of dry matter. In the high-producing dairy cow constrained by DMI, this makes it possible to feed more energy without exceeding the cow's ability to eat the ration. Caution is required when feeding fats, however, because feeding more than 3% to 5% rumen available fat in the ration dry matter may be toxic to rumen microbes and interfere with rumen fiber fermentation (Chalupa and Ferguson, 1988; Palmquist, 1983). Some fats bypass the rumen, thus avoiding rumen toxicity and microbial degradation. These fats are digested in the same manner as with monogastrics.

If supplied in excess of the cow's protein needs, protein may also serve as an energy source, but feeding excess protein as an energy source may have several disadvantages. Generally, protein sources are expensive. The ammonia produced as amino acids are deaminated and must be metabolized to urea by the liver, a process that itself requires energy (Tyrrell et al, 1983). The nitrogenous waste products associated with metabolizing protein for energy may interfere with reproductive performance (Ferguson, 1988; Ferguson and Chalupa, 1989; Ferguson et al, 1988). Feeding excess protein is an inefficient and expensive way to provide energy.

There are practical limits to the energy density of lactating cow rations. Minimum levels of forage fiber are needed to maintain health and rumen function. For the highest producing cows, the energy density possible on a practical basis, without added fats, is approximately 1.72 Mcal/kg (0.78 Mcal/lb) dry matter. It is difficult to formulate rations that are more energy dense than this without reducing the fiber content of the ration below minimum levels. For high-producing cows that demand more energy-dense rations, fats must be fed, often in a form that bypasses the rumen. Saturated fats (animal sources) are generally preferable to unsaturated fats (vegetable sources). Vegetable fats in whole raw oil seeds (whole cottonseed, whole soybeans) are an exception to this generality. Whole oil seeds may tend to bypass ruminal degradation, releasing their fats only as they are digested in the abomasum and intestines.

Cows in the first 3 weeks of lactation may need to be introduced to the energy-rich ration slowly, allowing time for rumen adaptation to the diet. Feeding a small portion of the lactating cow ration to cows in the last 7 to 14 days prior to calving may help with this acclimation process. Such advanced feeding of lactating cow rations to dry cows is not without risks. If not carefully managed, such programs can lead to a higher incidence of peripartum metabolic disease.

Generally, the energy needs of early dry cows (Phase 4) are easily met. More commonly, overfeeding dry cows is the problem. Grain intake in dry cows should be restricted. High-energy forages such as corn silage should also be limit-fed to avoid overconditioning dry cows. During phase 5, the transition period, energy needs of the dry cow may be difficult to achieve because of a decline in DMI (Grummer, 1995). The challenge can be similar to rations for high producing dairy cattle—maintaining adequate energy intake during a period of lower DMI.

Energy Calculation

As suggested earlier, in most cases the direct measurement of the energy available within a feed to the animal is expensive and difficult experimentally. Empirical relationships between various components of feedstuffs and energy have been observed and are frequently used to estimate energy content. Many laboratories calculate energy of a feed based on a correlation between acid detergent fiber (ADF) and energy. The ADF content is measured and a series of equations (depending on the specific feedstuff, geographic location, maturity, and species) are used to estimate the energy available (NRC, 2001). An alternative method has been developed which is believed to be more accurate, particularly for nontraditional feeds such as by-products or high fat products. This method incorporates measurements of protein, carbohydrate fractions, indigestible carbohydrate and protein (lignin bound), and fat. Energy value of the feed is then predicted based on the known energy of these constituents (Weiss, 1993). This method is based on known conceptual relationships and should be more applicable to a wider variety of feeds than the ADF correlation. It remains to be seen if it will prove to be more accurate and effective in the field.

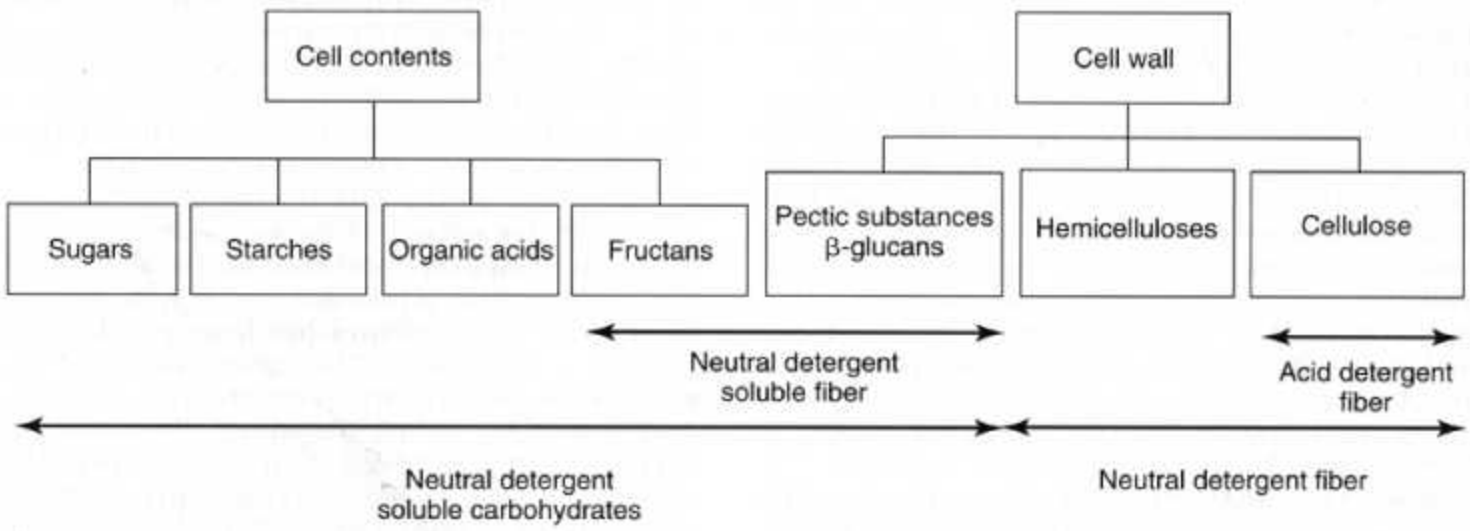

FIG. 11-2 Plant carbohydrates.

Downloaded from Vet-e-Books.com

but it is being widely used and is consistent with more recent publications (NRC, 2001).

In all considerations of feed energy values it is important to recognize that the availability of energy from a feed is a dynamic value. It is affected by the efficiency of VFA production and absorption of the specific feedstuff in the rumen, which in turn is affected by interactions with other feed items in the diet, and such factors as plant maturity, rumen pH, rumen turnover and rumen passage rate. It is affected by the metabolic state of the animal and its efficiency of utilization of various end products of digestion for a variety of metabolic fates. Although assignment of a particular "energy concentration" to a particular feedstuff has proved to be a powerful ration balancing tool, remember that it is a potentially highly variable number and can be influenced by a variety of interactions.

Fiber and Ration Carbohydrates

The makeup of the carbohydrate fraction of the dairy cow's diet is critical for optimizing both health and performance. The carbohydrates are derived from plants and contain the entire plant—both structural and nonstructural, and both cell wall and cell contents. The cell wall constituents provide the plant with its structural support and contains cellulose, hemicellulose, and lignin. It closely, although not precisely, corresponds to the fraction referred to as NDF. Lignin is contained in the NDF fraction but is not a true carbohydrate. The cell contents roughly correspond to the nonfiber carbohydrate (NFC) fraction, also described as nonstructural carbohydrate (NSC). A more accurate term would be neutral detergent soluble carbohydrate (NDSC). The correspondence with cell wall and cell contents is not exact. A diagram clarifying the various carbohydrate fractions that make up the NDF and NDSC is shown in Fig. 11-2. There is an absolute necessity to provide adequate digestible NDF to support a population of cellulolytic and other fiber-digesting bacteria in the rumen. If inadequate cellulolytic bacteria are maintained, the ability of the dairy cow to efficiently utilize fibrous feeds suffers. In addition to the fact that fiber provides a large proportion of the energy in the diet, dairy cows have an absolute need for a certain fiber content. Adequate fiber content is necessary for optimizing digestibility of the ration, maximizing DMI, maintaining butterfat levels in the milk, stabilizing the ecosystem of the rumen, and preserving the health of the cow (Allen, 1995). Many metabolic diseases can be traced to inadequate fiber levels in a cow's ration at some stage of lactation, including indigestion and rumen acidosis, lameness, abomasal displacement, milk fat depression, ketosis, and fat cow syndrome. Table 11-3 provides guidelines for the optimal NDF content of dairy rations.

As the fiber level of a feed or ration increases, the energy content decreases. The fiber level in a ration also correlates with total feed intake. If too much NDF or fiber is fed, the NDSC fraction is necessarily reduced. The NDSC fraction, particularly sugars, starches, and fructans, ferment more rapidly, producing more VFAs. This permits more rapid microbial growth. Higher milk production is thus favored by a higher proportion of NDSC in the diet, provided that not so much is fed that acid production becomes excessive and rumen acidosis results. Rumen acidosis has detrimental affects on cow health and reduces the population of fiber digesting bacteria. Fiber content can be calculated directly from measurements taken in feed testing laboratories. There are three commonly used measures of the fiber in the diet. The oldest, crude fiber (CF) is still the legally reported fiber level required on feed labels. It is inadequate for estimating either energy levels or DMIs. ADF is a better indicator of digestibility (Van Soest et al, 1978; NRC, 2001). NDF is the better measure when predicting total DMI from a particular ration (NRC, 1989). The digestibility of fiber also depends on the other components of the diet. In particular, there must be adequate rumen-available peptides and ammonia nitrogen to promote the growth of the microbes that ferment the various carbohydrate fractions of a feed (Sniffen and Robinson, 1987). Inadequate rumen-available protein reduces the rate and extent of fiber digestion.

As plants mature, their fiber content increases, particularly the lignin fraction. The plant's digestibility and energy content thus decrease with advancing maturity. The content of other nutrients decreases as well. This process is accelerated as the plant shifts from vegetative growth to seed formation. Although total dry matter yield per acre may increase, total

TABLE 11-3

*Optimum Levels of Net Energy for Lactation (NEL), Neutral Detergent Fiber (NDF), and Acid Detergent Fiber (ADF) for Dairy Cow Rations**

Milk Production (kg)	NEL (Mcal/kg)	NDF (% DM)	ADF (% DM)
<14	1.43	45	31
14-21	1.52	39	28
21-29	1.63	33	24
>29	1.74	27	21
Early dry cow	1.34	49	34
Late dry cow	1.54	33	24

Downloaded from Vet-eBooks.com

feed value decreases as a crop becomes fully mature. Hays and haylages should be cut in the prebloom stage (Jorgensen, 1988). If cut for forage, small grains should be harvested at the boot stage, before the grain reaches a soft dough stage. Corn silage should be harvested by the dent stage (kernels dented), when the milk line is between one half and two thirds of the way down the kernel (Linn et al, 1989). The central failure of many dairy farm feeding programs is that the farmer harvests the forages too late. No amount of clever ration balancing can completely overcome poor forage in a cow's diet.

Formulation guidelines to ensure adequate dietary fiber have changed over the years. At one time ADF was preferred as the measure of fiber adequacy. Most nutritionists now use NDF or forage NDF as their primary criterion in establishing fiber requirements. A minimum amount of forage is also frequently recommended, regardless of fiber concentrations. In addition to the chemical composition of the fiber in a feed, the physical form of the fiber is also important (Woodford and Murphy, 1988). The length of the fiber (effective fiber or roughage value) must be long enough that it forms a floating mat in the rumen. This mat of long fiber traps smaller particles and promotes thorough fermentation of all ration constituents. Long fiber is eructated and chewed, encouraging saliva production and rumen buffering. If fiber levels in a ration are too low (and sugars and starches are too high), the rumen pH may fall below 6.0, reducing fiber digestion (Hoover, 1986). At least 50% of the forage should have a fiber length of 2.5 cm or greater (Linn et al, 1989). Silages should be cut coarsely, although there is a tradeoff between the feeding value of having coarse silages and the ease of handling and properly ensiling of more finely chopped silages. Silages should be chopped so that the theoretic length of cut is between 0.6 and 1.2 cm (Linn et al, 1989). A series of screens have been used to divide a diet or feed into fractions of various particle lengths (Penn State Forage Particle Separator). The percentage of the feed or feeds by weight found on each screen can then be calculated and graphed, giving an indication of relative particle length. This has proved to be a useful tool for evaluating particle length for a forage or a TMR. Guidelines for the percentage of particles greater than 19 mm (the coarsest screen) are presented in Table 11-4 (Lammers et al, 1996). Other methods of estimating particle size have been published (American Society of Agricultural Engineers, 1993; Ruppel et al, 1995) Recommendations for particle size should be tied to the method used for evaluation.

TABLE 11-4

Recommended Amount of Course Particles Retained on Screen with the Penn State Forage Particle Separator

Sample	Particles Retained on 19-mm Screen (%)
Corn silage (≤50% of forage)	2-4
Corn silage (>50% of forage)	10-15
Haylage (upright silo)	10-15
Haylage (bunker silo)	15-25
Total mixed ration	6-10

The optimum level of fiber in a cow's diet varies with the size of the cow, her level of production, timing of feeding, and the sources of fiber in her diet (NRC, 1989, 2001). Table 11-3 provides guidelines for fiber and energy in dairy cow rations (Sniffen, 1988). With conventional feeding programs in North America—with alfalfa and/or grass and corn silage as the primary forage sources and starchy concentrates such as corn or barley—suggested guidelines are 28% to 30% NDF with 21% to 23% NDF from forage. Forage should provide a minimum of 40% of the ration dry matter (with low quality, higher lignin forages) and a larger percentage of the diet as quality and intake increases. Use of by-product feeds may change the optimum blend of forages and concentrates in the diet. By-product feeds such as beet pulp, citrus pulp, brewer's grains, or cottonseed are high in NDF, but they are generally higher in carbohydrates such as fructans and pectins than forages and low in starch and sugars. Their NDF ferments more rapidly than most forages, but slower than starches and sugars in conventional grains. A higher NDF diet can be fed with these feeds—with less forage—provided starch and sugar levels are reduced compared to conventional diets. A minimum level of forage should continue to be fed, but that minimum level has not been well defined experimentally or in the field. Recent research has focused on methods by which the fiber requirement can be more accurately and precisely predicted across a variety of diets and feedstuffs (Mertens, 1997). Physically effective fiber (peNDF) has been suggested as a more accurate method of describing the fiber requirement. Physically effective NDF is defined as the amount of time a cow chews her cud per unit of NDF in the diet, in relation to a standard of long grass hay. It is closely tied to saliva production and can be measured directly. It is influenced by the particle size and physical form of the diet as well as the chemical composition. Physically effective NDF should be tied more closely to optimizing rumen function and health than other adjustments. Minimum values suggested in the diet to optimize rumen pH are ~22%. An alternative method of estimating peNDF has been suggested. A standard dietary concentration of 30% NDF has been set as a base requirement. Adjustments above or below this number, determined by such factors as forage particle length, degradability of carbohydrate sources, and frequency and pattern of feeding the diet, can then be made to ensure adequate fiber for optimum rumen function (Allen, 1995). Although similar to practical adjustments made in the field, experimental trials tying these adjustments to cow performance are limited.

Balancing the relative amounts of carbohydrates supplied to the rumen including sugars, starches, pectins, and NDF; providing adequate particle length to maintain the rumen floating fiber mat; and ensuring optimum fiber digestion are all important to avoid rumen acidosis and to maintain optimum production and herd health.

Protein

Protein is one of the most expensive constituents of the dairy cow's diet. The requirement for "protein" (nitrogen) in dairy cow rations is really a requirement for amino acids absorbed from the intestines. These amino acids are derived from two sources: digested protein that escapes degradation in the rumen and microorganism protein from bacterial and protozoal protein synthesis in the rumen (Fig. 11-3). True protein in the diet has one of two fates. Some protein is degraded into amino acids and nonprotein nitrogen (ammonia and other nitrogenous compounds). These sources of nitrogen are used by the rumen microbes for their own protein

Downloaded from Vet-eBooks.com

synthesis. Nonprotein nitrogen sources in the diet (e.g., ammonia, urea, nitrates, and others) are also used for protein synthesis through the same pathways. The ability of the rumen microbes to incorporate nonprotein nitrogen into microbial protein is limited by various factors, such as the type, amount, and rate of fermentation of energy sources and the rate of passage of rumen contents (Chalupa and Sniffen, 1991). The energy in fats is not used in microbial protein synthesis, although there may be a direct requirement of rumen bacteria for a small amount of free fatty acids (Spartan Ration Evaluator, 1992). If a significant portion of the ration's energy content is from fats (and therefore not carbohydrates), then more of the protein must bypass the rumen. Otherwise the protein degradation products formed in the rumen lack available energy for microbial synthesis and are lost in the urine (Chalupa and Ferguson, 1988). Protein not degraded in the rumen (bypass protein, escape protein) is either digested along with the microbes in the abomasum and intestine, as in a monogastric, or else passes unabsorbed in the feces.

The rumen microbes cannot synthesize enough protein to support high levels of milk production in the lactating cow. Dairy cow diets require that some of the protein escape degradation and bypass the rumen. In a typical diet, approximately 40% of the protein eaten must be true protein that escapes degradation, whereas 60% of the protein value can be a mixture of protein and nonprotein nitrogen that is degraded and incorporated into rumen microbes (NRC, 2001; Chalupa and Sniffen, 1991). The degradability of a particular protein depends on the type of feed, method of processing (e.g., grinding, heating, drying, extrusion, pelleting), schedule of feedings, and other constituents of the diet. In the final analysis the cow's nutrient needs are for absorbed amino acids, not simply protein. For many years, protein nutrition in monogastrics has evolved in the direction of describing nutrition requirements not in terms of protein but of specific amino acids. While in ruminants the physiology at the tissue level is similar, describing requirements in terms of amino acids has proved to be much more difficult and complex. This is primarily due to the changes in digestive products presented to the stomach and intestine because of fermentation in the rumen as well as the difficulty in measuring those changes.

Nonetheless, experimental models and methods have been developed that have attempted to identify limiting essential amino acids in ruminant systems, particularly in milk production. Production should respond to supplementation with the limiting amino acid(s). They must be provided in a manner that results in their delivery to the tissues, without confusing any effects of the amino acid(s) with the microbial mass and undegraded intake protein already present in the diet. Several different experimental approaches have been used in determining the first limiting amino acids and the response to them. These experimental approaches include (1) infusion of amino acids directly into the bloodstream and measurement of extraction efficiencies by the mammary gland and response; (2) abomasal or duodenal infusion of amino acids and measuring response; and (3) calculation of amino acid requirements by the factorial method, including product composition and metabolic transfer efficiencies, and then comparing that with estimated or measured amino acid composition of duodenal contents and evaluating response. All three approaches have led to reasonably consistent results, providing some degree of confidence in the accuracy of these results. (See Erasmus, 1999 for review.) On conventional diets,

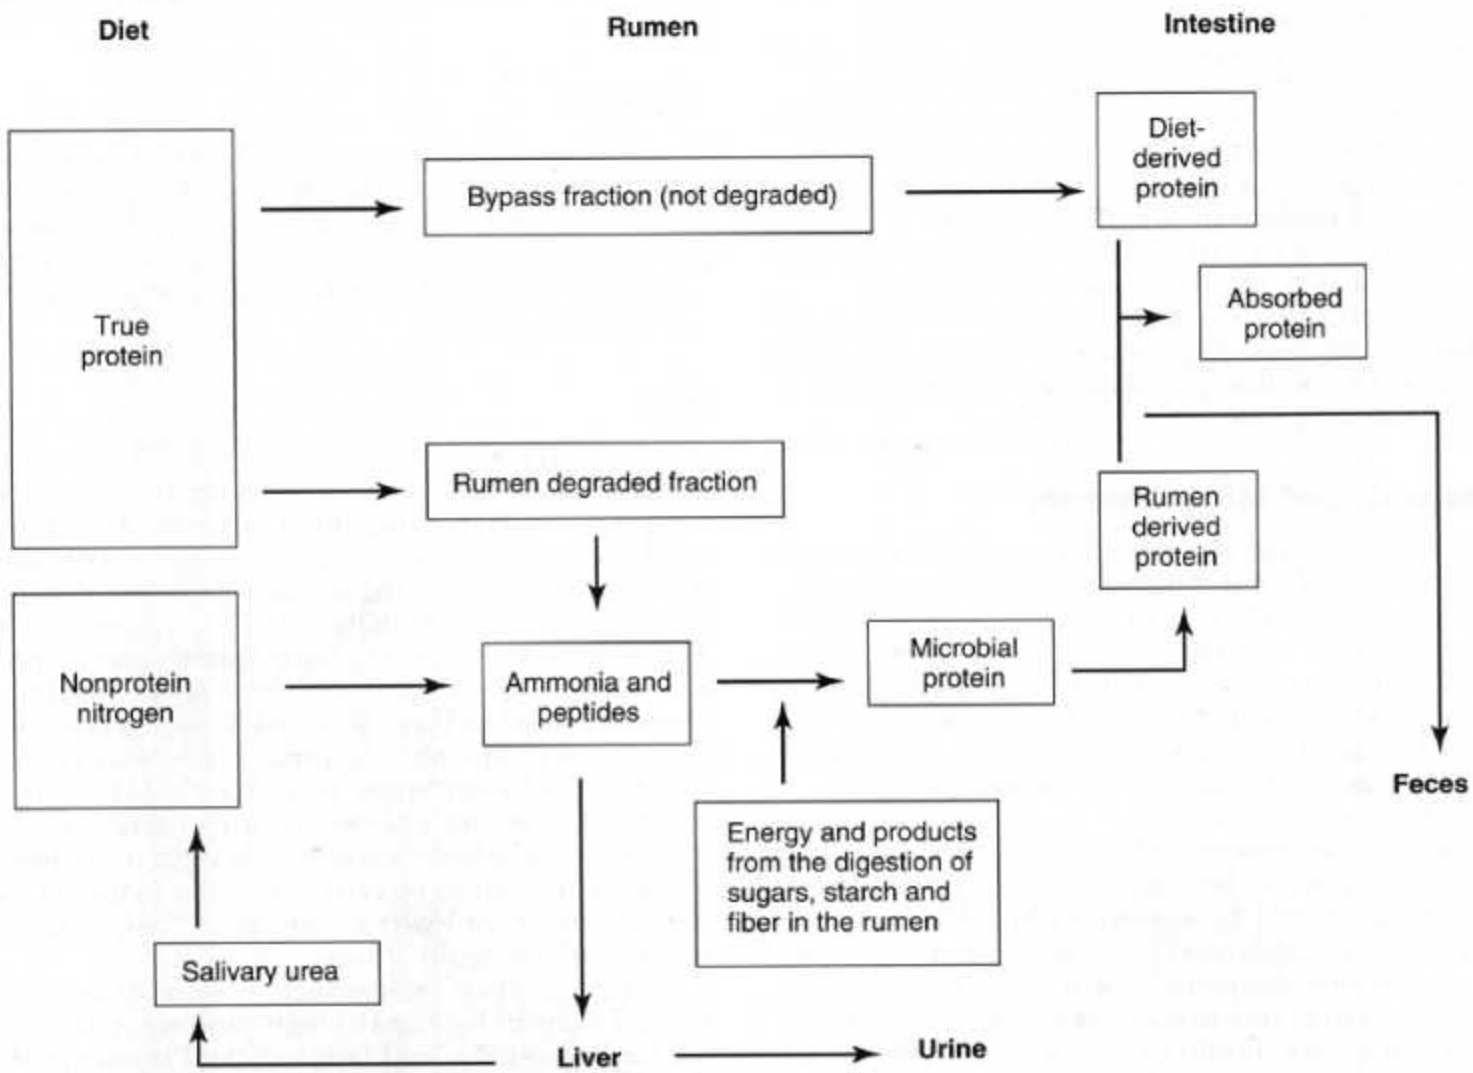

FIG. 11-3 Protein and nitrogen use in the dairy cow.

Downloaded from Vet-e-Books.com

lysine and methionine are usually considered the first two limiting amino acids for milk production, with lysine frequently considered first limiting on corn-based diets, and methionine perhaps first limiting on other common diets. Approximately 15% of the essential amino acids from microbial production and bypass sources should be lysine and 5% methionine. Similar results are obtained using both the factorial calculations and dose response studies. Feeding trials using encapsulated lysine and methionine treated to prevent rumen degradation, yet permit intestinal digestion, have tended to validate these predictions (Armentano et al, 1997). In early lactation the response is frequently increased production of milk. After peak, the response is usually an increased milk protein percentage. An increased milk response is rarely observed with supplemental lysine and/or methionine after 120 days in milk of lactation. In addition, a decline in milk yield has been observed if methionine is supplemented without first meeting the lysine requirement (Robinson et al, 1996).

Protein quality in terms of its ability to support milk production is highly variable. A comparison of the amino acid profiles of milk and a variety of protein sources is shown in Table 11-5. The amino acid composition of microbial protein is very close to ideal for milk production. Unfortunately, the quantity of microbial output is sufficient to supply the protein needs for only 60 to 70 lb of milk production. High-producing cows require additional essential amino acids from bypass protein. Of commonly used supplements, it can be seen that only fish meal comes close to approaching microbial protein in quality for use in supporting milk production, based on amino acid composition. In a recent review of multiple feeding experiments, replacement of degradable protein with more undegradable protein sources rarely improved milk production or milk protein percentage. The consistent exception appeared to be when fish meal was the source of undegradable protein, in which case there was a positive response to undegradable protein supplementation (Santos et al, 1998). Selection of dietary ingredients based on amino acid content of the bypass component is a realistic approach to feeding dairy cattle. Selection of a blend of bypass sources to achieve a desirable amino acid profile, or supplementation of specific protected amino acids to complement the undegraded protein sources in the diet, may be the most feasible approach. It should be evident that maximizing output of rumen microbial protein, by ensuring efficient rumen microbial growth, should be the first priority when meeting the protein needs of the dairy cow.

Macrominerals and Microminerals

The total mineral content of a lactating cow's diet is a small percentage of the total DMI. Adequate mineral composition in dairy cow diets is usually easy to achieve, provided the nutrient composition of the major feedstuffs is known and accounted for during ration formulation. Supplemental minerals are widely available and should be a small percentage of the total cost of the ration. Despite these facts, imbalances, deficiencies, and excesses of various minerals are common in lactating cow rations.

The phosphorus requirement for dairy cattle is receiving intense scrutiny, primarily because of the negative effects on the environment created by excessive phosphorus supplementation. Excess phosphorus is excreted primarily through the feces, and chronic oversupplementation can lead to an excess in soils, water, and runoff (Tamminga, 1992). The current NRC guidelines should be considered to provide adequate phosphorus, in most cases, and feeding higher levels should be discouraged.

Table 11-6 summarizes some of the major roles of minerals in the cow and calf (Linn et al, 1989; NRC, 1989, 2001). The macrominerals are calcium, phosphorus, magnesium, sulfur, potassium, sodium, and chloride. Their requirements are best expressed as percentage of total DMI. The microminerals include iodine, iron, selenium, copper, cobalt, manganese, and zinc. They are needed only in minute quantities, and their requirements are usually expressed in parts per million of the diet dry matter.

Vitamins

The fat-soluble vitamins A, D, and E (Table 11-7) are all recognized as necessary additives in dairy cow diets (NRC, 1989, 2001; Herdt and Stowe, 1991). Vitamin K is usually present in common feedstuffs, is synthesized in the rumen, and does not need supplementation unless dicumarol poisoning is present from eating moldy sweet clover hay. It has been generally assumed that ruminants, including dairy cattle, do not need water-soluble vitamin supplementation because their diets are often rich in B vitamins, and that rumen microorganisms synthesize adequate amounts. It seems likely, however, that certain B vitamins should be supplemented in dairy cow rations under some conditions, including possibly niacin, choline, and thiamine (NRC, 1989). Dairy cattle can become vitamin B_{12} (cyanocobalamin)-deficient with diets inadequately supplemented with cobalt.

FEEDS FOR THE DAIRY COW

There are several broad classes of feedstuffs fed to dairy cattle: forages, concentrates, by-products, minerals, vitamins, and additives. Several excellent references are available for more information about the feeds used in dairy cow diets (Bath et al, 1998; Dale, 1998; NRC, 2001; Linn et al, 1989; MacGregor, 1989).

Forages

Forages typically make up the majority of the dry matter in a dairy cow's diet (McCullough, 1989). The major forages are hay, silages and haylages, green chop, and pasture. Most of the fiber in a dairy cow's diet is derived from forages, and in most cases a large proportion of the energy and protein also comes from forages.

Hay

Hay is dried grass or legumes (e.g., alfalfa, clover). By drying these plants to about 90% dry matter, they can be stored for long periods. Harvesting results in some loss of feed in the field and some nutrients may be lost gradually during storage (e.g., vitamin A). The quality of the hay depends significantly on the stage of maturity at harvest and the care taken in drying and storage. As plants mature, energy, protein, calcium, phosphorus, and digestibility all decline, whereas fiber increases. As these fiber levels rise, so does the proportion that is indigestible lignin and ADF. Hay is best if cut in the early, prebloom stage, and certainly before any seeds are produced. Care must be taken during harvest to avoid losing too many leaves from legumes (the most nutrient-dense part of the plant) and to be certain that dry matter is above 80% before storage. At lower dry matters, there is enough moisture to support mold growth.

Other dry plant forages such as straw or corn stover have limited value in the diets of high-producing dairy cows. They are too indigestible and lack sufficient nutrients. If fed, they should be strictly limited so that they do not reduce the cow's total DMI because of their low rate of turnover in the rumen.

TABLE 11-6

Minerals in Dairy Rations

Mineral	Function(s)	Clinical Abnormalities	Feed Sources for Dairy Cattle	Recommended Levels for High-Producing Lactating Cows
Calcium (Ca)	Bone and teeth formation; blood clotting; muscle contraction; 0.12% in whole milk	Rickets; slow growth and poor bone development; easily fractured bones; reduced milk yield; milk fever	Alfalfa and other legumes; ground limestone; dicalcium phosphate; steamed bone meal	0.66% DMI* (0.8% with added fat)
Phosphorus (P)	Bone and teeth formation; energy metabolism, part of DNA and RNA; 0.099% in milk	Fragile bones; poor growth; low blood P (less than 4-6 mg/100 ml); depraved appetite (chewing of wood, hair, and bones); poor reproductive performance	Monosodium, monoammonium and dicalcium phosphates; steamed bone meal; cereal grains; grain by-products; oilseed meals	0.41% DMI* (0.48% in early lactation)
Sodium (Na)	Acid-base balance; muscle contraction; nerve transmission	Craving for salt; reduced appetite; if severe, incoordination, weakness, shivering, and death	Common salt and buffer products	0.18% DMI
Chlorine (Cl)	Acid-based balance; maintenance of osmotic pressure; manufacture of hydrochloric acid in abomasum	Craving for salt; reduced appetite	Common salt and commercial supplements	0.25% DMI
Magnesium (Mg)	Enzyme activator; found in skeletal tissue and bone	Irritability; tetany; increased excitability	Magnesium oxide; forages and mineral supplements	0.25% DMI (0.3% with added fat)
Sulphur (S)	Rumen microbial protein synthesis, especially when nonprotein nitrogen is fed; found in cartilage, tendons, and amino acids	Slow growth; reduced milk production; reduced feed efficiency	Elemental sulfur, sodium and potassium sulfates; protein supplements; legume forages	0.20% DMI

Downloaded from VetBooks.com

Potassium (K)	Maintenance of electrolyte balance; enzyme activator; muscle function; nerve function	Decrease in feed intake; loss of hair glossiness; lower blood and milk potassium	Legume forages; potassium chloride; potassium sulfate	1.00% DMI
Iodine (I)	Synthesis of thyroxine	Big neck in calves; goitrogenic substances may cause deficiency	Ionized salt, trace mineralized salt, and commercial supplements	0.60 ppm DMI
Iron (Fe)	Part of hemoglobin; part of many enzyme systems	Nutritional anemia	Forages; grains; trace mineralized salt and commercial supplements	50 ppm DMI
Copper (Cu)	Needed for manufacture of hemoglobin; coenzyme	Severe diarrhea; abnormal appetite; poor growth; coarse, bleached, or graying hair coat; osteomalacia	Trace mineralized salt and commercial supplements	10 ppm DMI
Cobalt (Co)	Part of vitamin B_{12} needed for growth of rumen microorganisms	Failure of appetite; anemia; decreased milk production; rough hair coat	Trace mineralized salt and commercial supplements	0.10 ppm DMI
Manganese (Mn)	Growth; bone formation; enzyme activator	Delayed or decreased signs of estrus; poor conception	Trace mineralized salt, and commercial supplements	40 ppm DMI
Zinc (Zn)	Enzyme activator; wound healing	Decreased weight gains; lowered feed efficiency; skin and hoof problems; slow healing wounds	Forages; trace mineralized salt, and commercial supplements	40 ppm DMI
Selenium (Se)	Antioxidant; needed for red blood cell glutathione peroxide enzyme	White muscle disease, unthriftiness, retained placenta, elevated milk somatic cell counts	Trace mineralized salt, and commercial supplements	0.30 ppm DMI

TABLE 11-7

Fat-Soluble Vitamins in Dairy Rations

Vitamin	Functions	Clinical Abnormalities	Common Feed Sources for Dairy Cattle
A	Essential for normal vision, cellular function, and maintenance of epithelial linings of respiratory, reproductive, and digestive tracts	Night blindness; skin problems; blind, dead, or weak calves; reproductive problems	Sources of carotene: green, leafy forages; hays; haylages (little weathering) unfrosted corn silage; synthetic A; vitamin premix; fish liver oil
B	Normal bone growth and development; mobilization of calcium, and phosphorus	Rickets, osteomalacia	Sun-cured forages; fish liver oils; synthetic premixes
E	Antioxidant; associated with selenium	Oxidized flavor in milk; muscle problems; white muscle disease; cardiac muscle abnormalities	Alfalfa; germ of cereals; wheat germ oil; cereal grains; synthetic premixes
K	Required for blood clotting	Hemorrhaging; moldy sweet clover disease	Green, leafy forages; ample amounts normally are synthesized in the digestive tract

Adapted from Linn JG, Hutjens MF, Howard WT, et al: *Feeding the dairy herd*, St Paul, Minn, Minnesota Extension Service, University of Minnesota, 1989, North Carolina, North Central Regional Extension Pub No 346.

Silages and Haylages

Silages are forages with somewhat higher water content than hays (25% to 50% dry matter). These feeds are harvested and then packed in some sort of storage container (e.g., upright silo, trench silo, plastic bags) in which there is limited oxygen. The sugars and starches in the forage are fermented anaerobically until the acidity rises to high enough levels that it serves as a preservative (ensiling). Silages can be stored for extended periods without significant spoilage as long as they are protected against oxygen. Quality of silage fermentation is a critical factor in ensuring a nutritional, palatable feed. It can be affected by a variety of factors, including moisture, packing, availability of substrate, environmental temperature, and additives.

In recent years, plant breeders have begun to pay attention to qualities that enhance suitability as silage. Particularly with corn, but also with small grains and alfalfa, selection of specific varieties according to their suitability as silage is now practical and feasible.

Corn Silage

If cut at the right stage, corn silage is an excellent dairy feed. It can be as much as 50% grain on a dry matter basis and can supply a large proportion of the cow's energy needs. Corn silage must be supplemented with protein and minerals to balance a ration for a dairy cow. Corn should be harvested for silage when the ears are fully mature and the tops of the kernels have begun to dent. The "milk line" visible on the kernel should be one half to two thirds of the way down the kernel. At this stage the corn is approximately 30% to 35% dry matter. Silages harvested at earlier, wetter stages yield less dry matter per acre and tend to lose nutrients by seepage once ensiled. Drier, more mature corn makes silage that is less digestible, is harder to pack in storage, and is thus more accessible to oxygen and more prone to molding. In recent years, corn plant breeders have focused on developing corn varieties specifically for use as corn silage. Mechanical processors that increase the availability of energy from the ensiled corn plant have also been developed.

Legume and Grass Haylages

If legumes and grasses are harvested and stored at higher water contents than hay (30% to 50% dry matter), they can also be ensiled. Haylages offer an advantage over hay in that they can be stored sooner after cutting, reducing the risk of rain damage during the drying process. Haylages usually suffer less leaf loss during harvest and commonly require less labor both during and after harvest than hay. Alfalfa haylage is the most common haylage. It is a palatable, high-protein, highly digestible source of nutrients while also providing needed fiber in the ration. Alfalfa should be cut in the prebloom stage of growth for best use in the rations of high-producing dairy cows. Haylages should be chopped reasonably coarsely (1 to 1.5 cm theoretic length of cut) so that they pack and ensile properly while still stimulating cud chewing and proper rumen fiber mat status. In bunker silos, good preservation with a longer theoretical cut can be achieved.

Downloaded From Vet-eBooks.com

Grasses can also be ensiled, including small grains such as rye, oats, triticale, barley, or wheat. The stage of maturity at harvest and care in storage are critical to the success of small grain silages. It is recommended that they be harvested in the "boot" stage of maturity. Sorghum can also be ensiled. Its properties as a forage fall between those of corn silage and grass haylage.

Green Chop

During the appropriate seasons, forage plants (e.g., legumes, grasses) may be cut and fed directly as green chop to the milking cows without drying or ensiling. These feeds are usually palatable and can be good sources of digestible nutrients if cut at the right stage of maturity. If green chop is too wet or is a large proportion of the total ration, its bulk may reduce total DMI. It may be difficult to monitor DMI and to balance other needed nutrients when feeding green chop, because the dry matter content of the green chop can vary widely. Green chop spoils quickly and feed bunks must be cleaned daily to avoid moldy feed. Feeding green chop to high-producing dairy cows must be managed expertly, but it remains a very inexpensive method of harvesting and feeding forage.

Pasture

Pasture has many of the same advantages and disadvantages as feeding green chop. It has the added advantages of needing no harvesting, providing exercise and a clean environment to the cows, and reducing the need for manure management. It has the disadvantages that bad weather can make the pasture a dirty and inhospitable place for the cow and that cattle must be brought in twice daily to be milked. Even with its disadvantages, grassland feeding systems are the basic structure of much of the world's dairy industry.

Grassland dairying tends to be more seasonal than dairying in which all feeds are brought to the cow. Calving and lactation must be timed to take advantage of seasons with the greatest grass growth. Pasture management is of paramount importance, including fertilization, pasture rotation, water for the cattle and for irrigation, and selection of grass and legume varieties on the pasture. In extremely wet regions the cows themselves may churn up large proportions of the land, thus reducing total forage production per acre. Levels of milk production are typically lower on pasture-based dairies. Despite all these difficulties, pasture is still the most efficient means of milk production in some regions, particularly because pasture commonly offers lower feed and labor costs.

Relatively recent advances in fencing and watering technology have improved the ability to manage pastures in smaller subdivisions. A precise matching of herd needs with forage production is thus possible by more intensive rotation of smaller paddocks for the herd. This system is referred to as management intensive grazing (MIG) or intensive rotational grazing (IRG). Better forage quality, more productivity per acre, and greater profitability would characterize an intensively managed pasture system versus one that was not managed intensively. Selection of plant pasture species varies according to geographic location and soil type, but a legume-grass mixture is frequently a suitable combination for best growth during varied day length and moisture conditions. The number of North American dairies adopting a more intensive pasture program for at least some of their forage requirements is increasing, primarily for economic reasons. When compared with conventional systems, intensively managed pasture systems have consistently been more profitable (Schraufnagel et al, 1998; Dartt et al, 1999).

Grains

The major role of grains is to provide energy in the diet. Some grains are also moderately high in protein. The energy in the grain is mostly in the form of sugars and starch. The digestibility of grains is commonly increased by processing, either by making the contents more accessible to rumen bacteria (e.g., by rolling, grinding, or cracking) or by also changing the structure and digestibility of the starch (e.g., by steaming, extrusion, popping, heat drying, pelleting, or flaking). If grains are overprocessed (ground too finely), they may be broken down too rapidly, with an increased risk of rumen acidosis. Grains are digested at different rates. Roughly, wheat is most rapidly broken down in the rumen, followed by barley, oats, corn, and sorghum (Sniffen, 1988). Careful feed management is necessary when feeding grains so that the proper rumen environment and buffering are maintained and acidosis is avoided.

Corn

Shelled corn or ear corn is the most commonly fed grain. Ear corn (which includes the cob) has about 10% less energy than shell corn (kernels only) but is higher in fiber. It is commonly the least expensive grain available for dairy rations.

Barley

Barley is a good source of energy and protein. It should be rolled, not ground, in dairy rations.

Oats

Lower in energy and higher in protein than corn, oats may help maintain rumen function because of their higher fiber content and slower digestion in the rumen.

Wheat

Because of its cost, wheat is used less often than other grains in dairy rations. It is high in energy and relatively high in protein. The starch in wheat is rapidly digested in the rumen, and in a dairy ration the amount of wheat in the diet should be strictly limited to avoid rumen acidosis.

Most grains are stored at approximately 90% dry matter. If the moisture content is higher than 12% to 15% at harvest, the grain should be dried before storage to avoid mold growth. It is possible, however, to harvest grain, particularly corn, at a higher water content and to ensile it in an anaerobic environment. If stored in an airtight silo or bag, corn can be stored whole. In conventional silos it should be ground before storage. Such "high-moisture corn" (70% to 75% dry matter) has several advantages (Linn et al, 1989):

1. Corn can be harvested 2 to 3 weeks earlier, reducing the risk of crop loss if the fall weather suddenly turns bad.
2. Drying, storage, and handling costs may be reduced.
3. The need for frequent grain processing (e.g., grinding, rolling) is reduced.
4. The palatability of the corn is improved.

Protein Supplements

Protein supplements are concentrated sources of protein or nitrogen. They are derived from four major sources: oil seeds (e.g., soybeans, peanuts, sunflower seeds, flax, cottonseed), grain processing and fermentation by-products (e.g., corn gluten meal, distiller's dried grains), animal products (e.g., meat and bone meal, blood meal, fish meal, feather meal), and nonprotein nitrogen sources (e.g., urea). This category

Downloaded from Vet-e-Books.com

of feeds overlaps with the by-product feeds (see later discussion). Several common protein supplements are used. In the selection of a specific protein source, several criteria should be used. These include: the profile of the protein source compared with what is needed in the diet (i.e., the fraction of degradable and undegradable protein that is supplied by that protein source); the amino acid profile of the bypass fraction of the protein compared with the needs of the animal and the other sources in the diet; and cost, both per unit of protein and unit of bypass protein, if that is the most limiting nutrient.

Soybean Meal

Soybean meal is the most commonly used source of supplemental protein in dairy cattle diets. The protein in soybean meal is relatively degradable in the rumen. Similar to whole soybeans, the amino acid profile of soybean meal is relatively high in lysine and low in methionine, compared with the essential amino acids required for milk production. The most commonly used soybean meal is 44% protein, as fed. Soybean meal derived from dehulled soybeans (48% protein) is also commonly available. Most commercial dairy concentrate mixes contain soybean meal.

Soybeans

Whole soybeans can be fed in dairy cow diets. Beans can be fed raw, roasted, or extruded. Roasting and extrusion increase the proportion of soy protein that bypasses rumen degradation and increases palatability. Soybeans contain approximately 18% fat. Because of the rumen's limited ability to digest vegetable fats, only a limited amount of soybeans can be fed. Raw soybeans also contain urease, an enzyme that breaks down urea. They should not be fed when urea is included in the diet.

Distiller's Dried Grains

Derived as a by-product of the alcohol distillation industry, distiller's dried grains are an excellent source of rumen undegradable protein and energy. The composition varies depending on the grain that was fermented for distillation. Corn is the most common grain used.

Corn Gluten Meal

Derived from the wet milling of corn for starch and corn syrup, corn gluten meal is a source of protein with low rumen degradability. It has a high energy content. Corn gluten meal should not be confused with corn gluten feed, a moderate source of relatively degradable protein. The bypass fraction of corn gluten meal is relatively high in methionine content but low in lysine.

Meat and Bone Meal, Meat Meal, Blood Meal

These feeds are by-products of abattoirs. They are excellent sources of protein, are relatively undegradable in the rumen, and may serve as important sources of limiting amino acids in dairy cow diets. They are relatively unpalatable. However, animal-derived protein sources may transmit disease, including salmonellosis. In England and other European countries, rendered meat and bone meal has been implicated as a cause of bovine spongiform encephalopathy (BSE, or "mad-cow" disease) (Gibbs et al, 1992). Feeding ruminant derived meat and meat and bone meal to cattle has been prohibited in the United States since 1997. Porcine derived meat and bone meal is still a common feedstuff in dairy cattle diets. Animal protein products tend to be higher in lysine but may be low in methionine. Fish meal is a relatively good source of both lysine and methionine, usually the first limiting amino acids for milk production.

Urea

Urea is an inexpensive and potent source of nonprotein nitrogen in dairy diets. It is rapidly converted to ammonia in the rumen and should not be fed with raw soybeans because they contain urease and can potentiate urea's toxicity. Urea contains the equivalent of 287% crude protein because of its high nitrogen content compared with true protein. It should be fed to dairy cows only if there is a deficiency of rumen-degradable, soluble protein in the remainder of the diet. If there is insufficient energy for the rumen bacteria to process the nonprotein nitrogen from urea, the potential protein value is lost and the ammonia nitrogen is processed by the liver (at an energy cost) and excreted in the urine.

By-Products

As ruminants, dairy cows can digest many feeds that are essentially indigestible for monogastrics. This means that a broad range of by-products and residues of other industries can be fed to cattle. These feeds might otherwise have no value or might add to the economy's waste disposal problems. Many of these products are only available in limited local areas, some are only seasonally available, and many require special handling, storage, and delivery arrangements. By-product feeds are often very economical and supply valuable nutrients and diversity in dairy cow diets. Some by-product feeds are cottonseeds, citrus pulp, bakery waste, potato waste, corn gluten meal and feed, distiller's dried grains, soy or peanut hulls, hominy, wheat midds, rice bran, tallow, grain screenings, tomato pomace, pea vines, meat and bone meal, brewer's grains, and beet pulp, with many other possibilities. In fact, even soybean meal is a by-product feed. It is a "residue" of the vegetable oil industry.

By-product feeding is likely to play an increasingly important role in dairy cow rations as larger herds move more and more toward blended and total mixed rations. Each by-product feed has its own special characteristics in dairy rations, nutrient profile, feeding qualities, palatability, and biologic limits on the amount that can be fed. Veterinarians who design feeding programs for their client dairies must be familiar with the by-product feeds available in their area, their costs, and their possible role in the dairies' overall feeding programs. Some by-product feeds are consistent from batch to batch (soybean meal), whereas others may vary widely depending on the batch's source, processing, and storage history. There are good sources of information about the quality control and evaluation of by-product feeds (Bath et al, 1998; Schingoethe, 1991; UMC, 1988; MacGregor, 1989; NRC, 2001).

The following are some commonly available by-product feeds. Others were described earlier (see Protein Supplements).

Whole Cottonseeds

Whole cottonseeds are a rich source of energy because of their oil content. Whole cottonseeds also are moderate sources of protein and provide some fiber in the diet. If fed whole, some of the seeds escape rumen degradation and provide bypass protein and oil that are digested after leaving the rumen. Because of the oil content and potential for gossypol toxicity, generally no more than 3.5 kg should be fed per cow per day.

Downloaded from Vet-eBooks.com

Brewer's Grains

Brewer's grains are commonly delivered as a wet slurry from the brewery, although dry brewer's grains are also available. Brewer's grains are a reasonable source of energy and relatively high in protein. They are useful for "extending" a limited supply of corn silage on a farm. In warm weather, wet brewer's grains spoil quickly, so inventories must be turned over every few days. Because wet brewer's grains are 80% water, their bulk can reduce DMI if more than approximately 15 to 20 kg/cow are fed daily.

Beet Pulp

Beet pulp is a by-product of the sugar beet industry. It is a palatable feed, high in energy and digestible fiber.

Soybean Hulls

Soy hulls are sources of highly digestible fiber that can replace some of the starch in diets prone to rumen acidosis.

Wheat Midds

One of several similar by-products of the flour milling industry, wheat midds are a common ingredient of commercial dairy cattle feeds. They are a high-energy, moderate protein feed.

Citrus Pulp

A feed relatively high in energy and fiber, citrus pulp shares many characteristics with beet pulp. Because of its unusual flavor, it must be introduced into rations slowly to allow the cows to become accustomed to it.

Molasses

A by-product of the manufacture of sugar, molasses is used principally to reduce the dustiness of feeds and to improve palatability.

Tallow

Derived from animal fat, most commonly beef, tallow is a source of energy for dairy rations. Although much of the fat in tallow is probably inert in the rumen, it still can be used only in limited quantities because of the limits of the rumen to handle fats.

Minerals

Minerals play an obvious critical role in dairy cow nutrition (NRC, 2001; Beede, 1991). Because the total mineral intake needed by the dairy cow is such a small part of total DMI, providing adequate mineral nutrition is more a matter of paying attention to details, rather than difficulty of obtaining or providing adequate levels. Many dairy farms pay too much for minerals in their ration, buying expensive "custom" mineral mixes when simpler basic ingredients would do just as well. Like all nutrients, minerals in a cow's diet are needed in absolute amounts, not ratios. The relative balance of minerals is important (say, calcium-to-phosphorus ratio), but proper ratios of inadequate quantities are not effective. Table 11-6 outlines the major minerals needed in dairy cow diets, their functions, deficiency symptoms, and common sources for lactating cows. Dairy cows do not preferentially select feeds that balance their mineral needs. Minerals must be fed in a way that forces cows to consume adequate amounts, usually by blending the minerals with the grain mix or as part of a TMR.

Vitamins

Vitamins, like minerals, are easily included in dairy cow diets if attention is paid to details. The fat-soluble vitamins are typically added to dairy cow diets at levels that satisfy the total requirements, ignoring any possible contribution of vitamins present in the forages or concentrates (Table 11-7).

Additives

Additives are materials added to rations for a variety of reasons that enhance performance. They fall into many categories—some nutritive, some not. Whether a particular additive is desirable depends on many factors, including price, production effect, specific factors on the farm, and others (Hutjens, 1986, 1991). Many of the additives pushed onto farms by enterprising salespeople are of little or no value to the producer. Some of the commonly used additives follow, and there are many other additives beyond those mentioned. Other sources have presented more extensive discussions (Hutjens, 1986, 1991; Linn et al, 1989).

Buffers or Alkalinizing Agents

There are several compounds that serve as buffers or alkalinizers for dairy cattle. Through moderation of the acidity resulting from high-concentrate diets, these compounds preserve a hospitable environment for cellulolytic bacteria in the rumen. This effect helps maintain rumen and cow health and, by enhancing fiber digestion, preserves normal butterfat levels in the milk. Sodium bicarbonate is the most widely used buffer. Magnesium oxide is also commonly added as an alkalinizing agent and as a source of magnesium. The effect of magnesium oxide is enhanced if used in concert with sodium bicarbonate. Other buffers or alkalinizing agents used in dairy diets are sodium sesquicarbonate, and calcium carbonate. Most buffers are unpalatable and must be blended with other feeds to be consumed. Cows cannot be depended on to consume adequate levels of buffers free choice. Buffers are usually added at the level of 0.1 to 0.2 kg/cow/day.

Niacin

The B vitamin niacin has been shown to have positive effects when fed to high-producing cows in negative energy balance (early lactation). Although not consistently effective on every farm, added niacin on some farms can increase milk production in those stressed, early-lactation cows. Niacin is too expensive to be fed to all cows routinely.

Ionophores

Monensin, decoquinate, and lasalocid are ionophore antibiotics that alter metabolic patterns in the rumen. When added to the rations of growing heifers, the rates of growth and feed efficiency are improved. They should be recommended for most youngstock rations. They are not approved for use in lactating dairy cattle in the United States. In Canada, monensin has been approved for lactating cattle as an aid in the treatment and prevention of ketosis. The recommended level is approximately 300 mg/head/day.

Yeast and probiotics

Many direct fed microbials have been marketed and researched as additives for dairy cattle. They include yeast and/or bacterial cultures and have been used to improve fiber digestion and enhance intake performance, particularly in times of stress. They may provide a cost effective benefit in some circumstances.

Downloaded From Vet-e-Books.com

Mold and mycotoxin inhibitors

Mold and mycotoxin inhibitors can be divided into three categories: (1) mold inhibitors such as propionic acid, which are used to prevent mold growth, (2) adsorbents, such as bentonite or activated clays, which are designed to bind with mold toxins to prevent mold absorption, and (3) direct fed microbials, which can metabolize or detoxify some mycotoxins. All may be of some benefit in circumstances where feeding mycotoxin contaminated feed cannot be avoided. Need, cost, and response should be assessed and monitored.

Larvacides

Larvacides may be added to dairy cow rations for fly control. The larvacides pass through unabsorbed and are present in the manure to kill developing larvae. They are not a substitute for good hygiene.

ANALYSIS AND EVALUATION OF FEED CONSTITUENTS

Regardless of the feed being used to formulate a dairy cow ration, the first step is to obtain accurate measurements of the nutrient content. For some feeds (most grains, soybean meal, minerals, vitamins, additives), "book values" from publications are usually adequate measures of their nutrient content. There are many sources of feed information (Dale, 1998; NRC, 2001; Linn et al, 1989; MacGregor, 1989; Penn State Extension Service, 1995). For all forages, most by-product feeds, and some grains, laboratory analyses are necessary to determine nutrient content. The sample being analyzed must be collected carefully so that it is a good representation of the feed that is to be fed. Box 11-2 shows some of the more common constituents of feeds that are routinely determined by laboratory analysis.

Fig. 11-4 is a schematic representation of the constituents of plant materials in dairy feeds, broken down in three different ways (Linn et al, 1989). The center column depicts the main chemical constituents of a feed. The left-hand column depicts the results of the proximate analysis (Weende) system. In this system, ash is determined by burning part of the sample to destroy all organic components. Ether extraction of another part of the sample removes all lipids (fats). Total nitrogen is measured and crude protein is calculated by multiplying nitrogen by 6.25 (on average, protein is 1/6.25, or 16% nitrogen). Crude fiber is calculated by the residue remaining after successive boiling of a sample with dilute acid and alkaline solutions. A nitrogen-free extract can then be calculated by subtracting the other components that were measured. Proximate analysis is the system legally required for feed labeling but is an anachronism that is little used by nutritionists in formulating dairy cattle diets.

In the Van Soest system, ash, lipid content, and crude protein are determined as in a proximate analysis. NDF is determined by subjecting a sample to treatment by a neutral detergent solution and measuring the residue. Treatment with sulfite and α-amylase may then be applied to leave true NDF complex without any complex starch. It is the least destructive of the fiber measurements. NDF includes lignin, cellulose, and hemicellulose. Acid detergent treatment is more destructive, leaving only some of the lignin and cellulose. ADF is frequently used to predict the energy content of the feedstuff. The protein in a feed sample can be corrected for unavailable protein by subtracting out the ADF-bound protein content predicted based on the nitrogen content in the ADF. Predictions of DMI are better based on NDF content, particularly if corrected for physical form (Linn et al, 1989).

BOX 11-2

Nutrient Constituents of Feeds Commonly Reported by Analytic Laboratories

Dry matter
Energy and fiber
Acid detergent fiber
Neutral detergent fiber
Net energy of lactation (calculated)
Nonfiber carbohydrate (calculated)
Ether extract or fat
Starch
Protein
Crude protein
Heat damaged or unavailable protein
Undegraded or bypass protein (calculated)
Soluble protein
Macrominerals
Calcium
Phosphorus
Magnesium
Potassium
Sulfur
Trace minerals
Copper
Iodine
Iron
Manganese
Zinc
Other
Ash
Lignin

The proximate analysis and Van Soest systems for feed analysis are both wet chemistry approaches. Another, more rapid approach for determining nutrient content is the use of near-infrared radiation (NIR) testing of feeds. Based on the spectrum of absorption of infrared light on a feed sample, nutrient content can be predicted. The accuracy of NIR testing is dependent on the number of calibrating samples of a particular feed that have been used to provide the data for predicting equations. The NIR test can be accurate for commonly tested feeds with reasonably normal nutrient content and has the advantage of being cheaper, quicker, and portable. Whatever the analytic method used, it is essential that the laboratory used for analysis be accurate, consistent, and reliable.

FEEDING SYSTEMS FOR DAIRY HERDS

There are several major systems for feeding dairy cattle, each with its own advantages and disadvantages. With excellent management, any system can be effective. The challenge is to find systems that are effective and efficient for the management level on the farm.

Pasture

Pasture-based feeding systems can generate excellent profit per cow, and in many cases are much less capital intensive than other systems. For that reason they are increasing in popularity in North America. They have long held a dominant position in Australia and New Zealand as well as

Downloaded From Vet-eBooks.com

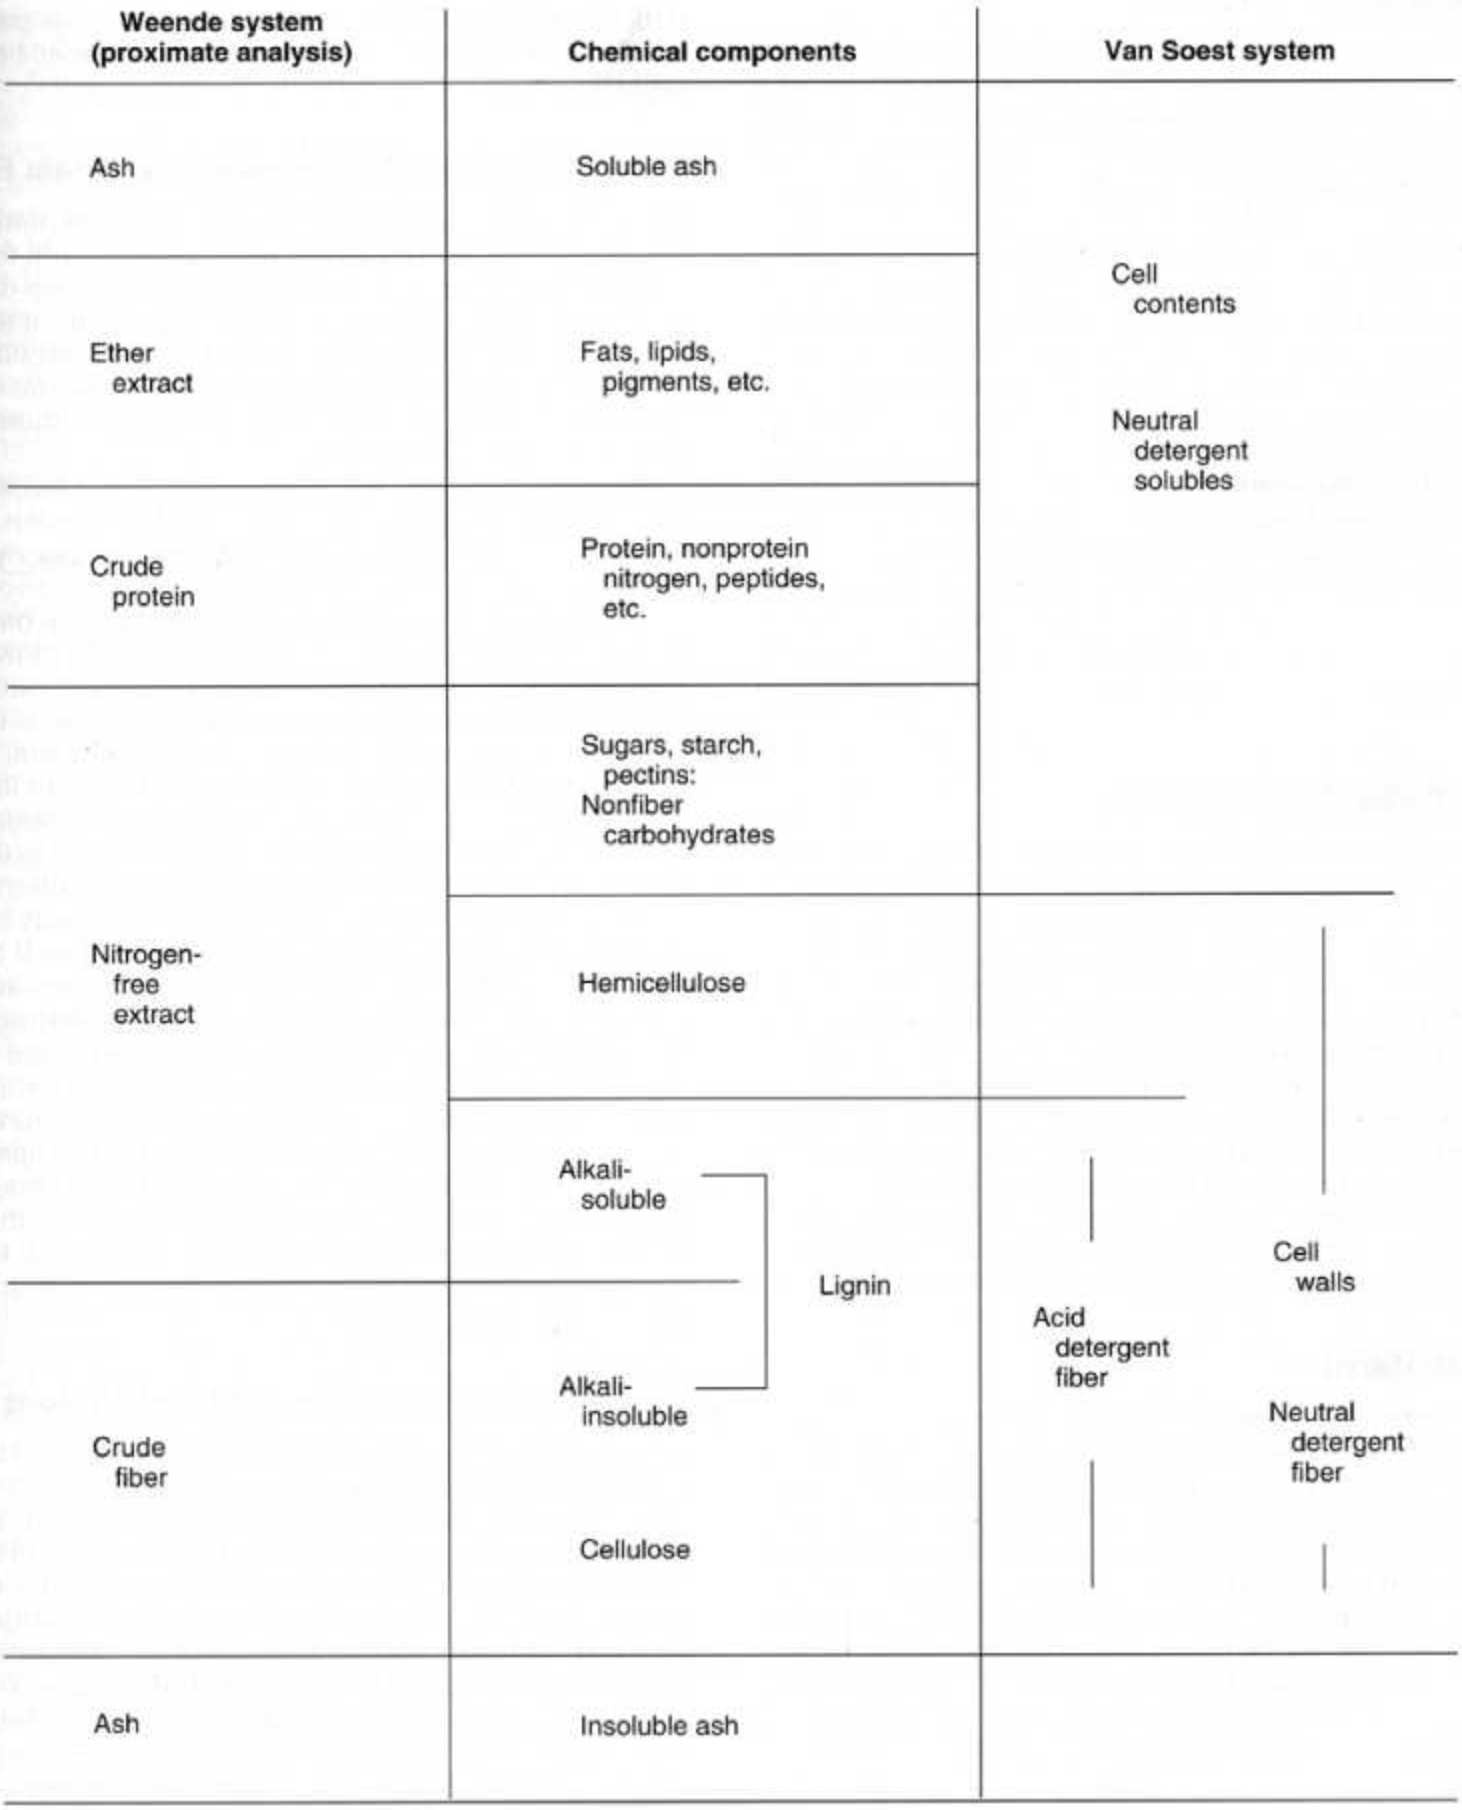

FIG. 11-4 Nutrient and structural components of feedstuffs. (From Linn JG, Hutjens MF, Howard WT, et al: *Feeding the dairy herd,* North Central Regional Extension Pub No 346, St Paul, 1989, University of Minnesota, Minnesota Extension Service.)

lesser developed countries. In Europe, utilization of pasture is somewhere in between that of New Zealand and North America. For maximum benefit, pasture should be managed intensively with frequent movement of cows between paddocks and limited time spent on a given paddock. In North America, maximum profit with pasture systems usually occurs by seasonally calving the cows, so pasture utilization is best matched to cow requirements, and by providing significant concentrate supplementation (Schraufnagel et al, 1998) Provision of water and shade and laneway maintenance are major issues affecting pasture utilization and profitability. Pasture systems usually require less labor and less manure management and produce less milk per cow.

Downloaded from Vet-e-Books.com

Stanchions and Tie-Stall Barns

In these systems, cows spend much or all of their time constrained in individual stalls. Cows may be fed their entire ration in the stanchions or may consume a variable amount of the feed (particularly forages) free choice from separate feed bunks during exercise or turn-out periods. Stanchion systems usually require more labor per cow than free-stall systems. Mechanized feeding and TMRs are more difficult to implement in stanchion barn systems but can be done effectively. Labor-saving mechanization in stanchion barns is commonly more expensive than with other systems. Stanchions offer the advantage of allowing individual cow care and feeding. Stanchion barns are typically warmer and more comfortable for the dairy producer in climates with cold winters, although these same "warm" barn systems also tend to provide inadequate ventilation for the cow's comfort and health. Where forages are fed free choice outside the stanchions and mostly grain is fed in the stanchion, there is a risk of rumen acidosis. Because cows can eat variable amounts of forage from the bunks, they might not achieve the proper balance of forages and grain.

Milking Parlor Grain Feeding

A once-popular approach to feeding grain to dairy cows was to provide grain feeders in the milking parlor. These individual feeders were metered so that each cow could be fed her individual grain ration to match her production. Parlor grain feeding suffers from several problems. First, high-producing cows may simply not have enough time to eat their allotted grain during milking. Second, the timing of grain feeding may not match forage intakes, leading to a twice-daily risk of rumen acidosis. Third, the metering systems in milking parlors are commonly out of adjustment or dysfunctional, leading to errors in the amounts fed. Eliminating parlor feeding speeds cow flow through the parlor and reduces dust and defecation during milking. Today, very few operations feed concentrate in the milking parlor.

Free-Stall Barns

Free-stall housing is typically cheaper to construct and requires less labor than stanchions or tie stalls. Cows are fed in bunks, with a variety of systems for feeding grains. Unless they are properly designed and maintained, free stalls may become uncomfortable for the cow and for the operator. As is true for all types of high-density housing, if good ventilation is not provided for in the building's design, air quality, cow comfort, and health may suffer. If humid air is allowed to collect and condense under the roof, structural damage to the barn may also develop. The following describes typical feeding systems found in free-stall operations.

Bunk Forages with Top-Dressed Grain

The simplest system for feeding cattle in free stalls is to provide the forages in bunks, with the grain or concentrate portion (including trace minerals and vitamins) placed on top of the forage. Hay might be fed separately in racks. On many farms feeding with this system, cows are commonly grouped by production so that low-producing cows can be fed less concentrate top dressed on their forages. This feeding system is easy to organize and requires little or no special mechanical system. It has the disadvantage that dominant cows may consume more grain than less aggressive ones. Grain may be consumed in large quantities first, without adequate forage intake to encourage cud chewing and provide for buffering. The dominant cow risks nutrient imbalance and rumen acidosis, whereas the more timid cow eats less grain and is shorted for nutrients. Her milk production or health may suffer.

Bunk Forages and Individual Cow Grain Feeding

There are several systems for feeding the grain portion of the ration to cows housed in free stalls. Commonly, forages are fed in bunks. Part of the grain might be fed top-dressed on the forage, with additional grain fed in relation to production in the milking parlor. Again, such a system suffers from the disadvantages of both parlor feeding systems and from top-dressed bunk grain feeding. This system must be managed carefully to be effective.

Another method of individual grain feeding is by transponder, magnetic key, or computer feeders. Each of these systems attempts to allow access to extra concentrate for high-producing cows while denying access to others in a free stall. Each cow wears a mechanical device on her neck chain that is recognized by a specialized stall. As the cow enters the stall, the system releases a measured amount of grain to the cow. The simplest system feeds all cows with a "key" (e.g., chain, magnet) the same amount of grain. Sophisticated computerized systems use transponders to identify individual cows. The system can feed specific amounts to different cows and simultaneously feed different grains to the same cow (to balance energy and protein at different levels). These computer systems can track the amounts consumed by individual cows and flag the dairy producer if cows consume less grain than expected. The computerized systems can dole out small portions many times during the day, smoothing the rate of grain consumption and reducing rumen input variation. These computerized systems must be managed carefully to ensure that complex systems of feeding equipment, hardware, software, and ration design all work together. The stall layout and number of stalls must be adequate to allow timid cows to have access to the system. Heifers often must be trained to use the system. Computer systems require significant initial capital investment and may not be cost justified.

Blended Rations and Total Mixed Rations

In TMRs, the forages and concentrate portions of the ration are first mixed together and then delivered to the bunk to be eaten. They can be fed both in free-stall and in stanchion barn systems. To work well the various portions of the ration must be weighed to ensure that the mix matches the ration design. There are a variety of mixing systems, including both stationary mixers (that deliver feed by motorized belts, feeder wagons, or feed carts) and mobile mixers mounted on wheels that can deliver feed directly to the bunk. Some TMRs include all portions of the ration, including the hay, whereas others blend the silages, concentrates, and by-product feeds for the bunk while feeding hay separately. TMRs have distinct advantages over other feed delivery systems. They lend themselves to total mechanization and make it easier to incorporate by-product feeds into the ration. Total DMI and milk production are commonly increased compared with the same feeds fed using other systems (McCullough, 1991). TMRs may make hay feeding difficult and require frequent adjustment if the dry matter content of silages changes.

The relative constancy of ration and rumination in diets fed as a TMR may account for some of their advantage over other approaches to feeding dairy cows. With a TMR, each mouthful eaten is much the same as the next, so the rumen environment is more stable. The mechanized systems needed to manage a TMR require initial capital outlay. As in

Downloaded From Vet-e-Books.com

all dairy rations, forage nutrient content should be based on laboratory analysis, not feed table averages. In most areas of the United States, a TMR is the most common way to feed dairy cattle.

TMRs may have their greatest influence if the farm can separate cattle into different feeding groups. There are several strategies for grouping. Some dairies group based on production levels to try to save money in the formulation of rations to lower-producing cows (Linn et al, 1989). On other farms, particularly high-producing herds, grouping strategies might be based more on stage of lactation or reproductive status (early postpartum versus later, not pregnant versus pregnant) or parity (heifers versus older cows) (Sniffen, 1991). In every case, dry cows should be fed separately from lactating cows.

BALANCING RATIONS

Ration analysis can be a highly effective aid for the diagnosis of deficiencies in a feeding program. Once such deficiencies have been identified, however, the next logical question is "What should be fed?" For this, ration balancing programs are needed. Historically, the ability to formulate rations for dairy cattle has been limited by two constraints: (1) knowledge of ruminant nutrition, including both animal requirements and the physiology of fermentation, digestion, and absorption, and (2) computational ability to incorporate knowledge into a mathematical system for calculating rations.

Simple algebraic calculations have been used to balance rations for basic requirements such as crude protein, calcium, and phosphorus concentrations. An algorithm known as a "Pearson square" was a method frequently used to determine the proportions of two feedstuffs in a mix with a desired final concentration. Programmable calculators permitted easier diet formulation because of their ability to do a large number of algebraic calculations quickly and were widely used in dairy cattle diet formulation and evaluation before the availability of computers. The formulator could compare the diet being evaluated with requirements, either in desired concentrations or amounts. If more or less of a specific nutrient was needed, the amount of various feedstuffs could be altered and the nutrients supplied in the new diet compared with the requirements. This "cut and fit" approach is also the basis for many ration balancing programs available today, which are sophisticated spreadsheets that permit rapid comparison of provided nutrients with required nutrients. They provide a skilled consultant with an effective, rapid method of formulating rations.

Linear programming is a ration balancing method requiring greater computer computational capacity and more complex mathematics. Linear programming (LP) nutrition software is the application of a more general mathematical technique that involves the optimum solution of a constrained problem. The mathematical approach is applied widely in business in fields as diverse as oil refining, ambulance allocation, personnel scheduling, and stock investing. In nutrition, the technique is applied to optimize an outcome (develop a least-cost ration) subject to certain constraints (nutrient requirements, feed limits, DMI limits). The linear programming process calculates the cheapest possible ration that can satisfy the constraints specified (VandeHaar and Black, 1991).

The desired end in a linear program is a linear equation called the objective function. In dairy ration programming the objective function is an equation calculating the total cost of the ration (the amount fed times the price for each feed, summed for all feeds in the ration). The program is designed to minimize this equation. For a dairy LP there are also sets of linear equations called constraints. In general, there are two types of constraints: nutrient constraints and feed constraints.

Fig. 11-5 illustrates a simplified example of a linear program to solve for a least-cost balanced ration. In the example, only net energy, crude protein, and bypass protein are considered. The bottom two sections show the solution calculated by the LP program. The "Objective" section shows the costs of each feed in the final solution and the sum, $3.62, for the ration as a whole. This is the cheapest ration that satisfies all the example's constraints. The bottom section shows that this ration contains 6.5 kg of shelled corn, 3.9 kg of soybean meal, 4 kg of distiller's grains, 30 kg of corn silage, and no hay. What was the setup that created this solution?

The top section sets the nutrient requirements that must be met by the final solution. The Feed Specifications section describes the cost and nutrient contents of the feeds that can be used. The next section sets the nutrient constraints. For example, consider DMI. The nutrient requirement (LP limit) is set at 22 kg of dry matter. The amount of dry matter contributed by each feed in the solution is calculated and then summed on the dry matter line in the "Nutrient Constraints" section. The amount fed times the dry matter percentage, summed for each feed (a linear equation), is the total dry matter in the ration. This total is constrained to be less than a certain value (e.g., 22 kg for a high-producing cow). In the optimum solution in the example, the sum from all feeds exactly meets the constraint of 22 kg of dry matter. The program found that the cheapest solution was to feed as much dry matter as possible.

Feed constraints are limits set on the amounts of each feed that can be fed. For example, farm inventories might restrict the ration to use no more than 20 kg of corn silage/cow/day. Feed constraints are also linear equations, albeit trivial ones. For shelled corn, for example, the equation is as follows: (1 × amount of corn) + (0 × amount of soybean meal) + (0 × amount of distiller's grains) + (etc.) = amount of corn fed. As the example shows, each feed fell within its constraining LP limit. The solution fed all the distiller's grains and corn silage it was allowed, and could have fed more shelled corn, soybean meal, and grass hay if it would have made a cheaper mix.

Nutrient and feed constraints can be set as minimums or maximums. For DMI, the constraint level is the maximum amount of dry matter the cow can consume. For crude protein, the 3.7-kg setting in the example is the minimum amount of protein that can be allowed. Constraints can also be set as equals. For example, selenium might be set so that it must be fed at exactly 0.3 ppm in the diet. Setting "equal to" constraints for macronutrients generally complicates the chance of finding a solution. Often, constraints are set as windows by having two constraints for the same item. For example, a window for shelled corn might be set that specified that a minimum of 2 kg, but no more than 8 kg, must be fed. This would force at least some shelled corn into the ration.

In practical use, then, an LP program requires the same inputs as a cut-and-fit program (feed library, nutrient requirements) but also requires prices and constraint settings. Once these are set, the program attempts to find a feasible solution that minimizes costs while satisfying the constraints. If the constraints are set so that no feasible solution can be found, the program returns an infeasible solution message. For example, suppose that, by mistake, the program limits for DMI were set at 2.2 kg instead of 22 kg. There is no way to satisfy the cow's nutrient needs in a 2.2-kg package, so the program would return an infeasible solution message. Different packages provide differing amounts of information about why an infeasible solution was reached.

Nutrient requirements and limits

22 kg expected total dry matter intake

37.0 Mcal NE(l)	(1.68 Mcal/kg of dry matter intake)
3.7 kg crude protein	(17% crude protein in dry matter)
1.3 kg by-pass protein	(6% by-pass protein in dry matter)

Feed specifications

	Shelled corn	Soybean meal	Distiller's grains	Corn silage	Grass hay
$/1000 kg	$150	$280	$200	$25	$120
Dry matter	90	90	90	30	90
NE (L)	1.76	1.72	1.72	1.60	1.32
Crude protein	8.0	44.0	28.0	8.0	16.0
By-pass protein	4.0	16.0	16.0	2.0	4.0

Nutrient constraints

	Shelled corn	Soybean meal	Distiller's grains	Corn silage	Grass hay	Total fed	LP limits	Slack	Shadow price
Dry matter	5.9	3.5	3.6	9.0	0.0	22.0	22.0	0.0	($0.13)
NE (L)	10.4	6.0	6.2	14.4	0.0	37.0	37.0	0.0	$0.15
Crude protein	0.47	1.54	1.01	0.72	0.00	3.7	3.7	0.0	$0.42
By-pass protein	0.24	0.56	0.58	0.18	0.00	1.6	1.3	0.2	$0.00

Feedstuff constraints

	Shelled corn	Soybean meal	Distiller's grains	Corn silage	Grass hay	Total fed	LP limits	Slack	Shadow price
Shelled corn	6.5					6.5	8	1.5	$0.00
Soybean meal		3.9				3.9	5	1.1	$0.00
Distiller's grains			4.0			4.0	4	0.0	($0.02)
Corn silage				30.0		30.0	30	0.0	($0.02)
Grass hay					0.0	0.0	5	5.0	$0.00

Objective: minimize total feed costs

Total cost	Cost of each feed ingredient in the ration				
$3.62	$0.98	$1.09	$0.80	$0.75	$0.00

Solution: amount to be fed for a least cost ration

	Shelled corn	Soybean meal	Distiller's grains	Corn silage	Grass hay
amount (kg)	6.5	3.9	4.0	30.0	0.0

FIG. 11-5 Simplified example of linear programming.

Better packages at least say which constraint appears to be the problem. In general, working toward a feasible solution involves "loosening" some constraint and rerunning the LP. Many LP packages have the disadvantage over cut-and-fit packages in that they are rather like black boxes. Inputs, requirements, and constraints are entered and an answer is derived, but some of the underlying relationships are not at all clear. Like any mixture of art and science, using an LP effectively takes time, mentoring, and experience.

LP programs have a distinct advantage over cut-and-fit approaches because they provide a least-cost solution for a particular ration. They do not guarantee, however, that the ration developed by the LP program is biologically sound. Once a feasible solution is found by the LP software, it often cannot be fed to a dairy herd. Often the best mathematically feasible solution is not biologically feasible. The example's optimum ration, for example, fed 30 kg of corn silage without "knowing" that cows are probably not able to eat that

Downloaded from Vet-eBooks.com

much wet forage. The practitioner would have to go back and reduce the LP limit for corn silage and rerun the LP. Finding a good solution is also an iterative process, therefore, just like the cut-and-fit process. No program can completely replace the need for the knowledge and experience of the person running it.

Whether a "cut and fit" spreadsheet or least cost linear program is used to balance a ration and formulate a diet, the requirements programmed into the system will be based on a model. In general, this model will be either an empirical or mechanistic model, or a combination of the two. Empirical models are developed strictly from experimental observation; they mathematically express relationships that have been observed. They can be highly accurate and precise, but they may or may not be based on the biology of the system or our understanding of that biology. A mechanistic model uses an understanding of the biology of the system to arrive at an estimate of the requirements. An empirical model may be very accurate at predicting results or requirements on observations or circumstances similar to those that were used in the data set that was used to develop the model. Observations under different circumstances, however, are probably not predicted accurately. A mechanistic model, on the other hand, is developed in an attempt to use an understanding of the biology of the system to predict results. It may or may not be more accurate than an empirical model predicting the same thing(s), but the mechanistic model is probably more useful in predicting relationships or outcomes in circumstances significantly different than those used in developing the model. In dairy nutrition a good example of use of an empirical model is that used to predict NE content of a feed by measuring ADF. The more mechanistic model using NDF, fat, lignin, crude protein, and ash content to estimate the energy content of the feed may not be more accurate on typical forages but probably is more reliable when incorporating byproduct feeds or atypical forages into the diet (Weiss, 1993).

Computer programs used in formulating rations for dairy cattle today involve both empirical and mechanistic components. As more sophisticated mechanistic models are developed, understanding of the biology of the system should improve by testing and observing against predictions.

Regardless of the model embedded in the program used to balance a ration, and irrespective of whether a "cut and fit" or linear programming method is used, the priority and constraints of nutrients needed should be similar. The first constraint will be DMI. The nutrients needed must be delivered within the dry matter that the animal actually consumes. At several times during the lactation cycle, it is difficult, if not impossible, for a dairy cow to eat enough of a diet that will meet all of her energy needs. Prediction of DMI remains largely empirical, and direct measurement when formulating diets is much preferred over use of computer predictions. After DMI constraints are observed, the nutrient that should receive first priority when formulating dairy cattle diets is the fibrous fraction. Providing adequate fermentable fiber and avoiding excessive rapidly degraded carbohydrate are critical to maintaining a healthy rumen ecosystem and avoiding rumen acidosis and its associated complications. A conflict arises when formulating early lactation diets because attempts to increase the energy density of a diet tend to result in a reduction in fermentable fiber. The best measure of adequate fiber is subject to debate and was discussed in more detail earlier in this chapter. Whatever method is used to determine fiber adequacy—NDF, forage NDF, peNDF, forage particle size, or forage:concentrate ratio—this requirement should be met first.

The next priority should be providing adequate degradable energy and protein to meet the requirements of the rumen. This includes sufficient fermentable carbohydrate for productive rumen fermentation. Research suggests an optimum concentration of fermentable carbohydrate is needed. Less than or more than the optimum compromises rumen function and energetics. Too high a concentration of NSC, NFC, starches, or sugars results in rumen acidosis. Too low a concentration provides inadequate substrate for microbial growth. In vitro observations and clinical trials suggest this optimum to be 35% to 40% NSC. Degradable protein—including ammonia and peptide sources—should be adequate to support the microbial fermentation of available carbohydrate. Between 9% and 13% of ration DM (60% to 65% of CP) is an optimum concentration of degradable protein. A ratio of NSC:degradable CP of 3.0 to 3.3 may optimize rumen microbial output (Hoover et al, 1990). Once dietary ingredients and amounts supporting productive rumen fermentation have been incorporated into the diet, additional concentrated energy sources such as supplemental fat and additional undegraded protein or amino acids should be incorporated into the diet at levels appropriate for the desired production response. The first priority should be to support a healthy rumen fermentation by addressing fiber, degradable carbohydrate, and degradable protein requirements! Supplemental vitamins, macrominerals, and trace minerals then should also be incorporated into the diet in appropriate amounts.

Whether using an empirical or mechanistic model, a "cut and fit" or linear program, this sequence of steps for ration balancing is appropriate to use in formulating dairy cattle diets and gives first priority to supporting top rumen function.

Designing the Diet as a Whole

The cow's diet must be seen as a whole, not as a series of parts. The calculated balance of a ration may be accurate when summed over a whole day but significantly unbalanced when fed piece by piece to the cow. The nutritive value of the parts depends on how they are consumed by the cow in relation to other parts of the ration. When TMRs are fed, this is of less concern; each mouthful is generally the same, and the homeostasis of the rumen is optimized. However, attention to rumen release rates of carbohydrate and protein, for example, are important. Feeding lots of rapidly degradable protein without rapidly available carbohydrate could produce a wasting of both protein and carbohydrate in a TMR, even though total amounts of protein and carbohydrate were fed in "correct" amounts. When different constituents are fed separately, the order and timing of the feeding program become more important. For example, if grains are fed in the morning before the cow has eaten enough forage to stimulate buffering, then rumen acidosis may result. If rumen-degradable protein is not fed in time to match the needs of the microbes as they digest the carbohydrate fractions, then fiber digestion may be impaired and microbial protein production reduced. There is art and skill to the process of delivering rations to cows if production is to be optimized. Efforts to encourage consistency in content and frequency of delivery are generally well rewarded.

MONITORING DAIRY FEEDING PROGRAMS

If a veterinarian is providing nutritional consulting services, then a routine, consistent monitoring service is essential. There are many parameters that can help determine the adequacy of a feeding program. A well-conducted production program incorporates these into its routine monitoring services on the dairy.

Downloaded from Vet-e-Books.com

Dry Matter Intake

DMI should be measured routinely and is best done daily. Actual measurements are a must. Some method needs to be arranged for measuring the total feed fed and feed not consumed, so that an accurate picture of intakes is available. To accurately measure DMI, a convenient method of measuring dry matter is essential. Electronic measuring devices are simple and convenient, though can be relatively expensive. Their accuracy requires fairly careful maintenance, too. The use of a microwave oven to dry the forage and weigh the residue is accurate and effective, but tedious. Use of an inexpensive food dehydrator has proved to be a convenient method of drying a sample to determine its dry matter content. A comparison of methods has suggested all are generally accurate (Oetzel et al, 1993). If DMI varies significantly from predicted values, adjustments in the ration or investigation of the reasons for the variance are indicated.

Feed Quality

Monitoring feed quality means many things. First, look at the feed itself. Is it fresh, clean smelling, free of foreign material, homogeneous, and free of evidence of mold? Run laboratory analyses for nutrient content and, where appropriate, for toxins, particularly mycotoxins.

Fecal Consistency

Fecal consistency and content, easily monitored at each herd visit, can provide valuable information about the cow's digestive status. Overly firm feces suggest too much fiber or too little water. Overly fluid feces may reflect too little fiber (too much readily fermented carbohydrates), too much fat, or too rapid a passage rate. Whole grain in the manure suggests inadequate rumen fiber mat formation to trap grain until it can be fermented. It may also be observed with excessively dry corn silage, where the starch is less digestible in the rumen. "Greasy" manure may indicate too much rumen-degradable protein.

Cud Chewing

If undisturbed, most cows should be either eating at the bunk or lying down and chewing their cud. If many cows are seen standing while chewing their cud, it is a clear indication that the free stalls or stanchions are uncomfortable. At any given time, 60% to 70% of all cows lying down should be chewing their cud. If not, total effective fiber intake may be inadequate. If cows show an unusual habit of chewing on walls or fences or eating dirt, consider too little fiber as a possible cause as well as pica from inadequate phosphorus intake.

Body Condition Scoring

The body condition of dairy cattle can be scored easily and consistently on a 1 to 5 scale (Wildman et al, 1982). The system is fairly simple to learn and there are excellent charts to guide the scoring process (Edmonson et al, 1989). The score correlates well with total fat stores in the cow. With training, this measure is repeatable across time and across observers (Edmonson et al, 1989).

Body scoring is based on the degree of flesh covering the skeleton of the lumbar vertebrae (loin), the pelvis (hooks, pins, and the area between them), and the sacral and coccygeal vertebrae (tail head). Palpation may be helpful, but visual inspection alone is sufficiently accurate. Scoring can usually be performed to a quarter-point level. Most lactating dairy cows fall between body scores of 2 and 4. Box 11-3 summarizes the criteria for condition scoring.

Changes in body score provide an indication of weight loss and weight gain during lactation. Under normal conditions, cows lose weight in early lactation as milk production exceeds their ability to consume enough dry matter to supply their nutrient needs. Excessive losses of body condition in early lactation are associated with reduced reproductive performance (Butler and Smith, 1989). Cows that lose more than one body score point have significantly reduced first-service conception rates and have increased days to first ovulation and first observed estrus. Cows should calve with body scores of 3 to 4 and should lose no more than one point during early lactation. Ideally, the loss should not exceed half of a body score point. Weight is most efficiently gained during the end of lactation, rather than during the dry period, so mid- and late-lactation rations should allow for extra energy to support increasing body condition (Moe et al, 1971). Body condition gains during the dry period may lead to "fat cow syndrome" and peripartum disease (Morrow, 1976). The ideal body condition may vary according to herd. Herds that manage DMI well may prefer a slightly greater body condition score (BCS) than those that do not. One study suggested cows calving at 3.0 to 3.5 were more profitable than those at 3.5 to 4.0, as there were no differences in production and performance between groups, but heavier cows had a longer period of BCS loss and gain than thinner cows (Ruegg and Milton, 1995). In all herds the average BCS is not nearly as important as the number of outliers—the number of cows that are too fat or too thin at a given lactation stage.

Milk Production

Many different parameters monitor milk production. Most are derived from DHIA reports, although more and more dairy producers are using on-farm testing equipment that can provide daily and summary milk production data. No single parameter is adequate for monitoring milk production on a dairy. When using a parameter to monitor milk production over time, one must keep the momentum of the parameter in mind. The momentum of a parameter is the rate at which the parameter can change as the actual farm situation changes. Parameters that include a great deal of history in their calculation have high momentum—that is, they cannot quickly reflect a sudden change in the herd's status. The rolling herd average, for example, carries a full year's history in its calculation. Short-term production fluctuations do little to change the rolling herd average. High-momentum parameters have the advantage of providing a better measure of the general trend, but they can obscure sudden changes for the worse that deserve immediate attention. Low momentum parameters such as daily milk per cow can change quickly in response to changes on a farm. They are sensitive measures of change, but the use of them as the sole monitoring index can lead to erratic and reactive management. Frequent changes of management in response to low-momentum parameter shifts can actually lead to wider swings in performance as consistency is lost to inappropriate responses to each next "crisis."

Whatever the parameter, remember that monitoring is about trends more than about absolutes. Keep track of the same parameters month to month and watch changes over time. For many parameters, it is also often useful to partition the herd into categories by lactation number and stage of lactation for monitoring purposes. For example, milk production may be fine in older cows, but a change in bunk space or cow numbers may create havoc with first-lactation animals in early lactation.

BOX 11-3

Body Scoring

SCORE 1: SEVERE EMACIATION

Individual bony parts are all prominent: the vertebrae are sharp and distinct, hooks and pins are sharp, with negligible flesh covering them, and the pararectal fossa below the tail head is deeply sunken. The area over the gluteal musculature (between hooks and pins) is severely sunken. This score is extremely rare in healthy dairy cattle. It is indicative of severe cachexia.

SCORE 2: THIN CONDITION

Bony processes are notable, but not sharp. Individual lumbar vertebrae are not distinct but are visible. The transverse processes of the lumbar are prominent and stand out sharply. They form a notable shelf. The area between the hooks and pins is more filled than with a score of 1 but is still concave. The pararectal area is still concave and depressed, but the bones have a fleshy covering.

SCORE 3: MODERATE CONDITION

There is a smooth covering of flesh over all bony parts. Individual lumbar prominences are not visually discernible but form a rounded ridge. The transverse processes of the vertebrae no longer form a distinct shelf. Pins and hooks are rounded. There is only a slight concavity between them. The pararectal fossa is smooth, without obvious fat filling.

SCORE 4: HEAVY CONDITION

All bony parts are well covered. The lumbar area is fat, with no dorsal processes of the spine visible. The hooks and pins are well covered and the area between them is flat. The tail head is surrounded by obvious subcutaneous fat.

SCORE 5: OBESE

Almost no bony structure is visible. There is significant subcutaneous fat. A body score of 5 is rare in dairy cattle.

Milk per Cow per Day

Perhaps the most easily collected number, milk per cow per day, can be calculated by dividing the amount of milk shipped by the number of cows milking and the days since the last milk pickup. It should be adjusted for cows whose milk was not added to the bulk tank (e.g., treated cows, fresh cows, or mastitic cows). Milk per cow per day can vary widely day to day in response to feeding changes, cows dried off or newly freshened, weather, and milking crew. It is probably too sensitive (too low momentum) to be relied on heavily, particularly in small herds. Like DMI, it should be monitored frequently, but one should avoid overreacting to small variations.

Rolling Herd Average

This is a calculated estimate of the amount of milk produced by the average cow in the herd during the past year. If milk per cow per day has the least momentum of milk production indices, the rolling herd average has the most. Major changes in overall herd productivity can occur, and the rolling herd average will be largely unaffected for several months. The rolling herd average is, however, the measure most often watched by most farmers, because it correlates well with annual income for milk sales. The quality of a dairy is usually summarized by citing the herd's rolling herd average. The rolling herd average does not necessarily correlate well with a herd's profitability, because two herds with the same level of production (revenue) may have different levels of debt and operating and feed costs (expenses).

Even given the inadequacy of the rolling herd average in characterizing a herd's current biologic or financial status, it still is useful to understand the forces that drive it. Rolling herd average is affected by the following three major factors:

"Real Productivity"

How well is each cow in the herd milking in terms of her genetic potential? Obviously, this is affected by a host of factors, such as nutrition, housing, and health. This real productivity consumes most of the attention of the production medicine clinician.

Herd Demographics

How many first-lactation animals versus older cows are milking? For example, the rolling herd average is likely to drop in the near term in a herd that is actively culling cows for staphylococcal mastitis and replacing them with heifers. Neither the remaining cows nor the heifers are milking less than expected. Heifers simply make less milk than older cows, on average.

Reproductive Efficiency

Herds in which average days open creeps up gradually find that cows are spending more of each lactation at the end (i.e., where production is lower). The cows' milk production is not reduced from normal; rather, the cows are simply spending more time at a less productive stage of lactation. Thus some drops in the rolling herd average reflect inadequacies in the reproductive program, not the nutrition or genetic program or other aspects of management.

Adjusted Corrected Milk, Standardized Milk, Management Level Milk

As a seasonally calving herd moves through the year, there are times when most of the herd is in early lactation (fresh herd) and times when most of the herd is at the end of lactation (stale herd). Milk per cow per day is less in a stale herd than in a fresh herd, even with the same cows at the same level of real productivity. Because of the desire to compare production among different months without confounding the herd's seasonal status, several different calculated measures of production have been developed. Each attempts to adjust for the herd's average days in milk, and some adjust for the herd's demographics and herd butterfat production (Nordlund, 1987). In general, these measures are superior to monthly milk per cow per day in monitoring for real changes in productivity.

Lactation Curves

Lactation curves of milk production are typically summarized by two parameters, peak (or summit) milk and persistency. Peak production is the point of maximum daily milk output, usually within the first 2 months of lactation. The

Downloaded From Vet-eBooks.com

magnitude of peak determines much of the shape of the total lactation curve. For every kilogram of additional peak milk production, the cow gives approximately 200 kg of milk more in the first 10 months of lactation. Persistency refers to the rate of decline in production beyond peak. Good persistency means a relatively low rate of decline. Mature cows typically decline between 8% and 10% of peak/month. Heifers have lower peak productions than cows, but the persistency of their lactation is generally better than for cows. Declines in heifers are usually between 4% and 6% per month. Use of recombinant bovine somatotropin has significantly changed the persistency component of the lactation curve; a slower decline is observed in herds using this product.

Much has been made of graphic lactation curves for cows. Milk by stage of lactation, as well as butterfat, protein, and SCCs, can all be graphed. Generally, one of two types of herd or group curves are generated. In the first, the data from one day's herd DHIA test are used to plot production by days in milk. In a sense, this is like milk per cow per day that it is low momentum, and it reflects only the herd's current status. This sort of graph may be useful for identifying cows that are "outliers" in terms of expected production. This type of graph suffers from the fact that the cows graphed in early lactation are different from those graphed in later lactation. It is easy to be tricked into thinking that those early-lactation cows will follow the pattern set by those in late lactation. This may not be the case. For example, cows in early lactation in July in the southeastern United States follow different lactation curves than their herd mates, who calved in the previous winter.

In the second type of lactation curve, all test day data for each cow's current lactation are used to construct the graph. This is similar to the rolling herd average and has a high amount of momentum. It risks masking serious, current, early-lactation problems by mixing recent performance with performance from as long as 10 months ago.

Both types of lactation curves can suffer from the danger of using averages alone to describe a population's status. They can mask a great deal of variability and trouble in individual cows as they aggregate the data into a smooth curve of average points by stage of lactation. Curves based on few individuals can be skewed widely by a single outlier cow. Viewed as a diagnostic test, lactation curves run a risk of both false-positive and false-negative diagnoses for significant herd problems and must be interpreted with caution (Galligan and Ferguson, 1991).

305 Mature Equivalent and Breed Class Average

The calculations for 305 mature equivalent (ME) and breed class average (BCA), provided by the DHIA and some microcomputer records programs, provide an "apples to apples" method of comparing two cows of different age and stage of lactation, or for comparing the same cow over time. The calculation process involves first projecting the cow's actual milk production in her first 305 days of current lactation. For this reason, 305 MEs cannot be calculated for cows until they have more than one DHIA test and are far enough into their lactation so that an accurate prediction can be made. Once the actual 305-day projection is made, it is multiplied by a factor that adjusts for the cow's age at calving and her season at calving. The adjustment factors are specific for each region and reflect the region's average effects of season, age, and genetics. In Canada, BCA calculations then take these adjusted numbers and standardize them to a hypothetic standard cow with a score of 100. Thus a cow with a BCA of 140 is 40% more productive on a mature equivalent basis than the standard cow.

Although no single measure is a sufficient monitor of productivity, of all DHIA milk production parameters, 305 ME milk production (or BCA) is probably the best single monitoring parameter for real productivity and therefore for the effectiveness of a nutrition program. Mature equivalent production takes out the effect of the herd's reproductive status by considering only the first 305 days of lactation. Thus a cow with prolonged days open is not penalized in the measure of her lactation productivity. By adjusting all 305-day projections to a mature equivalent basis, heifers are not penalized for being naturally less productive than older cows. The herd's average 305 ME, perhaps broken down by lactation number, is therefore an excellent measure of the real productivity of the herd. It has a moderate amount of momentum and is a useful parameter if trends are followed month to month. Changes in 305 ME milk can also be compared using paired t-tests or sign tests to determine whether an observed change is real or just normal variation (Galligan and Ferguson, 1991).

Milk Components

Milk fat and protein content should be monitored on a regular basis. Deviation in butterfat content of milk is most commonly related to dietary fiber. With inadequate fiber (either form or amount), butterfat level in the milk will be reduced. Milk protein will be influenced by ration energy and carbohydrate content, as well as dietary fat levels. Milk urea nitrogen (MUN) is a relatively recent tool being used to assess the balance between rumen-available protein and carbohydrate in the diet. Target levels for MUN have been suggested to be between 10 and 15 mg per 100 ml. Using MUN levels in association with milk protein can provide more information than either parameter alone (Nelson, 1996).

Disease

Many clinical diseases have their origins in nutrition. Monitoring the incidence of metabolic disease serves as another window on the feeding program. Table 11-8 lists some common nutritionally related diseases and suggests target performance levels for those diseases for monitoring purposes.

Income Over Feed Costs

Although overall profitability is the final goal, farm profit is affected by too many nonfeeding program factors to be an effective monitor of the impact of a feeding program. The most useful practical measure of the economic impact of a feeding program is income over feed costs (IOFC) for milking cows. To calculate this number, the cost of feeding the milking herd is subtracted from the value of milk produced. This remainder is the money left to the dairy producer for all other purposes, such as living expenses, farm labor, interest, and other feeding costs. Calculating the IOFC can be difficult because many farms do not account for feed expenses in a way that allows the costs for the milking herd to be differentiated from total feed expenditures.

Cost of Feedstuffs

Feed costs account for 40% to 60% of all costs on a dairy. There is a major potential to reduce operating expenses by selecting feeds that minimize the money spent on feeds for a given level of production (Galligan and Ferguson, 1991). The most effective approach to monitoring costs of feeds is to collect routine feed prices from normal market channels and to use a linear programming package to set substitution prices for a particular farm.

TABLE 11-8

Causes, Occurrence, and Prevention of Nutritionally Related Diseases or Suboptimum Performance in Dairy Cows

Signs of Disease or Suboptimum Performance	Cause	Occurrence	Prevention
Simple indigestion, <2% of calvings	Change of feed a few days before or at parturition	Within a few days after calving	Avoid marked changes in nature of feed in periparturient cows
Fat cow syndrome <3% of calvings	Excessive intake of energy during dry period	Within a few days before but most commonly a few days after calving	Feed for maintenance and pregnancy during dry period; feed dry cows separately; monitor body condition score
Parturient hypocalcemia (milk fever) <5% of cows	High calcium and/or potassium intake during dry period; anion-cation imbalance	Within 48 hours before; or after calving; midlactation cases also occur	Feed low-calcium diets during dry period; inject vitamin D metabolites before calving; do not overfeed potassium; feed negative dietary cation-anion difference diet before calving
Hypomagnesia (lactation tetany) rare or none	Relative deficiency of dietary magnesium in lush pasture; stress of cold weather	Within first few weeks after calving	Supplement diet with magnesium at strategic times
Downer cow, <10% of hypocalcemia	Complication of milk fever (traumatic injuries, prolonged recumbency)	Recumbent cases of milk fever fail to rise following treatment with calcium	Recognize and treat cases of milk fever in first stage
Left-sided displacement of abomasum, <5% of calvings	Uncertain; epidemiologically related to feeding grain before calving	Within a few days to a few weeks after calving	Feed adequate transition diet, especially adequate fiber postpartum; feed long hay during dry period
Right-sided displacement and torsion of abomasum, rare	Uncertain; epidemiologically related to high grain feeding in early lactation	Usually 2 to 3 weeks after calving	Ensure high intake of high-quality forage in early lactation
Cecal dilation and torsion, rare	Uncertain; may be related to high grain feeding in early lactation	Usually 2 to 3 weeks after calving	Ensure high intake of high-quality forage in early lactation

TABLE 11-8—cont'd

Causes, Occurrence, and Prevention of Nutritionally Related Diseases or Suboptimum Performance in Dairy Cows—cont'd

Signs of Disease or Suboptimum Performance	Cause	Occurrence	Prevention
Primary acetonemia <5% of calvings	Insufficient energy intake because of physical inability to consume, lack of energy in diet, or secondary disease affecting appetite	<6 weeks after calving before peak milk production	Ensure an increasing plane of energy intake in early lactation; ensure adequate transition, especially starch, from prepartum to postpartum ration
Postparturient hemoglobinuria rare	Deficiency of phosphorus intake	2 to 6 weeks after calving	Ensure adequate level of phosphorus in diet
Early-lactation drop in milk production	Insufficient intake of energy and low body condition score at calving, thus providing no body fat for mobilization	6 to 8 weeks after calving	Ensure adequate intake of energy and protein during first 6 to 8 weeks after calving
Postpartum uterine infections <10% of calvings	May be caused by mismanagement of dry cow rations	First month postpartum	Check dry cow ration Ca, Se, vitamin A, watch for over-conditioning during dry period
Lameness, laminitis, ulceration, white line weakness, and abscessation	Inadequate effective fiber	Most common in early lactation; effects long lived	Maintain adequate ration of effective fiber
Milk fat depression	Inadequate fiber	Any stage of lactation	Maintain adequate ration of fiber
Delayed onset of estrus	Inadequate heat detection; may be caused by inadequate energy intake and excessive loss of body weight in early lactation	8 to 10 weeks after calving	Provide good heat detection of cows beginning 40 days after calving; monitor body condition and ensure adequate energy intake
Retained placenta, 5% of non-twin pregnancies	Interference with normal detachment and expulsion of placenta	24 hours after parturition	Provide adequate vitamins A, D, and E in dry period; provide adequate trace minerals especially Se; prevent subclinical hypocalcemia

FEEDING THE DRY COW

The dry period should best be seen as the beginning of the next lactation. Too often, dry cows and their nutrition are neglected on dairies. Because the nutritional demands of the dry period are far lower than for lactating cows, dry cows are often fed poorly balanced rations of inferior feedstuffs. Many postpartum diseases find their beginnings in the dry period, including hypocalcemia, hypomagnesemia, downers, ketosis, delayed conception, retained placenta, uterine infection, udder edema, and displaced abomasum (Van Saun, 1991). There is a close association among many of these diseases; if a cow suffers from one, she is more likely to suffer from others (Erb and Gröhn, 1988; Erb et al, 1985). More than 60% of the total weight of the conceptus is gained during the last 2 months of the dry period. During the last 1 to 3 weeks of the dry period, the cow must make the transition from body and fetal tissue deposition to tissue mobilization to support lactation (Bell, 1995). This transition means that the dry period really has two phases: the early dry period (or far-out dry period) and the near-parturient phase (or close-up period). The nutrient requirements of the two phases are different, and the best dry cow programs segregate these two groups for feeding and management purposes (Van Saun, 1991).

The far-off dry period (phase 4) requires a diet designed to maintain body weight and allow for fetal growth. This can usually be achieved with relatively small quantities of concentrate and large quantities of forage. Forages fed during this period should *not* include ad libitum feeding of high-energy-density forages such as corn silage or some alfalfa haylages. Ad libitum intakes of these high energy feedstuffs can lead to excessive weight gain and a predisposition to ketosis and hepatic lipidosis. Feeding significant amounts of long stemmed hay or pasture during the dry period is generally considered desirable. It maintains rumen fill. When feeding only ensiled forages in the dry cow diet, there is an increased tendency toward displaced abomasum postpartum (Nocek et al, 1983).

Ideally, the dry period should be between 50 and 70 days long. Shorter dry periods are associated with reduced milk production (Funk et al, 1987), whereas longer dry periods are economically inefficient (Dias and Allaire, 1982) and may lead to excessive body condition at calving (Morrow, 1976). The transition period in the last 3 weeks prepartum is critical. This late dry period requires a diet considerably different in energy and protein density than phase 4. The fetus is growing rapidly, and the mammary gland is rapidly generating milk secretory tissue. The requirements for glucose and amino acids are increasing dramatically. All of this is superimposed on an animal where the DMI is usually declining. Within the last 5 to 7 days prepartum, it frequently drops precipitously, to 10 kg/head/day or less (Grummer, 1995). Thus a diet with greater energy and protein density is needed, without underfeeding fiber. The diet should contain adequate glucose precursors and an adequate source of amino acids. Beginning to feed or an increase in the amount of concentrates in the ration at this time is desirable, both to increase the energy concentration of the diet and to help the rumen adapt to a higher concentrate diet by bacterial adaptation and increasing papillae growth. Recommended nutrient concentrations for both phase 4—the far-off dry cow—and phase 5—the transition cow—are shown in Table 11-1.

Trace mineral and vitamin nutrition of dry cows is often inadequate. Antioxidant requirements—vitamin E and selenium—are probably similar to that of lactating cattle, particularly for the transition cow. High levels of vitamin E supplementation (1000 IU/day) during the dry period have been shown to substantially reduce the risk of mastitis after calving. Inadequate vitamin D may contribute to parturient hypocalcemia. Other trace mineral and vitamin supplementation levels should be adequate. Suggested guidelines are listed in Table 11-1. Inadequate supplementation may reduce expenses temporarily but is likely to result in increased rates of retained placenta, stillbirths, and other health problems.

Macromineral intake recommendations have changed in recent years. Restricting calcium during the dry period, particularly the last 3 weeks prepartum, has historically been advocated as a means of reducing the incidence of parturient paresis (Gerloff and Herdt, 1985). More recent research has suggested the anionic-cationic balance is much more important in preventing parturient paresis than the calcium concentration of the diet. Diets high in cations—sodium and potassium—are alkaline and tend to result in a high incidence of hypocalcemia and parturient paresis. Diets relatively high in the anions chloride and sulfur are acidic and tend to reduce the incidence of hypocalcemia and parturient paresis (Oetzel, 1993). The dietary cation-anion difference (DCAD) is a calculation that can be determined and manipulated to make an acidic diet during the last 3 weeks prepartum to prevent hypocalcemia. High-quality alfalfa has long been avoided during the dry period as a feed likely to result in a higher rate of parturient paresis. It now appears its potassium content is more likely responsible for the problems than its calcium content (Goff and Horst, 1996, 1997). Addition of feeds or salts high in sulfur and chloride during the transition period may allow a higher potassium feed such as alfalfa to be fed during the dry period without significant risk of hypocalcemia. A more detailed discussion of DCAD can be found in the section on metabolic disease.

The nutrient needs of the dry cow are critical and should be delivered and monitored carefully. Separate dry cow diets should be provided to the far-off dry cows and the close-up dry cows to meet their specific nutritional needs.

METABOLIC DISEASES AND NUTRITION

The complexities of the ruminant digestive system and the significant metabolic work that a lactating dairy cow is expected to perform, result in a susceptibility to a relatively large number of metabolic disturbances, or metabolic diseases. Despite an improved understanding of the mechanisms of these diseases, incidence rates remain high, particularly for displaced abomasum and ketosis (Herdt and Gerloff, 1999). Diseases commonly viewed as metabolic diseases with a nutritional cause include retained placenta, ketosis, hepatic lipidosis, parturient paresis (milk fever), displaced abomasum and rumen acidosis.

Retained Placenta

Expulsion of the placenta is a complex cascade of events that begins with the breakdown of the caruncle-cotyledon junction and ends with uterine contractions to expel the placenta within 12 hours of delivery of the calf. Retained placenta can occur when there is a failure at any one step in this process. Failure to expel the placenta frequently is associated with other, more severe consequences to the animal, including extended days open, ketosis, and displaced abomasum (Curtis et al, 1985). Twin births frequently result in retained placenta, as does induction of parturition. A normal rate of retained placenta has been reported as <15% of calvings. Rates higher than this should trigger an investigation of the dry cow diet, both close up and far off. Nutritional causes of retained placenta include inadequate selenium supplementation. Inadequate antioxidants may play a key role in the pathogenesis of retained placenta, as vitamin E supplementation also appears necessary for normal placental expulsion. Recommended dietary intakes of these nutrients for the

Downloaded From Vet-eBooks.com

dry cow are >3 mg (>0.3 ppm) selenium and 1000 units/day vitamin E. Inadequate vitamin A supplementation has also been linked to an increased incidence of retained placenta. Recommended dietary amounts are >100,000 units/head/day supplemental vitamin A. Retained placenta has also been shown to be epidemiologically related to hypocalcemia and parturient paresis. Reducing hypocalcemia by feeding anionic salts during the dry period also improved subsequent production and reproductive performance (Beede et al, 1991). Thus effective strategies to prevent hypocalcemia are important in the prevention of retained placenta, and a high rate of retained placenta within a herd should trigger an assessment of the effectiveness of the dry cow diet in preventing clinical or subclinical hypocalcemia. A variety of trace minerals may also be necessary for the normal process of placental expulsion, and an elevated rate of retained placentas within a herd should prompt an evaluation of the total vitamin and mineral supplementation program.

Parturient Paresis and Hypocalcemia

Parturient paresis, or milk fever, occurs around the time of parturition when a dairy cow's blood calcium concentration drops so low that muscle and nerve functions are compromised. It has been recognized in the veterinary literature for at least 100 years. Early on, intravenous calcium was recognized as an effective treatment, and it was slowly recognized that the condition developed because of an inability of older, high-producing dairy cattle to maintain their serum calcium concentrations in an acceptable range under the pressure of rapid initiation of milk secretion. Historical preventive strategies have focused on restricting calcium intake during the dry period. These strategies have been only sporadically effective, except when calcium is severely restricted (<30 g/head/day) (Wiggers et al, 1975), which is difficult to achieve with common feedstuffs and probably undesirable for an extended period of time.

More recently, the tendency of the diet to be acidic or basic has been recognized as having a more profound influence on the development of hypocalcemia and parturient paresis. Diets that are slightly acidic promote calcium absorption from the intestine and bone and calcium excretion in the kidney (Fredeen et al, 1988). These diets thus act to stimulate the calcium homeostatic system, and when it is challenged at the time of parturition, calcium levels can remain within the desired range. This appears to be true provided dietary calcium levels are adequate; otherwise there is a risk of depleting bone calcium. Alkaline conditions, on the other hand, inhibit calcium absorption from the intestine and bone and thus favor the development of hypocalcemia around the time of parturition (Goff and Horst. 1998). Diets high in cations (sodium and potassium, for example) cause a slightly alkalinizing effect on the body. Diets higher in anions (chloride and sulfur) produce a slightly acidifying effect. The DCAD has been used as a calculation to assess the acidifying or alkalinizing effect of the diet. One method of calculating it is shown in Box 11-4. It has been suggested that achieving a negative DCAD, in conjunction with feeding >120 g Ca/head/day, is an effective method of manipulating the phase 5 diet to prevent parturient paresis and subclinical hypocalcemia (Oetzel, 1993). Since many grass and most alfalfa forages are relatively high in potassium, achievement of a negative DCAD with them in the diet requires addition of acidic salts high in chloride or sulfur. Most of these salts are unpalatable, and care must be taken when feeding them that appetite is not suppressed significantly. Some by-products high in chloride and sulfur are more palatable than the anionic salts and are currently being marketed for the purpose of preventing hypocalcemia. Monitoring of urine pH may be an effective method of monitoring the effectiveness of dietary manipulations to acidify the diet to prevent hypocalcemia. A sufficiently acidic condition may be achieved when urine pH is <6.5 (Jardon, 1995). Because this practice stimulates bone resorption of calcium, as well as intestinal absorption, it should be emphasized that dietary calcium levels need to be maintained >120 g/head/day while a negative DCAD diet is being fed. For similar reasons, a negative DCAD diet should probably be fed only during the prefresh period (Phase 5)—not the entire dry period. A more conventional dry cow diet with a calcium content 80 to100 g/head/day may be effective at preventing parturient paresis and clinical hypocalcemia if dietary potassium levels are low (<1.2% of DM). Parturient paresis should occur in <5% of calvings. Prevention of subclinical hypocalcemia is also important because of its association with other metabolic diseases, particularly retained placenta and displaced abomasum.

Ketosis and Hepatic Lipidosis

Ketosis and hepatic lipidosis are metabolic diseases of excessive fat mobilization. They represent points on a fat mobilization continuum that includes the normal periparturient cow, a cow with subclinical or clinical ketosis, and a cow with hepatic lipidosis (Herdt and Gerloff, 1999). As such, the discussion will, in most cases, refer to both ketosis and hepatic lipidosis concurrently.

During the last few weeks before calving, the metabolic requirements of the cow change at an accelerated rate because of the rapid growth of the fetus and the initiation of milk production. Glucose and amino acid requirements, particularly, increase. Immediately after parturition, with a dramatic increase in milk production, the requirement for free fatty acids also increases dramatically. (Bell, 1995). These escalating energy and protein requirements are superimposed on a cow with a declining DMI, which usually reaches its nadir on or about the day of parturition and then increases more slowly than the energetic requirement (Grummer, 1995). Even under normal circumstances, then, a rapid rate of adipose mobilization can be expected, and a moderate increase in nonesterified fatty acid (NEFA) concentrations can be measured in the blood, beginning one week prepartum and extending for several weeks postpartum. Cows that develop hepatic lipidosis and ketosis have a greater increase in NEFA concentrations before calving than cows that do not have problems (Gerloff et al, 1986). Some of these NEFA are taken up by the liver and reesterified to triglyceride or oxidized to ketone bodies. Excessive rates of fat mobilization cause excessive liver fat accumulation and ketone production, which can further suppress appetite and interfere with normal immune function (Reid, 1980; Grummer, 1995).

Nutritional strategies to avoid ketosis and hepatic lipidosis should focus on reducing excessive NEFA mobilization from adipose tissue. Excessive weight gain, particularly during the dry period, should be avoided. If cows are obese entering the dry period, excessive weight loss should be prevented, since a starvation diet can trigger hepatic lipidosis in dry cows prepartum (Gerloff and Herdt, 1984). Thus during the far-off dry period, cows should be fed to maintain body weight with adequate allowance for fetal growth. During the prefresh transition period, diets should be formulated to provide adequate energy within the restrictions of the expected decline in DMI. Prefresh diets higher in energy concentration than current NRC requirements have been associated with reduced rates of metabolic disease and higher milk production (Curtis et al, 1985; VandeHaar et al, 1999). In the prefresh diet an energy density of 0.67 to 0.72 Mcal/lb dry

Downloaded From Vet-eBooks.com

BOX 11-4

Calculating the Dietary Cation-Anion Difference (DCAD)

The DCAD gives an indication of the acidic or basic potential of a diet. The more common calculation is the following:

$$(Na^+ + K^+) - (Cl^- + S^-), \text{ expressed in mEq/100 g or mEq/kg}$$

Na, K, and Cl are monovalent ions. S is a divalent ion. To convert dietary percentages to mEq/100 g, the following formula can be used:

$$[(\%\ Na/.023) + (\%\ K/.039)] - [(\%\ Cl/.0355) + (\%\ S/.016)] = DCAD\ (mEq/100\ g)$$

A negative DCAD diet can be fed in the prepartum transition ration, with a target value of −10mEq/100 g, or −100 mEq/kg. In the feeding of a negative DCAD diet, >120 g of Ca/head/day should be fed.

matter (1.47 to 1.58 Mcal/kg) usually requires the introduction of limited concentrate into the ration. Efforts to maximize total DMI (and minimize the decline in DMI observed prepartum) are critical in reducing fat mobilization. Other, nonnutritional factors, such as crowding, stress, heat, and water availability, can all exacerbate a DMI decline, and trigger increased rates of NEFA mobilization. Prepartum and postpartum adequate forage fiber and NDF concentrations must be provided in the diet. Inadequate levels can trigger subclinical rumen acidosis and begin the vicious cycle of declining DMI and excessive NEFA mobilization. Suggested nutrient concentrations are indicated in Table 11-1. In Canada, as well as other parts of the world excluding the United States, the feeding of monensin at approximately 300 mg/head/day, or providing it as a slow release bolus beginning 3 weeks prepartum, benefits the prevention of ketosis and improvement of milk production, at least in cows with BCS >3.5 (Duffield et al, 1999).

Normal or target incidence rates of ketosis should be <5% of cows calving. Rates significantly higher than this should trigger an evaluation of the transition cow diet, both prepartum and postpartum. An excessive drop in DMI is frequently the cause and may be influenced by other management factors in addition to nutritional ones.

Displaced abomasum

Left-displaced abomasum usually occurs early in the postpartum period. Identified risk factors include inadequate dietary fiber, presence of retained placenta, delivery of twin calves, hypocalcemia, and ketosis. Feeding all ensiled feeds prepartum significantly increased the risk of displaced abomasum postpartum, compared with including long-stemmed hay in the dry cow diet (Nocek et al, 1983). Evidence suggests that many cases of displaced abomasums are preceded by ketosis, rather than followed by it. Prevention of the initial ketosis should reduce the incidence rate of DA. Abrupt feed changes, particularly an increase in concentrate level, can trigger a DA, too. Less than 5% of cows calving should develop a DA. Prevention should focus on providing adequate long-stemmed hay prepartum, and transition diets prepartum and postpartum, which are balanced to avoid ketosis, retained placenta, and hypocalcemia. Energy density should be adequate and still provide adequate fiber to avoid rumen acidosis.

Rumen Acidosis

Lactic acidosis, or grain overload, has long been recognized as an acute clinical syndrome that occurs because of an abrupt increase in grain intake. In the unadapted rumen, the starches and sugars are rapidly fermented to lactic acid, which accumulates. This accumulated lactic acid profoundly depresses rumen pH and can represent a life-threatening situation to the animal. Sequelae in animals that survive can include rumen ulcers, hepatic abscesses, and laminitis (Nocek, 1997). Prevention focuses on making ration changes gradually (<10% increase in energy density in any one step) and on keeping below a maximum level of starch and sugar in the diet and above a minimum level of forages and NDF (Table 11-1). Subclinical rumen acidosis, not caused by lactic acidosis, is beginning to be recognized as a clinical syndrome in dairy cattle. It appears to be caused by an imbalance between the production of VFAs by bacterial fermentation and their neutralization and absorption (Nordlund, 1995). Rumen papillae in the early postpartum period have not grown physically and increased their surface area from the low concentrate diet usually present in most dry cow feeding programs. Consumption of a balanced lactating cow diet may cause more acid production (as VFAs) than the papillae can absorb, leading to a decline in rumen pH. This can affect the efficiency of the rumen, since cellulose and fiber digestion is inhibited as the pH drops below 6.2. This rumen pH decline, although not as severe a drop in pH as that occurring with lactic acidosis, may produce similar long-term effects, including laminitis, abscesses, and ulcers. Rumen pH can be measured using percutaneous rumen taps. The best time to sample TMR fed herd is 4 to 5 hours after feeding. Rumen pH values should be >5.8 (Nordlund, 1995). Too high a pH (>6.5) may indicate inadequate acid production for good performance because of inadequate carbohydrate in the diet. Too low a pH (<5.5) indicates a potential acidosis problem. Feeding strategies to avoid subclinical rumen acidosis include gradual or step-wise ration changes in which the energy density does not increase more than 10% between steps; formulation of a phase 5 transition ration that introduces carbohydrate 3 weeks before freshening to allow the papillae to begin to grow before the introduction of the lactating cow diet; adequate forage (>40% of diet DM) and adequate NDF (>28%) in the diet, with an upper limit on the amount of starches and sugars (<32%) and NFC (<42%) in the diet; and inclusion of buffers in the lactating cow diet.

Table 11-8 summarizes the more common nutritionally related diseases and their cause, occurrence, and control. Most of the major diseases with nutritional causes are avoided if attention is paid to the fundamentals of feeding dairy cows, including the provision of separate, balanced dry cow rations for far-off and close-up dry cows. Subtle inadequacies of the diet that manifest themselves in reduced production are more difficult to diagnose and correct. The best approach is to develop a program that consistently monitors the status and trends of a herd's health and productivity. Following trends provides a better indication of the herd's status and can allow intervention before a serious problem manifests itself. Good nutritional consultation is always iterative and proactive. Nutritional consultation demands a long-term commitment and relationship with the dairy producer. It is one of the most interesting opportunities available to veterinarians. Through nutrition, veterinarians can make a significant difference to their client dairies.

HEIFER NUTRITION

An adequately grown heifer, ready to calve at 22 to 24 months of age, has a significant influence on the profitability of most

Downloaded from Vet-eBooks.com

dairy herds. Delaying calving beyond 24 months of age represents an added cost to an owner of from $1.17 to $3.00 per day (Buchanan and Skidmore, 1996). Even in a small herd, this can represent opportunity costs of tens of thousands of dollars. The goal of heifers calving between 22 and 24 months of age, with a post-calving weight >250 lb (567 kg), involves several factors. Good reproductive management is essential. Breeding should begin at 13 months, with good conception rate and heat detection efficiency so that more than 75% calve by 24 months of age. To accomplish this, heifers must gain over 1.8 lb (0.82 kg)/day until 13 months of age, and continue to gain more than 1.5 or more lb (0.68 kg)/day after breeding. At one time these goals were considered too aggressive, but they are being achieved routinely today.

Earlier researchers observed that very rapid heifer growth rates (>2.2 lb [1.0 kg]/day) caused lower first lactation and lifetime milk production. These observations were believed to be related to the presence of greater fat and less DNA concentration in the mammary fat pad of heifers undergoing this "rapid rearing." This caused more fatty tissue and less secretory tissue in the mammary glands of these heifers (Sejrsen et al, 1982, 1983).

From birth until approximately 3 months of age, the mammary gland fat pad (the matrix in which the ducts of the udder subsequently develops) grows at the same rate as the body. This is referred to as a *period of isometric growth.* Then, from approximately 3 months until the onset of puberty (~600 lb [~275 kg]), the fat pad shifts to an allometric growth rate—approximately 3.5 times faster than the growth rate of the body. After the onset of puberty, the mammary growth rate again becomes isometric until influenced by pregnancy. During the allometric growth period, mammary ductular development occurs. Very rapid growth rates are believed to interfere with this critical, allometric growth phase of the mammary parenchymal tissue. Possible mechanisms include a reduction in circulating growth hormone because of the high plane of nutrition or a curtailment of the allometric growth phase because of a younger onset of puberty (Van Amburgh et al, 1992).

It should be apparent that when formulating rations for a rate of gain adequate for breeding at 13 to 15 months, care should be taken to avoid excessive weight gain (>2.2 lb [1.0 kg]/day), particularly during the prepubertal, allometric, mammary growth phase. The diet should provide adequate protein and amino acids to allow for adequate structural, skeletal, and muscle growth in addition to providing adequate energy. Maintenance of adequate protein nutrition may be a crucial aspect of avoiding the negative aspects of rapid growth on subsequent milk production.

For the first 8 to 12 weeks of life, the dairy heifer is a preruminant. Milk or milk replacer provides a significant portion of the diet. Recommendations include ensuring consumption of at least 4 L of high-quality colostrum in the first 12 hours of life—the sooner the better. Heifers should then be fed at least 12% of their body weight in milk equivalent from milk or milk replacer. For large breed dairy calves, this translates into at least 2 L twice daily of milk or milk equivalent. A high-quality calf starter should be available free choice, with a protein content of 20%. Energy requirements can vary tremendously, depending on environment. Cold, particularly, can increase the amount of milk or milk equivalent needed by 30% to 50%. Recent research suggests that limiting milk or milk replacer to current commonly recommended levels of 10% to 12% of body weight may be inappropriately reducing gains during this first 2-month period (Diaz et al, 1999). There may be physiological and economic advantages to feeding milk or milk equivalent with a high protein content at these higher rates, and relying less on dry feed consumption before weaning. More complete discussions of preruminant calf nutrition are available (Tompkins and Jaster, 1991).

Beginning at approximately 2 months of age, or 200 lb (90 kg), the concepts involved in successful feeding of dairy heifers more and more closely resemble those involved with adult cows. The rumen becomes more functional, and by 400 lb (180 kg) the calf can be considered a functional ruminant. At this point, adhering to the concept of providing adequate nutrients for maximum rumen performance applies to heifers as well as cows. Before this, there are differences of opinion on the attributes of an ideal calf diet, particularly in the recommended forage content. Some advocate little or no use of silages before animals weigh 300 to 400 lb (135 to 180 kg), and others advocate high quality fermented forage immediately after weaning. Many successful heifer-raising programs are successfully incorporating silages into rations for heifers immediately after weaning. These successful programs are marked with excellent quality forages, however, and this young calf should receive only excellent quality feed and forage. It is also well established that the stimulus for the development of the rumen in the young calf is not forage but VFA production (Bovine Alliance on Management and Nutrition, 1997). As such, palatable, fermentable calf starters are much more important in establishing good rumen development than the inclusion of forages in the diet.

Because energy is used for gain, maintenance, and lactation with different efficiencies, the net energy evaluation system describes heifer diets differently than lactating cow diets. Energy is expressed as net energy for maintenance (NEm) and net energy for gain (NEg). The energy available from a diet first is allocated to provide for maintenance needs, and only then is it available for gain or growth. The biological reality is not quite that simplistic, but this has provided a useful framework for balancing and evaluating growing and gaining cattle diets. Recommended dietary guidelines for heifers from 200 to 1350 lb (91 to 612 kg) are provided in Table 11-9. These guidelines should provide adequate nutrients for gains between 1.8 and 2.0 lb (0.8 to 0.9 kg)/day—adequate for breeding at 13 to 15 months of age and for calving at 22 to 24 months. An ionophore such as monensin or lasalocid should be included in the diet of growing heifers to improve feed efficiency.

The veterinarian can help provide a vital role in monitoring the effectiveness of the heifer nutrition programs on their clients' farms. In many cases this may involve just helping to systematize a method for comparing growth to standards at selected management events such as brucellosis vaccination, breeding, and calving. If there are significant differences in age or size at these selected events compared with recommended standards, then a more complete evaluation of the heifer operation is indicated. Monitors of growth should focus on height and body condition. Measuring only weight may obscure the development of fat heifers with inadequate skeletal growth. The reader is referred to Chapter 9 for heifer growth charts and standard curves, as well as additional information on heifer nutrition and management.

Heifer raising costs represent a significant overhead expense of most dairies. Assistance in formulating, evaluating, monitoring, and implementing a good nutrition program for heifers is a valuable service the veterinarian may provide their clients.

CONCLUSION

Nutrition and feeding programs play a pivotal role in the daily activities, economics, animal health, survival, and profitability of every dairy herd. Veterinarians must become actively involved in the nutritional programs of herds they serve. If veterinarians focus only on the results of nutritional

mismanagement (disease) without attending to the fundamental nutritional cause, they are not providing a complete animal health and production veterinary service. Nutritional consultation provides an opportunity for veterinarians to have a large influence on the dairy herds they serve. Dairy practitioners must make the effort to acquire the knowledge, skills, and experience required to provide a profitable nutritional health and production management veterinary service. Providing a role as an informed professional on a team of advisors to the dairy is an opportunity for which the veterinarian is well suited.

CHAPTER 12

Housing and Environment for Dairy Cattle

WILLIAM G. BICKERT and OTTO M. RADOSTITS

Buildings and equipment on a dairy farm facilitate the job of caring for the animals. They are the tools that allow essential tasks prescribed by the management plan to be carried out on a regular basis. Creation of an environment that meets the needs of the animals being housed is essential also. Calves, heifers, and cows require an environment that permits them to grow, mature, reproduce, and maintain health. If the basic needs of the animals are not met, no amount of management can guarantee success. Management requirements and animal environment along with labor requirements, flow of animals and materials, pollution control, and future expansion are important considerations in design.

Decisions about new or changing facilities are difficult. Facilities are expensive, and the required capital investments do not occur uniformly over time. Coupled with the fact that the farmer must live with the consequences of decisions about facilities for many years makes the process even more difficult. Thus long-range planning is important to changes in facilities, as it is to all aspects of a dairy operation.

PLANNING FOR MANAGEMENT

A prerequisite to contemplating any change in facilities is to have in hand a current management program for the farm. This management program consists of a planned series of actions based on current recommendations as applied to a specific situation (in this case, the particular farm). The program sets forth all factors related to nutrition, health, and growth as well as all other activities of the dairy farm operation. An awareness of the current recommendations of all of the experts is essential. More importantly, since no single program suits everyone, decisions must be made as to how each of these current recommendations applies to the particular farm and, if it does apply, how it will be implemented.

Style of Management

Ideally, the management program is based on a management style befitting the dairy farmer and farm family. Style of management reflects values held as well as attitude, outlook, viewpoint, and philosophy. Just as there are differences in dairy farmers, there are differences in their style of management. For example, a dairy farm based on total confinement of all ages and groups of animals is based on a style of management very different from a dairy farm based on rotational grazing and seasonal calving. Neither one can be judged right or wrong, good or bad, or superior or inferior. But in each case the dairy farmer must consciously determine and be committed to the style of management on which the system is based. For each to be successful, decisions about management must be made with full awareness of eventual consequences.

Different types and combinations of buildings and equipment are appropriate for different styles of management. Therefore, if investments in facilities are to be wise investments, decisions about facilities must be preceded by a conscious determination of management style and practices.

The buildings and equipment that comprise dairy facilities are merely tools that allow essential tasks prescribed by the management plan to be carried out on a regular basis. The buildings and equipment on the dairy farm, in fact, make it possible to implement a management program. Haphazard planning or impulsive acquisition of buildings or equipment will lead only to facilities that impede implementation of updated management plans and hinder future development and expansion.

Management Groupings

Viewing the dairy herd as a series of management groups is the primary basis for a management program. A group is simply a collection of animals that have similar needs in such areas as nutrition and environment, so similar that these animals can be viewed collectively. In terms of day-to-day management, each animal in the group can be thought of as the same. As herd sizes grow, it becomes simply too much to think about every animal every day.

Table 12-1 gives typical management categories for dairy herds of various sizes. The table can help to determine management strategies for the different groups in the management plan. Eventually, the table can serve as a guide when determining housing needs. The numbers in the table are approximations. You may need to adjust certain numbers to fit a particular management plan, because a plan may depart from the criteria set forth in the footnote to Table 12-1.

View the groupings in Table 12-1 from the standpoint of the management concepts to be limited, not as rigid rules. Some management groups may be housed in the same building, or separate facilities may be provided for each group. Regardless, allow for implementation of appropriate management recommendations for each group. Also allow for different requirements for sanitation, environment, and other factors that will affect housing design.

ANIMAL ENVIRONMENT

A goal in housing design is to provide an environment for an animal that has a positive influence on the animal's health, welfare, and productivity. Essentially all aspects of the animal's surroundings and activities are taken into account. For purposes here, environmental considerations include ventilation, stalls and beds, access to feed and water, and walking surfaces. Each of these factors is directly associated with housing design and management.

*This is only a management guideline. Numbers refer to animals in categories and not group sizes. Numbers assume uniform calving year-round, 12 months calving interval, first calving at 24 months of age, all males sold at birth, a 30% culling rate, zero mortality, and a stable herd.
†Number of days of lactation.

Ventilation

Ventilation permeates all aspects of the animal environment. Most often, ventilation is associated with respiratory health of animals. Of course, the quality of the air animals breathe directly influences animal health and disease. But ventilation—directly and indirectly—affects many other aspects of animal health as well. Good ventilation in the freestall area of the lactating cow helps to keep bedding dry, a factor in favor of good udder health. Good ventilation along alleys helps to keep walking surfaces dry, a condition that contributes to healthy feet. Good ventilation may lead to greater productivity (e.g., maintaining air movement in the area of the feed manger makes the cow more comfortable), especially important during hot weather as an aid to maintaining dry matter intake (DMI). A comfortable, well-ventilated stall area encourages animals to lie down, an important contribution to many aspects of animal health.

During ventilation, outside air is brought into a barn where it collects moisture, heat, and other contaminants, all produced by the animals. Air is then exhausted to the outside. Ventilation is an air exchange process in which contaminated air inside the barn is exchanged for fresh outside air. To determine ventilation rates, veterinarians focus on the moisture content of the air, measured by relative humidity. But moisture is only one aspect. Ventilation removes other undesirable contaminants as well.

Downloaded from Vet-eBooks.com

Air Quality

Animal health and disease are influenced by air quality. Air quality, in turn, is related to ventilation and its impact on removing contaminants from the air. Empirical observations and field trials suggest that the aerosol spread of pathogens between animals and the influence of air pollutants on pulmonary defense mechanisms are important, especially to respiratory health. Excess moisture, gases, and other contaminants in the air are considered to be problematic as well. But the exact relationship among these factors is not fully understood.

The term *air quality* itself is not easily defined. With respect to animal spaces, good air quality generally implies that the characteristics of ambient air bear no harmful effects on the animals in the space. Actually, the ambient air itself is not at issue—the contaminants in the air are. Ambient air, in itself, begins as a mixture of clean, dry air (a mixture of gases, chiefly nitrogen and oxygen) and varying amounts of water vapor. When moisture in the air in an animal space is considered to be a problem, it is actually the concentration of moisture in the air above some arbitrary level that is of concern. Above some concentration, moisture can be considered an air contaminant. Other contaminants may include pathogens, harmful gases, dust, and undesirable odors. The contaminant itself does not give rise to concern. Rather, it is the concentration of a contaminant above some predetermined level that causes concern. Thus, for purposes here, it is the concentration of each of these contaminants that will be considered when assessing air quality.

Many animal pathogens apparently are spread by the airborne route (Constantine, 1969), and concentration is a factor. The bacterial content of the air in cattle barns can be as high as 10^6 organisms/m^3 and many of these are potential pathogens (Fisher, 1976). Numerous viral pathogens also are known to survive in aerosol (Donaldson, 1978). Two factors can be significant in the relationship between microbial aerosols and disease incidence: the survival duration of the aerosolized pathogen and the total number of pathogens per volume of air or concentration. Survival is influenced by conditions of the ambient air and concentration relate to ventilation.

Relative humidity is the most important factor influencing pathogen survival, but its effects vary greatly between pathogens—some survive best in humid conditions, others survive best in dry air (Donaldson, 1978). Note that, with respect to air quality and animal health, the influence of relative humidity on concentration of pathogens is important.

Maintenance of a relative humidity in the range of 55% to 75% apparently produces the shortest survival time for the greatest number of potential pathogens. Ventilation is used to remove moisture from an animal space with the intention of maintaining relative humidity in this range. In effect, inside air is diluted with outside air and, in the process, concentrations of moisture in inside air are reduced. Interestingly, continuous replacement of contaminated air with fresh outside air is also the most effective way to reduce the concentration of aerosol pathogens.

Reduction of the concentration of any air contaminant, including gases, is important to decrease its detrimental effect. For example, ammonia is produced by the decay of feces and urine and is probably the most significant air pollutant in cattle barns (Marschang, 1973). If ammonia is allowed to accumulate, its irritating effects on the respiratory epithelium apparently directly reduce the number of ciliated cells and thus decrease the efficiency of mucociliary transport (Marschang, 1973; Kilburn, 1967; Gosselin, 1966).

Dilution Effect of Ventilation

Ventilation is truly a process of dilution. Air moved through a barn actually serves to dilute the inside air and, very importantly, to dilute all of its components. Dilution reduces concentrations of moisture and heat. Dilution reduces concentrations of airborne disease organisms, harmful gases and dust, and undesirable odors as well. According to Curtis (1983), one air change can theoretically reduce the concentrations of air pollutants by 63.2%.

Conversely, concentrations of air pollutants increase when ventilation is lacking. As much as a 7.8-fold increase in airborne bacteria occurred when the outlet ventilation openings in a 15-stall dairy barn were closed (Malecki et al, 1993). Odors also increase and, in fact, can be an important indicator of the poor air quality that results from underventilation. Terms like *barny, close,* and *stuffy* are sometimes used to describe the environment inside a barn that is suffering from underventilation and poor air quality.

The concentrations of gases are related to ventilation. An Alberta study of air quality in six freestall barns found that average ventilation rates could, in fact, be estimated by measuring building carbon dioxide concentrations (Clark and McQuitty, 1987).

When ventilation is reduced below recommended levels—usually in a misguided effort to warm the barn using animal heat—less moisture is removed. Sometimes the consequences of the resulting moisture buildup and lack of proper ventilation are masked by (1) insulating the barn, (2) using a greenhouse effect, (3) providing supplemental heat, or (4) dehumidifying the inside air. For example, as explained later, the addition of heat to the air reduces relative humidity, without the need for air exchange. It is quite possible to have substantial quantities of moisture added to the air and, if accompanied by heating of the air, have the relative humidity remain in an acceptable range. Thus, if relative humidity is the only measure of air quality, air quality may be deemed satisfactory. But even though excess moisture may not be apparent, the reduced dilution does indeed cause increased concentrations of airborne disease organisms, harmful gases and dust, and undesirable odors. If these increases are ignored, animal health problems are inevitable.

Essential to maintenance of a healthy animal is providing an environment that does not needlessly stress or challenge the animal. Maintenance of good air quality is a fundamental aspect of that healthy environment with ventilation providing the key. But air quality is more than just measuring relative humidity. Through ventilation the air inside the barn is continually diluted, assuring that the air the animal breathes has low concentrations of all contaminants that threaten the animal's health.

Air-Water Vapor Relationship

Because ventilation involves moisture in the air, relative humidity—a measure of the concentration of moisture in the air—is of primary interest. Understanding the relationship between relative humidity and ventilation is helpful to comprehending the ventilation process itself.

Relative humidity expresses, as a percentage, the relationship between the amount of moisture present in a quantity of air and the amount of moisture the air is capable of holding. For example, if the air in a room is at 40% relative humidity, 40% of the moisture-holding capacity of the air is occupied (Fig. 12-1). Considering the example from the standpoint of ventilation and the need to pick up moisture, 60% of the air's moisture holding capacity remains. If no air exchange occurs, the air can take on moisture only until its

Downloaded from Vet-eBooks.com

relative humidity reaches 100%. Thus ventilation requires continuous air exchange, and the rate of exchange must be sufficient to maintain relative humidity below 100%. A range of 60% to 75% is preferred for animals.

The relative humidity of a quantity of air depends on temperature. This fact is useful in controlling the ventilation process (Fig. 12-2). As moist air is warmed, its moisture-holding capacity increases markedly. Although the air expands as it is warmed, its moisture content, expressed in absolute terms, does not change; relative humidity therefore drops. This warmed air of lower relative humidity becomes more able to pick up moisture.

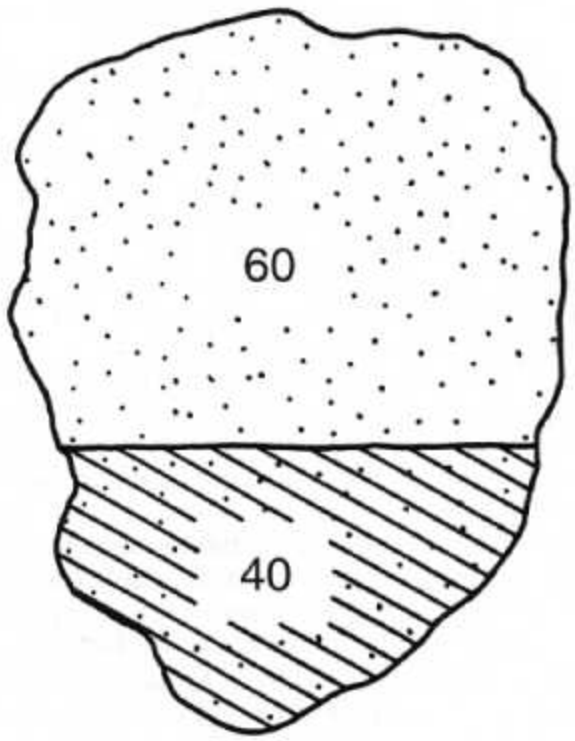

FIG. 12-1 Illustrated quantity of air at 21° C and 40% relative humidity; 40% of the air's moisture holding capacity is occupied, and 60% remains.

For example, if typical outside winter air at −18°C and 80% relative humidity is used for ventilation (Fig. 12-3), this air will not be very useful for picking up additional moisture and certainly not for achieving a relative humidity of less than 80%. But if this air is used for ventilating a warm calf barn kept at 7° C, the air will be heated to 7° C as it mixes with inside air and passes through the barn, reducing its relative humidity to about 10%. From the standpoint of ventilation for moisture control, heating the air increases its moisture-holding capacity. What remains is to carefully balance the calves' moisture production rate, the rate at which heat must be added to the air, and the necessary ventilation rate so the resultant relative humidity in the calf barn is controlled at 60% to 75% and the desired temperature is maintained. This is the basis for determining the minimum continuous ventilation rate for moisture control.

If calves are to be kept in a warm barn (e.g., 10° C), supplemental heat must be provided. Calves simply do not produce enough heat to properly warm the amount of ventilation air that is required to remove the moisture they produce. On the other hand, mature cows do produce substantial amounts of heat in relation to their moisture production. This heat, when used to warm the ventilation air required for moisture removal, allows stanchion and tie-stall dairy barns to be kept above freezing in the winter. But there is a limit to the temperature rise that cow heat can impart to the ventilating air. In a well-insulated tie-stall barn filled to capacity with cows, the maximum temperature rise of the

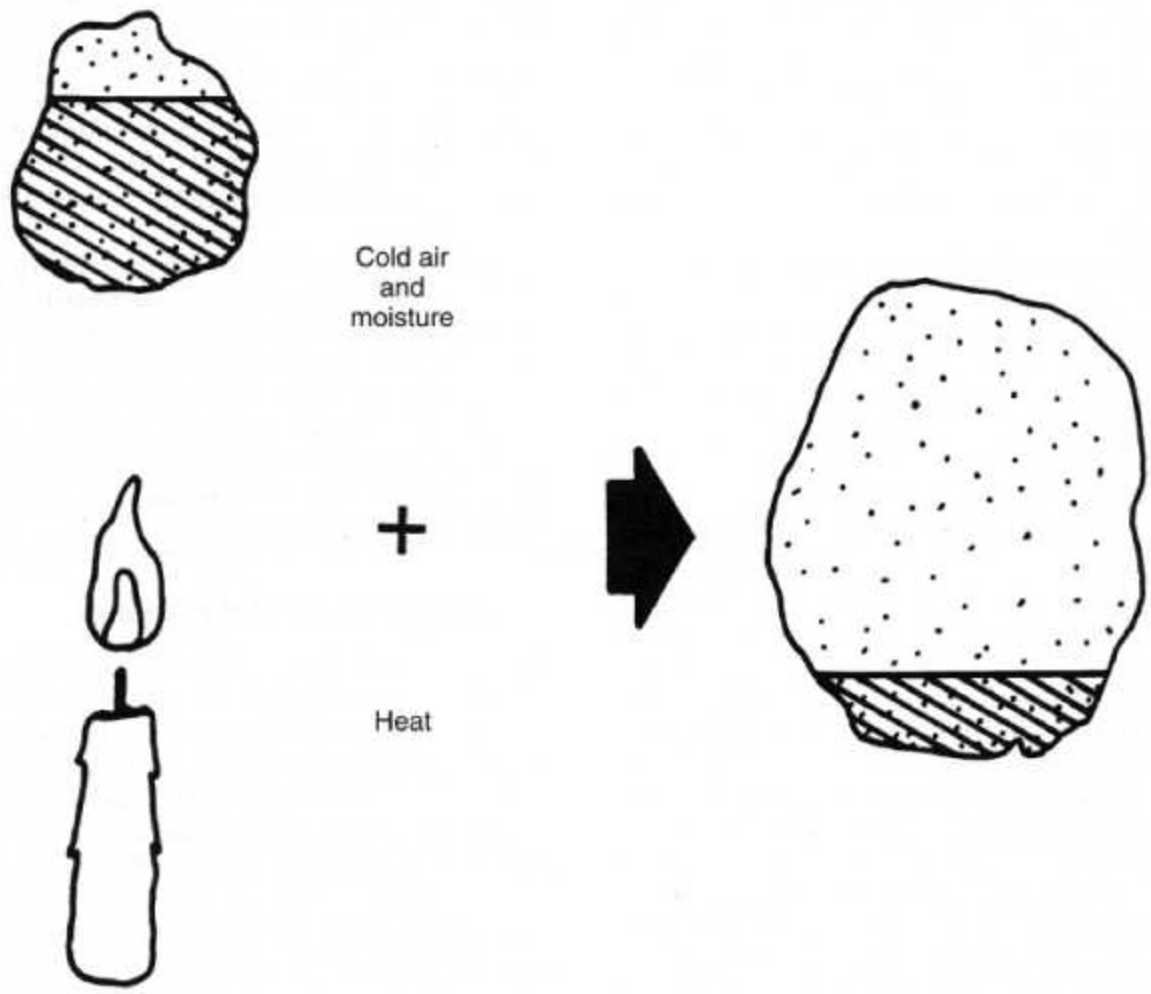

FIG. 12-2 Heating a quantity of air and raising its temperature reduces its relative humidity and increases its moisture holding capacity; the change in relative humidity is dependent on the temperature rise.

Downloaded from Vet-eBooks.com

ventilating air that can be obtained from cow heat alone is on the order of 20° K. This means that ventilation can proceed without interruption until outdoor temperature falls below about −20° C. Beyond that, the indoor barn temperature would fall below freezing and water lines would freeze, a condition that is avoided by installing a safety thermostat on the fan providing the minimum continuous ventilation.

In a cold barn the temperature rise of the ventilating air is limited to 3° to 6° K. Even so, the dependence of relative humidity on temperature is beneficial. For example, if the −18° C, 80% relative humidity outdoor air is warmed by only 5.5° K, its relative humidity decreases to less than 50%. Thus even this cold air, warmed just slightly, is useful for picking up moisture. Moreover, the heat produced by the animals themselves can cause this slight temperature rise. Care must be taken, however, to ensure sufficient air movement, preferably by natural means, to limit the temperature rise to 3° to 6° K. This is the basis for cold housing, a preferred alternative for all dairy animals.

The goal of winter ventilation design is the maintenance of good air quality for the animals. The basis for design is removal of the moisture produced by the animals themselves. Reducing the concentrations of airborne pathogens and noxious gases is important also, but if sufficient ventilation is provided for moisture control during the winter, the undesirable effects of other airborne pollutants apparently are minimized.

Minimum Continuous Winter Ventilation

A minimum rate of ventilation is required in animal housing in the winter regardless of outside temperature. This minimum rate is necessary whether the barn is designed to be a warm barn or a cold barn in winter. In addition, the minimum ventilation should be continuous. Continuous dilution of inside air acts to maintain concentrations of contaminants in the air at minimal levels. The minimum rate depends on outside weather design conditions, number and type of animals in the barn, age and size of animals, and whether the barn is intended to be cold or warm.

With mechanical ventilation, the capacity of the fan chosen to supply the minimum continuous rate should closely match the rate of ventilation that is calculated for a particular housing situation. Mechanical ventilation is most often associated with warm housing where ventilation must have a high degree of control. For certain situations the minimum rate requires a very small fan (e.g., in a warm calf barn), and a fan that small may not be available from a particular source. The practice of using a larger fan on a percentage timer should be avoided. For example, suppose that 500 l/s is the minimum continuous ventilation rate desired, but the smallest fan available is rated at 1500 l/s. Operating the larger fan one third of the time (i.e., 5 min every 15 min) produces an effective rate of 500 l/s. Unfortunately, the wide fluctuations and lack of uniformity in indoor conditions are not in the best interest of animal health. Small fans are available, but it may be necessary to search them out.

With natural ventilation, minimum ventilation is less controlled. Depending on thermal and wind forces, natural ventilation is most often associated with cold housing. As will be described in later sections, deciding between warm and cold housing is critical to the design and subsequent management of the ventilation system. Understanding the differences between the two types of environments is especially important as related to the need for maintaining the minimum continuous ventilation for winter in either situation that is in the best interest of animal comfort and health.

Barn Categories and Winter Temperatures

Barn environments can be categorized according to temperatures maintained in the barn in winter. The particular environment, based on desired indoor temperature, must be established before ventilation system design can begin.

In a *cold barn*, indoor temperatures are allowed to fluctuate with outdoor temperatures. Ventilation is sufficient to maintain indoor temperatures within 3° to 6° C of outdoor temperatures. Usually the barn is not insulated and ventilation is largely unregulated, except to adjust for seasonal changes.

Warm barns are well insulated and, by necessity, have a well-controlled ventilation system. These barns are designed to provide a relatively uniform environment throughout the winter. Tie-stall barns, where indoor temperatures are to be

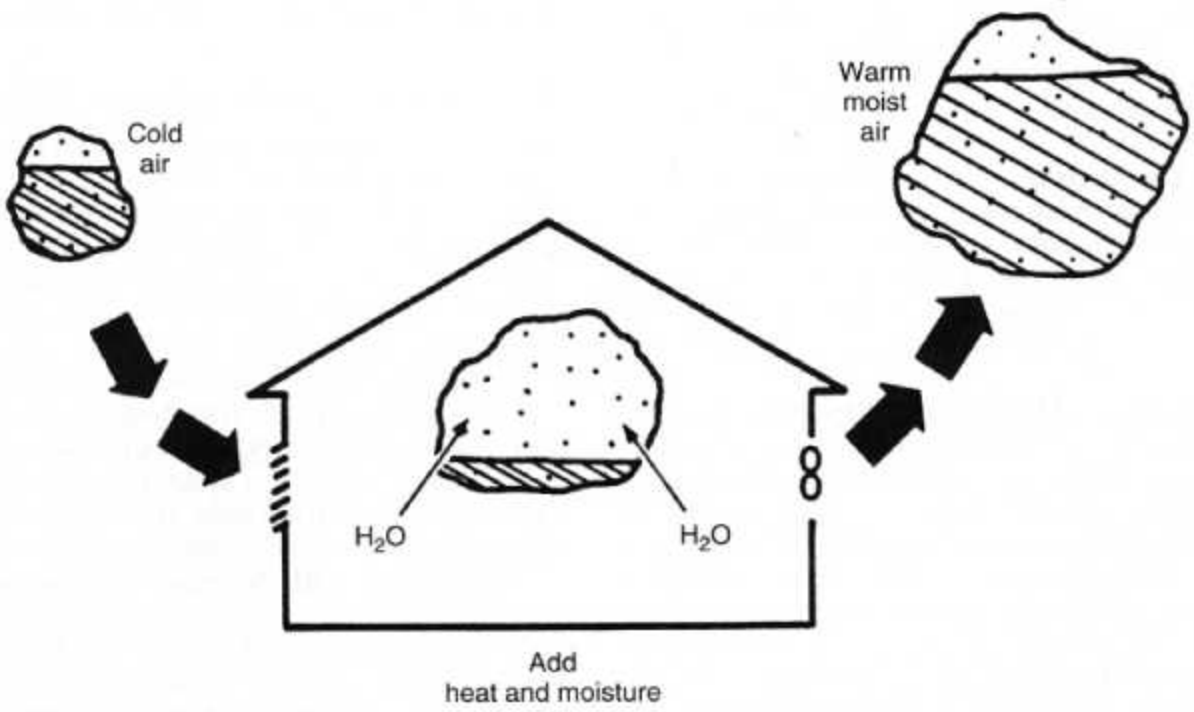

FIG. 12-3 Cold outside air with a high relative humidity can pick up large quantities of moisture in a barn if the air is heated. Even a slight temperature rise of 5.5° to 8.3° C, as can occur in cold dairy barns, is useful.

Downloaded From Vet-eBooks.com

maintained at least above freezing, remain the principal example of this type of housing for dairy animals. The key to success is ventilation that is well managed and regulated in order to compensate for changing outside climatic conditions.

Some barns do not fit into either the warm or cold category. An *in-between barn* or *modified environment barn* usually has indoor temperatures above freezing in winter. These buildings have some insulation, perhaps only under the roof, and are naturally ventilated (usually with open ridge, eaves, and sidewalls). Unfortunately, even though a minimum ventilation rate is always necessary, ventilation openings may be closed or blocked during extreme weather to keep manure from freezing and for other reasons. This practice can cause inside temperatures to rise 10° to 20° C above the outside temperature, significantly higher than the 3° to 6° C temperature difference limit considered acceptable for cold barns. This alone can create problems because of excess moisture buildup and a high relative humidity. But, even more seriously, openings remain closed or blocked after severe weather conditions have passed. As a consequence, blocked ventilation openings restrict airflow during less severe conditions, causing underventilation and poor environmental conditions. A properly designed and managed in-between barn is more like a warm barn, in terms of both design and operation. Thus, to avoid problems, the design and management of in-between barns should follow the guidelines for a warm barn.

Consequences of Mismanaged Ventilation in Winter

Underventilation in winter is one of the most serious threats to the environment of animals. Both improper design and improper management of the ventilation may be reasons that wintertime ventilation is lacking, compromising animal health. Problems are most likely during winter, spring, and fall, especially during rainy weather and warmer days coupled with cold nights.

Reduced Dilution of Ambient Air. A major reason for air quality problems in barns in winter is adjusting ventilation for the worst case—severe winter weather—and not readjusting to allow increased ventilation when milder winter weather appears. This is especially true for cold barns with manually controlled natural ventilation. Perhaps ventilation openings are closed in anticipation of a windy, cold, blustery night, but they are not opened the next day when, although the temperature may still be cold, the wind subsides and the sun shines. Very simply, lack of wind reduces ventilation, reducing air exchange and the positive effects of dilution.

Sometimes good ventilation system management does indeed call for openings to be reduced. For example, a slot inlet in a mechanically ventilated tie-stall barn is adjusted to match the lower ventilation rate in winter. Fabric may also be placed over on open sidewall. But openings are never completely covered that would leave no means of air exchange for moisture control.

Building Components Affected by Poor Ventilation. Besides adversely affecting the animal environment, the design and operation of naturally ventilated barns influence moisture related deterioration in wood members and metal fasteners as well. Naturally ventilated dairy barns have been studied in Michigan (Harrigan and Bickert, 1986). In barns where air exchange in winter was defeated by blocking ventilation openings, average wood moisture contents exceeding 30% dry basis (capable of supporting wood decay and corrosion in metal fasteners) were found after 2 to 3 months of cold weather operation. Moreover, restricted air movement in these barns inhibited drying and allowed wood moisture contents to remain elevated even into warm weather. Warm, moist conditions favor growth of mold, bacteria, and decay fungi and accelerate metal corrosion. The presence of insulation under the roofing in these problem barns fostered this situation.

In barns studied, moisture content rise was minimized where design details and management efforts allowed optimum air exchange rates. Even if free water from precipitation and condensation caused slightly elevated moisture contents, adequate air exchange, especially during warm weather, promoted drying of wood truss components so that deterioration was not a problem.

Misguided Use of Insulation in Cold Barns. In a cold barn the inside temperature is maintained no more than 3° to 6° K above the outside temperature in winter. Usually this is accomplished through largely unregulated natural ventilation with appropriately sized ridge and eave openings along with adjustments in door and wall openings. Adequate air exchange during cold weather to ensure moisture control eliminates the need for insulation.

If insulation is installed under the roof, a potentially cold barn may not be operated and managed as a cold barn. The presence of insulation suggests that the barn is something other than a cold barn, that an available option is to close or block ventilation openings during extreme weather conditions to restrict ventilation. The most serious deficiency associated with this approach is the lack of proper control to restore ventilation rates when extreme weather has passed. The consequences of this mismanagement are even more serious with high-producing cows because of their higher rates of heat and moisture output. For a barn with insulation to operate successfully, it must be operated more like a warm barn than a cold barn, as just discussed for modified-environment barns. Proper insulation, a high level of management, and well-regulated ventilation are necessary ingredients.

Barns with insulation under the roof are often underventilated because evidence of a moisture problem does not appear. Besides contributing to problems with animal health, underventilation can lead to the premature deterioration of structural components in buildings. Condensation on the underside of the roof of a cold enclosed barn can be considered a management tool or signal for the farmer that excess moisture buildup is occurring and additional ventilation openings must be provided for better air exchange. The presence of insulation can take away this important indicator, creating a potentially unfavorable environment!

Types of Ventilation Systems for Dairy Barns

Two types of ventilation systems are used in enclosed dairy barns: natural and mechanical. Most often, naturally ventilated barns are associated with cold housing where indoor temperatures remain within 3° to 6° K of outdoor temperatures in winter. As a cost-saving measure, natural ventilation is used for warm barns as well. But care must be taken to conscientiously adjust ventilation openings in order to avoid the problems mentioned for in-between barns where ventilation is restricted for the purpose of using animal heat to maintain higher indoor temperatures. A well-controlled mechanical ventilation system is desirable for a warm barn in order to minimize risks associated with the reduced rate of air dilution that accompanies warm housing.

Cold Barns with Natural Ventilation. In general, a cold barn with natural ventilation has these minimum characteristics: no insulation, open ridge and eaves, and sidewalls and endwalls that open. Providing an open ridge along with open eaves has long been recognized as a means of using a stack effect to cause air exchange, especially for controlling moisture in winter. Indoor temperatures are expected to be a few degrees warmer than outdoor air temperature because of

Downloaded From Vet-e-Books.com

the heat being given off by the animals being housed. Current recommendations call for providing a ridge opening of 5 cm per 3 m of barn width and equivalent open area divided between the two eaves. Raised ridge caps are to be avoided. Their performance has been unpredictable because of local wind patterns. In fact, raised ridge caps often channel winds into the structure, thereby increasing the entry of wind-blown snow and rain.

Very importantly, the combination of the open ridge and eaves can be viewed as the sole source of ventilation only during the most severe winter weather—during periods when temperatures reach the lowest levels or times when especially windy, stormy conditions are present. During all other times in winter, additional ventilation must be provided. Typically, doorways are left open for this purpose, portions of the endwall sections of the gable roof may be left uncovered, or sidewalls away from prevailing winter winds may be left open. Then, as temperatures rise into spring and summer, sidewalls and endwalls are opened fully. As a general rule, too much ventilation is preferred over too little.

In winter, air movement through the barn should be sufficient to maintain inside temperature within 3° to 6° K of outside temperature. A thermometer can be hung inside the barn. If the temperature inside is more than 3° to 6° K above outside temperature, more ventilation is necessary. Also, persistent condensation on the underside of the roof is a further indication that additional ventilation openings must be provided.

Various materials and methods are used to cover sidewalls for colder weather. Automatic control or even frequent manual adjustment of air inlets is unnecessary. The dairy cow can tolerate usual diurnal fluctuations in environment and even fluctuations during the season, especially in summer. The simplest and cheapest method of covering sidewalls uses a fabric covering over the full sidewall. For summer, the fabric is manually rolled up as a rug and tied at every post. To close the sidewall, ties are released and the hanging curtain is then fastened in place using a vertical nailing strip at each post and horizontal nailing strips all along the bottom.

Substantial areas of the triangular endwall sections of gable roofs, from the eave line to the roof line, are left open as well. These areas, well above the height of the cows, may be the last covered as winter begins and the first opened as winter abates. This ensures adequate ventilation during periods of fluctuating ambient temperatures while minimizing excessive movement of colder air in the vicinity of the animals—without frequent adjustment of openings.

Barns with open sidewalls and endwalls in summer have improved ventilation, creating lower average temperatures inside the barn in summer. However, the real advantage to the cows is related to the extremes—specifically, during the heat of the day and the cool of the night. Not only are cows exposed to lower temperature peaks during hot weather, but they are also exposed to these peaks for shorter periods of time. In addition, inside temperatures closely follow outside temperatures as they lower at night, allowing cows to take advantage of whatever cooling effect may result from lower nighttime temperatures.

Summer ventilation depends on the wind. The main factors that affect ventilation rates are area of building openings, local obstructions (hills, vegetation, nearby buildings), wind speed, and wind direction. Air exchange rates resulting from wind forces can be maximized by increasing inlet and outlet openings and by accurately locating buildings for maximum exposure to existing winds.

Warm Barns with Mechanical Ventilation. In a warm barn the indoor temperature is maintained substantially higher than outdoor temperature during winter. For example, a tie-stall dairy barn is commonly held at 5° C or higher. A swine nursery is maintained at about 30° C with the addition of supplemental heat. These buildings are well insulated. Fans with thermostat controls automatically regulate the ventilation rate as outside conditions change, diurnally and seasonally. Three levels of ventilation must be provided for year-round ventilation. Three fans can achieve this. However, with the high ventilation rates being used today, more than one fan may be used, especially to achieve the summer level. Summer ventilation rates of 60 to 90 air changes per hour are not uncommon. These levels are on the order of ten times the minimum continuous rate for winter.

Exhaust fans, sized according to the number and size of the animals present, draw air out of the building. This creates a slight vacuum or negative pressure inside the building. This pressure difference between indoors and outdoors causes air to move into the building wherever there are openings. The air inlet openings are sized and located properly so that fresh air enters the building uniformly and is mixed with the other air. Typically, an adjustable slot inlet, continuous along both sidewalls except in the immediate area of the bank of fans, distributes incoming air.

Insulation in a warm barn performs three main functions. First, insulation reduces heat loss from the building, conserving heat generated by animals and other sources inside the building for use in heating the ventilating air. Second, the surface temperature of inside wall surfaces will be higher, reducing the possibility of condensation occurring. Third, radiant heat loss from animals located near outside walls will be less with higher inside-wall surface temperatures.

Warm Barns with Natural Ventilation. Natural ventilation for warm barns came about in the interest of lowering investment and operating costs for livestock and poultry buildings. The buildings remained essentially the same with respect to insulation and a warm environment in winter. However, natural ventilation was substituted for mechanical ventilation. In some livestock and poultry buildings, mechanical ventilation was used for winter, spring, and fall, but the sidewall openings were provided to allow wind forces to produce air exchange during summer. This eliminated the need for fan operation during the time of the year when the highest rates of ventilation—and highest energy costs—would be required. In other situations, natural ventilation was to be used year-round.

Well-regulated naturally ventilated warm buildings, relying on stack and wind effects, have been successful. For example, the modified-open-front swine finishing building was designed to be a well-insulated barn with natural ventilation. Adjustable openings were provided for modulating both the stack effect and the wind effect as necessary, depending on outside conditions. The inside temperature was to be maintained at least a few degrees above freezing in the interest of maintaining feed efficiency. At the same time, ventilation was always to be maximized so as not to compromise air quality. To achieve this balance, frequent adjustments in ventilation openings are required, sometimes several times per day, to compensate for changes in outside conditions (e.g., wind velocity or direction, temperature, solar radiation). In the end, some of these modified-open-front swine finishing buildings were very successful. Some were not because the building manager either did not understand the need to frequently adjust ventilation openings in order to maintain optimum air quality or was unwilling to devote time and energy to the task. The building concept is still popular. But most buildings of this type constructed today have ventilation openings that are opened and closed automatically by various types of actuators controlled by thermostats.

Downloaded from Vet-eBooks.com

Natural ventilation for warm housing has been described by Choiniere and Munroe (1990) for buildings that are temperature controlled in cold weather. Their recommendations for construction and for sizing chimney and sidewall openings (Choiniere et al, 1994) do not apply to cold or modified environment barns where inside temperature is at or slightly above outside temperature.

Animal Lying Places

A reasonably clean, dry, resilient bed on which to lie down helps maintain a dry erect haircoat for the small calf in cold weather as well as provides the larger cow with a clean, comfortable place to lie down for rest and to relieve stress on feet and legs. A cow will lie down for longer periods of time and more total hours per day in a more comfortable stall. The outcome is longer resting time, less time for the cow to be standing in wet manure, and more drying time for wet feet.

Bedded Areas

Loose housing of dairy cattle on bedded manure packs with separate facilities for milking were established concepts by the middle 1950s. Of course, loose housing has long been the rule in warm climate areas with herds kept in a corral or barnyard. Even now, bedded areas are common for housing groups of young animals and dry cows; bedded pens that are frequently cleaned are recommended for calving as well. However, in most areas today, when barns are provided for lactating cows, these barns are equipped with freestalls.

Groups of animals provided with a bedded area for resting should have access to another area—an outside paved lot or a scraped alley—for feeding. This reduces the amount of manure deposited in the bedded area. Also, the problems that develop with wet, trampled bedding when the bedded area is next to the feed manger are eliminated. Recommended bedded area per animal varies with the size of the animal, from 2.4 to 2.8 sq m for calves that are 6 months of age to 4.6 to 6.0 sq m for mature cows. If cows close to calving are housed on a bedded pack, the bedded area should provide at least 9.0 sq m per cow.

Freestalls

A Washington dairy farmer, Adolph Oien, is credited with developing the freestall when in 1959 he installed a series of individual stalls in a loose housing shed. Adoption of the idea was rapid. In fact, an article in the January 25, 1963, issue of *Hoard's Dairyman* magazine reported that the freestall system was the subject of more inquiries and comment than any recent development in dairy farm management.

Basis for Freestall Design. Cleanliness and comfort are two basis prerequisites that must be satisfied in freestall design and construction. Cleanliness relates to clean, dry conditions, especially a clean, dry stall bed in the vicinity of the udder. Comfort means a comfortable bed to allow the cow to lie comfortably in the stall along with roomy dimensions that make it easy for the cow to enter the stall, lie down, rise, and exit. In simplest terms the main purpose of a freestall is to reduce exposure of the teat ends to mastitis causing organisms. What follows is to make the stall so appealing that a cow chooses no other place but a freestall to lie down 10 to 14 hours per day.

A freestall should enable a cow to rise and lie down naturally. (See Figs. 12-4 and 12-5 for illustrations of the rising movements of a cow.) A 635-kg cow requires 168 cm for body space and about 47 cm for head space to lie comfortably. This adds up to 215 cm (7 ft), a commonly recommended freestall length. Freestalls must provide a lunge space for cows to rise. This lunge space ranges from 25 to 55 cm added onto the combined 215-cm body and head space (or, the space is 70 to 100 cm measured ahead of the foreknees). Accounting for this lunge space is the first and most important aspect of stall design and a key to providing stalls that cows will use readily.

The lunge space may be provided either forward or to the side. The option chosen determines both the type of partition to use and the overall length of the stalls. If the forward lunge is to occur within the stall envelope, the recommended length overall is at least 245 cm. Or, if space for the lunge is provided to the side into an adjacent stall space, overall stall length need be only 215 cm. Other alternatives are to allow the cow to lunge forward into a stall space opposite the cow or into an adjoining alley or even to the outside of the barn itself.

Types of Freestalls and Components. Depending on provisions for the thrust of the cow's head during the lunge, freestalls may be in one of two categories: forward lunge or side lunge. Fig. 12-4 shows two examples of forward lunge stalls; Fig. 12-5 shows side lunge stalls. Certainly other designs may satisfy the concepts and principles of freestall design equally well. Therefore an evaluation of a particular freestall begins with assessing its merits in meeting the basic needs of the cow from the standpoint of comfort and cleanliness.

Side lunge and forward lunge freestalls differ in partition shape and in stall base design at the front of the stall. Designs are similar at the rear of the stall. Both types provide space beneath the lower rail to minimize contact with the hip and pelvic area of the cow, reducing the potential for injury.

In a side lunge freestall, the cow turns and thrusts her head into an adjacent stall space as she rises. The lower rail of the partition is either high enough at the front to allow the cow to thrust her head under the lower rail or low enough to allow the cow to thrust her head over the lower rail without interference. If the cow thrusts her head under the partition rail, the bottom partition rail should be installed a minimum of 72 cm above the stall surface. If the cow thrusts her head above the bottom rail, the bottom partition rail should be a maximum of 18 cm above the stall surface. In Figs. 12-4 and 12-5, the values given for these dimensions are greater since the dimensions are measured from the top of the back curb—a more stable reference point, especially in sand-based freestalls.

In a forward lunge freestall, additional stall length is needed to allow the cow to lunge forward, either within the stall envelope or through an open front to space beyond. If the lunge is within the stall envelope, the stall must be at least 245 cm long. If the lunge is through an open stall front, a minimum of 54 cm of open vertical space must be provided.

The brisket board defines the space for the body of the lying cow and discourages her from moving too far forward into the stall when she is in a lying position. A brisket board is essential in a stall where space for the lunge is provided ahead of the cow. A neck rail across the top rail of the stall partition is important for maintaining stall cleanliness. The neck rail encourages cows to back up when rising and stops cows from moving too far forward when standing without being a nuisance to them. A neck rail that is too low hinders the rising movement. A neck rail that is too close to the curb does not allow a cow to enter the stall and stand comfortably on all four feet, a prelude to lying down. Neck rails should be 167 cm (66 in) ahead of the alley side of the curb and at least 101 cm (40 in) above the stall bed.

Each type of freestall is a unique system, depending on provisions for the lunge space, type of partition chosen, etc. All components act together, related to one another with ap-

propriate dimensions, to provide the best environment for the cow. Arbitrary changes disrupt the system. The following is an example of when a dimension from one freestall system is applied to another.

With side lunge stalls, a cow must have easy, natural access to the lunge space. Side lunge partitions are manufactured accordingly. When the recommended freestall length is used (215 cm for a 635-kg cow), the partition is mounted at the front of the stall such that the cow can easily reach the lunge space. However, making the freestall bed longer than necessary (say 230 cm versus 215 cm) positions the partition and the lunge space 15 cm farther forward in the stall, well

ahead of where it should be for the cow's comfort. Without a brisket board, the cow will move too far forward in the stall, increasing the likelihood of her defecating in the stall. A brisket board will help position cows to prevent dirty stalls. But, cows will then have to reach forward awkwardly to use the lunge space in a longer stall equipped with a side lunge partition.

Recommended Dimensions. Ultimately, dimensions chosen for freestalls represent a compromise between cow comfort and cow cleanliness. Stalls must enable cows to lie down and get up naturally and comfortably. Stalls should be wide enough that cows normally do not contact stall partitions in any way that could cause injury or that could damage the partitions. However, stalls that are too wide may

TABLE 12-2

Suggested Freestall Dimensions

Weight (kg)	Freestall Width (cm)*	Freestall Length (cm)*		Neck Rail Height Above Stall Bed (cm)	Neck Rail and Brisket Board, from Alley Side of Curb (cm)
		Side Lunge	Forward Lunge		
365-545	107-112	198	230-244	94	158
545-680	112-122	215	244-260	102	168
over 680	122-132	228	260-275	107	180

*Width: "center-to-center" with 5-cm pipe partitions; length: alley side of the curb to the front of the stall.

allow cows to turn around in them or lie diagonally. Stalls that are too long may allow lying too far forward unless brisket boards are used. All of these conditions increase the possibility of manure being deposited on the stall bed.

Table 12-2 shows a range in the recommended stall widths and lengths. The lower values of the ranges in the table represent a livable compromise between cow comfort (high rate of stall usage) and cow cleanliness. The upper values, which provide for wider and longer stalls, favor cow comfort over cleanliness and allow more time being spent in stall maintenance.

With two rows of freestalls placed head to head and designed for forward space sharing, stall partitions are usually mounted on posts. This allows for unrestricted open space for the forward lunge into the adjacent stall space. When a row of building support posts are located down the center of the two facing rows, spacing between the support posts must be a multiple of the freestall width (115 cm on center for typical Holstein herds). Otherwise, building support posts will be located periodically in the forward lunge space needed by the cow. Freestall width should determine building post spacing, not vice versa. In hot climates consideration to heat buildup in the freestall area may lead to wider freestalls (e.g., 120 cm). Although, in a well-ventilated building equipped with cooling fans, the advantage of wider freestalls has not been established.

Freestall Base and Bedding. The stall base and bedding act together to provide a resilient bed and a clean, dry surface. Of all the factors that discourage cows from lying in freestalls, an uncomfortable freestall bed is likely the most important. Beds that do not provide sufficient cushion (concrete, concrete with a rubber mat, compacted earth) often cause swollen hocks and knees. Beds with mounds, lumps, or holes reduce comfort for the cow but, worse yet, can cause difficulties for the cow upon rising. Lack of comfort and difficulty in rising both discourage freestall use. The base of the freestall should slope upward 4% from the rear to the front. A curb at the back puts the stall beds 15 to 25 cm above the alley and keeps scraped manure or flush water out of stalls.

Two methods have emerged as top candidates for freestall base and bedding: mattresses with bedding on top and a deep layer of sand. Bedding mattresses, 8 to 10 cm thick, over hard stall bases such as concrete or well-compacted earth can provide a satisfactory cushion. A bedding mattress consists of bedding material sandwiched in a fabric-heavyweight polypropylene or other material. Various materials are used as filler—long or chopped straw, sawdust, shavings, or shredded or ground rubber.

Bedding material added on top of the mattress absorbs moisture and manure tracked into the stall. Also, chopped straw or similar material on a bedding mattress acts as a lubricating layer, reducing abrasions to the skin when the lying cow tends to slide around while lying down. Dry bedding on the surface is an essential aspect of a mattress system. The use of short, fine bedding material reduces the amount of bedding material dragged into the manure alley. Choice of bedding material may influence selection of a manure handling and storage system. Too much long straw or other organic material can build up a substantial crust in a storage. A crust reduces odor from the storage but creates problems with agitation at emptying.

A bed of loose sand—15-cm minimum—maintained in the stall area can be considered as the gold standard for a freestall base and bedding. Sand contributes to cow comfort, good udder health, and clean cows. In addition, sand kicked into the alleys improves cow footing. If other materials are to be considered as alternatives and are to be evaluated on the basis of cow comfort, sand is the basis for comparison. The only logical reason for not using sand has little to do with the cow comfort and udder health, but with the difficulty it adds to the manure system or the availability of high-quality sand. Sand bedding may greatly complicate the manure handling system.

As a cushion or for resilience, loose sand conforms to the shape of body components (knees, hocks, etc.). This reduces pressure on projecting bones and body parts by distributing downward force or weight over a larger area. This is important to the lying cow; the total weight of the cow is transferred to the lying surface through the contact points of the cow's body.

Spreading the cow's weight over a larger area protects the front knees of the cow during rising also. A cow rising from a lying position lunges forward, transferring the weight of her body forward so she can more easily rise on her hindquarters. The knees act as the fulcrum for this teeter-totter action, with the stall bed providing the cushion for the knees. During the lunge the weight transfer process increases the downward force on each knee from 160 kg (about one fourth of the cow's weight) to 230 kg or more—on each knee! As the sand conforms to the shape of the knee,

Downloaded from Vet-e-Books.com

increasing the area over which this downward weight of the cow is distributed, the potential for injury to the knee is decreased.

Good footing in the freestall is essential to the cow's ability to lie down and rise easily. In this case, "footing" means not only reducing the tendency to slip but allowing the cow to more or less embed her foot in the surface in order to provide good leverage. When a cow can rise more confidently, rising time is reduced. Also, the tendency to rock back and forth is lessened, and rising is accomplished more smoothly, reducing trauma to knees, ankles, etc. Loose sand provides excellent "footing." Beds of other materials must be equivalent.

Every one to four weeks, sand is added to the front of the stall bed, leaving it to the cow to work toward the rear of the stall. The sand should not contain small rocks or pebbles, which could cause damage to the hoof or lameness. Sand should be replenished before the front of the stall bed becomes lower than the rear, a condition that makes it difficult for cows to rise and causes them to lie diagonally in the stall. A stall that is lower in the front leads to more manure in the stalls and to dirtier cows.

The search goes on for the ultimate freestall bed. Meanwhile, a bed of loose sand and rubber-filled mattresses with organic bedding on top are two methods for satisfying the requirements for freestall beds that promote cow comfort and good udder health. Sand appears to have the advantage. However, either system, properly installed and maintained, can contribute to a desirable environment for the dairy cow.

Freestall Care. Proper freestall care includes daily inspection and removal of wet bedding and manure, besides adding dry bedding periodically. Neglected freestalls with excessive moisture or accumulations of manure can lead to an increased incidence of mastitis. For stalls with bases that must be replenished, such as sand, an upward slope of the base toward the front should be maintained. This upward slope helps position cows more squarely in the stall when lying down, and this contributes to cleaner stalls and cleaner cows. Freestall hardware and other components should be kept in good repair.

Access to Feed and Water

Feed mangers and bunks have developed around two basic forms: (1) mangers where the animal eats from a surface that is at or slightly above the floor on which it stands, or (2) feed bunks where the bottom of the bunk is substantially higher than where the animal is standing. The first type has been associated with open dry-lot systems in warmer climates where the feed mangers are along a side or end of dirt lots with mobile scale-mixers usually used for feeding. In colder climates this arrangement is common in tie stall or comfort stall barns, where the feeding surface is one to two inches above the cow platform, and in free stall barns designed for mobile feeding.

The elevated type of feed bunk was clearly the choice as loose housing developed in colder climates. The most likely reason for the elevated design was to accommodate bedded manure packs. Sufficient height was necessary to allow for the manure pack to build up, not only in the pen or loafing barns but in outside lots where infrequent manure removal and accumulations of snow and ice gradually raised the elevation of the cow. In fact, construction plans for feed bunks sometimes included the recommendation to increase the height of bunks intended for use where manure, snow, or mud may accumulate. Quite possibly, the cow could end up standing on a manure pack higher than the bunk floor itself, which may have prompted Loughary and White (1950) to write: "Provide . . . adequate manger guards to prevent cows from falling into the manger."

However, cows prefer mangers that offer the opportunity to eat in a natural grazing-like position compared with eating from elevated bunks (Albright, 1983). Also, behavioral activities contributing to feed wastage, such as rooting feed out of shallow, elevated bunks and feed tossing, are virtually eliminated. Preferred manger floor height is slightly above the floor on which the cow stands. Albright pointed out also that cows produced 17% more saliva, a natural buffer, when eating with their heads downward. Here is an example of a situation in which consideration to facility design can have a positive impact.

A post-and-rail feed manger is shown in Fig. 12-6. The position of the neck rail, offset away from the cow, allows the animal to reach further while exerting less force on the rail. Also, offsetting and raising this rail allows cows to stand closer to the manger wall, increasing the ability of cows to reach feed while reducing the possibility of injury. The feed surface may be elevated 2 to 6 inches above the cow alley in the fenceline manger. Minimizing this elevation maximizes the height of the manger wall against which the cows' ration is piled. This maximizes the amount of material that can be deposited in a given feeding.

Suggested dimensions for post-and-rail feeding mangers according to the design of Fig. 12-6 are given in Table 12-3 for dairy heifers and cows.

Recommendations for waterers, including location, size, height, and number, seem to have evolved over the course of time. Design guidelines at this time are to provide at least one watering space or 60 cm of tank perimeter for every 15 to 20 cows. At least two waterer locations are needed for each group of cows. Provide more space and more locations if 2-year-olds are housed with older cows. Limit water depth to 15 to 20 cm for fresher water and less debris accumulation.

Access to adequate fresh water becomes even more important in summer as consumption per cow increases. Extra water tanks in the barn should be considered for use during hot weather. In fact space should be designed for such tanks in new barns. Heaters will not be required, since these tanks will be removed for cold weather.

Walking Areas and Surfaces

Substantial competition occurs among cows as they used the space allocated to them in freestall barns (Potter and Broom, 1990). Areas used most intensively are the crossovers be-

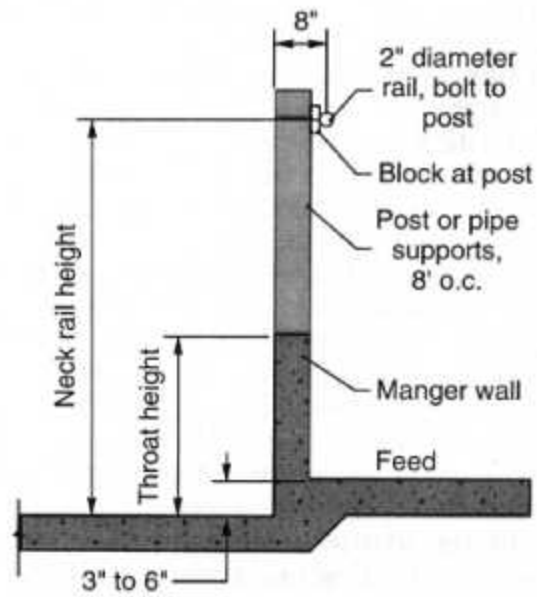

FIG. 12-6 Post-and-rail feeding fence. Refer to Table 12-3 for neck rail and throat heights.

Downloaded From Vet-eBooks.com

tween rows of freestalls, spaces around waterers and other prime sites within the barn such as feeding areas, holding areas, and entries and exits from the milking parlor. An underlying level of social aggression, promoted by social hierarchy of animals and the competitive use of space, can often produce sudden actions of avoidance, causing animals to slip and to fall on manure-covered surfaces. This can lead to damage to legs, followed by upper leg lameness.

The width of alleys between a feed bunk and an opposite wall should be 3.5 to 3.7 m. This allows two cows to pass each other while others are feeding. If, as in Fig. 12-7, a row of freestalls opens to the alley opposite the feed bunk, the width of the alley should be 3.9 to 4.3 m to allow for the additional activity of cows entering and leaving stalls. Oftentimes, waterers are located at the end of freestall rows in the crossover area. The width of the crossover should be at least 3.7 m plus the space occupied by the waterer.

When a cow is in the alley away from the feed manger (the alley along an outside wall in Fig. 12-7), the distance that she must walk to access a crossover, and thus the feed manger, is of interest to nutritionists. A rule of thumb is to limit the cow's walking distance to access a crossover to the equivalent of 15 to 20 freestall widths. Thus, if a cow is standing at the midpoint of the outside alley, she could walk 15 to 20 freestall widths either way. Therefore, the maximum number of freestalls in a row between crossovers is 40, or a maximum of 80 freestalls in a group of stalls head-to-head as shown in Fig. 12-7.

The drive-through feeding alley is for a feed truck or a tractor and trailer-mounted mixer. A minimum width of 5.5 m is recommended to avoid the possibility of driving over feed already deposited while making a return trip through the barn to deliver feed to the other side.

Skid-resistant walking surfaces reduce injuries; improve movement to feed, water, and resting areas; and enhance estrus detection. The walking surface for the cow must be sufficiently aggressive to prevent her from slipping or skidding as she walks but not so aggressive as to injure the underside of the foot. Thus choice of floor surface is a matter of compromise, as is all of design.

Dumelow and Albutt (1990) examined the design of the optimum slip-resistant concrete floor surface for dairy cattle using a mechanical foot simulator rig. This allowed for precise measurement of the spatial dynamic movement of the mechanical foot on different surfaces. They concluded that, for optimum slip-resistance, floors for dairy cattle should be wood-float finished and that they have parallel grooves 10 mm wide running perpendicular to the direction of walking. The grooves should be spaced at 40-mm intervals. In the general circulation areas a pattern of hexagons with 46-mm sides formed by 10-mm grooves improves the antislip properties of the concrete floor.

In practice, parallel grooves approximately 12 mm deep, 12 to 19 mm wide, and spaced 90 mm on center are sawed or formed in concrete surfaces. These grooves act to arrest a skid perpendicular to the groove, but they are not effective when the skid is in the same direction of the groove. In high traffic areas, grooves are formed in two directions, causing a diamond-shaped pattern.

TABLE 12-3

Suggested Dimensions for Post-and-Rail Feeding Fence

Age (mo)	Weight (kg)	Throat Height* (mm)	Neck Rail Height* (mm)
6-8†	165-225	355	710
9-12	225-295	405	760
13-15	295-355	430	865
16-24	355-545	480	1040
Cows	545-680	530	1220

*Consult manufacturer for manger wall dimensions when installing self-locking headlock stanchions.
†A diagonal feeding fence (250-mm spaces between diagonal bars) is recommended for this group.

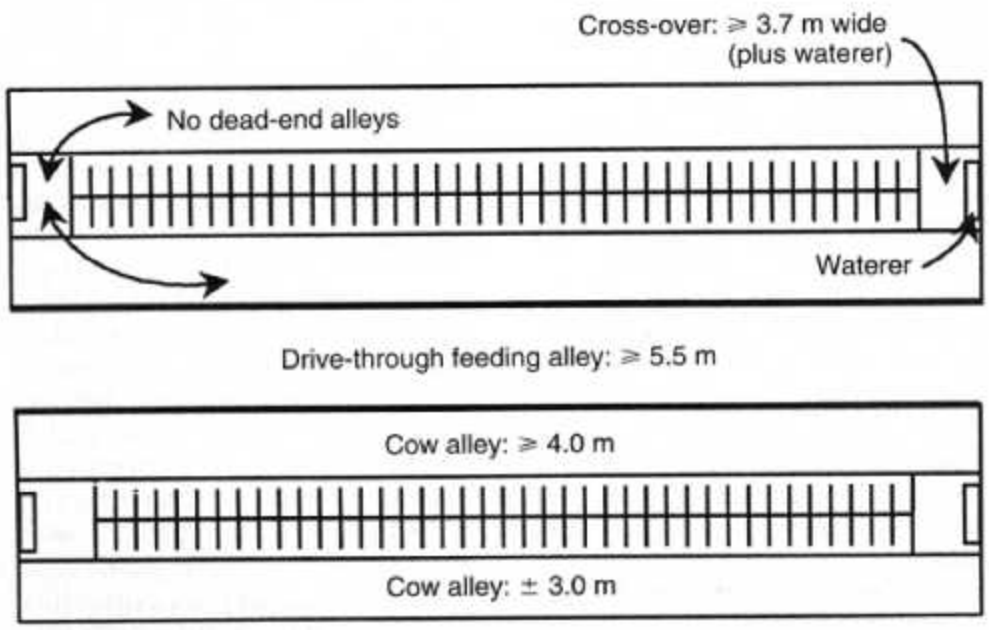

FIG. 12-7 Animal movement areas. The dimensions shown in this plan view of a four-row drive-through barn allow cows to have access to feed, water, and freestalls with a minimum of interference. The distance between crossovers should be limited to the equivalent of 40 stall widths, or 80 stalls in a module when two rows of freestalls are head-to-head.

Downloaded From Vet-eBooks.com

Concrete surfaces may have a texture that is too aggressive. Jagged edges, sharp points, and protruding aggregate that result from improper finishing and texturing all may be injurious to the sole of the claw. Impressing a texture into the concrete surface is preferred over dragging rakes or other tools across the surface in order to create roughness. During the impressing process, a lip may be formed at the edge of the impression because of displaced concrete. This lip traps liquid. Also, during forming, wet concrete may cling to the impression tool and be pulled upward, creating a feathered edge that protrudes above the alley surface and becomes very sharp as the concrete cures. This should be corrected by repeatedly dragging a heavy concrete block or a weighted steel-blade scraper over the concrete surface after the concrete is cured but before cows are introduced to the area. This procedure chips off sharp points, lessening their damaging effect. The alley surface should be swept clean after the sanding operation. Equally injurious is broken or highly eroded concrete that has a very rough and irregular surface. A qualified craftsman should repair such surfaces.

Frequent removal of manure (at least twice daily) greatly helps to enhance foot-floor grip and reduces exposure of the claw horn to manure and wetness. Prolonged contact between the claw horn and manure leads to softening of the claw wall and increases the rate of abrasion. This could lead to other forms of claw lameness.

HOUSING SYSTEMS

Factors Affecting Choice of Housing Type

Climate has had much to do with the type of housing used in certain areas and the developments that have taken place. In northern climates, barns were built to provide protection for the animals and the people keeping those animals against the long, cold winters. Pastures or other outside areas were likely used during milder times of the year. In areas where freezing temperatures and snow are not problems, shelter was less necessary. Year-round pasture systems may have provided the source of energy for the cattle, or corrals or dry lots where feed is brought to the animals may have been used.

The number of cattle on a farm has been another factor affecting type of housing, especially in colder climates. Stanchion and tie stall barns served well for herds ranging up to 50 or 60 milk cows. However, stall barns are labor intensive, both for milking and feeding. This has been and will continue to be an important reason for dairy farmers with larger herds to consider loose housing systems with milking parlors.

Changing economics has played a major role in determining the number of cattle on a particular farm, generally having a greater impact on dairy farms with fewer cows. Smaller dairy farms often experience higher costs and lower net returns than larger farms, a situation that worsens if costs of fixed assets-fixed investments on the dairy farm continue to rise in relation to the returns per cow. In some cases, revenues of the business may not be sufficient to support the capital investment and corresponding debt capital necessary to stay in business. For the farmer seeking profitability, one of the options available under these circumstances is to increase the size of the dairy herd. Fixed costs can be spread over more cows, and the farmer is in a better position to benefit from economies of scale. In countries with a milk marketing system based on supply control, the smaller dairy farm is at less of a disadvantage.

However, one of the most important reasons for changes in housing and equipment has been to keep abreast of the improvements in the genetic base of the animals on the typical dairy farm. With increasingly superior animals from the standpoint of their genetic potential for milk production, the more traditional facilities and methods become an obstacle to higher milk production. Existing facilities limit the ability to implement appropriate management recommendations. In addition, existing facilities may not meet the needs of animals from the standpoint of their environment, thus placing restrictions on productivity, health, and general welfare. Contemplating change is a dilemma for the dairy farmer (i.e., having to decide whether to make changes in an effort to maintain the status quo or to make no changes and fall behind). Meeting this challenge requires a careful examination of values, management style, and goals and development of a long-range plan for the dairy farm.

Housing for Milking Cows

Stall Barns

Early stanchion barns were typically two-story buildings with two rows of stanchions in a face-out arrangement and a few pens for calves and freshening cows on the first floor. The row on the second floor was devoted to hay storage. Sometimes the rows of stanchions were arranged in a face-in arrangement to facilitate feeding and the mechanization of feeding, but this arrangement compromised the milking operation. Engineers understood needs for insulation and ventilation, mechanical or gravity, but application of these principles often was lacking in actual practice. Some barns were equipped with mechanical gutter cleaners that eased manure removal and allowed a narrower center alley in face-out barns.

The typical northern stall barn of today is a well-insulated, single-story structure with mechanical ventilation. In some cases, natural ventilation has been used. Barn space is primarily for milking cows, with calves and other animals housed in other facilities. Comfort or tie stalls are more common than stanchions. Gutter cleaners are standard equipment, although a few stall barns have gravity-flow gutters. A trend to year-round housing and feeding in the barn has required more ventilation. In addition to continuous winter ventilation and thermostatically controlled spring and fall fans, fans are installed to provide summer ventilation on the order of 60 to 90 air changes per hour.

Freestall Barns

Freestall barns constructed today generally are based on using a mobile feeding system with a truck-mounted or trailer-mounted feed mixer equipped with electronic scales. Horizontal silos for corn silage, and possibly grass silage, and bulk storage for dry grains and supplement are compatible with this system. A tractor with a front-end loader loads feed components into the mobile scale-mixer. The scale-mixer itself is used to deliver the mixed rations to the cows. Groups of cows then can be fed differently according to their particular nutritional requirements. This has led to barn arrangements that permit division of milking herds into groups, usually by production.

Other grouping strategies and management practices may have positive effects on animal health (e.g., reducing incidence of lameness). Groups of older heifers housed in freestalls during the year before parturition, having already experienced use of stalls, will likely demonstrate a higher rate of freestall use as primiparous animals. As already discussed, freestall use has important implications with respect to lameness. Primaparous cows segregated in a group from multiparous cows are subject to less bullying by the older animals, reducing the possibility of animals falling. From a nutrition standpoint, high-producing cows will show a lower incidence of laminitis when grouped separately and fed a separate ration during the 2 to 3 prepartum weeks. Maintaining DMI during this critical time helps avoid numerous other health-related problems as well.

Downloaded From Vet-eBooks.com

Freestalls are used to some extent in combination with outside lots or corrals, particularly where periods of excessive rain make concrete in the housing and feeding area desirable. In the north, these open-lot systems, where feeding was done in an exposed concrete feed alley or lot and a feed bunk, are gradually being abandoned or converted in favor of a completely covered facility. In new construction, joining of the milking center to the freestall barn allows all animal traffic areas to be covered. This reduces problems arising from frozen manure and snow and the need for runoff control.

Corral Systems

In warmer areas where freezing temperature and snow are not problems, loose housing systems usually are based on outside corrals or lots. Freestalls are used to some extent, particularly where periods of excessive rain make concrete in the housing and feeding areas desirable. In most cases a dirt lot is provided as well.

Open dry-lot corral systems without freestalls remain popular where rain does not pose a problem during most of the year. These systems are based on dirt lots, sloped for drainage, with feed mangers along one end or a side. Drives are provided for mobile scale-mixers usually used for feeding. In some cases, evaporative coolers are incorporated into shade structures to reduce stress further during hot weather. Cow traffic patterns to and from the milking center are an important part of the overall design.

Dry Cow Housing

The early dry cow management category begins with a successful transition from a lactating state to a nonlactating (dry) state. Early dry cows are housed as one group for approximately 40 days. Early dry cows may be housed on pasture, on a bedded pack, in free stalls or in comfort stalls.

Approximately 2 to 3 weeks before expected calving date, dry cows and heifers should be moved to the precalving group. The precalving management program calls for more careful attention to nutrition and sanitation, since cows and heifers near, during, and after giving birth to offspring are at greater risk for infectious diseases and noninfectious disorders. Housing for precalving cows and heifers should allow for frequent observation and be convenient to the maternity area. Free stall housing is recommended to reduce exposure of the udder to mastitis-causing organisms. Restricting access to outside dirt lots reduces risk of mastitis also.

Just before calving time, cows and heifers should be moved to individual pens that are separate from other animals, especially younger calves. The location of this area and assignment of responsibilities to personnel should encourage frequent observation. Then the animal that has just calved should be observed frequently for problems before moving her to the milking herd. The newborn calf, having received about 2 to 4 L of high-quality colostrum, a dry haircoat, a disinfected naval, and other medical treatments, should be moved to a calf hutch or individual pen until weaning.

Calf and Heifer Housing

The calves and heifers on a dairy farm represent the future of the milking herd. Beginning at birth the replacement animals should be the best of the lot, genetically superior to the older animals. Accomplishing this is the result of a well-managed breeding program; taking advantage of the genetic superiority requires implementing a sound management program based on current recommendations.

From an environmental standpoint, raising healthy, potentially high-producing replacement animals requires housing that provides adequate space for water, feed, resting, and exercise. High humidity is especially detrimental to animal health requiring adequate ventilation to remove the moisture produced by the animals themselves. Adequate ventilation also removes other air pollutants so as to maintain suitable air quality.

Calf Housing

From birth to age of weaning (2 months), individual hutches, pens, or stalls should be provided. Cold, naturally ventilated housing is preferred. A calf hutch that is clean and dry with ample amounts of dry bedding has proved to be a desirable option. From an environmental view, the benefits of a hutch are:

- No contact between calves (reduces spread of disease)
- Well-ventilated area (air inside hutch is similar to outdoor air)
- Adequate space (dry bedding is easier to maintain)
- Ability to move to a clean spot (breaks a potential disease cycle)

The calf hutch is the gold standard for calf housing in terms of the environment it provides. Any decision to choose something other than hutches in the interest of working conditions for people or for equipment must be made in full view of the potential consequences. Thus, before making a decision to choose something other than hutches for housing calves, consider the attributes listed above. Whenever an attribute is lost, calf health is placed in greater jeopardy—the more attributes that are lost, the greater the jeopardy. For example, choosing group housing over individual housing places risk on calf health from the standpoint of spread of disease and competition. Moving calves to pens inside a building may compromise ventilation or the ability to provide a clean, fresh place for the newborn calf. Thus, as in all facilities' decisions, choice of calf housing is the result of a compromise and a process of making choices after carefully considering all of the consequences.

Transition Housing

An important management category is comprised of calves from weaning up to 5 or 6 months of age—the transition group. From an environmental standpoint, these calves have special needs that differ from older heifers. Small groups should be maintained. For a 100-cow dairy, four to six calves per group will sufficiently minimize the difference in size among calves in the group. Well-bedded pens should allow 2.3 to 2.8 sq m/calf—a 3.65 m × 3.65 m pen can hold up to five calves.

Transition housing for calves that have been raised in individual hutches or other cold housing can be provided with the following:

- Portable calf shelters or super hutches
- Group pens in an existing well-ventilated building
- A transition barn or a building constructed specifically for the transition stage

The environment should be similar to that in which the calves have already become acclimated with sufficient ventilation for moisture control and protection from the elements in winter. In cold weather a thick, dry, erect haircoat is essential to reduce heat loss from the calf and accompanying environmental stress.

Heifer Housing

In colder climates heifers are usually housed on a bedded pack or in free stalls, at least in winter. Pasture and other

Downloaded from Vet-e-Books.com

outside lot systems are used as well. Regardless of housing type, animals should be grouped according to a management plan. Variations in size and nutritional health and reproductive needs may then be accommodated.

SORTING, HANDLING, AND RESTRAINT FOR TREATMENT

Handling, restraint, and treatment facilities are essential to a successful dairy facility, permitting implementation of many management recommendations. As a rule, a sorting and restraint system should provide one person with the ability to perform the following:

- Observe calves, heifers, and cows
- Identify selected individuals for sorting or treatment purposes
- Separate selected animals from the rest of the group
- Move sorted animals to a treatment location
- Restrain animals for medical examination, treatments, and other procedures as needed.

Treatments and examinations include vaccinations, dehorning, weighing, artificial insemination, estrus synchronization, and pregnancy checking.

Each group of animals, organized for management purposes, must have provisions for sorting and restraint. Choice of method will vary with age or size and the particular housing facility. Provide feed and water for animals that may be restrained for treatment in an area away from regular sources. Provide the capability of lifting individual feet of animals to allow for inspection and treatment of the claw and associated areas. Do not examine or treat dairy animals in the milking parlor.

Three locations are available for sorting milking cows: the milking center, the freestall barn, and a separate facility. The milking center is a convenient place to sort cows as they exit from the milking parlor if cows travel single file. Two parallel lanes—one for returning cows to the housing area, the other for catching cows—are provided at the parlor exit. A power-operated cutting gate located in the return lane may be used to divert individual animals. If manually controlled, the cutting gate is situated near the rear of the parlor in an area easily viewed by the person milking. Moreover, if the parlor is to be idle for more than 2 hours between milkings, provisions for restraining cows for treatment may be included. Plans for using the holding area, the return lanes, and the area alongside the holding area for sorting, restraint, and treatment are available (Bickert and Stowell, 1997; Mid-West Plan Service, 2000).

More recently, automatic sorting systems based on cutting gates coupled with electronic identification of animals have come into use. Power-operated cutting gates programmed to operate in combination with an automatic cow identification system may be located (1) in a return lane near the rear of the parlor, (2) at the extreme end of a return lane, or (3) beyond the return lane.

Ganglock stanchions along a feed manger can restrain animals for various purposes. This is common on dairies where milking parlors are operated most of a 24-hour day and sorting capability is not part of the milking center. Each ganglock stanchion is equipped with a self-locking feature that is actuated when the cow puts her head in a stanchion and reaches for feed. Stanchions designed to allow individual release of animals might be used for sorting purposes as well. Whether associated with a freestall barn or with open lot housing, ganglock stanchions along the feed manger are used similarly.

For large herds a separate handling and treatment facility may be desirable. On some farms this facility may be the sorting site and may provide restraint for treatment and other purposes. In other words, all such work is done here. Usually, animals needing treatment would be sorted elsewhere first and would then be brought to this separate facility as individual animals or groups of sorted animals. For example, animals could be sorted as they leave the milking center. Sorted animals could be held in the catch lane (or diverted to a pen or other holding area) and then moved to the separate treatment facility.

The separate facility should be equipped with enough pens to accommodate the number of different sorted groups expected to accumulate during the course of a milking shift plus any groups that might be held for longer periods. Smaller pens for individual cows could be equipped with individual stanchions; larger pens could be equipped with a section of ganglock stanchions. Pens may be bedded and freestalls may be provided for larger groups. A chute and headgate system(s) as well as a tilt table or a stand-up hoof-trimming chute might be included in the facility. Feed and water should be provided for animals to be held more than a few hours.

A loading chute with solid sides for receiving and shipping animals is highly desirable. The ability to quarantine animals coming to the farm is also desirable. Practitioners should provide a holding pen to hold animals before loading and provide adequate consideration to safety in all cases: safety of persons handling, examining, and treating animals and safety of the animals themselves.

MANURE MANAGEMENT

Manure management is one of the major issues facing animal agriculture. The traditional view of a manure system—production, collection, storage, transport, and land application—has led to manure system designs that meet the needs of the dairy farm as well as satisfying the interests of the rest of society. But future planning must go beyond the traditional view. Manure management is a complex issue and is different from other farm management problems. Manure management decisions are closely intertwined with decisions about many different aspects of the dairy production system, including the buildings and other equipment selected for managing the herd and the cropping program.

Unique Aspects of Manure Management

Manure management is different from most other farm management problems. Also, many of the problems related to manure are of a different type, more social in nature than experts in the physical sciences are accustomed to addressing. The following are some examples of differences:

- Solutions to manure management problems require knowledge from several different subject matter areas. Manure management is not a discipline in itself, thus it is not identified with a specific discipline. Manure management is made up of bits of knowledge from several subject matter areas (engineering, microbiology, chemistry, agronomy, economics, and even the social sciences). Integrating inputs from these several subject matter areas is essential to addressing the problems faced by the livestock producer and the rest of society. But this integrator has generally been lacking.
- The issue involves a wide variety of agencies—local, state, federal—as well as wide variety of individuals. They may have very different perspectives on manure. Their reasons for being interested and becoming involved in the manure management issue vary widely. In addition, some of these agencies do not have a long history of working with one another.
- Manure management has the attention of several segments of society—besides dairy, livestock, and poultry

Downloaded From Vet-eBooks.com

farmers—and all of this attention is not necessarily an asset. This is particularly true in areas where animal agriculture is well established and wishes to coexist in harmony with other segments of society, some already there, some new to the area. Informing the general public about the positive actions regarding manure management that are already occurring on dairy farms is essential. This applies also to food safety and animal welfare, two other topics attracting the attention of the rest of society. Informing the general public can, of course, be accomplished more easily and more effectively if done through an organized approach.

Traditional View of Manure System Design

The traditional view of manure system planning centers on viewing the system as components of collection, transfer, storage, possible treatment, and nutrient utilization. Good design ensures that all components of the manure system will operate together to economically and effectively manage the manure until it reaches its final destination, typically being applied to the land.

Collection

In freestall barns, manure collects in the barn alleys and must be removed. Conventional or skid-steer—type tractors equipped with a bucket loader, steel blade, or rubber-tire scraper are common, especially in cold climate areas. Manure is removed from the animal area, perhaps each time a group of cows is away at the milking parlor. In warmer climates and in some barns in colder climates, manure is removed from concrete cow alleys by flushing with large volumes of water. Another alternative is a mechanical alley scraper, a device that is pulled along the alley by cable or chain and moves manure to the end of the alley.

Transfer

Methods of transferring manure to storage include scraping, pumping, and gravity flow. Often, manure is moved directly to storage by the tractor scraper. This is especially true when sand bedding is used in the freestalls. To reduce wear on equipment and problems with clogging of pipes with settled sand, a storage for sand-laden manure is usually located very close to the barn so that the storage can be loaded through a push-off wall along the side of the storage. Moving the manure from the alleys to an intermediate pit from which it is pumped to storage is another option. If topography allows, gravity flow pipes can be used to transfer manure to storage using the hydraulic head exerted by the more-or-less liquid manure. The latter two options do not work well with sand.

Storage

Manure is stored in earthen storage basins and below- and above-ground tanks. Typically, 10- to 12-month storage capacity is recommended and may include all animal manure, milking center effluent, and polluted runoff. Manure from freestall barns bedded with organic material, diluted with milking center effluent, and rainfall on the storage, can usually be agitated and pumped. In some cases, especially with sand-laden manure, a storage with a concrete bottom that can be entered with a tractor is required to completely empty the storage.

Possible Treatment

Treatment options for dairy manure include composting, anaerobic digestion, and, for sand-laden manure, sand separation. Composting requires that large masses of bulking material be added to the manure for purposes of reducing moisture content, adding carbon and enhancing aeration. The final mixture, positioned in windrows or piles, requires frequent stirring for aeration purposes. The benefits of composting are a stable end product, reduced odor, and reduced volume.

Methane, a product of anaerobic digestion, has been used to generate electricity. The complexity of the systems and components and the questionable economic return have limited application of this alternative.

Sand-manure separation significantly reduces the amount of sand entering a manure storage, thus reducing settling and handling problems. Furthermore, the reclaimed sand may be reused for bedding.

Nutrient Utilization

Spreading manure on the land has been the traditional method of disposing of manure. Ideally, the manure nutrients are considered in the cropping program, especially to offset the use of commercial fertilizers. Because excess nutrients are primarily why manure is an environmental concern, animal scientists are now examining ration formulation, realizing that a high percentage of the various nutrients fed to animals are excreted in the manure. Lowering the percentages of nutrients passed in the manure not only reduces feed costs but reduces pollution potential as well. Moreover, the land area required for spreading may be less if manure nutrients are reduced.

High-Priority Decisions in Manure System Design

Decisions about manure system design are among the most complex decisions on the dairy farm. This is not because equipment choices for manure collection and transport, or the types of manure storage available, or the methods of land applying manure are so complicated. Rather, the complexity arises because of the impact that the manure system has on numerous other aspects of the buildings and equipment on the dairy farm. The buildings and equipment on the dairy farm enhance the ability to manage animals. As well, they aid in providing a quality environment for the animals. Thus decisions about the manure system are related to the requirements of a well-thought-out management program and a clear description of the environment to be provided for every animal on the farm.

Ultimate Fate of the Manure

If manure is to be applied to the land to meet agronomic needs, the land must be deficient in those nutrients contained in the manure that are needed for the crop. Not applying nutrients in excess of a crop's needs is in the interest of both good nutrient management and responsible environmental management. Thus land may become a limiting factor when considering expansion or construction of a new dairy.

If land is limited, options include arrangements with nearby crop farmers to utilize the manure and purchase of additional land to receive the manure. If the land available is not immediately adjacent to the dairy, manure transport or remote storage may be considered. Large over-the-road tankers are being used to haul manure to remote locations where the tanker itself is used for spreading or the tanker is used to supply smaller field spreaders. Manure may also be transported to a remote storage.

Downloaded from Vet-eBooks.com

Pumps may be used to move manure up to several miles to a remote storage or to apply the manure directly to the land. Irrigation is a lower-cost method of applying manure to the land and may be an appealing way to spread manure. The water contained in the manure will likely supply only a small percentage of the total crop need. Other sources of irrigation water (e.g., a well) must be available to supply the remainder. There are other considerations in the decision to irrigate. The odor created while irrigating can be substantial, possibly affecting neighbors. If sand is used for freestall bedding, special consideration must be given to removing this sand to minimize impact on pumping and irrigation equipment.

In all cases, maintaining a low profile is advised—reducing visual awareness, reducing objectionable odors, and avoiding runoff. With irrigation systems this may mean changing to low trajectory equipment. Other options include tank spreaders equipped with deep or shallow injectors, or an umbilical hose pulled across the field may supply injectors on the tool bar of the tractor. Low trajectory boom attachments and dribble bars are alternatives.

Choice of Freestall Base and Bedding

Choice of bedding is a critical decision. Choice of bedding should reflect management style and goals, especially with respect to level of milk production and SCC. At the same time, choice of bedding has a profound impact on manure system design.

Two methods for satisfying the requirements for freestall beds that promote cow comfort and good udder health are 6 to 8 inches of loose sand and rubber-filled mattresses with organic bedding on top. Although mattresses, properly installed and maintained, can contribute to a desirable environment for the dairy cow, sand appears to have the advantage. In fact, the only logical reason for not using sand has little to do with cow comfort and udder health. It has to do with the difficulty it adds to the manure system or the availability of high quality sand. This may lead to a decision to (1) use sand despite the difficulties, (2) use sand but seek ways to reduce its impact on the manure system, or (3) use mattresses and organic bedding and avoid the problems with sand altogether.

In spite of the difficulty, many dairy farmers have chosen sand for freestall bedding and are using a variety of handling and storage methods (Stowell and Bickert, 1995). Simply put, the final decision is whether to favor cow comfort and udder health or manure handling and storage.

Method of Applying Manure to the Land

Another decision that must be made early in the process is choice of method of applying the manure to the land and whether the manure will be handled as a semi-solid or a liquid. The majority of dairy manure is stored, handled, and applied to the land in liquid form. But, in fact, liquid manure handling is more energy intensive, and the equipment is more expensive than if the manure were to be handled as semi-solid. But the trend toward liquid manure has continued because it is the most timely alternative and generally involves less labor.

The actual method selected for applying manure to the land depends on many factors. If manure is broadcast, losses of nitrogen from volatilization of ammonia can be high and odors may be more objectionable to neighbors. Incorporation by plowing or disking is advisable. Injection of manure, either deep or shallow, reduces potential odors, runoff, and nitrogen loss as well.

Allowing bedding sand to remain with the manure greatly complicates, if not eliminates, the possibility of handling manure as a liquid. At the very least the sand in the manure is very abrasive to the equipment that has been developed for liquid manure.

HEALTH PROBLEMS RELATED TO ENVIRONMENTAL MANAGEMENT

In addition to diseases of the respiratory tract of housed dairy cattle (especially calves) that are associated with housing and environmental factors, lameness occurs commonly in confined mature dairy cattle. The trend of the last 25 years to confine high-producing dairy cows on concrete floors has been associated with an increased prevalence of diseases of the feet, causing lameness that is considered to be the third most economically important disease after reproductive failure and mastitis. The epidemiological aspects of lameness and other diseases associated with housing, including parasitism and behavioural abnormalities, are described here. For the clinical details of lameness in cattle and descriptions of the various lesions causing lameness in dairy cattle, the reader is referred to other textbooks (Greenough, 1997) and documents (Bergsten, 1995).

Lameness in Dairy Cattle

Prevalence, Incidence, and Economic Losses

Lameness in dairy cattle is a major cause of financial loss and inconvenience to dairy farmers and of pain and discomfort to cows. Next to mastitis and reproductive failure, lameness is an important cause of involuntary culling in dairy herds. Approximately 90% of cases of lameness in dairy cattle are caused by lesions of the feet and 10% by lesions elsewhere on the limbs. The proportion of cows culled for locomotor disease may be as low as 2.7% in studies in France (Seegers et al, 1998) and up to 5.6% in England (Esslemont and Kossaibati, 1997). Lameness, mastitis, and teat injuries collectively may have a large effect on culling in some dairy herds (Rajala-Schultz and Gröhn, 1999). In a study of culling of Holstein herds in Quebec, over a period of 16 years for 1.5 million lactation records, involuntary culling increased from 23% to 32%, as opposed to voluntary culling for low milk production, which decreased from 16% to 4.5%. The increase in involuntary culling was mainly due to increased trends in culling for reproductive problems, mastitis, and feet and leg problems (Durr et al, 1997).

The reported frequency of lameness, based on 39 citations in the literature from 1972 to 1995, ranged from a lactational incidence of 1.8% to a mean annual incidence rate of 30% (Kelton et al, 1998). The median lactational incidence rate was 7.0%. A cow is considered to be clinically lame if she had an episode of abnormal gait attributable to either the foot or limb, regardless of etiology or duration. A case is considered new if the cow has not been clinically lame in that limb during the preceding 30 days. A case is considered as a first occurrence if it was the first recorded case of lameness for a cow in the current lactation. A lactational incidence rate, expressed as affected lactations per 100 lactations at risk, is reported as follows: (number of lactations with one or more lameness events / number of lactations) × 100. A cow is included in the numerator only once per lactation. A true incidence rate, expressed as cases per 100 cow-days at risk, is reported as follows: all cases, (number of cases of lameness during the time period [TP] / number of cow-days at risk during the TP) × 100; first cases, (number of first cases of lameness during the TP / number of cow-days at risk during the TP) × 100.

The prevalence and severity of lameness in lactating dairy cows in a sample of Minnesota and Wisconsin dairy herds found the prevalence of clinical lameness was 13.7% in

Downloaded from Vet-e-Books.com

summer and 16.7% in spring (Wells et al, 1993a). These prevalence rates were 2.5 times higher than those estimated by the herd managers. A higher prevalence of lameness occurred in cows of higher parity. In a survey of 185 dairy herds consisting of 21,000 cows, the average incidence of treatments for lameness was 25% (Whitaker et al, 1983). An annual incidence of up to 60% has been suggested if all treatments given by the farmer and the veterinarian are included (Eddy and Scott, 1980). Approximately, 7% of Danish dairy cows receive veterinary treatment for lameness during a lactation (Alban, 1995). In Denmark the cow's incidence risk of foul-in-the-foot was 0.6% during the first month postpartum (Alban et al, 1995). This was six times higher than in the last month prepartum and in any other month postpartum. Almost half of the first treatments for foul-in-the-foot were provided within the first 30 days after calving.

In a survey of 90 Holstein dairy herds in England (average size of 152 cows) over a 12-month period, 17.4% of the cows were affected with lameness, with 1.4 cases/affected cow and a total of 24 cases/100 cows (Esslemont and Kossaibati, 1996). It is suggested that the increased incidence of lameness in dairy cattle in the last 30 years is associated with the introduction of cubicles compared with 3 decades ago when cows kept mainly in straw yards.

In a survey of 37 dairy farms in England over a 30-month period, the incidence and prevalence of lameness in the cows was obtained from records made whenever a cow was examined for lameness or her feet were trimmed prophylactically. The mean annual incidence of lameness was 54.6 new cases/100 cows with a range from 10.7 to 170.1, and the mean values during the summer and winter were 22.9 and 31.7, respectively (Clarkson et al, 1996). The prevalence of lameness was measured by regular visits at which locomotion was scored on a scale of 1 to 5, and the prevalence of lameness was calculated for each visit as the proportion of cows with scores of 3 or more. The mean annual prevalence over the whole period was 20.6% with a range of 2.0 to 53.9% for the 37 farms. *There was evidence that educating farmers to recognize early cases of lameness and requesting veterinary care caused a marked reduction in the duration of cases of lameness.*

Lameness in dairy cows is both a welfare problem and a source of economic loss to the dairy herd and the industry (Logue, 1995, 1998). In the United Kingdom, annual losses caused by lameness have been estimated to be about £90 million annually (Bennett et al, 1999). Lameness may affect the producer in several ways: *increased labor requirement, increased treatment costs, reduced milk production, reduced fertility and involuntary culling, and decreased slaughter value.* The economical loss is difficult to evaluate, but the average cost of sole ulcer in dairy cows has been estimated to be £227 to £297 (Esslemont, 1990). The direct cost of a sole ulcer is estimated at £72. However, the cost associated with reduced fertility is far more expensive, estimated at about £246 assuming that the affected cow will have a calving interval extended by 22 days, with a need for an extra 0.7 services per conception and an 18% increase in the risk of culling (Kossaibati et al, 1997). On a cow basis, the average dairy herd is losing £27 per cow per year when compared with the average performance of the top quarter of herds, whereas the potential losses are £55 per cow for a herd within the worst affected quartile (Kossaibati et al, 1997). In dairy herds in England, it is estimated that the main economic losses are due to mastitis and lameness at 38% and 27% of the total health cost, respectively (Kossaibati and Esslemont, 1997). In the Netherlands lameness in dairy cattle accounts for an estimated loss of 4% to 5% of a typical dairy farm income (Enting et al, 1997). Digital disease in dairy cattle in Quebec has been estimated to cost $10 million (Can.) annually (Choquette-Levy et al, 1985).

Lameness is also associated with reduced milk production. A lame cow, if left untreated, may decline in body condition because of its inability to feed normally. A review of the published literature on the effects of disease on milk production found that across the lactation, loss estimates averaged 80 to 350 kg of milk (Fourichon et al, 1999). The effects of foot lesions on milk production are most pronounced in mid- to late-lactation stages (Boulon et al, 1996). In studies in the United Kingdom, cows lame during the summer months lie down for longer than normal periods and spent less time eating (Hassall et al, 1993). Cows also grazed more slowly as measured by the bite rate. Affected cows lose weight, come into milking parlour later, and may be more restless when being milked. During the winter months, lame cows lie down for longer periods in the cubicles (Singh et al, 1993a). They may also stand or lie in unusual postures in an attempt to alleviate discomfort.

Lameness may also reduce the expression of estrus, thus affecting reproductive performance, which increases the risk of early culling. Lameness can prolong the interval from calving to first service and the interval from first service to conception (Barkema et al, 1994). Dairy cows with a lameness score greater than 2, based on a 5-point lameness scoring system, may have an extended interval from calving to first service and to conception, spend more days in the breeding herd, require more services per pregnancy, and be 8.4 times more likely to be culled (Sprecher et al, 1997).

Frequency of Lesions that Cause Lameness in Dairy Cattle

There has been a notable lack of basic and applied research on lameness in cattle. Consequently, there is insufficient reliable literature on the subject. One major problem has been the lack of a consistent nomenclature with which to describe the several different lesions of the feet of cattle. There is now international agreement on the nomenclature of the diseases of the ruminant digit, which should improve communications and understanding of the literature on the subject (Weaver et al, 1981).

The most common causes of lameness in dairy cattle are due to diseases of the claws. In a survey of 37 dairy farms, in four regions in England and Wales, data on 8991 lesions and the preventive trimming of 4837 cows' feet were tabulated (Murray et al, 1996). Lesions in the hindfeet accounted for 92% of lameness, of which 65% were in the outer claw, 20% in the skin, and 14% in the inner claw. Sole ulcers (40%) and white line disease (29%) were the predominant diseases of the horn, and digital dermatitis (40%) was the most common disease of the skin. The laminitis-related diseases of the claw (sole ulcers and white line disease) account for about 70% of the lesions, and digital dermatitis accounts for about 30% of the acute lameness. Similar frequencies of claw lesions have been found in dairy herds in the United States (Bergsten et al, 1998). In a survey of lameness in dairy herds in Israel, the most prevalent lesions were solar hemorrhages averaging 28.6% and white line separation at 26.7% (Bargai and Levin, 1993a,b). These two lesions are considered to be sequelae to subclinical laminitis.

Diseases of the Feet

Lesions of the Sole and Bulb Horn. Sole and bulb lesions are the most common causes of lameness.

Sole hemorrhages of different sizes and severity appear in the surface of the sole as the result of lesions originating in the corium. At the normal rate of growth of the horn, two to three months are required before the hemorrhages become visible at the surface of the sole. The hemorrhages are

Downloaded From Vet-eBooks.com

considered to be retrospective evidence of laminitis. Slight hemorrhages usually regress spontaneously. More severe hemorrhages in the corium develop into a double sole, sole ulcer, white line disease, or underruning of the heel.

Sole ulcer is a circumscribed defect of the sole horn continuous with the corium.

White line disease is a lesion of the lamellar horn of the sole, most often in the posterior abaxial wall. It is thought to be derived from a hemorrhage in the laminar corium and is often observed with other hemorrhages in other parts of the surface of the sole. The site of the lesion adjacent to the wall makes the wall less resistant to torsion, abrasion, and load bearing. Thus the incidence of white line disease is higher in animals kept on abrasive floors and in grazing animals that have to walk long distances.

Claw abscess is a local, septic inflammation of the sole corium. It may develop from a secondarily infected double sole, from a sole ulcer, from underrunning of the heel, or from a white line or wall lesion. It may also be due to a traumatic lesion of the sole caused either by a foreign body or by trimming the foot too deeply or by excessive wear.

Heel erosion is a disease characterized by erosion of the heel horn. It may be caused by bacterial infection or physical or chemical agents eroding the heel. Lameness is usually minimal. It is also called *chronic foot rot, underrunning of the sole-heel junction, slurry heel,* or *contagious interdigital dermatitis.*

Lesions of the Digital and Interdigital Epidermis. Most of the diseases of the skin of the bovine digit associated with lameness are infectious, and most are due to bacterial species specific to the digits (Demirkan et al, 2000). Infectious diseases of the skin of the digits of dairy cattle are usually associated with muddy corrals and alleyways.

Digital dermatitis (also termed *Mortellaro disease, papillomatous digital dermatitis* or *hairy warts*) was first described in Italy and occurs in dairy herds throughout the United Kingdom, Europe, Asia, Africa, Australia, and North America (Demirkan et al, 1999). It has now become one of the most common causes of lameness in dairy cows. The lesions are characterized by a diffuse or circumscribed inflammation of the skin at the coronary margin, commonly occurring at the plantar aspect of the interdigital space just above the cleft and midway between the heel bulbs. Initially there is severe lameness, forcing the cow to walk on its toes. The disease responds well to topical administration of antibiotics. The precise etiology is uncertain, but spirochetes have been found in lesions, and serological evidence of infection with *Borrelia burgdorferi* has been found (Demirkan et al, 1999).

Foul-in-the-foot or *interdigital necrobacillosis (footrot)* is caused by *Fusobacterium necrophorum* usually following injury to the interdigital skin. The characteristic clinical findings are acute lameness, swelling of the coronary band forcing the two claws apart, and a crack in the interdigital skin that exudes a foul-smelling exudate.

Interdigital dermatitis (Dermatitis interdigitalis) is a superficial inflammation of the interdigital skin, most commonly in the plantar commissure (Bergsten, 1995). The disease is most common in poor hygienic conditions in intensively managed dairy herds. The hindfeet are most commonly affected. *Dichelobacter (Bacteroides) nodosus* has been isolated from affected cows. The lesion does not generally cause clinical disease and can be prevented by adequate hygienic measures, the use of local antiseptics, and foot bathing.

Verrucose dermatitis is a chronic proliferative inflammation of the dorsal and/or plantar aspects of the skin in the interdigital space, nearly always occurring in the hindfeet of housed cattle. The lesion appears as a cauliflower-like hyperplasia with a serous, oozing discharge just above the heel bulbs. Only individual cows are affected, and it is rarely a herd problem.

Interdigital hyperplasia is a proliferative reaction of the interdigital skin or subcutaneous tissue localized in the dorsal aspect of the interdigital skin but may extend to the palmar-plantar area. The mass of tissue is continuous with normal interdigital tissue, covered by hairless, thickened integument characteristic of this site. The hyperplastic tissue consists of fibrous connective tissue, some fat and is comparatively avascular. The cause is uncertain. There may be an inherited risk factor. Cattle with a narrow interdigital cleft are more prone to the lesion than in those animals with normal claws. It has been suggested that dirt becomes trapped between the claws, causing interdigital skin irritation and stimulating skin proliferation. Incorrect claw trimming, poor claw conformation, and slippery floors have been identified as potential risk factors. In older animals it may be a sequel to other lesions of the skin of the feet. Surgical correction is necessary.

Pathogenesis of Foot Lesions of Dairy Cattle

The pathogenesis of foot lesions of dairy cattle has been controversial. It is commonly said that lameness in dairy cattle is a multifactorial disease complex. There are some hypotheses. Lesions may result from direct trauma to the feet or from a combination of predisposing factors that have a nutritional or environmental and behavioral basis. Longitudinal studies of lameness in dairy cattle have found that many of the different kinds of lameness interrelate from one lactation to the next (Alban et al, 1996). Foot lesions of dairy cattle may be clinical causing lameness or subclinical with sole lesions only recognizable at trimming. They are thought to be the end result of interactions between multiple risk factors related to the cow or the environment, including factors related to both the housing system (type of floor) and management routines such as feeding and moving cows from the pasture to the milking parlor. Some of the commonly described factors are described here.

Nutritional or Metabolic Factors. A varying degree of laminitis is hypothesized to be the underlying lesion that causes metabolic or noninfectious lesions of the feet, such as sole ulcer, white line disease, heel erosion, and interdigital growths (Greenough and Vermunt, 1991; Enevoldsen et al, 1991a,b). It has been proposed that diffuse, acute, subacute or chronic laminitis precedes these lesions. A primary vascular change in the laminae causes edema and hemorrhage, stagnant hypoxia, and an inadequate supply of nutrients to the keratin-producing cells. Initially, there is toxic damage to the capillary walls. The final result is poor horn quality, followed by deterioration of horn (Bergsten, 1994). The inciting cause is hypothesized to be ruminal acidosis as a result of abnormal rumen fermentation associated with feeding a diet with high level of concentrate and a low level of roughage. The results of some feeding trials have supported the hypothesis, but the results have been controversial and in other feeding trials no effect of diet on the incidence of laminitis was found. In earlier feeding trials the incidence of solar lesions was higher in dairy cattle fed a high-level concentrate and low-level fiber diet than in cows fed a higher level of fiber. Also, the incidence of solar lesions was higher in cows fed a high-level protein diet in early lactation compared with a low-level protein diet. It has been hypothesized that the high protein diet causes an allergenic-histaminic reaction, leading to thrombosis of the laminae and laminitis. However, the hypothesis has not substantiated.

The literature on the predisposing factors of laminitis in cattle has been reviewed (Vermunt and Greenough, 1994). The cause of the disease is not well understood and is considered to have a multifactorial etiology. Considerable evidence suggests that laminitis can be a precursor of

Downloaded From Vet-e-Books.com

the common lesions of the sole and white line, which cause lameness in dairy cattle (Logue, 1995). Lesions of subclinical laminitis can be found in dairy calves 6 to 7 months of age raised outdoors (Vermunt and Greenough, 1995). Sole hemorrhages may be present in 77% of dairy heifers from 13 months of age to 2 months after calving—managed either indoors or in dry lots—and permanent injury to the claws may have already occurred before they reach maturity (Vermunt and Greenough, 1996).

The prevalence of lesions associated with subclinical laminitis in first-lactation cows from herds with high milk production is high, but there is a marked difference in the prevalence among herds. This suggests causative factors may vary among herds (Smilie et al, 1996, 1999).

In at least one study, sudden changes in nutrition, lack of transition in increased protein and carbohydrate levels in the ration, any increase in energy above 17.5 Mcal/kg of feed or in protein above 18%, sudden introduction of orange peels, and others have been associated as nutritional factors associated with subclinical laminitis (Bargai, 1998).

The source of dietary protein to dairy cows from week 3 to week 27 of lactation has no effect on locomotion, lameness, lesion formation, or any other hoof measurement (Offer et al, 1997). Cows were fed either a proprietary protein supplement of animal origin or soybean meal as the protein source in the concentrate. Sole hemorrhages, indicative of subclinical laminitis, were observed throughout the experiment but were most severe at approximately 16 weeks after calving. Levels of heel erosion remained constant. There was no significant effect of treatment on either heel or sole lesion formation.

The influence of diet before and after calving on feed intake, and on production and health of first-calf heifers, with special reference to sole hemorrhages has been examined experimentally (Olsson et al, 1998). Feeding high or low levels of concentrate during the last 2 to 3 weeks before calving had no effect on feed intake after calving; on milk yield, health and fertility; or on scores for udder edema and sole hemorrhages.

If some of these pathogenetic mechanisms are valid, the nutritional factors or practices that predispose to abnormal rumen fermentation need to be explored to determine if they can be prevented or minimized without sacrificing production.

Environmental and Behavioral Factors. Lameness in dairy cattle resulting from lesions of the feet has commonly been associated with environmental factors. The disease is most common in confined dairy cows compared with the lower incidence in cows kept on pasture. Many field observations have suggested an association between the incidence of lameness in mature cows and the quality of the indoor and outdoor walking surfaces. This includes the alleys or paths (cow tracks) that the cows use to walk from the pasture or housing to the milking parlor. Confinement of dairy cows on concrete floors is thought to contribute to the development of lesions of the claw horn and sole. Cows housed in poorly designed cubicles (free stalls) may refuse to lie down in them or lie down for only short periods This increases the total amount of time spent standing on concrete floors, which are unyielding compared with straw-covered wooden stalls of the past. Concrete floors may become eroded with concrete aggregate being exposed, which causes bruising of the soles. New concrete may be injurious because of the excess surface alkali. Slatted floors may cause lameness if the slats are fitted incorrectly or poorly maintained.

Lesions of the feet of dairy cows, such as white line disease, sole penetration, and bruising of the sole have often been associated with cow tracks, which are stony, rutted, and generally unsuitable for cows.

Constant wetness of the feet, as in cows forced to stand in slurry for long periods, probably contributes to infectious diseases of the feet, such as footrot and verrucose dermatitis (Williams et al, 1986). Constant wetting of the interdigital skin allows for propagation of the bacteria responsible for footrot.

Case-control studies in New Zealand have indicated that any management factor causing congestion or crowding of cows in the pathways to and from pasture can increase the incidence of traumatic lesions of the feet. The most influential variables in explaining variation between case and control herds were the average level of maintenance of the path and the degree of patience shown by the farmer in bringing in the cows for milking (Chesterton et al, 1989).

Traumatic flexor tendon injuries in cattle are commonly caused by accidents involving farm machinery (Anderson et al, 1996).

Risk Factors Contributing to Lameness in Dairy Cattle

Most cases of lameness in dairy cattle are due to lesions of the feet; the risk factors associated with lesions of the feet are complex, interrelated, and not well understood. Lameness in dairy cattle may be associated with herd-level or individual-cow-level risk factors. Herd-level factors include nutrition, housing, and flooring, and general management including frequency and adequacy of foot trimming. These variables contribute to differences in lameness among herds of dairy cows. Individual-cow factors include age, stage of lactation, breed, and season of the year. Other potential factors include body weight, body condition score, claw angle, and presence of limb lesions.

Herd-Level Risk Factors. There is a large variation in prevalence of lameness between herds. In some herds, severe claw disorders may be present whereas in other herds almost none may occur. The management routine for each herd is unique, which may account for the herd effect (Vaarst et al, 1998). Some of the herd-level risk factors can be considered.

Farmer's Knowledge Of Lameness. The attitudes and practices of dairy farmers can have a profound effect on the health and productivity of the herd. In a survey of 15 dairy farms in England, the prevalence of lameness was highly correlated and inversely with the knowledge, level of training, and awareness of the producers (Mill and Ward. 1994). Veterinarians evaluated the prevalence of lameness over a period of 8 weeks, and the farmer's knowledge of cattle lameness was assessed during that period. Factors evaluated included significance of lameness; economic importance; perception of risk factors; recognition of lameness; attitude toward treatment of lameness; prevention of lameness; and relationship between cubicle design, comfort, and lameness. The level of knowledge of lameness was low on farms with a high prevalence lameness; conversely, the prevalence of lameness was lowest on the farms in which the farmer had a high level of knowledge of lameness. This indicates a need for the promotion of educational programs designed to improve the farmer's level of knowledge about lameness.

Ratio of Concentrate to Fiber in the Ration. Feeding excessive quantities of energy relative to the requirements for milk production during the first several weeks of lactation has been associated with an increased incidence of lameness and foot lesions and with varying degrees of laminitis (Manson and Leaver, 1989). In one study of 30 first-lactation cows on a dietary energy intake 10% to 40% above recommended levels, 17 developed chronic laminitis with falling milk yield (Moser and Divers, 1987). However, a cause-and-effect relationship between diet and lameness in dairy cattle has not been substantiated.

Downloaded From Vet-eBooks.com

Cow Comfort and Quality of Indoor and Outdoor Walking Surfaces. Field observations suggest that abrasive concrete floors, particularly new concrete in new barns, some slatted concrete floors, and "rough" floor surfaces, contribute to traumatic injuries of the soles of dairy cattle (Rowlands et al, 1983).

Case-control studies of dairy herds under loose-housing systems and cubicles (free stalls)—with a high incidence of lameness caused by laminitis, leading to sole ulceration in replacement first-lactation heifers—found that in the problem herds, the heifers and cows *stood for significantly longer periods* than did herds with a lower incidence. A greater percentage of the heifers did not use the cubicles. The main difference between the management of the two herds was the amount of straw being used: one bale per 45 cows daily in the problem herds and one bale per 10 cows daily in herds with a lower incidence of lameness. In cubicles with deep straw, cows were lying down 14 hr/day, whereas in concrete beds with no bedding, cows were lying down for only 7 hr/day.

Laminitis has occurred in dairy heifers that calved in the autumn and that were housed in stalls with concrete floors and fed a high concentrate diet (Bergsten and Frank, 1996a,b). The risk of developing laminitis is high during the periparturient period, and the type of floor appears to be more important than the level of concentrate fed.

The influence of the cleanliness of the stalls of cows on the cleanliness of animals and their hooves, and the effect of cow trainers on the health of hooves, has been examined (Bergsten and Pettersson, 1992). Electric cow trainers reduce the prevalence of heel-erosion in housed dairy cows, and the reduction is related to the cleaner condition of the stalls and the improved condition of the hooves of the cows as a result of the cleaner conditions. Heel erosions are reduced in association with the introduction of a footbath (Bergsten and Herlin, 1996). Heel erosions are absent or rare in the fore hooves of both primiparous and multiparous cows in tie stalls (Bergsten and Herlin, 1996). Cows in cubicles have higher heel horn erosions in their fore hooves than do cows in tie stalls.

Papillomatous digital dermatitis ("Mortellaro's disease") is a major cause of lameness in dairy herds (Read and Walker, 1998). Morbidity may reach 75% within a few months. Epidemiological case-control studies in California dairy herds found that muddiness of corrals was strongly linked to a high prevalence of the disease (Rodriguez-Lainz et al, 1996). In the United Kingdom and Europe, poor foot hygiene has also been associated with the occurrence of the disease in winter-housed cattle (Blowey, 1994). In addition to muddy corrals, the importation of heifer replacements from affected herds is a risk factor (Rodriguez-Laing, 1996). In Chilean dairy herds, cows on farms that bought heifers in the past 10 years had a threefold increase in the odds of the disease compared with those on farms that never bought heifers (Rodriguez-Lainz et al, 1999).

The behavior of dairy cows has been suggested as a possible risk factor in cattle lameness, and lying down is considered an important part of the behaviour of dairy cows. Field observations suggest that in a herd with a high incidence of laminitis and other hoof lesions, the cows and heifers spent longer periods standing than those in a comparable herd with less lameness. Some heifers may stand for long periods and most will become lame. Heifers introduced suddenly to unfamiliar cubicles (free stalls) may spend most of their time standing on concrete floors, which could cause a localized circulatory disturbance and predispose the hoof to sole ulcer (Greenough and Vermunt, 1991). The times spent lying and standing and the frequency of lying have been associated with the incidence of sole lesions (Singh et al, 1993b). It is suggested that in countries that house cows during the winter months, the welfare of cows could be improved by training first-lactation heifers to use cubicles and by providing large well-bedded cubicles.

In small-scale dairy farms in Kenya, the prevalence of lameness was 11.7%, and the most important farm characteristic associated with increased prevalence of lameness and foot lesions was confined housing (Gitau et al, 1996).

Holstein-Friesian cows on pasture need 240 cm × 120 cm lying space and a further 60 cm lunging space for rising (Faull et al, 1996). By these standards of space requirements, 87% of the cubicles in 37 dairy herds were too short and 50% were too wide or too narrow. Over 1500 observations of cows lying down, rising, and standing found that only 12% of the cubicles permitted adequate freedom of movement; 91% of the top partition rails were judged to be too low, and 70% of the bottom rails were too low or too high. The curb was too high in 76% of the cubicles. As a result, 10% of the cows appeared moderately or severely restricted when lying down—33% when rising and 55% when standing. Over 2000 cubicle beds were examined; 75% had a concrete base, and of those, 63% had too little bedding and 11% almost none. The incidence and prevalence of lameness were associated with limited borrowing space (at the side and front of cubicles), low bottom rails, and inadequate bedding. Most of the indoor and outdoor walking surfaces were unsatisfactory. The indoor walking surfaces are concrete and too smooth, and the outdoor walking surfaces are commonly too rough.

The effect of free stall and straw yard housing of the behavior, production, and hoof health of dairy cows has been examined. In straw yards cows spent longer lying down and feeding than did cows in free stalls (Phillips and Schofield, 1994). Cows in free stalls had a reduction in heel depth, which predisposes to lameness. Cows housed in straw yards will spend 10 hours per 24-hour period lying down and ruminating (Singh et al, 1994). The effects of overcrowding on claw health of first-calved Friesian heifers indicate that reduced lying time acts as an exacerbating factor in the development of claw lesions (Leonard et al, 1996).

Lameness may be associated with the type and maintenance of the farm tracks to and from the pasture, the patience of the stockperson in handling, and herd size (Hemsworth et al, 1995). Hematoma of the heel causing lameness in dairy cattle has been attributed to traumatic injury incurred while the cows walked from the pasture to and from the milking parlor when the heel could have injured (Blowey, 1997).

In Australia and New Zealand, foot lameness in dairy cattle is most frequently associated with overworn, bruised soles or stones becoming embedded in the interdigital cleft. The most important environmental factor affecting lameness is the farm track to the pasture. The track should be surfaced with a fine, nonabrasive material to ensure drainage from the center of the track. Cows walking on the track should not be hurried more than necessary; they should be allowed to choose their steps as they move along the track (Chesterton, 1989).

Frequency and Adequacy of Foot Trimming. The undue mechanical pressure on the solar corium that occurs when too much weight is borne by the pedal bone, or when the corium is inadequately supported by the horny sole, predisposes to sole contusions. This is more likely to occur in untrimmed claws and with longer toes as well as where more load bearing is placed on the softer, midsole region. Trimming of hooves reduces the hardness of the heel bulb center. A reduction in the load bearing of the heels because of trimming of the toe length maintains a soft heel bulb that

Downloaded from Vet-eBooks.com

acts as a cushion, spreading the load evenly and absorbing energy (Smit et al, 1986).

The length of the toe is positively correlated with the lameness score. The trimming of hooves can have significant effects on the incidence of lameness in dairy cattle. To maintain a short toe length and steep angle of toe, which appears necessary to reduce lameness, regular trimming is required, at least once per lactation. The best time for trimming seems to be before calving. Using this approach, hoof shape is at its optimum in early lactation, when the incidence of lameness is highest (Manson and Leaver, 1989).

For the details of foot trimming of cattle, the reader is referred to the excellent publication by Toussaint Raven, "Cattle footcare and claw trimming" (1985).

Individual-Cow Risk Factors.

Age and Stage of Lactation. The population at risk in most studies are adult cows, including first-calf heifers. The prevalence of lameness is highest during the first 3 to 4 months of lactation, which coincides with the high level of energy intake and negative energy balance (Rowlands et al, 1985). In Quebec, 66% of lesions appeared during the first 3 months of lactation (Choquette-Levy et al, 1985). The increased incidence of sole hemorrhages and laminitis in periparturient cattle is indirect evidence that events relating specifically to calving are likely to be crucial risk factors (Bergsten and Frank, 1996a,b). Some observations found a strong positive association between 61 and 120 days postpartum and the presence of sole disorders (Vaarst et al, 1998). Claw hemorrhages are uncommon in first-calving heifers 4 weeks before calving, but the extent and severity of hemorrhages increase after housing and calving, with lesions in the white line being most severe at 9 weeks, and in the sole at 14 weeks after calving (Leach et al, 1997). Claw lesions occur commonly in dairy heifers shortly after calving (Whay et al, 1998). It is hypothesized that an initial insult to the corium primarily affects the laminar region and that corium damage increases with the resulting alteration in the physical forces on the sole. Changes in the white line do occur during the first lactation (Kempson and Logue, 1993). Different risk factors for sole disorders in first and later parities have been found, which suggests the importance of distinguishing between the development of sole disorders in first parity and older cows (Vaarst et al, 1998).

Previous Lameness in Affected Cows. Previous treatment for lameness in a cow appears to be a risk factor for acute sole hemorrhage (Vaarst et al, 1998).

Body Weight and Body Condition Score. Body weight and body condition score (BCS) have been associated with clinical lameness in some dairy herds (Wells et al, 1993b). In one survey, each 100-kg increase in body weight was associated with a 1.9-fold increase in the odds of clinical lameness. There was a positive association between prevalent clinical lameness and heavier body weight, lower BCS, and shallower slope of rear lateral claw angle (Wells et al, 1993a,b). A lower BCS was associated strongly with clinical lameness, which may be a result of, rather than a cause of, lameness. Body weight at calving was a significant risk factor for acute hemorrhage in cows from parity 2 upwards; a strong negative association between acute hemorrhage and a body weight more than 50 kg below the herd average (Vaarst et al, 1998).

Growth Rate of Heifer Replacements. The calving heifers at too early an age may contribute to an increased incidence of laminitis and its sequelae. The examination of the hind hooves of dairy heifers from 4 to 24 months of age revealed that subclinical laminitis characterized by sole hemorrhages can occur in the hoof horn of calves as young as 5 months of age. There was evidence of sole hemorrhages deep within the sole 30 to 35 days after calving, which by 70 days postpartum had developed into extensive sole and white line hemorrhages. There was often a deep hemorrhage at the site of sole ulcers. Sole overgrowth was also present in all heifers. Thus subclinical laminitis of varying degrees can be common during the early growing period of young dairy heifers (Greenough and Vermunt, 1991).

Breed and Genetic Predisposition. Breed disposition and genetic composition to lameness have long been of interest to the dairy cattle industry. Dorsal angle claw angle has been used as a repeatable measure of hoof shape with a heritability high enough for genetic change. However, its relationship with lameness or claw abnormalities has not been shown conclusively. Because 70% to 85% of rear foot lesions occur in the lateral claws, an association between these lesions and rear lateral claw angle has been suspected (Wells et al, 1993a,b). Among the conformation type traits that may be correlated genetically to clinical lameness, foot angle, rear legs (rear view), and rump width had strongest associations with clinical lameness (Boettcher et al, 1998).

Control of Lameness in Dairy Cattle. The control of lameness in dairy cattle is empirical based on field observations. A number of guidelines are recommended.

Improved Awareness of the Problem. There is a need to improve the level of knowledge that farmers have about lameness. This includes recognition of lameness, recording of lameness cases, the causes of lameness, early treatment of lameness cases, and the principles of prevention of lameness in dairy cattle (Mill and Ward, 1994; Kossaibati and Esslemont, 1997).

Early Diagnosis and Treatment. To accurately document a herd problem of lameness, the feet of all cows must be examined. To establish an adequate diagnosis and the actual frequency of foot lesions, the foot has to be examined thoroughly. This is ideally done at the time of routine foot trimming. The methods for assessment of lesions of the sole and white line have been described (Leach et al, 1998). All lame cows should be examined and treated as soon as possible. Isolation in a well-bedded hospital pen for several days may be necessary. A record of each lame cow and the diagnosis should be kept. Details for the treatment of specific diseases of the feet are available in other textbooks such as "Lameness in cattle" (Greenough, 1997).

Cubicle Design and Bedding. Cubicles or free stalls must be designed to meet the requirements of the cows in the herd. Cubicles must be of the correct design so they do not cause injury. The design specifications were presented earlier in this chapter. *Unnecessary prolonged weight-bearing by the feet and trauma to the feet must be reduced. Cows must be provided with comfortable places for lying down for up to 12 hours/day.*

There must be a sufficient number of free stalls for all cows to lie down at the same time. Training animals to use the free stalls is important. Heifers that have been reared in free stalls adapt more quickly when they join the main herd. Heifers often find it difficult to adapt to the main herd because of the stress of parturition, aggressive behavior of other animals, and dramatic changes in feeding behavior. If they are exposed to a new and uncomfortable environment, they may spend excessive periods standing and thus develop lameness.

The bedding used in free stalls must be comfortable, clean, and well maintained. The bases of cubicles must be kept clean and dry by scraping out manure at least twice daily and renewing the bedding as necessary. Many different materials have been used as bedding including earth, sand, sawdust, shavings, fabricate cows mats, and used tires. Chopped straw or sawdust is commonly used as bedding in the United Kingdom. It is suggested that mats or mattresses provide more comfort (Kossaibati and Esslemont, 1997). Some studies have found that cows do show a preference for

Downloaded from Vet-e-Books.com

lying on certain materials such as mats and sawdust (O'Connell and Meaney, 1997). The important principles are that the bedding must be soft and comfortable and easy to keep clean.

Indoor and Outdoor Walking Surfaces. The floor surfaces of the indoor alleyways between the rows of cubicles are usually made of concrete, which may be too smooth or too rough. The frequent scraping of the alleyways often produces a very smooth surface, making it slippery and insecure for cows (Faull et al, 1996). When walking on smooth surfaces, cows may have a shuffling gait that may affect the type of wear on the sole and white lines and increase the duration of contact. Concrete alleyway surfaces should have a good grip without coarse projections. This requires mechanical tamping when the concrete is being poured to ensure that the aggregate is sufficiently covered by "fines" and provides a satisfactory surface. Exposed aggregate made from hard, sharp-edged stone creates an unfriendly surface and an unsuitable material for walking.

Outdoor cow tracks from the milking parlor to the pasture must not be hard or rough. Cow tracks should be made from soft materials such as wood chips or grass lanes without stones and other hard substances. Dairy cows show a marked preference for soft bark walkways as opposed to concrete or stone tracks. The walkways are constructed by excavating the ground to a depth of 0.5 m and a width of 1.0 m. The trench is filled with a specialized geotextile membrane, as used in road construction, and a drainage pipe is run along the base. This is surrounded by stone aggregate, with fine stone towards the surface, and covered by a second reinforced geotextile membrane. Finally, 50 to 100 mm of cundy peelings, a type of bark chipping, are placed on the surface. The improved comfort causes a marked increase in the speed of walking (Blowey, 1997). Specific track designs made from tough, synthetic, nonwoven fabric are now available for construction of cow tracks.

Emphasis should be placed on maintenance of the surface of cow tracks and on the patient handling of animals before and during milking; these are high-priority strategies in which changes could reduce lameness in severely affected herds (Chesterton et al, 1989).

The walking surfaces adjacent to feeding areas, watering areas, and gateways need to be maintained with adequate drainage and scraped clean of stones and other hard loose objects.

Inspection of the housing facilities can be performed, and recommendations and improvements can be made. Cow comfort can be improved and the incidence of lameness decreased (Goodger et al, 1996).

Sanitation. Floor surfaces and alleyways must be cleaned as necessary to remove collections of urine, water, and manure that contribute to constant wetting of the feet.

Foot Bath. Foot baths containing formaldehyde or copper sulfate solution have often been advocated to control foot disease in cattle (Davies, 1982), but this recommendation is empirical. No documented information exists on the effectiveness of footbaths for the control of diseases of the feet of cattle. The regular use of a footbath has been recommended in herds with a high incidence of interdigital disease, heel erosion, and sole ulceration. With a footbath containing 1% formalin (1 part formalin:39 parts of water), the cows can be walked through the bath after each of four successive milkings; this process is repeated weekly (Davies, 1982). However, results have been variable, perhaps because of the accumulation of excessive amounts of feces on the feet of the animals. This results in contamination of the footbath, rendering the solution ineffective. Another reason may be that the lesions are not caused primarily by infectious agents. It appears logical that, for maximum effect in problem herds, the feet of the animals should be cleaned with a pressurized spray of water before the animals are walked through the foot bath.

Papillomatous digital dermatitis is most effectively treated with topical application of an oxytetracycline solution on a individual cow basis (Hernandez et al, 1999). Lincomycin hydrochloride solution used as a topic spray daily for several consecutive days is also successful (Shearer, 1998).

Footbaths should be located in a passageway 1.0 to 1.2 m wide on the return route from the milking parlor. It is useful to have two baths in series, the first containing water to wash the feet and the second to reduce contamination of the astringent. The specifications for a footbath are at least 300 cm long, 100 cm wide at the top, 60 cm wide at the bottom, 30 cm deep, sloping ends, nonslip surface, solution depth of 17 cm, and the exit area sloping back to the bath. Adherence to these specifications reduces the amount of solution used, reduces the loss of solution, and allows emptying the footbath with a brush. It should open onto a large, clean area to prevent immediate recontamination of feet with feces. Astringent chemical solutions of either 5% copper sulfate or 5% formalin should not be used more than twice a week, even for herds with soft feet. Use should be even less frequent as the feet harden. The skin of the coronary band and the soft tissues of the claw should be monitored in representative cows for evidence of chemical injury.

Regular Foot Trimming. Surveys have found that only about 20% of healthy dairy cows have their feet trimmed regularly.

The feet of all cows should be examined and trimmed (if necessary) at least once annually. The claws of the hind feet of housed cattle should be examined and trimmed midway through the housing period. Underrunning of the bulbar horn (erosion ungulae) and pododermatitis circumscripta (Rusterholz sole ulcer) are more common in housed cattle and can be controlled by preventive hoof trimming (Andersson and Lundstrom, 1981). Commercial foot trimmers are now becoming popular. They visit the farm with a hydraulic trimming table and foot trimming instruments and trim the feet of all cattle in the herd during one visit. Veterinarians can also supply this type of service as part of a health management program. However, some field trials have indicated that routine foot trimming alone does not significantly reduce lameness (Arkins and Hannan, 1982). More field research is needed on this subject.

Balanced Ration. The diet of high-producing dairy cows should be balanced with the inclusion of sufficient fiber to minimize rumen fermentation disorders.

Nutritional Management For Replacement Heifers. The ration for replacement females should be managed to optimize the growth rate.

Monitoring Lameness and Its Risk Factors

Because of the multifactorial causes of diseases of the feet, especially the pathogenesis of laminitis and its sequelae, the problem of lameness in the field needs to be examined using an epidemiological approach. With information from computerized health management databases, it is possible to study the characteristics and predisposing factors for a large number of lameness cases. Several identifiable variables can be evaluated simultaneously (Box 12-1).

It is clear that lameness in cattle is a complex subject. A detailed description of individual lameness conditions and the predisposing factors has been published (Greenough, 1997). It is also clear that management of the cows' environment can have a substantial impact on the occurrence and

Downloaded from Vet-eBooks.com

BOX 12-1

Characteristics and Predisposing Factors for Lameness

- Seasonal effects
- Type of housing (loose housing versus tie stalls); design of free stalls
- Quality of the floor: concrete floors, slatted floors, stony tracks
- High-energy, low-fiber diets in early lactation
- Handling of cattle at milking time or at other times when they are being crowded
- Lack of exercise during winter housing, causing circulatory stasis in the foot
- Prolonged wet conditions, which affect horn quality
- Inadequate foot trimming
- Unhygienic conditions, which cause irritation and contamination of the skin tissues of the feet
- Overgrown feet, in which excessive horn is prone to erosion

severity of lameness in dairy herds. Veterinarians involved in dairy health management programs should be familiar with epidemiological associations between the environment and lameness. The evaluation of records on the incidence of lameness and an assessment of environmental and nutritional influences should be incorporated into the health management program.

Internal Parasitism

An important environmental management challenge as part of dairy herd health programs is the control of internal parasites. Veterinarians involved in dairy health management should have the necessary depth of knowledge about the elements that must be addressed in crucial decisions on worm control. It requires a good understanding of the epidemiology and biology of the parasites, the influence of seasonal conditions, the effectiveness and limitations of available drugs, and the costs and benefits of various control strategies. This information should be considered in context with the nature of the individual farm and its management.

It is not unusual for health management advisors to have a blanket recommendation on parasite control for all herds. However, no single recommendation applies to every farm; each herd must be evaluated individually. A customized worm control program should be devised for each farm. It should be based on the practitioner's general knowledge of internal parasitism and on information on the farm's management, grazing history, and seasonal conditions. The practitioner should also consider each age group of cattle separately and provide specific control programs for adult cows, replacement heifers, and calves (Herd, 1991).

There are two key issues that determine parasite infection levels and ultimately dictate the design of an effective and prophylactic parasite control program. First, it is important to determine the parasite immune status of each group of cattle. Second, the likely degree of pasture infectivity and potential exposure to internal parasites are also important. Information on these two issues requires an ongoing knowledge of the individual farm. In addition, the results of appropriate quantitative laboratory techniques are useful, as long as the results are interpreted in relation to the herd's history and management.

Factors Affecting Parasite Infection Levels

Immune Status. Adult dairy cattle on a sound nutritional program usually have a high degree of acquired immunity to internal parasites. Laboratory evidence indicates a low level of worms per animal (<3000) and low mean fecal egg counts (<10 eggs/g). Dairy cows may exhibit a slight periparturient depression of immunity to worms. Fecal egg counts may rise slightly, from a mean of about 5 eggs/g to about 20 eggs/g after calving. This increase is usually epidemiologically insignificant. Cattle younger than 2 years of age may have little immunity to worms. Large worm burdens (>100,000) and high fecal egg counts (>100 eggs/g) often occur. These levels of infection are associated with significant losses in growth rate and even with mortality.

It is not uncommon for a whole group to fail to develop adequate immunity to worms because of lack of exposure. This includes dairy cattle that have been raised in confinement, in arid regions, or in drought conditions during which infective larvae failed to survive in pastures. These cattle are later susceptible to worms if moved to a contaminated pasture. Animals that were once strongly immune can lose immunity to worms through poor nutrition, concurrent disease conditions, or lack of exposure. Cattle that lose their immunity can exhibit high fecal egg counts and represent a serious source of pasture contamination.

Dairy replacement heifers during their first year of grazing are usually susceptible to worms. In addition, they are likely to be exposed to significant pasture contamination if they are grazing pastures that were previously occupied by similar batches of calves.

Pasture Infectivity. Housing and climate strongly affect the epidemiology of worm parasites in dairy cattle. Because pastures perpetuate parasites, the greatest risk of infection occurs in nonimmune cattle on pasture. In contrast, cattle housed continually in confinement are rarely exposed to parasitic larvae, except for *Nematodirus* and *Strongyloides* sp.

The degree of pasture infectivity is strongly influenced by the previous grazing of a pasture. Young, untreated, nonimmune animals cause the greatest pasture contamination with worm eggs. The degree of infectivity of a pasture is also strongly influenced by seasonal environmental conditions. Warm, wet conditions favor hatching, development, and migration of infective larvae from feces to pasture. Drought conditions enhance larval mortality.

Once a pasture becomes highly infective, the larvae survive long periods and pose a threat to all grazing animals. In the northern United States and Canada, larvae commonly survive until late spring of the year after hatchings. In the southern United States, larvae survive well through the autumn, winter, and spring. However, they do not survive in high summer temperatures. Pasture and manure management can have a significant impact on the level of inactivity.

A review of the literature suggests that *Ostertagia ostertagi* appears to be the most prevalent parasite among adult dairy cattle in temperate regions of the world. *Trichostrongylus axei* and *Cooperia* sp. are frequent isolates associated with ostertagiasis (Bauck, 1991). Abomasal worm burdens are present in a high percentage of adult cows, and some cows may have relatively high levels. There is a seasonal pattern of inhibition of *O. ostertagi*. The seasonal inhibition is moderated somewhat by age-related immunity. However, it is nonetheless essentially the same in adult animals as in yearlings. Fecal egg counts in cows are generally low throughout the year. However, there is a rise in fecal egg counts associated with parturition, suggesting a reduction in host immunity at this time. If calving coincides with seasonal resumption of development of inhibited *O. ostertagi*, the rise in fecal egg counts may be substantial and indicative of a significant infection (Michel et al, 1979).

Relationship of Parasitism to Performance and Anthelmintic Treatment

The effect of subclinical parasitism on milk production in dairy cows is highly controversial. There is no definitive evidence that low worm burdens in immune cows cause a reduction in milk production. However, a review of studies published on the effects of anthelmintic treatment of dairy cows has revealed extreme disparity in the results of benefits in milk production (Bauck, 1991). Most publications almost invariably begin with a statement such as "deworming of dairy cattle with various anthelmintic treatments in different geographical regions has had inconsistent effects on milk production. Some reports show deworming increases milk production, whereas others show a decrease or no change in milk production" (Block et al, 1987).

The results of more than 80 experiments on gastrointestinal parasitism and effect of anthelmintic treatment on milk production in dairy cattle have been reviewed (Gross et al, 1999). Abattoir surveys of culled dairy cows, fecal egg counts in milking cows, and serological tests and worm counts in cull cows in milk production studies were collated to assess the level of parasitism in dairy herds. The studies were divided into four general categories: induced infections in previously uninfected cattle; naturally infected cattle treated in mid-lactation; naturally infected cattle treated one to three times during the dry period and/or just before or after parturition; and naturally infected cattle treated repeatedly from early lactation or given strategic treatments throughout the year. In most studies, the milk production of anthelmintic-treated cattle was compared with that of untreated animals. The anthelmintics used included members of the organophosphate, benzimidazole, imidazothiazole, and macrocyclic lactone groups. Overall, the studies found that grazing dairy cattle are likely to be infected with gastrointestinal nematode parasites, usually *O. ostertagi* and *Cooperia* sp. These infections may be present as inhibited larvae, and a periparturient or spring rise is associated with their emergence. There is, at present, no reliable means of determining if a cow or herd is parasitized subclinically at a level sufficient to interfere with milk production. In 80% of trials, there was an increase in milk production after anthelmintic treatment, with a median increase of 0.63 kg/day. In each of four categories, a majority of the studies showed that anthelmintic treatment increased milk production (Gross et al, 1999).

There are many difficulties in the interpretation of the data from the published studies. There are often highly significant between-farm and within-farm factors responsible for differences in milk production, irrespective of any treatment response. There is marked inherent variability in milk production among cows. It is affected by a host of variables, including genetics, nutrition, and environment. In addition, there has been little consistency in the protocols used for the evaluation of treatment effects. The timing and frequency of treatment, cattle management practices, and the response variables measured were considerably different from study to study.

The predominant finding in the literature is that the effects of anthelmintic treatment are greatest in the periparturient period. Milk yield in postcalving dairy cows is closely correlated with energy balance. In addition, the body condition of cows at calving may also be a determining factor in subsequent milk yield, because body fat reserves represent a source of energy for the lactating cow. There is evidence that parasitism in livestock can affect both feed intake and the efficiency of nutrient utilization. It follows that parasitism before and at the time of calving can lead to reduced milk yield (Bauck, 1991). Experimental parasite infections of dairy cattle at parturition and in midlactation have indicated that the effect of parasitism on milk yield ıt significant in the first 100 days of lactation (Barge ibbs, 1981). Many studies have evaluated the effect of parasitic treatment at the time of parturition on subsequent milk yield. Although a negative response or no effect is reported in some experiments, the majority of studies have indicated a positive effect. However, the factors that determine which cows and herds have the most significant benefit remain difficult to determine.

A further difficulty in interpreting the results of clinical trials is the effect of treatment against inhibited *O. ostertagi*. Compounds with little or no activity against this component of the worm burden at certain times of the year could allow subsequent development of these inhibited larvae at some time after calving. Thus the expected increase in milk production for these treated animals would not occur. In one study that evaluated the effects of treatment with ivermectin during the dry period, the level of *O. ostertagi* antibodies measured at the end of the previous grazing season was correlated with the magnitude of the response to treatments (Ploeger et al, 1989). In this experiment higher-producing cows had a greater treatment response, the response was highest in early lactation, and the improvement was most notable during the season when a large portion of the worm burden of calving cows should have inhibited *O. ostertagi* larvae. Treatment with an appropriate anthelmintic at dryoff appears to show great promise, and further research is indicated.

Monitoring Internal Parasite Levels in Dairy Herds

As has been emphasized repeatedly in this text that monitoring performance, and factors that affect it, is the key to an effective health management program. With respect to internal parasitism, it is important to monitor the degree of immunity to worms and the severity of pasture contamination (Herd, 1991). It is also important to monitor the incidence of clinical and subclinical parasitism. These parameters should be assessed in context with the monitoring of productivity and growth, as well as the incidence of other diseases. Based on the results of these monitoring methods, a farm-specific parasite control program can be developed.

One research study has indicated that determination of fecal egg counts, performed and interpreted correctly, is a valuable monitoring tool for assessing immune status and the degree of pasture contamination (Herd, 1991). When considered in relation to the history and management of the farm, fecal egg counts also provide an ongoing indicator of the success of the worm control program. The efficacy of the drugs used and the need for any changes to ensure low pasture contamination can be determined. Feces should be monitored by an appropriate quantitative fecal flotation technique (Herd, 1991). Individual fecal samples should be taken at critical periods from an appropriate number of randomly selected animals in each age group. The number of animals to be sampled depends on the size of the group, and this can be calculated (Martin et al, 1987). A wide variation in counts from the samples from one herd, however, indicates the need to sample a larger group of animals. It should be emphasized that nonquantitative fecal flotation techniques have little diagnostic value in dairy cattle.

Fecal samples taken on the day of treatment can be used to assess whether the previous treatment was successful in suppressing fecal egg counts for the full interval between treatments. Fecal egg counts are also useful before cattle are moved to a new pasture. If the counts are high, the cattle should be treated to ensure that little contamination is carried into the new pasture. In this way, clean cattle going into a safe pasture may be protected for months instead of only

Downloaded From Vet-eBooks.com

for a few days. Adult cattle require fewer egg count determinations than young cattle because of acquired immunity to worms. However, a suspected loss of immunity can be detected early by a rise in egg counts.

Control of Internal Parasitism in Adult Dairy Cattle

An internal parasite control program should be planned for the specific needs of each farm. Also, different age groups have different control needs. The specific details of parasite control in replacement heifers are discussed in Chapter 9. This is an important aspect of heifer health management. Much less is known about designing and monitoring a parasite control program for adult dairy cattle.

The use of pasture as a nutritional source is becoming infrequent in dairy production systems in North America in contrast with Australia, New Zealand, and some regions of Europe. However, it is common to use a small, grassy area (1 to 5 hectares) as a summer exercise area and dry lot. This area is used continuously year after year. There is considerable potential for parasite infectivity to develop in this small field. Thus the need for a parasite control program in the adult herd should not be dismissed.

Important considerations in determining the nature of a control program should be the results of quantitative fecal egg counts, the production performance, and the management system. Fecal egg counts should be interpreted in the context of levels indicative of good immunity and low pasture infectivity. Counts that deviate from an expected pattern may indicate a need to consider management changes or a prophylactic anthelmintic program. Based on the available literature, the use of ivermectin at dryoff shows considerable promise as a control program (Ploeger et al, 1989). More research is needed, and label withdrawal criteria must be followed. Alternatively, deworming at parturition has been effective in a number of studies (Block et al, 1987; Fetrow et al, 1985). It may be appropriate for practitioners to conduct within-farm or within-practice efficacy evaluations to determine the most suitable approach. With the use of computerized herd data management programs, cohort or case-control analysis is straightforward. As well as an anthelmintic program, steps to alter the environment to reduce pasture infectivity should be taken (Herd, 1991).

Control of Flies In and Around Dairy Barns

Changes in animal production systems often favor fly populations. This is usually the unplanned result when the problem of fly propagation is not considered during the design of facilities that enhance the efficiency of production.

Fly control measures must evolve to accommodate changing animal production and housing practices. The species of flies, their relative abundance, and the success of fly control measures are affected by animal husbandry practices, especially housing and manure-handling systems. A multimethod management program is necessary to provide a rational approach to fly control. This involves a mixture of cultural, biological, and chemical control measures adapted to the production system. In order to use this approach, considerable knowledge about the fly species, their biology and behavior, their parasites and predators, manure management techniques, insecticides, and insecticide application methods is required (Axtell, 1986).

Cultural Methods. Cultural control of fly populations is basically the manipulation of the abiotic factors that suppress fly numbers. In other words, this means proper management of manure, feeds, and facilities. Removal of the manure frequently and thoroughly, or keeping it dry, reduces the habitat for fly larval development. The prevention of feed spoilage and keeping the feeds dry reduce habitats for fly breeding. Spillage around the bases of silos and feed bunks, improperly covered silage, and unprotected hay bales are all prolific fly breeding sites when there is sufficient moisture.

Preventing moisture in the potential fly breeding areas is the critical cultural factor in fly control. Watering areas are a potential source of moisture if those systems are poorly designed or maintained. Concrete aprons around feed bunkers and waterers encourage runoff, simplify cleaning, and lessen fly breeding.

Ventilation and airflow in animal housing affect the rate of evaporation. This may be a critical factor in producing sufficient drying to suppress fly breeding. Housing a large number of cattle in a confined space contributes substantial moisture to the air. Without proper ventilation and airflow, ideal habitats for adult fly survival and moist fly breeding media are created. On the other hand, the compactness of manure affects the amount of fly breeding. Trampling and compacting the manure and bedding in a pen with high animal density render the habitat poorly suited for fly breeding. Compacting and covering manure piled for storage also reduce fly populations. Housefly populations are reduced by the excessive dilution of manure with water. This concept is used in outdoor waste lagoons in conjunction with flushing systems for manure removal in free-stall dairy housing.

Biological Methods. In dairy production systems with prolonged accumulations of manure, a diverse fauna of arthropods develops. Among these are species of mites and beetles that prey on fly eggs and larvae. Also, there are a number of species of parasite that develop in the fly pupae and, as a result, kill the flies. The maximum benefit from predators and parasites is achieved with dry manure. In very wet manure, predators cannot move about effectively to find and consume the fly eggs and larvae. Therefore the cultural practices designed to promote manure drying in order to reduce fly breeding at the same time encourage predators and parasites of immature stages of the flies. Manure removal schedules should be staggered so that the predator and parasite populations are not decimated. Chemicals for fly control should be used selectively to preserve the predator and parasite populations.

Chemical Methods. After maximum effort to suppress fly numbers by proper cultural and biological methods, there is still often a need for use of insecticides to achieve the degree of fly control desired. The most effective insecticide use is in an integrated control program in conjunction with cultural and biological methods. If fly suppression by these methods is maximized, then the effectiveness of the insecticide treatments is enhanced. The rate of development of fly resistance to the chemicals is also reduced.

There are two general methods of controlling fly populations by the use of insecticides. Chemicals used as adulticides are available as baits, surface sprays, and mists. Larvicides can be used for spraying breeding sites and as feed additives. Baits consist of an insecticide mixed with some attractive substance, such as sugar. Surface sprays applied to the walls and ceilings of buildings are designed to provide a long-lasting toxic surface where flies rest. Adult fly control can also be attempted with the use of mists. This provides temporary control, because only the adults exposed at the time of the application are killed. Misting is most effective when ventilation is limited.

Larviciding the manure or other fly breeding sites is accomplished with the same types of equipment used for residual surface sprays. A coarse spray and high volume are required. However, larvicidal treatment may be a useful adjunct to other control methods. Larviciding can also be accomplished by incorporating an insecticide into the feed of

Downloaded From Vet-e-Books.com

the animals. However, few insecticides are registered for this purpose.

Any insecticides that are used as part of a fly control program must be labelled and registered for their intended use. Extreme caution should be exercised in dairy facilities to be sure that only approved insecticides are used and label instructions and restrictions are followed. Another factor is resistance of flies to insecticides. Resistance to new insecticides after they are in widespread use has developed rapidly among fly populations, especially the housefly. Many standard insecticides formerly used for fly control are no longer effective. Reliance only on the use of insecticides seldom provides a satisfactory control program. The use of insecticides should be in conjunction with maximizing the cultural and biological measures of control.

Monitoring Fly Populations. In order to design and evaluate a fly control program, some method of monitoring the adult fly population in and around a dairy production facility is needed. Systematic monitoring provides a measure of the success or failure of control methods. It also serves as an early warning system so that changes can be initiated before populations increase wildly. Casual, subjective observations of fly numbers can be misleading. Systematic monitoring is an objective and reliable component of an integrated fly control program. Methods for monitoring populations of adult flies include fly grids, resting counts, sticky fly ribbons, baited jug traps, and spot cards. These methods are primarily used to obtain a measure of the number of houseflies in a facility. It is also important to monitor for fly larvae and pupae to determine specifically where the flies are developing.

Specific Fly Control Measures for Dairy Herds. Dairy cattle facilities have several potential major fly breeding areas. The relative importance of each area on a specific farm depends on the facilities and management used. Specific fly control measures are aimed at dealing with these fly-breeding areas. The most important fly control measures are summarized in Box 12-2.

BOX 12-2

Fly Control Measures

Clean maternity stalls, calf pens, and hutches frequently.
Because the life cycle of the housefly is 7 to 10 days, weekly cleaning can drastically reduce fly propagation.
Move calf hutches frequently. This allows the ground to dry out and limits fly breeding.
Enclose the space under bunk feeders. This prevents spilled feed from accumulating in this area.
Provide curbs and a concrete surface in the loafing area.
Clean stanchions and gutters frequently.
Scrape and clean the loafing area frequently.
Provide a concrete apron around feed bunks and waterers.
Provide a sloped and curbed concrete area for loading the manure spreader.
Cut the vegetation adjacent to manure pads.
Provide concrete channels and a settling basin for runoff water.
Keep the manure and runoff lagoon free of debris and floating solids. Do not overload the lagoon.
Clean up spilled feed on a weekly basis.
Use shelters over the feed bunkers.
Cover and store hay bales on a sloped concrete surface or on raised pallets.
Cover and seal the edges of horizontal silage silos and silage piles.
Clean around the base of tower silos and provide good drainage.
Use window screens on the milk house and milking parlor.
Use residual insecticide spray on the buildings and adjacent vegetation.
Monitor fly populations with fly bait stations.
Employ a misting program for adult fly control, as needed.

Behavioral Disorders

The behavior of dairy cattle has been reviewed (Arave and Albright, 1981). In one study the daily pattern of behavior and duration of various activities of confined cows appeared similar to the pattern and duration of activities in field-grazed and partially confined cattle (Hedlund and Rolls, 1977). Study of the behavior of dairy cows during a 24-hour period can help determine the requirements of a housing facility. The total amount of time lying down during a 24-hour period averaged 11 hours (range, 9 to 13 hours) on pasture, 11 to 11.5 hours for loose or free-stall housing, and 12 hours for stanchion stalls. Observations of dairy cows in total confinement revealed that, during 15 hours of daytime, they spent an average of 45% of the time lying down, 26% eating, 22% ruminating, 1% drinking, and 2% socializing (Hedlund and Rolls, 1977). Periods of eating, drinking, and social activity are most intense during and shortly after the morning and afternoon milking and feeding times. Conversely, periods of greatest recumbency, rumination, and rest occurred between feeding times, from midday to late afternoon.

These observations indicate that cows spend about 50% of a 24-hour day lying down. This emphasizes the importance of comfortable stalls, regardless of the system used. Cattle ruminate a total of 4 to 9 hours daily, in 15- to 20-minute periods. A large proportion (65% to 80%) of this time is spent in the recumbent position. Active sleep occurs in the cow only when she is lying down.

There is a close relationship among environment, behavior, performance, and disease (Collis et al, 1980). There is little information available concerning the diagnosis, prevention, and treatment of primary behavior disorders of dairy cattle, including behavioral causes of clinical disease and suboptimum performance. However, the major behavioral disorders of dairy cattle have been reviewed (Luescher et al, 1989). It should be emphasized that further study is needed in this area, and that the individual animal approach is ill suited for dealing with the behavioral problems of farm livestock. An epidemiological approach is necessary for these investigations. At the practical level, problems have to be dealt with on a herd basis. The behavioral problems of dairy cattle can be categorized based on their economic impact, even though exact figures regarding their prevalence and economic significance are largely unavailable.

Behavior Problems with Direct Economic Impact

Teat Sucking in Dairy Cows. This undesirable behavior may be displayed either by a cow sucking the teats of another cow or, more seldom, by a cow sucking her own teats. It leads to obvious economic loss. One report suggested that up to 50% of herds may be affected (Grommers, 1979). However, the general prevalence is assumed to be much lower than this figure. Cows within a herd form steady pairs for unidirectional or mutual sucking. This behavior may derive from intersucking in calves and may be related to housing conditions. It has also been associated with tongue rolling. Preliminary recommendations for prevention in-

Downloaded from Vet-eBooks.com

clude the early separation of calves from their dam, feeding calves using nipple drinkers, and avoiding grouping calves together until well after weaning.

Behavior Contributing to Teat Injury and Mastitis or Both. Housing conditions are an important causative factor for environmental mastitis (Klastrup et al, 1987). This relationship is largely because of the influence on cow behavior. Poorly designed tether systems and stalls that prevent cows from rising and lying down normally promote teat injury. Stalls that are too short may force the cows to lie on the edge of the stall and thus exert pressure on the udder. Poor freestall design can have similar effects. Other factors, such as stalls that are too narrow or allow too much freedom of movement, the lack of partitions between cows, and any factors hampering rising and lying down (such as slippery floors), may contribute significantly to the occurrence of teat injury on the neighboring cow and thus can lead to an increased risk of mastitis. Lying on bare or dirty concrete flooring is contrary to the cow species' typical preference. Lack of bedding in the lying area increases the risk of mastitis. (Unless an appropriate housing environment is provided, and behavioral changes occur, these problems can be long standing.)

Behavioral Causes of Injuries. Injuries to the brisket, carpal joints, hocks, stifles, hips, claws, and udder are far too common in modern dairy housing. In some herds these injuries occur in a high percentage of animals on the same anatomic location. This suggests that the cows' ability to adapt behaviorally to the housing conditions has been exceeded. These injuries may result from physical contact with the housing system, such as with poorly designed stalls (Cermack, 1987). Also, housing conditions may prevent normal movement patterns or stances when rising or normal body position when eating. A quantitative analysis of the incidence of these injuries, along with proper assessment of the housing system and behavioral observations, is necessary for a satisfactory solution.

Behavior Problems with Indirect Economic Impact. A large number of abnormal behaviors have not been linked directly to an economic impact. These problems are largely regarded as not warranting any action and are ignored. However, abnormal behavior can be an important indicator of deficiencies in management or environment. These deficiencies often have indirect effects on performance, efficiency, and health.

Quantitative Behavioral Changes Indicating Stress. A high frequency and long duration of lying down represent signs of stress caused by poor adaptation to the housing system. In addition, a higher than normal proportion of time spent standing while ruminating can be interpreted similarly.

Tongue Rolling. Tongue rolling is one of the few stereotypic behaviors displayed by ruminants. It is considered a vacuum-feeding behavior caused by a lack of roughage.

Behavior Problems Without Apparent Economic Impact

Many other abnormal behaviors occur in dairy production systems. These are largely induced by the environment or management. Their impact on economic return is thought to be negligible, but economic return is not always synonymous with the optimization of individual performance. In addition, biological performance is not always directly linked with economic performance. With these abnormal behaviors, two important points should be emphasized:

1. The linking of accurate behavioral observations and herd level information on performance needs to be studied to understand these associations further.
2. There is increasing public awareness of the effects of environment and management on animal care. Situations in which abnormal behavior occurs are often interpreted as indicative of an inappropriate level of suffering.

One management method under debate because of its effect on cow behavior is the use of electric cow trainers for the purpose of keeping stalls and cows cleaner, reducing labor, and simplifying management. The electric cow trainer consists of an electrified bar mounted horizontally a few centimeters over the cow's back and at right angles to the spine. If a cow arches her back when she is standing in the front of the stall, she contacts the cow trainer and receives an electric shock. This occurs during urination and defecation. The animals are supposed to learn to step backward before urinating or defecating so that urine and feces fall into the gutter and not into the stall. There is debate concerning the usefulness of cow trainers for the improvement of udder health. There is also a belief that cow trainers may induce abnormal behavior predisposing cows to teat injuries. Behavioral methods for assessing the influence of electric cow trainers on animal health have now been developed (Hultgren, 1991).

Social licking in cattle may have cleaning, tension-reducing, and bonding effects (Sato et al, 1991). The environmental conditions and management methods currently used in the dairy industry may have an impact on the social licking patterns of cattle. Some critics of animal agriculture and other groups in society believe that altering normal behavior is cause for concern.

Behavioral data can be incorporated into a dairy health monitoring effort. Behavioral observations may serve as sensitive indicators of specific deficiencies in the production system, thus reducing performance. The process of behavioral assessment involves several well-defined steps. An accurate history of the herd's behavior patterns should be obtained. This information should identify the nature of the problem, characteristics of the affected portion of the population, magnitude of its impact, seasonal or temporal patterns, and any corrective measurements that have been attempted. Careful observation of an animal's interaction with the environment and management system is important. Specific parameters relating to the physical, climatic, and social environments should be measured. For example, accurate measurements of the housing and population density should be collected. A comparison between the behavior in the production system being investigated and what occurs in the natural situation should be assessed. Finally, the assessment should be documented and an action plan established. Lactating dairy cattle are susceptible to a total change in environment. The movement of a lactating herd from one environment to a totally different one, with changed methods of feeding, milking, and housing, can adversely affect milk yield and milk composition for several days after the change (Nasi and Saloniemi, 1981).

Environmental Mastitis

Perhaps the most important problem associated with housing and environment in dairy herds is mastitis caused by environmental organisms. With the implementation of standard mastitis control practices, the prevalence of contagious mastitis has decreased. However, there is ample evidence that mastitis caused by environment streptococci and coliform organisms has not decreased. In fact, in relative terms, environmental mastitis has surfaced as a major problem.

Any environmental management program in dairy herds should be cognizant of the control of environmental mastitis. See Chapter 10 for mastitis control of dairy herds.

BOX 12-3

Health Problems Associated with the Design of Facilities and Management of the Environment

1. Endemic respiratory disease occurs in calves raised indoors in close proximity to adult cows housed in poorly ventilated barns. Adult cattle are able to tolerate inadequately ventilated barns much more effectively than are young calves, which are highly susceptible to enzootic calf pneumonia. Outbreaks of acute respiratory disease also occur sporadically in adult cows kept indoors throughout the winter months in countries such as Canada, the United States, and the United Kingdom.

2. Lameness caused by diseases of the feet, such as sole ulcer and footrot, is associated with the quality of floors and environmental sanitation.* Acute traumatic injuries of the musculoskeletal system are associated with slippery floors. The level of the feeding manger bottom relative to the floor of the stall may be associated with traumatic injuries of the legs, feet, and udder.† A feeding level 16 cm above the stall floor causes the fewest injuries. A low feeding level forces cattle to spread their legs during eating, which may predispose to development of lesions of the feet.

3. An increased incidence of environmental mastitis is associated with unsanitary conditions because of the excess accumulation of manure on cows with inadequate bedding or the use of contaminated bedding.

4. Inefficient cow movement patterns among feeding, lounging, and milking areas represent a risk factor for an increased incidence of injuries because of inadequate design of facilities.

5. Insufficient space for each age group of animals in the herd may cause overcrowding. This increases the risk of the spread of infectious diseases and of problems with nutritional management.

6. Failure to provide separate feeds and feeding systems so that groups of cows can be fed according to their needs may lead to overconditioning or undernutrition as well as to subsequent health problems.

7. Inadequate housing facilities can limit the detection, identification, and handling of cows in heat. This causes suboptimum reproductive performance.

8. It is common to have an inadequate number of maternity box stalls for cows that are due to calve. Cows calving in well-bedded box stalls are less prone to traumatic injuries associated with slipping, falling, and recumbency as a result of parturient paresis. Calves born in clean, well-bedded box stalls have every opportunity to obtain liberal quantities of colostrum early in life.

9. Unsuitable housing for newborn calves can cause an increase in the incidence of infectious diseases, such as pneumonia and enteritis.

10. Inefficient milking parlor design can result in overmilking and an increase in the incidence of mastitis.

11. Inadequate, inefficient, and dangerous manure disposal systems can lead to gas poisoning during the emptying of manure pits as well as to possibly serious environmental contamination.

12. The lack of suitable animal holding and handling facilities for routine procedures and regular examination can limit the scope of health management programs and their impact on performance.

13. The availability and choice of suitable bedding materials, such as straw, wood shavings or sawdust, soil, newspaper, or sand, can be a problem. The bedding must be kept clean and dry in order to provide adequate comfort and limit environmental mastitis.

BOX 12-4

Criteria for Designing Dairy Housing

Site planning: placement, legal considerations, public relations
Services to and from the facility: electric power, water, transportation and access, communication, emergency services, feed storage and handling, required fuels, waste handling, drainage, animal disposal
The facility: climate control, space allocation, basic design, sanitation and contamination control, special equipment, instrumentation, animal behavior
Economics: construction costs of paramount importance

PROBLEMS ASSOCIATED WITH TOTAL CONFINEMENT

The complete confinement of a dairy herd is associated with many health and production challenges. Many of the housing features important for the maintenance of health and performance have been emphasized in this chapter. Some of the most important health problems associated with the design of facilities and management of the environment can be summarized in Box 12-3.

MAKING CHANGES IN HOUSING AND ENVIRONMENTAL MANAGEMENT

There are several important criteria for the design of any agricultural animal housing for comfort and productivity applicable to dairy housing. These include the major components shown in Box 12-4.

BOX 12-5

Checklist for Developing and Implementing an Appropriate Plan for Expansion or Replacement of Facilities

Evaluate land area, topography, and local climate
Conduct water analysis and soil survey
Determine local zoning and building codes
Evaluate existing facilities and determine new buildings required
Determine layout of operation and cow and vehicle traffic
- Free-stall and milking parlor complex
- Treatment and maternity facilities
- Dry cow facilities
- Calf barns and replacement heifers
- Waste handling, storage, and drainage
- Feed storage and delivery system

Contact soil and water conservation authorities
Contact all regulatory agencies for approvals of plans
Develop preliminary construction plans and cost estimates
Develop preliminary long-term business plan and budget
Prepare projected cash flow statement
Define parameters for dairy modernization and expansion
- Livestock numbers (number of milking cows, heifers, and calves) and space requirements
- Labor and management requirements
- Establish time frame
- Refine budget

Review initial plan and financial needs with financing agency, if needed
Initiate key supplier network
- Financing agency
- Dairy design consultant
- Dairy equipment dealer
- Waste management suppliers
- Feeding system suppliers

Solidify professional services supplier network
- Veterinarian
- State and county extension services
- Regulatory officials
- General contractor

Obtain blueprints
Secure financing
Secure bids from contractors and suppliers
Award job to builders
Secure permits
Establish coordination system for suppliers
Finalize construction timetable and critical completion dates

Dairy producers contemplating expansion or replacement of their facilities need to use a checklist for the steps involved in developing and implementing an appropriate plan. One form of this checklist has been proposed by equipment manufacturers (Babson Brothers, Naperville, Ill) for the stepwise approach to planning and completing the building of new or modernized dairy facilities. Veterinarians and other farm advisors can have important roles in completing this checklist, shown in Box 12-5. Although this is not a comprehensive list of all that is involved, the principle is to use a stepwise approach.

INTEGRATING ENVIRONMENTAL MANAGEMENT INTO DAIRY HERD HEALTH PROGRAMS

The veterinarian should be aware of the housing and environmental factors that affect health and production in the dairy herd. The effects of housing and environment are complex, and there is usually no simple solution to a particular problem. For this reason the interdisciplinary team approach should be used to identify and solve problems. Agricultural engineers with experience in animal housing and ventilation systems should be consulted, and the veterinarian and engineer should visit the farm together. Detailed observations should be recorded, ventilation tests conducted, and a clear report of the recommendations given to the farmer (Anderson and Bates, 1982a,b).

In a comprehensive dairy health management program, environmental considerations should be an active, regular component of the process. Monitors for the effects of the environment should be established. Several indexes have been discussed throughout this chapter. The assessment of performance against farm goals and industry standards should be carried out. A plan of action should be developed and implemented. Ongoing regular monitoring should be performed to determine the effects of the environmental management program. Completion of this cycle is the integral process of health management, as described in other chapters.

SUMMARY

Providing an environment for animals that has a positive influence on the animals' health, welfare, and productivity is a goal of housing design. Essentially all aspects of the animals' surroundings and activities are taken into account, including ventilation, stalls and beds; access to feed and water; and walking surfaces. Enhancing the farmer's ability to fulfill the requirements of a sound management program is a function of the buildings and equipment on the dairy farm as well. Decisions about facilities must be preceded by a conscious determination of management style and management practices that may influence the final choice. Generally, the ultimate goal is to permit the genetically superior cows in dairy herds today to produce up to their potential. The facilities on the dairy farm should not be an obstacle to progress.

CHAPTER 13

Health and Production Management in Beef Cattle Breeding Herds

PETER J. CHENOWETH and MICHAEL W. SANDERSON

BACKGROUND

The history of cattle domestication has evolved over at least 10,000 years of recorded history, where it is evident that cattle played a pivotal role in sustaining physical, social, and spiritual needs of ancient cultures. Cattle were important in the process of civilization by allowing early man to make the transition from small bands of nomadic hunters to larger, self-sustaining settlements. The reasons why cattle became domesticated when many other herbivores did not is largely open to conjecture. However, it seems reasonable to assume that certain evolutionary behavioral traits should be more conducive to domestication than others. Such favorable traits are suggested to include the following: a social structure that favors the formation of large, hierarchical groups; the association of males with females (at least on a seasonal basis); male dominance; promiscuous mating behavior; sexual signaling by movement or postural cues and early bonding of young (Hale, 1962) as well as relatively large adult size and lack of territoriality (Tennessen and Hudson, 1981); and polygyny, tractability, and nutritional adaptability (Price, 1984, 1985). It is perhaps fortuitous that cattle fulfill most of these criteria admirably.

Today, cattle, representing a large number of biological types, are raised for a variety of purposes in widely differing environments. Beef cattle traditionally have been most represented in areas where intensive agriculture is unsuited, uneconomic, or impractical. In the United States, it has been stated that cow-calf enterprises are usually the residual users of range and pasture land where the only other economic alternatives are wildlife and recreation (McGrann and Parker, 1999). Systems of husbandry and management differ throughout the world, posing difficulties in defining practical herd health programs that are universally applicable. However, commonalities imposed by behavior, physiology, and ontogeny allow a generic framework to be established on which health and production principles can be imposed.

BEEF CATTLE INDUSTRY

Although the beef industry is often considered to be a single, homogenous entity, in reality it is a multifaceted industry containing a number of segments that, at times, have differing perspectives. Thus, in the United States such segments as cow-calf (both commercial and purebred), stocker, feedlot, processor, retail, and consumer can be differentiated. Smaller, more specialized segments also exist. This chapter concentrates primarily on the cow-calf, or breeding, segment of the industry, with particular emphasis on North America.

Throughout the world, and also in North America, great variation exists in beef cattle breeding operations in terms of management, environmental setting, degree of intensification (and capitalization), types of cattle used, productivity, and profitability. Not surprisingly, great variation also occurs in those health and production programs that are used. In the United States, the U.S. Department of Agriculture (USDA) has conducted a series of surveys of different animal industries under the banner of the National Animal Health Monitoring System (NAHMS). For the cow-calf sector the relevant portions occur within the Cow/Calf Health and Productivity Audit (CHAPA). Reference will be made to these surveys throughout this chapter.

As of January 1, 2000, there were 33.5 million beef cows in the United States, which represents approximately one third of the total cattle inventory (USDA Agricultural Statistics, 2000). States with the most cows were, in descending order, Texas (5.4 million), Missouri (2.1 million), Oklahoma (1.9 million), Nebraska (1.9 million), South Dakota (1.7 million), and Montana (1.6 million). In terms of individual operation size, these cows were distributed in 1996 as shown in Table 13-1.

It is apparent that the vast majority of beef cattle operations in the United States are modest in size and most probably incapable of providing the sole means of family support. In the late 1980s approximately 90% of beef farms were estimated to be owned by individuals or families (Wise, 1987), with 40% of beef farmers reporting their principal occupation as farming (compared with 93% of dairy farmers). Changes in the beef industry include a trend toward increasing herd sizes and a separation of ownership and management. Other changes include a trend toward vertical integration of different industry segments and greater use of databases and records. With the latter, on-farm computer use doubled from 1993 to 1997 (4.7% to 9.5%), while hand-written records also increased over that period (65.2% to 80.0%) (NAHMS, 1998b).

Types of operation vary from those that are economically viable, with no other farming activity except perhaps feed crop production, to those in which most of the income is derived from the sale of weaned beef calves. Such operations are usually characterized by good animal and economic management and good record keeping. Owners are often innovators and early adopters and are aware of animal health and production management services provided by veterinarians; owners request cost-effective herd health services.

A second type of operation may be represented as mixed, in which cattle share priorities with other enterprises such as cereal grain or corn production, cash cropping, grass and seed production, hay production, and sheep production. The other farm enterprises often mandate that beef cattle work share precedence in priorities such as allocation of resources and scheduling. These producers may be industrious, educated, and opportunistic and have excellent records and

TABLE 13-1

Distribution of U.S. Beef Operations and Cow Inventories

Herd Size	1-49	50-99	100-499	500+
Operations	79.8%	11.9%	7.7%	0.6%
Cows	30.8%	19.5%	35.7%	14.0%

From National Animal Health Monitoring System: *Beef '97: Part IV: Changes in the U.S. cow-calf industry 1993-1997*, Fort Collins, Colo, 1998, U.S. Department of Agriculture.

facilities. At the other end of the scale, mixed enterprises may be represented by poorly efficient operations in which owners appear to have little control over events. Working with mixed enterprises requires an appreciation of the entire enterprise and not just the cattle component. In many parts of the world, such operations may be entirely pasture dependent for livestock, including year-round grazing, perhaps with prepared feed supplementation when required. In temperate zones, large amounts of hay must often be prepared, being fed for 2 to 6 months during the winter season.

Some beef cattle producers operate on a low-input, low-output basis. This may reflect realistic business principles for their region (as with parts of Northern Australia), a way of life that is resistant to change, or conflicting priorities. Here there may not be a recognizable breeding season, and there is often little monitoring of breeding or calving. Calves may be "harvested" at times that reflect suitable environmental conditions or convenience, or when some cash flow is necessary. Improvement of the production traits within the herd by input of good genetic material may not be a high priority for some producers. For many, their priorities are for more basic managerial inputs than for implementation of sophisticated herd-health programs or for exploitation of new reproductive technologies (Henderson, 1998). They also do not want to increase their management effort in the operation unless there is a demonstrable payoff in economic returns. In comparison with the United States, beef cattle production systems in countries such as Australia, Argentina, Uruguay, and Brazil are overwhelmingly based on pastures and likely to remain that way for the foreseeable future, despite increased use of improved pastures.

An important and influential segment of the industry consists of purebred beef cattle farms whose sole objective is to produce pureblood, pedigreed breeding stock for show and sale. Some of these are economically viable, based on cattle sales, but some are not and are subsidized by other enterprises of the farm, such as grain farming or commercial cattle production. The profitability of such operations is associated with overall industry profitability as well as marketing skills. Some of these producers have adopted high technology and are heavily involved with embryo transfer and related technologies. Many are interested in a complete animal health and production management service because of the high value of purebred breeding stock and their germ plasm.

The large number of small herds in the United States indicates that many cattle owners are reliant on other sources of income for economic survival. Many farms have cattle as an adjunct to income generators such as grain farming, oil wells, potato farming, schoolbus driving, or working off the farm. Profitability and programmatic commitment vary with size of operation, location, and motivation. Many small producers come from a farm background and live in a rural setting either by choice or by circumstance.

With such variations in the economic viability of commercial beef herds, a decision should be made as to the feasibility of adding the "costs" of a herd health program to existing costs on a beef farm. This decision is not necessarily related to size or production level. Other factors are important, including the awareness, motivation, resources, and priorities of the owner. The first step is to identify those procedures ("marketable skills") or products that can be identified as a sound investment, rather than as a cost. Here, it is assumed that emergency services are generally provided as well as standard components of preventive medicine relevant to most farms (e.g., regulatory disease testing and vaccination, basic vaccination against clostridial and perhaps other diseases, treatment for endoparasites and ectoparasites), with perhaps pregnancy diagnosis and other routine elective procedures. With such simple veterinary services, there is usually little attempt to accurately assess herd productivity or the financial impact of disease control.

A 1986 survey of the U.S. market for food animal veterinary services provided some relevant information concerning the relationship between farm characteristics and veterinary services provided (Wise, 1987). Here, the median annual sales from beef farms was estimated to be about $29,000, with median annual animal health expenditures by producers being approximately $500. Of this, 35% was spent on professional veterinary services and 65% on animal health products. Larger livestock farms and ranches spent proportionately (per animal) more on animal health products and less on animal health services than did smaller operations. In addition, larger livestock operations spent proportionately less of their animal health dollar with the veterinarian than smaller livestock operations. In this survey, producers perceived private veterinary practitioners as strong in their knowledge of diagnosis and treatment of sickness and injury and of reproduction and breeding, relative to themselves and other suppliers of animal health information. At least 7 in 10 producers would contact the veterinarian first for diagnosis and treatment of sickness or injury, 5 in 10 would contact the veterinarian first for a reproductive problem, about 3 in 10 would contact the veterinarian first for a herd management problem, and 1 in 10 would contact the veterinarian for a question on feed and nutrition. In the areas of animal and herd management and of feed and nutrition, veterinarians were thought to possess about the same level of knowledge as the producer and slightly less knowledge of feed and nutrition as feed salespersons. The veterinarians' knowledge of agribusiness and economics was perceived as weak compared with that of the producer and agricultural extension agent.

A more recent survey reinforces the previous positive perception of veterinarians as experts in matters of animal health, with signs of encouraging improvement in production areas as well (NAHMS, 1994a). Here, producers placed

Downloaded from Vet-eBooks.com

veterinarians in first position as sources of information for both animal health and beef production information, and in second position (to personal knowledge and education) as a source of nutritional information. This indicates that education, perception, and need have combined to improve the capabilities and contributions of veterinarians in wider aspects of cow-calf production than health matters alone, at least in the United States. The challenge remains for veterinarians to be remunerated adequately for their advice in these areas.

ANNUAL BEEF COW CYCLE

In a generic beef breeding herd, cows are bred naturally by bulls within a pasture or range environment. Calves are usually born in spring and nurse for 6 to 8 months before being weaned. Although principles for optimum beef production suggest that cows calve annually, constraints on this goal may be imposed by genetic and environmental interactions with normal physiological events. Diseases such as vibriosis or trichomonosis also may influence the annual beef cow cycle. However, a general aim is for heifer replacements to be bred at approximately 15 months of age and to calve as 2-year olds. Females that are already in the herd and have had calves in previous years are bred about 60 days after calving. For optimum efficiency, it is necessary to breed the heifers and cows over a period of 42 to 60 days in order to have a short calving period (span) and a concentrated calving pattern (a high percentage of calves born in the first 21 days of the calving period). Such a schedule is integral to any plan that aims to obtain a calf from each breeding female each year. Weaned calves may be sent to a feedlot to be fed for several months until slaughter as finished beef, or they may be placed in a feeder-stocker system for a period before being placed in a feedlot (or on pasture) for the "finishing" process that might take 3 to 6 months in different systems. Some heifer and bull calves are usually selected as potential breeding stock and placed on diets that provide for the optimum growth required for heifer replacements and breeding bulls. Thus the length of time from conception to finished beef requires up to 24 months, and from conception through the birth of another calf up to 42 months. This long intergeneration interval represents a disadvantage compared with other animal production systems, and it provides an incentive for improved efficiency of production in cattle.

Characterization of typical beef practices in Colorado herds was obtained from a study of management practices and their association with disease rates (Wittum et al, 1990). Here, most herds used crossbreeding, with two thirds using a breeding season of 90 days (range 60 to 365 days). Breeding soundness examinations of bulls were conducted by 35% of producers before each breeding season, whereas 42% performed breeding soundness evaluations on "new" bulls only. Pregnancy examinations were performed in 70% of herds. Most herds calved in the late winter and spring of the year. For newborn calves the most common management procedures were application of identification tags, dipping of the navel with iodine, and measurement of birth weight. Most producers gathered their cattle in the spring or early summer for branding, at which time they also castrated the male calves, dehorned the calves, and vaccinated them with a clostridial vaccine, whereas 50% of the producers implanted the calves with a growth promoter. Calves were weaned in these herds in September to November. Individual or group weights were determined on calves at weaning in 60% of herds. Other common management practices at weaning included vaccination for common viral diseases (infectious bovine rhinotracheitis [IBR], parainfluenza 3 [PI3], bovine virus diarrhea, and bovine respiratory syncytial virus [BRSV]) and treatment for internal and external parasites. The incidence and mortality rates resulting from enteric disease were higher in herds in which calves were not routinely handled immediately after birth compared with herds that did handle them at this time for routine procedures.

The disease problems that exist with extensive beef operations, such as those in Northern Australia, are varied, but the major epidemic diseases such as brucellosis, tuberculosis, and perhaps campylobacteriosis are likely reduced to low levels or almost eradicated. This is, however, not true of all diseases. For example, foot and mouth disease (FMD) is still endemic in parts of the world. Major problems include seasonally poor nutrition, low stocking rates, isolation from facilities, resources and markets, inadequate transport, large land areas, and poor records. Related problems include poor and unreliable reproductive rates, variable calf crops and greater selection emphasis on survival than on production traits. Disease entities vary with region, but trichomonosis is often endemic and external parasites may represent a large concern; micronutrient and mineral deficiencies may cause primary or secondary problems (as with the relationship between phosphorous deficiency and botulism in Northern Australia). Internal parasites tend to become less problematic as stocking rates decrease, although this can change whenever animals are forced to congregate.

"GOOD" COW-CALF PRODUCTION PRINCIPLES

A number of managerial practices are known to increase productivity within cow-calf herds when they are able to be implemented practically. These practices are mostly associated with the reproductive process, since improvements in herd fertility are considered to offer more potential for increased profitability in cow-calf operations than production traits (Wiltbank, 1994). Most indexes currently used to evaluate herd performance are related to reproductive efficiency, such as pregnancy rate, calving percentage, calving distribution, and percent calf crop. All of these affect pounds of calf produced per exposed female (Engelken, 1997). In turn, practices that have been shown to be of most advantage to herd reproduction include those in Box 13-1.

In addition, a number of other management practices associated with increased beef herd profitability in Kansas were identified by Engelken et al (1991) as follows: use of partial budgeting, fly control, use of growth promotants and creep feeding in calves, precalving parasite control in cows, and improved calf management.

BOX 13-1

Managerial Practices that Increase Cow-Calf Productivity

Restricted breeding season
"Optimum" calving season
Breeding season evaluation
Good heifer replacement program
Proper nutrition
Good herd health
Prior bull evaluation
Crossbreeding
Good records

Downloaded from Vet-e-Books.com

A number of these recommendations have been incorporated into different "packages" (Withers, 1984; Anderson et al, 1986; Prince et al, 1987), which have generally been shown to be cost effective. However, although the benefits of such proven management tools to increase herd productivity and profitability may appear to be evident, many producers are not taking advantage of them. In fact the low level of utilization of such knowledge has been identified as the most important constraint to the productivity of the U.S. beef cow-calf industry (Wikse et al, 1998). This perhaps explains why the weaning rate of calves has remained virtually static in the United States over the past several decades (Williams, 1990; USDA Agricultural Statistics, [available at http://usda.mannlib.cornell.edu/usda/reports/general/sb/b9530199.txt]).

A relative lack of adoption of "good" management principles is also evident from surveys in Ontario, Canada. Here, approximately 50% of producers did not use a specified breeding season. Of those who claimed to have a specified breeding season, only 24% restricted it to less than 90 days (McDermott et al, 1989). Approximately 12% of producers bred heifers earlier than cows, and only 30% of heifers and cows were checked for pregnancy. An earlier mail survey of reproductive efficiency and calf survival in Ontario beef cow-calf herds revealed mean losses of approximately 18% from breeding until calves were 4 weeks of age (Rogers et al, 1985). Veterinary involvement was low for recommended basic herd health procedures, with only 12% of the herds undergoing pregnancy examinations, 10% bull breeding soundness examinations, and 5% bull scrotal circumference (SC) measurement. A survey of health, productivity, and management of calves in Ontario beef cow-calf herds showed preweaning losses of about 7% (Alves et al, 1989), with 85% of this loss occurring from birth to 4 weeks of age.

In Texas, an integrated resource management (IRM) program survey revealed a relatively poor adoption rate of proven, and recommended, reproductive management principles (Williams, 1990). Here, 24.5% of producers used a controlled breeding season, 22.6% checked pregnancy, 20.8% conducted annual bull breeding soundness evaluations, 13% used artificial insemination (AI), and 7.8% used estrus synchronization methods. However, a more recent survey of successful Texas ranchers indicated a higher adoption rate of good management principles, with 75% having a defined calving season, 76% pregnancy-checking cows, and 53% using cow body condition scores (BCSs). This was considered to illustrate a positive association between adoption of such principles and profitable ranching (Wikse et al, 1998).

Data from a wide variety of U.S. locations reveal disappointing adoption rates of many proven management principles (NAHMS, 1994a, 1998a,b). In 1993, 47 percent of operations removed bulls from the breeding herd—a practice that increased with herd size to 92.8% of herds with 300 or more cows. Approximately half of the operations performed a semen test on newly purchased, leased, or borrowed bulls, whereas only 17% to 18% used this test on other bulls before the breeding season. Other data from the 1993 survey showed that nearly 18% of operations performed pregnancy testing on cows, and approximately 16% performed it on heifers. BCS was used with cows and heifers on 5.5% and 4.6% of operations, respectively, and the equivalent usage of body weight monitoring was 1.9% and 7.9%, respectively. The use of AI in beef herds remained relatively static (5% to 6%) between the two surveys.

The reasons for such relatively low adoption rates are probably many and complex. Beef producers tend to be conservative, with reasoning often based on previous experiences or hearsay. Regional differences in outlook, social pressures, and economics also occur, as well as the fact that many cow-calf producers, at least in the United States, are relatively small, are part time, or have mixed enterprises in which cattle have to share priorities. Despite such considerations, veterinarians should be in a unique position to convince clients to adopt cost-effective managerial changes and to assist clients to implement these changes. This is because no other professional has such regular and close involvement with many cattle operations, both small and large, and because veterinarians are regarded as the best single source of relevant information (NAHMS, 1994a). Encouraging results are being reported from collaborative educational programs for producers, such as one in Texas in which veterinarians, extension agents, and a major pharmaceutical company have combined forces (Wikse et al, 1998). The reasons for implementing a number of these practices are discussed below.

RESTRICTED BREEDING

In general any beef production system that requires animals to be grouped for managerial purposes such as weaning, vaccination, and marketing benefit from some form of restricted breeding season. Here, to some degree, nature imposes its own prerogatives such that, even in feral herds, a considerable degree of seasonality occurs with both breeding and calving (Spitzer, 1986). Thus, in most regions of the world, there is an "optimum" period for females to calve, suckle, and rebreed. This period is mostly related to nutritional opportunity, with other environmental factors such as heat stress and parasite populations also playing roles in different parts of the world. Producers have traditionally aimed for females to calve at this optimum period, since they tend to breed back faster, and their calves grow better, than those that calve at less opportune times. It is recognized that in some parts of the world such as northern Australia, the level of managerial inputs required to implement a severely curtailed breeding season would be uneconomic as well as logistically difficult. However, where restricted breeding seasons are feasible, their implementation is a major factor in achieving optimum production levels. Arguments in favor of restricted breeding seasons (<80 days) are given in Box 13-2.

The combination of the advantages just described has been estimated to provide an increased return of $50/cow, based on 1995 prices (Toombs, 1996). In the United States, surveys show that most calves (64%) are born within a 3-month period (February, March, April) in the spring (NAHMS, 1998b). If January and May are included, this figure rises to 80%. This reflects a breeding season that occurs

BOX 13-2

Advantages of a Restricted Breeding Season for Beef Cattle Breeding Herds

- Enhanced production potential
- Opportunity to work in concert with favorable environmental factors
- More homogeneous calf crop
- Opportunity to perform prebreeding management procedures
- Concentrated calving season
- Opportunity for strategic nutrition and improved monitoring
- Early problem detection (using herd pregnancy diagnosis and breeding season evaluation)
- Improved female replacement program
- Programmed herd health management
- Improved culling procedures

Downloaded From Vet-e-Books.com

predominantly in late spring and early summer. Despite this, indications are that breeding seasons of more than 5 months increased from 1992-1993 to 1997; there was no month in which less than 10% of operations had calves born (NAHMS, 1998b).

Although the figures indicate room for considerable improvement, it should not be assumed that the adoption of a severely restricted breeding season is advantageous in all situations and environments (Box 13-3). In a Nebraska study, comparison of breeding season lengths for crossbred females of 30, 45, and 70 days found that the highest productivity occurred with the longer breeding season (Deutscher et al, 1990). In a number of situations, very short breeding seasons produce unacceptably low calving rates (Larsen et al, 1994). The reasons for this include the extra pressure that such systems impose on normal physiologic events. For example, a generic, British-breed beef female will be pregnant for approximately 284 days, leaving 81 days to recycle and breed. However, even if she has no problems at parturition and her nutrition is good, she will still undergo delayed return to cyclicity (45 to 70 days). Thus if postpartum return to cyclicity is 40 days, the generic female will have 41 days of cyclicity to become pregnant. This translates to two to three estrus periods. Assuming that the bull (or bull battery) is fertile and sexually active, it is a reasonable assumption that she will have an approximately 60% chance of pregnancy at each estrus. Thus her chance of becoming pregnant in time to fulfill a 12-month calving interval is either 84% (two cycles) or 94% (three cycles). The variable period of anestrus following parturition is recognized as a major influence on the proportion of females that conceive during the breeding season (Wiltbank et al, 1961). Greater constraints are often imposed on this system in tropical and subtropical environments, as genotype-environmental interactions tend to cause delayed postpartum return to estrus (Chenoweth, 1994a). The result is that producers in such areas often adjust by using extended breeding seasons.

Thus calving rate may be influenced by breeding season length through three important parameters; postpartum return to estrus (PRE), conception rate per estrus exposed (CR), and gestation length (GL). The latter is influenced by calf sex (with male calves generally remaining in utero for several days longer than female calves). However, it may also be significantly affected by genotype with variation among breed-types being up to 19 days (Larsen et al, 1994). The extra gestation duration required by some breed-types necessarily reduces their postpartum period of opportunity to get pregnant within a 12-month calving schedule. Larsen et al (1994), using computer models derived from data obtained at USDA-STARS (Brooksville, Fla.) found that a decrease in the length of the breeding season does not necessarily increase calf crop and profitability. Here, models showed that when conception rate was 60% and the breeding season was 60 days, calving percentage was significantly affected by both gestation length and PRE. Variation of breeding season length (30 to 190 days) at different combinations of GLE and PRE at the same conception rate showed that even very long breeding seasons could not fully compensate for situations in which both GLE and PRE were extended. Amer et al (1996) showed that, under British systems for beef suckler herds, increasing gestation length imposed appreciable economic costs.

Moving cattle breeding operations from an extended breeding season to a restricted one can present a real challenge. If the move is made too quickly, a severe drop in production may result. Associated changes in culling patterns can alter herd dynamics with the result that it may take years for optimum production levels to be established. Prior consultation with clients should include such information. Use of computer generated "what-if" scenarios (e.g., as with DECI) is very useful in mapping different strategies and predicting outcomes, although their value is dependent on the accuracy of the "models" used. A relatively safe strategy is to reduce the bull presence in the herd in increments over a number of years so that the desired breeding season is achieved gradually. At the same time, late-bred females should be steadily removed from the female herd while emphasis is placed on getting heifers into a restricted breeding format (e.g., with estrus synchronization). For year-round breeding herds the initial strategy should be to first remove bulls during the period when experience and records indicate that little breeding activity occurs. This period of bull removal can then be extended gradually.

BOX 13-3

Possible Disadvantages of a Restricted Breeding Season

- Lost production can accompany the move to a shorter breeding season
- Difficulties can occur in coordinating calendar and season
- Closer monitoring usually required
- Good herd health becomes more important
- Late calvers, if not culled, will often miss years
- Breed and environmental differences occur in implementation

STRATEGIC PREGNANCY TESTING

Pregnancy testing should be regarded as an essential management tool in beef herds. As a technique, it represents an important "marketable skill" (Chenoweth, 1989) that allows veterinarians to gain access and credibility with cow-calf operations. However, for most effective utilization, it should be much more than a simple sorting exercise of female cattle into pregnant and nonpregnant groups. The addition of "value-added" information such as projected calving dates and patterns (as described below) makes this service more attractive (Toombs, 1996). The herd pregnancy diagnosis (HPD) represents an important starting point for beef herd diagnostics and advice, and it is a pivotal component for informed managerial decision making (Box 13-4).

For this information to be used most effectively, we need to be able to determine the distribution of pregnancies within the herd and its subgroups and to compare these with expected and actual herd averages. Analysis of this data will help to determine whether or not a problem exists and, if so, what might be the cause. In many cases this analysis will also help to indicate what needs to be done to specifically identify and rectify the problem and with which group(s). A description of such analyses is given in the discussion on breeding season evaluation later in this chapter.

When used in conjunction with a restricted breeding season, the HPD is best done relatively early after bull removal (6 to 8 weeks) but late enough so that early pregnancies are not missed. The most common method used by veterinarians to perform this task is transrectal palpation of the female reproductive tract; this technique has been well described elsewhere (BonDurant, 1986; Anon, 1998). With this method, greatest accuracy in aging the conceptus occurs between days 35 and 65, with precision being reduced as gestation proceeds. In this chapter, methodology is not presented because it is covered adequately elsewhere (Anon,

Downloaded from Vet-eBooks.com

BOX 13-4

Advantages of Herd Pregnancy Diagnosis

Identification of pregnant and nonpregnant animals
Analysis of group patterns for problem solving ("breeding season evaluation")
Sorting of animals into groups for specific purposes (e.g., strategic feeding, calving supervision, culling, or rebreeding)
Selection of replacement females
Culling for infertility*
Identification and treatment of other problems†

*Culling options vary; however, priority should be given to culling nonpregnant and "late" cows.
†For example, cancer eye treatment; a procedure that can add considerably to the value of cull cows and extend the useful life of others in the herd.

Information for Breeding Season Evaluation of the Beef Herd

Breeding herd inventory
Sires used
Pastures
Bull-to-female ratios
Breeding season dates
Pregnancy rates (overall, and per 21-day breeding period)
Expected calving dates and distribution
Herd averages (and variation)
Female factors
Age-parity
Breed
Body weight
Frame score
Body condition
Lactation status ("wet" or "dry")

From Traffas V, Engelken TJ: Breeding season evaluation in beef herds. In Howard JH, Smith RA, editors: *Current veterinary therapy 4, food animal practice*, Philadelphia, 1999, WB Saunders.

1998). However, it is of value to emphasize the importance of good working facilities (Grandin, 1993; Anon, 1998) that help to safeguard both the operator and animal and that facilitate accurate results. In addition, awareness of the biomechanical principles involved with this task (Anon, 1998) can help to prevent chronic injuries to palpators. The Australian Association of Cattle Veterinarians (AACV) has instituted a national accreditation scheme for cattle pregnancy diagnosis based on transrectal palpation (Anon, 1998). The objective of this scheme was to promote excellence in the skills of pregnancy testing and to introduce a system of accountability. With the latter consideration, accredited veterinarians are issued with plastic, wrap-around tail tags that are used to identify four classes of cattle as they are being tested. The categories represented are NDP (not detectably pregnant), CATA (open, or up to 3 months pregnant; this tag only used in Victoria, and it indicates category "A"), U4 (up to 4 months pregnant), and O4 (more than 4 months pregnant). Each tag has an individual animal number as well as the accreditation number issued to that veterinarian. In addition, the tag is identified as being issued by the Australian Veterinary Association. Procedures exist for the orderly handling of complaints. In addition the AACV has issued welfare guidelines for the use of cattle in pregnancy-testing schools.

Other methods in addition to transrectal palpation are available for pregnancy diagnosis in cattle. Tests of blood or milk progesterone levels can differentiate between a pregnant animal and one that is in proestrus or estrus (Anon, 1998). This method is more accurate for detecting "open" females (90%) than in correctly diagnosing pregnancies (32% to 34%). Since accurate breeding dates are necessary for best use of this method, it has most application in conjunction with AI programs, and more with dairy cattle operations than with beef cattle.

Ultrasonography—particularly that which uses real-time, B-mode technology—has shown rapid development and acceptance for pregnancy diagnosis within the beef industry. Ultrasound has advantages beyond those of transrectal palpation. These include the ability to accurately (and conclusively) diagnose early pregnancies (before Day 30), to determine fetal sex (after Day 55), and to help diagnose problems in the female reproductive tract. In addition, ultrasound can assess fetal viability through heartbeat, and the operator is less apt to "miss" detecting twin fetii than with transrectal palpation. Ultrasound images of actual pregnancies can also be useful as a marketing tool for purebred and specialty cattle operations. On the distaff side the equipment is expensive (although price per features is steadily reducing), it is susceptible to damage, and extra training is necessary for proficiency to be obtained.

Breeding Season Evaluation

Breeding season evaluation is a tool for assessing the reproductive performance of the cow herd (Spire, 1986). It includes obtaining relevant information, its analysis and interpretation, and recommendations for improvement. Here, reproductive performance is recognized as a factorial, influenced by many factors including sire fertility, herd health aspects, and female opportunity. One measure of reproductive performance is the number of exposed females that actually raise a live calf. Other valuable information may be obtained from an analysis of the distribution of pregnancies (and calvings) that resulted from particular breeding season (Mossman and Hanly, 1977). This distribution may be studied on the basis of timing (e.g., 21-day estrus periods), breeding groups, female age or parity, nutritional opportunity (e.g., BCS), or any other identifiable category. Such analyses provide the basis for evaluation of either the breeding or calving season (Mossman and Hanly, 1977; Traffas and Engelken, 1999). For evaluation of the breeding season, good records should be obtained at the time of pregnancy testing for the subsequent analysis to be valid. Useful information for this task is found in Box 13-5.

The interpretation of pregnancy (or calving) patterns may be illustrated with reference to three herd patterns (Table 13-2 and Fig. 13-1).

In this diagrammatic representation of the breeding performance of three herds, all herds ultimately achieve the same percentage of pregnant females (95%). However, differences in the path taken to achieve this result cause

Downloaded from Vet-eBooks.com

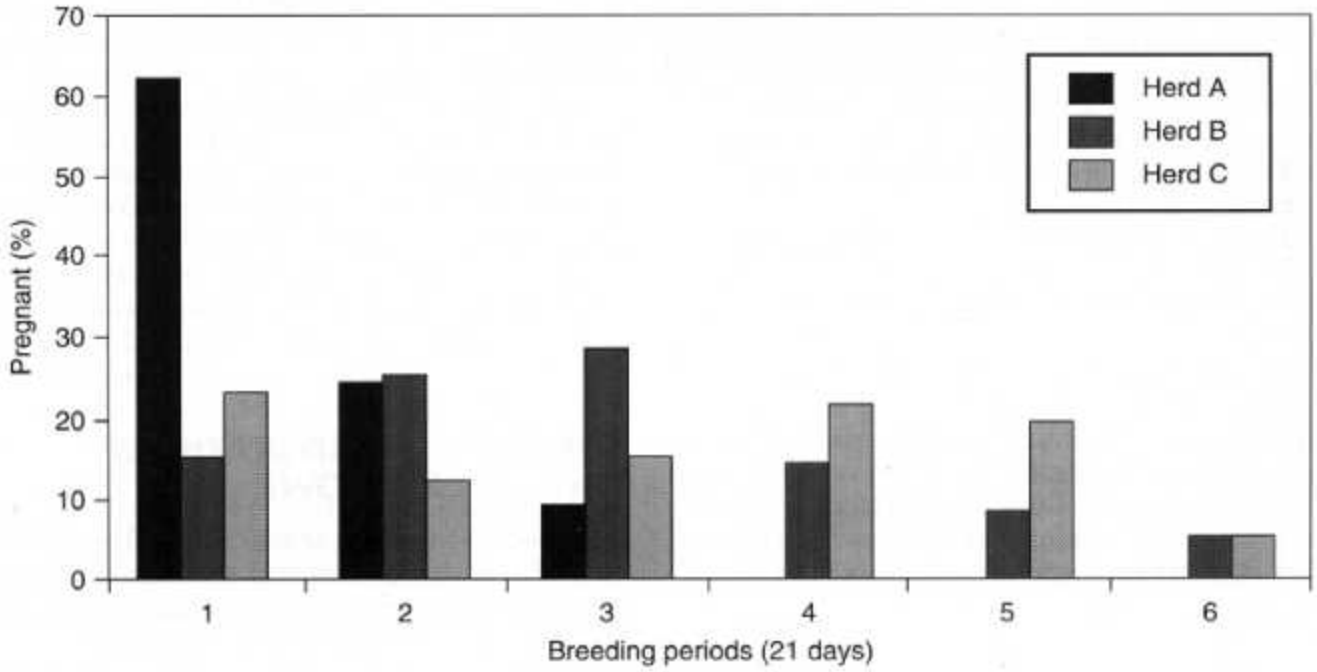

FIG. 13-1 Pregnancy patterns in three different herds per 21-day breeding period.

TABLE 13-2

Hypothetical Pregnancy Patterns per 21-Day Breeding Period in Three Herds

Periods	Herd A Pregnancy (%)	Herd B Pregnancy (%)	Herd C Pregnancy (%)
1st 21 Days (0-21)	62	15	23
2nd 21 Days (22-42)	24	25	12
3rd 21 Days (43-63)	9	28	15
4th 21 Days (64-84)	—	14	21
5th 21 Days (85-105)	—	8	19
6th 21 Days (106-126)	—	5	5

considerable difference in economic returns and provide valuable diagnostic clues.

Herd A

The pattern of pregnancies occurring with herd A—62%, 24%, and 9% of pregnancies occurring in the first, second, and third, 21-day period of the breeding season, respectively—is optimum. This is representative of all females cycling at the beginning of breeding, fertile bulls, and a conception rate (i.e., one cycle pregnancy rate) of approximately 60%.

Herd B

Herd B illustrates a problem of delayed, and perhaps inconsistent, conceptions. Delayed conception may occur for several reasons, as follows:

Females Were Not Cycling at the Start of Breeding. A common cause of delayed conception is lack of sufficient time postpartum for females to resume cyclicity, or a situation that is often compounded by interactions between growth and lactation demands and suckling stimuli. Beef cows often reach peak lactation between 6 and 8 weeks' postpartum. Younger females, particularly first-calf heifers, require longer postpartum intervals (PPIs) than do older, multiparous females. Some breed types (e.g., those of *Bos indicus* heritage) require longer PPIs than others. Female parity, calving dates, size and state of udders, and size of calves all provide valuable clues in relation to possible causes.

Inadequate Nutrition. The Herd B pattern may be encountered when nutrition is inadequate, although continuation of this problem would probably lead to lower final pregnancy rates than those shown in Table 13-2. If nutrition is a problem, BCS should provide valuable insights. Even though some months may have elapsed since breeding, important relationships between pregnancy status and BCS should still exist. Pasture differences may be evident, although strong BCS relationships should be evident here as well.

Bull Infertility. Another possible cause of delayed conception in the herd is use of subfertile bulls. Here, the final pregnancy rate would most likely also be depressed. Bull problems are usually identified with a specific breeding group and cause nonpregnancy or late pregnancy in females that should have been otherwise cycling and "eligible." This

Downloaded from Vet-eBooks.com

problem may well have been avoided with a breeding soundness evaluation of the bull team before the breeding season, especially if libido or serving capacity testing had also been conducted. Without that information, and assuming that bulls are not obviously lame or otherwise defective, veterinarians should conduct appropriate tests to rule out a bull fertility problem.

Infertility Disease. The Herd B pattern may also occur with infertility diseases such as vibriosis or trichomonosis, although this would not represent a typical pattern for these diseases when introduced into a naive female population. However, if the population contains a mixture of females of differing susceptibility to either of these diseases, then patterns such as this may occur. Again, lower final pregnancy rates than shown in this example could be expected. If the cause of this pattern is not readily apparent from the preceding considerations, and especially in the absence of vaccinal history, then the appropriate disease tests should be conducted.

Herd C

Herd C shows strung-out conceptions that lack a consistent pattern. This is more suggestive of infertility disease than the Herd B scenario, although lower final pregnancy rates again might be expected. Elimination of possible causes such as PPI (very young calves at foot), nutrition (BCS), and bull infertility would strengthen this supposition.

COST OF DELAYED CALVING

An economic estimate may be made of the effects of delayed calvings based on calf weaning weights and growth rates, and the price paid for calves. In the examples in Table 13-3, which are based on the three example herds from Fig. 13-1, the average weaning weight for calves born in the first 21 days of calving is assumed to be 500 lb (227 kg). If calves were born at an average weight of 80 lb (36 kg), then growth from birth to weaning (at approximately 7 months) averages approximately 2 lb (0.9 kg)/day. A calf price of 80 cents/lb is used in this example. Cow herds consist of 100 females, with ultimate pregnancy rates being similar (95%) for all herds.

The difference in calf receipts between an optimum calving season stretched over 63 days, and an extended one stretching over twice that period, was as great as $7500 in this example (Table 13-3) using 100 cow herds. For a 1000-cow herd the difference could be as great as $75,000. Managerial remedies for extended and erratic calving patterns are available, as discussed elsewhere in this chapter. The costs of these remedies need to be weighed against the losses estimated above.

GENETIC CONSIDERATIONS (THE "IDEAL" COW)

Selection of breeding females must be made within the context of environmental and managerial constraints, market dictates, economic realities, and conflicting priorities. Although such considerations imply that a certain degree of flexibility is necessary, it is apparent that many beef females are not productive. Bellows and Short (1994) reported that failure of cows to become pregnant was the largest single factor contributing to lowered calf crop.

Consideration of the attributes of the "ideal" cow is influenced by a number of factors, some of which might reasonably be expected to differ with region. However, Box 13-6 includes important traits for most environments.

Selection and maintenance of such traits in the cow herd requires good records and strict attention to a good replacement heifer program. Production and reproduction traits do not always go hand in hand, so it becomes a challenge for females to excel in all requirements. An ideal breeding system would allow some separation of lines that emphasize reproductive and maternal traits in breeding females from production traits of terminal offspring, as practiced in the swine industry. It is also difficult for a given genotype to excel in all environments, with this consideration being particularly relevant for temperate breeds raised in subtropical or tropical environments (Hauser, 1994).

TABLE 13-3

Effect of Calving Distribution on Calf Weaning Weights and Returns

Calving Period	Average Calf Weight (lb)	Herd A: Total Calf Weaning Weight (lb)	Herd B: Total Calf Weaning Weight (lb)	Herd C: Total Calf Weaning Weight (lb)
1	500	31,000	7,500	11,500
2	458	10,992	11,450	5496
3	416	3744	11,648	6240
4	374	—	5236	7854
5	332	—	2656	6308
6	290	—	1450	1450
Total lb weaned	—	45,736	39,940	38,848
Estimated returns (at 80 cents/lb)	—	$38,589	$31,952	$31,078

Herds A , B, and C consist of 100 cows..

In general, published results suggest that the heritability of cattle fertility in cattle is low (Bellows and Staigmiller, 1994), although this should not lead to the conclusion that the genetic component of fertility is small (Table 13-4).

Fertility is poorly defined and measured in cattle. It is a complex trait, with contributions from both male and female factors. Genotype-environmental interactions further obscure the issue, with some evidence that selection for fertility, at least in females, might be more rewarding in stressful environments (Deese and Koger, 1967). Despite these considerations, it is clear that selection against low fertility or infertility in cattle breeding herds is both important and rewarding (Koger, 1967; Bellows and Staigmiller, 1994). This presents a major opportunity for veterinarians to work with producers to identify and remove individuals that are below herd norms or goals in terms of reproductive or productive performance and thus to raise herd performance. Such selection should include not only "open" females but those that produce substandard calves. Although females that have had dystocia problems should be culled because of lowered productivity, it is not yet clear how successful genetic selection against dystocia might be (Bellows and Staigmiller, 1994).

Despite the relatively low heritability of cattle fertility, identification and selection for certain traits associated with fertility can be advantageous. For example, as discussed below, scrotal circumference in bulls is favorably associated with sperm numbers and semen quality in bulls as well as age at puberty in related heifers.

BOX 13-6

"Ideal" Cow Traits

High fertility
Early puberty
Longevity
Low maintenance
Milk and size compatible with ranch constraints
Calving ease
Production and raising of healthy calves of required beef quality-quantity

TABLE 13-4

Heritability Estimates for Beef Cattle

Trait	Heritability (%)
Female reproduction	10-20
Mothering ability	20-25
Weaning weight	20-25
Feed conversion	30-35
Yearling weight	60-70
Mature weight	60-80
Skeletal size	60-80

CROSSBREEDING

No single breed has all of the characteristics to excel in all beef production traits in all environments. Further, traits that are important for reproduction are not necessarily those that are equally important for production. One example is calf birth weight, which is related favorably to other aspects of growth but leads to dystocia, and subsequent rebreeding problems, in the dam (Laster and Gregory, 1973).

Heterosis has been shown to favorably influence productivity and profitability in cattle breeding enterprises by increasing the survival and growth of crossbred calves and by increasing the reproductive rate of crossbred cows and the weaning weight of their calves (Cundiff et al, 1992; Koch et al, 1994). In general, the performance of crossbreds exceeds that of either of the parental breeds, especially for composite traits such as lifetime productivity. Particular advantages in pounds of calf weaned occur with *Bos indicu-Bos taurus* crosses (Cundiff and Gregory, 1999), with this advantage being greatest in subtropical and tropical regions. Over time, two-breed rotations will retain approximately 68% of original heterosis and three-breed rotations retain 86%, whereas two-breed composites retain 50% and four-breed composites retain 75% (Cundiff and Gregory, 1999).

Complementarity is the process whereby breed types are crossed so that direct and maternal breed effects are combined with heterosis to optimize performance. This process can help match genetic potential for factors such as growth, size, reproduction, and maternal ability as well as carcass and meat characteristics with external factors such as climate, nutrition, and market preferences. Here, an example would be to use specialized male breeds as static terminal sires with crossbred females to maximize favorable, and minimize unfavorable, traits.

Important interactions occur between genotype and environment, such that it is useful to identify those biological types of cattle, or crosses, best suited for both production and market environments. Here the genetic potential for mature size (and maintenance requirements) and overall productivity should be matched with both actual environment and economic, available feed. For producers in areas such as Northern Australia and Argentina, Southern Brazil, and the United States, this often means using crosses between *Bos taurus* and *Bos indicus* breeds, which consistently outperform purebred cattle in subtropical and tropical environments (Franke, 1980).

CULL COW SELECTION AND MANAGEMENT

The identification and marketing of cull females has important economic and genetic implications for cattle breeders. Normal female replacement rates in U.S. herds vary from 10% to 20% (Engelken, 1997). This means that the sale of cull females represents a significant portion of income for many beef herds. Monitoring of the reasons for culling can shed valuable information on genetics and management within a herd, as well as possible disease conditions.

Culling of cattle in a beef operation usually implies removing those that have failed to meet or maintain performance criteria for the herd (Spire, 1997). Other reasons may include physical or temperament problems in animals as well as judicious culling during periods of environmental hardship or economic necessity (Table 13-5). Each operation has its own unique biological or economic criteria for culling animals (Spire, 1997). The identification of cull cows as a profit center provides the opportunity to develop programs that optimize cull cow management and returns. Cull animals represent an important component of farm economics, with approximately 11% of cows being sold annually for slaughter in the United States (NAHMS, 1998a).

Downloaded from Vet-e-Books.com

In the NAHMS (1998a) survey, culling patterns differed with size of operation. For example, pregnancy status (overall 25.6% of operations) increased its representation from 16.2% in operations with less than 50 females, to 69.4% in those with 300 or more females. Larger operations also put more emphasis on culling on the basis of age, physical soundness, and the production of poor calves. Some regional differences were also apparent, with less culling for pregnancy status in the south-central region, where more culling occurred on the basis of economics than in other regions. This last factor may, however, have been influenced by severe drought conditions in the south-central region of the United States during the survey period in 1996.

The judicious removal of nonperforming females is also important in maintaining or improving herd fertility, since the assumption is that these represent a subfertile group. Considerable progress can be made in improving herd fertility by regularly identifying and removing this group (Koger, 1967). However, it should be noted that the assumption that cull cows are necessarily unproductive may not always be correct, since recent surveys indicate that approximately 43% of cull cows in the United States are pregnant at the time of survey (NAHMS, 1998a). In addition, "open" females are not necessarily infertile (Neville et al, 1987). Identification of appropriate candidates for culling is critical and should be an important "value-added" component of pregnancy testing. Veterinarians have an opportunity to be more directly involved with culling decisions to ensure that these are made in the best interests of the client, especially since cull candidates are not necessarily obvious on superficial examination. Conflict might also occur between the needs of cash flow and herd improvement. However, when reproductive potential is considered, a culling decision "tree" for cows and first-calf heifers based on removal priorities can be established. Because culling often follows pregnancy testing, veterinary inputs in selection of best cull candidates are invaluable. A priority list of cull females may be established as shown in Box 13-7.

Cull cows represent a potentially valuable source of income that should be managed accordingly. Quality, food safety, and welfare issues are important, as well as those of maximizing returns from these animals. Veterinarians should play a pivotal role in ensuring that these considerations are best integrated.

ECONOMIC CONSIDERATIONS

Economic viability in cattle-breeding operations generally follows a cyclical pattern driven by supply and demand. The length of the cycle is influenced by both net reproductive rate and generation interval, which together determine how quickly herds can rebuild after prolonged periods of high slaughter rates (Holmes, 1989). A trend, which has only recently improved, has been for steady increases in costs associated with relatively static, or decreasing, returns. In the United States an estimated 90% of cow-calf producers recently did not return a profit (McGrann and Parker, 1999). This was reinforced by a standard performance analysis (SPA) survey performed in Texas (McGrann and Wilke, 1996) in which cow-calf producers were placed into quartiles based on profitability (Table 13-6). Despite similarity in a major measure of production performance (weaning percent) between groups, financial performance differed markedly. This illustrates how financial performance may be unsatisfactory, even though production appears to be satisfactory.

Profit is a term that is much misunderstood in the cow-calf industry, partly because many cow-calf operators are not attuned sufficiently to business practices. Financial profitability is defined as net return to business equity capital. As well as change in equity, measures used to assess profitability can include accrual net income, return on assets (ROA), and return on equity (ROE). The accurate estimation of profitability necessitates the use of business financial analysis through the use of accrual adjusted financial statements. The increasing acceptance of SPA in the United States is providing both financial and productive benchmarks for cow-calf operations, as well as education in the use of appropriate financial methodologies. However, to fully exploit such information, an enterprise needs to have good records of both economic and production factors. Such records are often not easily obtained, or compared, because of overlapping of production and fiscal years, resources shared with other farm activities, variation in claimed expenses and wages, and capital costs shared by different enterprises. Despite such problems, it is still im-

TABLE 13-5

Reasons for Culling Cows

Reason	Cows (%)	Operations (%)

portant for producers to analyze the profitability of the cow-calf enterprise to ensure their long-term survival (Jones and Simms, 1997).

Profitability of a cow-calf enterprise is influenced by a number of factors, the most important being production costs, percent of cows weaning a calf, calf weaning weight, and the prices received for those calves (Jones, 1997). Production costs, herd fertility, and calf weights are amenable to on-farm management, whereas calf price may be considered unmanageable at the farm level. However, some aspects of calf price can also be influenced on farm, including genetic selection, animal sorting (for market), restricted breeding seasons, timing of sale, retained ownership, and marketing methods.

Standardized Performance Analysis

Analyses of production costs and performance measures are useful to producers because they can compare the performance of their enterprise with their own goals, as well as relative performance compared with that of benchmarks. Obviously, to improve the efficiency and profitability of an enterprise, it is first necessary to have an accurate picture of its production and economic status. However, comparison of cow-calf performance in different locations and environments requires a standardized system of evaluation. SPA is a system developed by the National Cattlemen's Association (now National Cattlemen's Beef Association), in association with the Cooperative Extension Service, to provide a standardized basis for interranch comparisons in terms of production (SPA-P) and financial (SPA-F) efficiencies, which are integrated into key performance measures. As such it represents a valuable tool for beef producers to improve efficiency and lower costs of production.

Historically, determining cost of production has proved to be a frustrating, and consequently unusual, exercise for cow-calf producers. SPA helps producers identify major costs in their operation. It should not be regarded as a record-keeping system but as a tool to improve both management and competitiveness.

A simplified, more user-friendly version of SPA is SPA-EZ, an analysis system designed to calculate the cost of production. It is based on SPA and uses the same terminology and standards. The information used for SPA-EZ can be generated from tax return data, although expenses need to be allocated to just the cow-calf enterprise.

Standardized Performance Analysis Production and Reproduction Measures

The evaluation of reproductive efficiency requires analysis over the entire production cycle, which extends from breeding to weaning of the subsequent calves. The production cycle, however, refers to a calendar 12-month period. Thus some overlap occurs, and analysis for one fiscal year may involve production records from two or even three calendar years. For example, calves born in early 2002 are included in the production cycle for that year, even though the relevant reproductive cycle commenced at the breeding season in 2001. Reproductive efficiency measures for that herd, however, apply to the year that the calves were weaned (2002), based on the number of females actually exposed in 2001.

Among the reproduction and production traits analyzed by SPA are the following: pregnancy percentage, pregnancy loss, calving percentage, calving distribution, calf death loss, calf crop or weaning percentage, actual weaning weights, weaning age, pounds weaned per exposed female, and female replacement rate. Definitions of these terms are given in Box 13-8.

Standardized Performance Analysis Financial Measures

SPA attempts to isolate the cow-calf operation from other enterprise activities to arrive at a realistic, and comparable, financial picture. The overall financial performance, and

BOX 13-8

Selected Definitions of Reproductive Performance

PREGNANCY PERCENTAGE
(No. of females diagnosed as pregnant/no. of females exposed) × 100*

PREGNANCY LOSS PERCENTAGE
(No. of females diagnosed as pregnant that fail to calve/no. of females diagnosed as pregnant) × 100†

CALVING PERCENTAGE
(No. of calves born/no. of exposed females) × 100

CALVING DISTRIBUTION
Cumulative number of calves born by 21, 42, and 63 days of the calving season, as well as those born after 63 days‡

CALF DEATH LOSS BASED ON EXPOSED FEMALES§
(No. of calves that died/No. of females exposed) × 100

CALF DEATH LOSS BASED ON CALVES BORN
(No. of calves dead/no. of live calves born) × 100

CALF CROP, OR WEANING PERCENT
(No. of calves weaned/no. of exposed females) × 100

AVERAGE WEANING WEIGHT
Total weight of weaned calves/total no. of calves weaned

POUNDS WEANED PER EXPOSED FEMALE
Total lb of calf weaned/total no. of exposed females

FEMALE REPLACEMENT RATE
([Raised replacement heifers exposed for first calf breeding + purchased replacement heifers and exposed breeding cows]/no. of exposed females) × 100

From McGrann JM, Parker J: *IRM-SPA handbook: factors influencing profitability of the cow-calf operation, SPA 50-1*, College Station, Tex, 1999, Texas Agricultural Extension Service, Texas A&M University.

*Adjustments to "exposed" female numbers are made as follows: "exposed" animals that are sold or otherwise removed between breeding and pregnancy diagnosis are subtracted; "exposed" animals purchased during that period are added. All death losses of exposed females should remain within that group.

†The numerator should include females that abort between pregnancy test and calving. Purchased pregnant females should be added to the divisor whereas pregnant females sold should be subtracted.

‡The assumption is made that the first 21-day calving period should start 285 days following introduction of bulls to the mature cow herd. If this date is unavailable, then counting starts at the time of calving of the third mature (3 years and older) cow. All calves delivered, dead or alive, are included in this analysis.

§Calf death loss should include calves lost at birth plus calves that die before weaning.

status, of any business or enterprise is evaluated with measures of parameters such as profitability, liquidity, solvency, financial efficiency, repayment capacity, and change in equity. These are all specific, meaningful terms to the financial cognoscenti. Unfortunately, they are often poorly understood within the cow-calf sector.

Liquidity indicates the capability of the enterprise to pay accounts or bills when they become due. Although a positive cash flow may provide evidence of liquidity, this does not necessarily imply profitability. Solvency assesses the ability of the enterprise to meet all financial obligations if all of its assets are sold. A useful measure of solvency is the equity:asset ratio. As previously stated, profitability is the net return to business equity capital, and it measures the financial performance of the enterprise over a period of time (usually 12 months). Investments and returns are expressed on a per unit asset basis. Thus enterprise financial "health" (or profitability) may be represented on the basis of percent return on assets (ROA). This is best described in terms of total assets associated with the enterprise. In the case of a cattle-breeding enterprise, however, it may also be expressed in terms of return per breeding female or other specific assets such as designated land area. Change in owner equity (assets minus liabilities) is probably the best single value that summarizes overall business progress (McGrann and Parker, 1999).

The financial position and economic performance standards of a cow-calf operation may be assessed on a per-cow or per-hundredweight (100-lb) weaned basis. Primary measures that are obtainable from this analysis include capital investment per cow, debt per cow, the debt-to-equity relationship, the value of feeds fed, grazing costs, nonfeed costs, capital costs, income or return on assets, and unit costs of production (e.g., cost per pound of weaned calf, per cow, or per land area).

Good records are essential for the effective conduct of any enterprise analysis. These include herd inventory records at various times in the calf production cycle, including the following: females exposed to breeding, pregnant females sold and purchased, abortions observed, twins born, open females at calving, calf deaths before weaning, and purchases of foster calves. Useful management information includes dates of breeding season, calving, and weaning, as well as weaning weights. Good records are particularly necessary for feed inputs because these usually represent a major item. These should include details of all grazing resources used (dates, land area, number of head, rental, or agistment, etc.), as well as purchased and harvested feeds. Other expenses, such as repairs, interest, fuel, and veterinary expenses, also need to be assigned to the cow-calf enterprise, as well as labor (hired and family). Records should include the purchase of breeding stock and other capital costs. Finally, all income assigned to the cow-calf herd (including calf and cull animal sales, replacements, animals transferred to other enterprises such as stocker-feeder) is used to develop an income statement (listing all income and expenses for the enterprise) and a beginning and ending balance sheet for the fiscal year.

Analysis of these records is relatively simple once the effort has been put into obtaining them. Software such as FINPACK, as well as that provided by SPA, is useful in preparing the appropriate economic and production summaries.

Table 13-7 shows how such figures can be used for comparative purposes.

On an individual enterprise level, the amount of information generated can be comprehensive. For examples, economic and production summaries for a Kansas beef herd are given in Tables 13-8 and 13-9.

†Market value: current market value of the asset.

Analyses of Herd Performance

Such data as those just shown can provide useful information for evaluation of the performance of the cow-calf operation (Rogers et al, 1994). For example, pounds (or kilograms) weaned per exposed female is a useful estimate that combines a number of aspects of reproduction and production. These include nutrition, male and female fertility, genetics for growth and maternal traits, and loss from death and disease. The female replacement rate indicates the proportion of the female herd represented by replacement heifers and provides insight into culling strategies, cow longevity, and, possibly, genotype-environment compatibility. A high replacement rate generally means higher herd costs and lower productivity per cow, since a large proportion of the herd consists of first- and second-calf heifers (Rogers et al, 1994). The distribution of calvings by 21-day periods is also an important measure of reproductive efficiency. Since calf age is directly linked to weaning weight, more calves born earlier in the calving season will lead to heavier aggregate weaning weights. If calves grow at 2 lb (0.9 kg)/day, then a delay of one cycle will lead to a loss of 42 lb (19 kg) at weaning. If all females are cycling at the start of the breeding season, and bulls are capable, it is reasonable to expect a conception rate (one cycle pregnancy rate) of 60%. This would cause an expected distribution of pregnancies (and calvings) for 100 females, as shown in Table 13-11.

A realistic goal is for a 65% calving over the first 21 days of the calving season (Rogers et al, 1994). Variations on the normal pattern may be due to a number of reasons, including the following:

- Female infertility: lack of puberty, postpartum anestrum, nutritional deprivation, venereal disease
- Male infertility: primary bull infertility, lack of libido, social factors, venereal disease

Important clues as to patterns of pregnancy (and calving) and their causes can be obtained from analysis of HPD data.

Factors Influencing Cow-Calf Profitability

As previously observed, control of production costs is the key to profit in the cow-calf enterprise. These may be handled as follows:

1. Lower production costs while maintaining the same production level
2. Increase production while maintaining the same production costs
3. Lower both production and production costs but ensure that costs are lowered more than production
4. Increase both production and production costs but ensure that production is raised more than costs

The first step in any program to improve profitability must be identification of production costs. Although the use of SPA for this purpose has been highlighted in this chapter, there are many avenues of assistance (and programs) available from state extension services and university resources. Once production costs are identified, the contributions of different elements may be studied to locate possible areas for improvement. The influence of changes in a number of key factors based on 1995 U.S. prices is shown in Table 13-10.

A 10% change in total feed cost has a significant effect on both parameters, approximating a 5% change in weaned calf crop. Reducing feed costs by such an amount is not unreasonable, if innovative measures are taken, especially to reduce dependence on harvested and stored feeds. Veterinarians can have a great financial impact on the profitability of beef operations by formulating least cost rations for client's cattle (Toombs, 1996), with the most overlooked area for veterinarians and nutritionists alike being a cheaper feeding program over the winter months. The relative contributions of different factors to the cost of producing a calf in the United States have been estimated from SPA data. Here, approximately 65% of the total costs are attributable to feed (bought and raised feed and grazing), which indicates that this should be a major target for reducing costs. Veterinary and medical bills are relatively minor, comprising approximately 4% of variable costs. By combining NAHMS and SPA information, a number of U.S. producers were identified who reported either positive or negative net returns in 1993 (NAHMS, 1996). Here, the average size of operation (167 versus 162 cows, respectively) was very similar, indicating that size in itself was not a major influence on profitability. Positive return producers obtained a slightly higher price for their calves than did negative return producers ($87.97 versus $86.90/cwt respectively), indicating that price obtained for product was not a major determinant of profitability. The positive return group also fed less expensive feeds than did the negative return group. However, the biggest cost savings came through the amount of capital invested per cow. Those operations showing positive returns had considerably less investment per cow than did those showing negative returns ($2029 versus $3870, respectively). At a conservative interest rate of 6%, this would account for a difference of almost $26/cwt of weaned calf. Most of this extra capitalization was due to real estate. The collective differences were reflected in a lower debt per cow in the positive group than in the other ($275 versus $530, respectively), causing a further loss of $6.42/cwt of weaned calf for the group that had negative returns.

The resource base available to cattle producers will influence costs, as well as types of feed and weaning weights achieved. Here, considerable difference occurs in cow-calf production costs between different geographic and climatic regions in the United States, as shown in Table 13-12.

Economies of size have been reported (Langemeier et al, 1995), with herds of less than 500 cows having higher relative costs than those having more than 500 cows. Herds in the SPA program with less than 50 cows were considered to be losing equity.

Adapted from Jones RD: Kansas State University Extension Bulletin MF-2259, April 1997.

A number of management practices associated with increased beef herd profitability in Kansas were identified by Engelken et al (1991) as including use of partial budgeting, fly control, use of growth promotants and creep feeding in calves, precalving parasite control in cows, and improved calf management generally.

Programs that incorporate a number of managerial and veterinary inputs have been shown to increase returns (Anderson et al, 1986; Prince et al, 1987; Deutscher, 1988). The O'Connor system of beef cow management (Anderson et al, 1986), in which a restricted breeding season was combined with prior bull selection, good nutrition management, and early pregnancy testing, was shown to increase weaned calves by 14% and generate an extra $39 per cow. In the Washington program (Prince et al, 1987), which combined cow and heifer measures, increases provided an extra $48 per cow and an estimated 900% return on investment.

Costs of Animal Disease

In this discussion of factors affecting the profitability (and viability) of cow-calf enterprises, it is appropriate to consider the relative cost of disease. Survey data showed that, in selected Colorado beef herds (n = 86), the mean annual cost of disease prevention measures varied from $6.39/cow (Salman et al, 1990) in one survey to $11.24 and

$11.29/cow in two others (Salman et al, 1991a,b). This included the cost of vaccines and drugs ($5.11/cow) and the cost of veterinary service ($1.28/cow). In addition, 0.32 hour of labor was spent per cow. Approximately 60% of the total costs of preventive vaccines and drugs was for miscellaneous diseases. The prevention of reproductive diseases accounted for almost the entire cost of preventive veterinary services. Pregnancy examination, brucellosis vaccination of replacement heifers, and breeding soundness examinations were the three procedures that made up the majority of veterinary costs (Salman et al, 1991a,b). The most commonly reported disease entity was diarrhea in calves (25% of all disease cases). The second most commonly reported disease was pneumonia. The total annual cost associated with the occurrence of diseases in beef herds was $20.56 per cow. This included losses from deaths, culled animals, reduced production, veterinary costs for treatment of diseased animals, and miscellaneous expenses. The most expensive disease category on a total cost basis was that in the miscellaneous category, since this covered a large number of cases.

TABLE 13-12

Cow-Calf Production Costs in Different Geographic Regions of the United States for 1997 to 1998

Region	Northwest	Southwest	Midwest	Southern plains	Southeast
Low-cost producer	$273	$254	$239	$244	$224
High-cost producer	$399	$358	$340	$365	$342

Cattle-Fax Annual Cow-calf Survey Data. Available at http://www.cattle-fax.com (accessed June 19, 2001).

Sudden death–clostridial disease was the next most costly because of the high individual cost. The enteric category was the least expensive, even though it accounted for the second largest number of cases, because the cost per case was low. The cost of veterinary services for treating diseased animals was a relatively small amount of the total cost in each disease category. Veterinary costs were highest for reproductive diseases because of the expense associated with the treatment of dystocia and the treatment of vaginal and uterine prolapses.

Between 1986 and 1988, producers spent an annual average of $2.04 ($0 to $29.88) per cow on veterinary services for the treatment of diseases (Salman et al, 1991a,b). The cost of veterinary services was 5.4% of the total mean cost of disease incidence. Approximately 92% of the mean annual health management costs were associated with pregnancy examination, brucellosis vaccination, breeding soundness examination, pulmonary arterial pressure testing, and campylobacteriosis vaccination. The costs of veterinary services, vaccines, and drugs for treatment and prevention on a per-cow basis also varied greatly among herds. Most of the annual disease costs (over 90%) occurred in other areas, such as vaccine and drug purchases by the producer, as well as costs of labor, losses from lost production, deaths, and transportation.

In 57 California beef cow-calf herds studied in 1988 and 1989, the mean cost associated with episodes of disease was $33.90/cow-year, with $0.78 and $1.37/cow-year spent for veterinary services and drugs, respectively (Hird et al, 1991). For disease prevention, the mean expenditures for veterinary services were $1.67/cow-year, most of which was spent on the prevention of reproductive problems.

In a survey of 60 cow-calf herds in Tennessee in 1987 and 1988, 4% of the total cost of disease was attributable to veterinary services and 2.3% to the purchase of drugs for the treatment of sick animals (New, 1991). The cost of preventive veterinary services accounted for 8.8% of the total cost of all preventive veterinary services. Approximately 68% of the total cost of preventive actions was spent on drugs, with drugs to prevent intestinal and external parasites being the most costly ($5.99 and $1.80/cow-year, respectively). Only 28% of the producers used veterinarians to implement animal health management actions, only 15% used veterinarians to monitor the pregnancy status of cows and heifers, and only 3% used veterinarians as consultants.

Estimates of the financial impact of different veterinary interventions for the United States have been given by Toombs (1996), based on calf prices of 80 cents/lb. At an estimated calf value at weaning of $400, a combination of decreasing calf morbidity (from 50% to 10%) and mortality (from 5% to 1%) led to savings of an estimated $20/cow (or $2000 for a 100-cow herd). A program that increased weaning weights (450 to 500 lb), increased pregnancy rates (90% to 95%), and decreased calf mortality (from 5% to 2%) caused an estimated improved return of approximately $45,000 over 5 years for a 250-head cow herd.

NUTRITIONAL MANAGEMENT OF THE BREEDING HERD

Good nutrition provides the essential basis for optimum productivity in cattle breeding operations. Despite this, nutritional expertise has not been a traditional strength of many food-animal veterinarians.

Throughout the world, beef-breeding operations are generally range or pasture based. These operations are conducted in diverse environments, with great variation in nutritional management. Even within the United States, the area of pasture or rangeland required to maintain a cow-calf unit may vary from 30 acres or more in the southwest to 1 or 2 acres in more intensive regions. In parts of Australia the corresponding area may be measured in square miles. However, in general, the area of land, or amount of pasture, necessary for production is related to local economic realities. This, in turn, is related to levels of managerial and resource inputs that can differ with regions, markets, and enterprise priorities. Notwithstanding such caveats, there are a number of principles of good nutritional management that may be universally applied to cattle breeding operations (Spitzer, 1986). Regardless of region, an important consideration is that of maintaining or improving production while reducing costs. In simple terms, financial return from a beef breeding operation is a function of number of calves, their weaning weight, and price. On the cost side of the ledger is the maintenance cost of the breeding females. This varies considerably, both within and between regions. Market price, in general, is usually unmanageable at the farm level. However, both the number of calves born and their weaning weights are strongly influenced by nutrition. For example, good nutritional management helps to ensure that as many females as possible are cycling at the start of the breeding season. This, in turn, helps to ensure that calves are born early with the result that they are older, and heavier, at weaning than later-born calves, as shown in Fig. 13-2.

In general, nutrition is the most important limiting factor of beef breeding performance. For veterinarians, an understanding of the principles underlying the nutritional management of breeding females is necessary. Effective counseling and troubleshooting does not necessarily require a higher degree in nutrition, although it should include sufficient knowledge and wisdom to know when such expertise is needed. A starting point is to have a working knowledge of the different energy measuring systems (total digestible nutrients [TDN], metabolizable energy [ME], and net energy [NE]) that are commonly used, their applications for different classes of animals, activities and feedstuffs, and to identify one with

Downloaded from Vet-eBooks.com

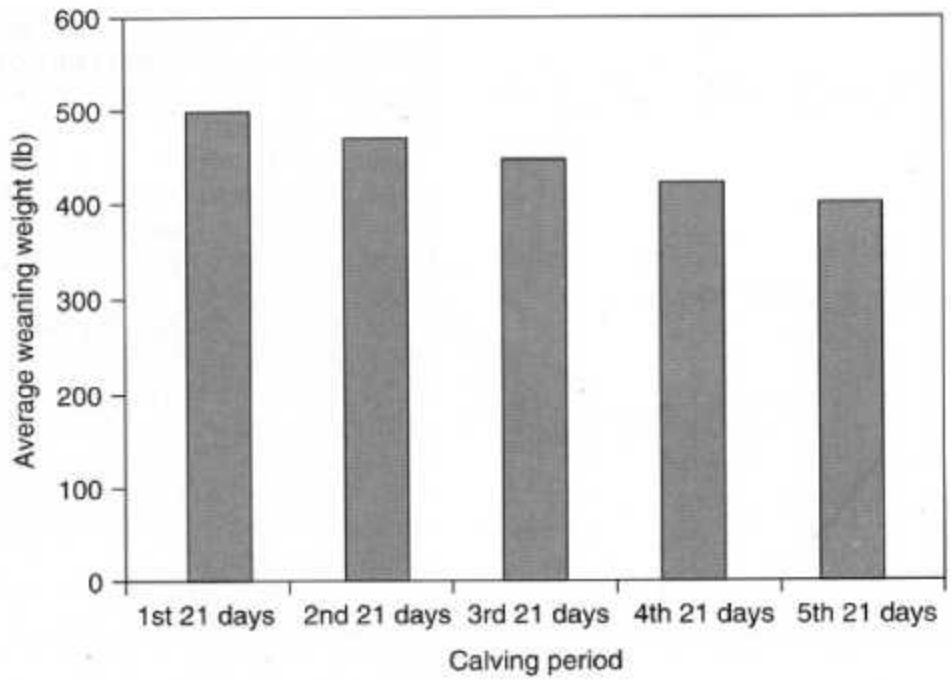

FIG. 13-2 Effect of cow calving time on average weaning weights.

which the veterinarian can work best. The *Nutrient Requirements of Beef Cattle* from the National Research Council (NRC) in the United States is a useful document revised in 2000. This is packaged with a computer program that includes ration formulators as well as a library of feeds and feedstuffs. A number of computer programs are now available for least-cost-ration formulation in beef herds.

A useful concept is animal unit (AU) equivalent values, which allow direct comparison of the resource requirements of different classes of animal. An animal unit is defined as a constant forage demand rate (Kothmann and Hinnant, 1999). An animal unit equivalent (AUE) for any animal type can be obtained by dividing the estimated forage demand of that animal by the selected constant, or benchmark. The number of animals multiplied by their AUEs gives the total number of AUs needed. In turn, stocking rate can be devised by multiplying this total by the number of days grazing a given area, providing animal unit days (AUDs). Table 13-13 lists AUEs for different classes of animals. Here, the benchmark (1.00 AU) is a spring-calving cow (1000 lb) of above-average milking ability with a 3- to 4-month-old calf, grazing adequate quality forage (Table 13-13).

Increasing stocking rate will tend to cause increased gain per unit land area (acre, hectare), but decreased gain per animal. This relationship generally holds true until lack of available forage leads to decreased intake. Optimum stocking rates are attained before this point is reached. Increasing stocking rate beyond this point leads to a decrease in both gains per animal and per land unit area.

Nutrition is a complex topic that includes aspects of forage quality and availability, as well as the contributing roles of water, vitamins, minerals, protein, and energy. Many of these aspects are beyond the scope of this discussion. For more in-depth information, readers can consult the NRC's *Nutrient requirements for beef cattle, update 2000*. A number of computer programs are available to assist with ration formulation. In the present discussion, however, the important contributions of dietary energy to female cyclicity and fertility necessitate that it receive closer scrutiny than other nutritional components. Dietary energy (carbohydrates and fats) may be measured a number of ways including gross energy (GE), digestible energy (DE), ME, NE, and TDN.

GE is the heat of combustion of a feedstuff, expressed as kilocalories per gram (Kcal/gm) or megacalories per kilogram (Mcal/kg). DE is a measure of the amount of energy absorbed by the animal (GE in feed minus GE in feces). ME accounts for extra energy loss, specifically in urine and gases, whereas NE allows an adjustment for the specific dynamic effect of captured energy. TDN has also been used widely to estimate energy content of feeds. TDN is a combination of digestible crude protein (CP) and crude fiber (CF) plus digestible nitrogen free extract (lipids). A rough conversion between systems may be obtained by the following equation:

$$1 \text{ kg TDN} = 4.4 \text{ Mcal DE}$$

TABLE 13-13

Animal Unit Equivalents for Grazing Beef Cattle

Class of cattle	AUE
Cow (1000 lb), with 3-4 mo calf	1.00
Calf, 3-4 mo	0.30
Replacement heifer (24-26 mo)	1.00
Cow (1000 lb), not lactating	0.90
Steer (24 mo)	0.90
Yearling (18-24 mo)	0.80
Yearling (12-17 mo)	0.70
Weaned calf (>12 mo)	0.50
Bull (>24 mo)	1.20
Bull (24-60 mo)	1.50

Cow Nutrition Year

Nutritional requirements vary throughout the "cow year." The most critical periods for reproduction are early postcalving (when maximum lactation is combined with the need for rebreeding) and immediately precalving (when maximum fetal growth occurs along with lactation preparation). Different periods within the "cow year" with varying nutritional requirements have been identified in Table 13-14 (Marston et al, 1998).

Downloaded From Vet-eBooks.com

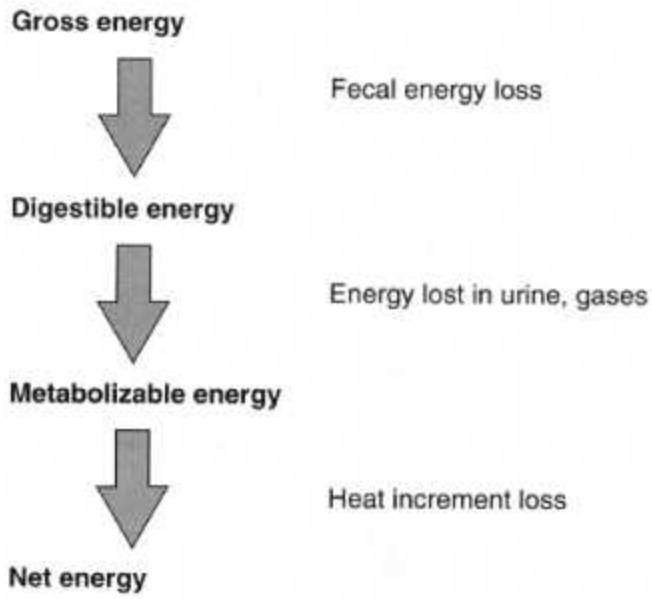

FIG. 13-3 Energy Utilization and Loses.

Environmental conditions can strongly influence the nutritional requirements of cattle, as well as the intake. For example, cold weather increases energy needs whereas hot or inclement weather can reduce foraging opportunity.

When nutrition is limited, the breeding cow meets her needs according to a priority list. First priority goes to maintenance, then growth, followed by milk production, with reproduction last (Marston et al, 1998). Because larger females have greater needs for maintenance, the effect of cow size on fertility should be considered, especially since recent trends have been toward increased growth as well as milk production. Both of these influence nutritional requirements for breeding females, as shown in Fig. 13-4. Here, a 5-lb increase in milk production per cow per day increases the net energy requirements of the cow by 10% and the CP requirements by 13% to 15%. Milk production needs of females are seldom considered by producers (Spitzer, 1986). Cow size also affects nutritional needs, with each 100-lb increase in cow weight changing net energy requirements by 6% to 8%. Thus increases in size and milking ability come with nutritional "costs," which, if not adequately met, will be extracted from the ledger of reproductive efficiency.

The quality and quantity of range forage varies greatly throughout the year and between years, influenced by moisture, plant species, and grazing pressure. Seasonal changes in the nutrient density of rangeland forages are mainly associated with the degree of plant maturity. In general the greatest nutritional value of plants occurs before maturity. Good nutritional management involves matching, as far as possible, the nutrient requirements of cows and nutrient density of the pasture. Some assumptions are necessary, since grazing animals are not fed a ration; they select a diet from the forage available (Kothmann and Hinnant, 1999). Grazing management can influence the quality of this diet. Grazing

*For 1100-lb beef cow of average milk production (15 lb/day).

†Period 1 represents the most important period for nutrition in the cow year, in terms of both reproduction and production. As well as nursing a calf (with peak lactation occurring at about 60-80 days postpartum), but she must recycle and rebreed within an 80-85 day window of opportunity to permit a 12-month intercalving interval. Thus nutritional requirements are maximum during this period, with the recommendation that females gain weight between calving and rebreeding. Inadequate nutrition during this period will lead to lower milk production and calf weaning weight as well as reduced rebreeding performance.

‡ During period 2, the cow is lactating although demands should be reducing. The female should also be pregnant, although the demands due to pregnancy should be relatively small. This period often coincides with good forage availability in spring calving programs. Thus period 2 is not usually regarded as a crucial nutritional period for reproduction.

§In Period 3, nursing should be completed while the demands of the developing fetal-placental unit are still relatively low. Thus period 3 is not regarded as a crucial nutritional period for reproduction either.

‖In Period 4, the final 60-90 days of pregnancy represent the second most important nutritional period for beef females. Fetal growth is maximum while fat stores are being augmented in preparation for lactation. Good nutrition at this juncture should aim for females to calve at a body condition score of approximately 5. Inadequate nutrition during this period can cause lighter calves at birth (although dystocia rates are unaffected), lessened calf survival, lower calf growth (because of less milk), and delayed return to estrus.

Downloaded from Vet-eBooks.com

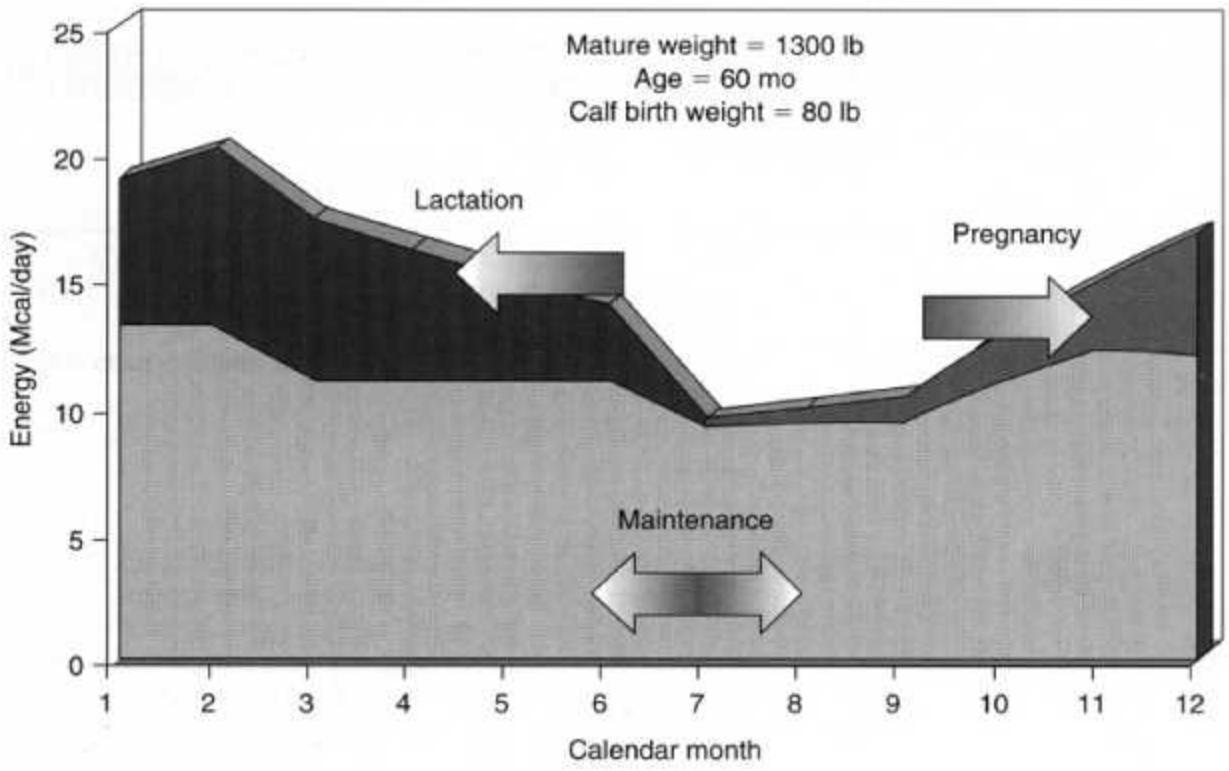

FIG. 13-4 Energy requirements of mature cows.

management includes considerations of factors such as the biological types of animals involved, stocking rates, plant species available, season of grazing, fertilization, and grazing methods used. It should also consider the long-term aspects of the pasture as a renewable resource. A software program—"The Grazing Manager"—assists with this task (Kothmann and Hinnant, 1999).

Body Condition Score

Accurate and timely determination of nutritional status of grazing animals represents a challenge for beef producers, especially because many variables can influence a cow's response to a given level of nutrition (Spitzer, 1986). This is compounded by the fact that relatively few cow-calf operations in the United States appear to use weigh scales (NAHMS/CHAPA, 1993). Fortunately, a large body of evidence exists to support the use of BCS as an effective indirect method for determining nutritional status in breeding females. This is reinforced by observations that BCS, and changes in BCS, are more reliable indicators of nutritional status than is body weight, or changes in body weight, which can vary with gut fill and pregnancy status (Kunkle et al, 1994). In addition, the assessment of BCS can often be made more conveniently than can the measurement of body weight.

BCSs represent a subjective assessment of body fat (or energy reserves), which is strongly related to female reproductive performance (Kunkle et al, 1994). Several systems exist, with a 1-9 system (Richards et al, 1986) most widely used within North America (Table 13-15). Another system in use is the ESCA 1-4 system, whereas a 1-9 system has been described for use with *Bos indicus* cattle (Nicholson and Butterworth, 1986).

BCS is not difficult to obtain, and it is both repeatable and accurate in experienced hands. It is best done through visual appraisal, reinforced by palpation of those body regions most likely to demonstrate fat deposits. For beginners, it is advisable to practice by comparing assessments with someone who is more experienced.

Use of Body Condition Scoring

BCSs generally vary throughout the year, and they should be monitored regularly. The "benchmark" for beef females is a BCS of 5, which represents an average, moderately fleshed cow that is neither fat nor thin. However, the BCS for optimum female efficiency varies with breed and operation and may be higher or lower under different conditions (Corah, 1989). In general, females should calve between condition scores 4 to 6 and then gain slightly to breeding. In this range of scores, a 1000-lb female gains or loses approximately 70 lb/condition score. It generally takes about 2 months to gain 1 score under pasture conditions. Care should be taken with overreliance on "averages," since these can mask variations that might adversely affect herd fertility levels. Care should also be taken with group observations of BCS made from a distance when animals are in the pasture or paddock. In general, such observations are less accurate than those made when animals are proximate in the pen or chute. Proximate assessment is often dependent on opportunity, as when animals are gathered for other managerial reasons such as prebreeding, pregnancy testing, or calving. Whereas each of these occasions presents particular advantages and disadvantages, the BCS-pregnancy relationships of each occasion appear to be similar (Fig. 13-5).

Despite similar relationships between BCS assessments at different periods in the cow-calf cycle and subsequent breeding success, managerial and logistic differences do occur with assessments at these different junctures, as explained in the following sections.

Body Condition Scoring at Calving

The body condition score of females at calving can tell much about their rebreeding prospects (Spitzer, 1986). However, assessment of BCS at this time provides a relatively small window of time in which to meet targets. Thus 1000-lb cows calving at BCS 4 might have, for example, 60 days before they reasonably might be expected to be bred at

Downloaded from Vet-eBooks.com

TABLE 13-15

System of Body Condition Scoring for Beef Cattle

Group	Score	Description
Thin	1	*Emaciated:* Extreme emaciation, no detectable fat over bony protuberances. Tailhead and ribs are prominent. Animal often weak.
	2	*Poor:* Cow somewhat emaciated, less prominent bony protuberances, some tissue cover along spine.
	3	*Thin:* Ribs individually identifiable, but less sharp. Some fat along spine and over tailhead, some tissue cover over the dorsal aspect of the ribs.
Borderline	4	*Borderline:* Individual ribs no longer visually obvious. Spinous processes individually palpable, although rounded. Some fat cover over ribs, transverse processes and around tailhead.
Moderate (optimum)	5	*Moderate:* Generally "good" appearance; fat over ribs is spongy and areas lateral to tailhead have fat cover.
	6	*High moderate:* Firm pressure necessary to feel spinous processes; fat is observable and palpable over ribs and around tailhead.
	7	*Good:* Cow appears "fleshy" and obviously carries considerable fat. Very spongy fat cover over ribs and around tailhead with "rounds" or "pones" beginning to become obvious. Some fat around vulva and in crotch.
Fat	8	*Fat:* Cow is very fleshy and "overconditioned." Spinous processes almost impossible to palpate. Large fat deposits over ribs, around tailhead, and below vulva. "Rounds" or "pones" are obvious.
	9	*Extremely fat:* Cow obviously extremely "waisty" and patchy and has block-like appearance. Tailheads and hips are buried in fatty tissue, and "rounds" or "pones" of fat are protruding. Bone structures not visible and barely palpable. Mobility may be impaired.

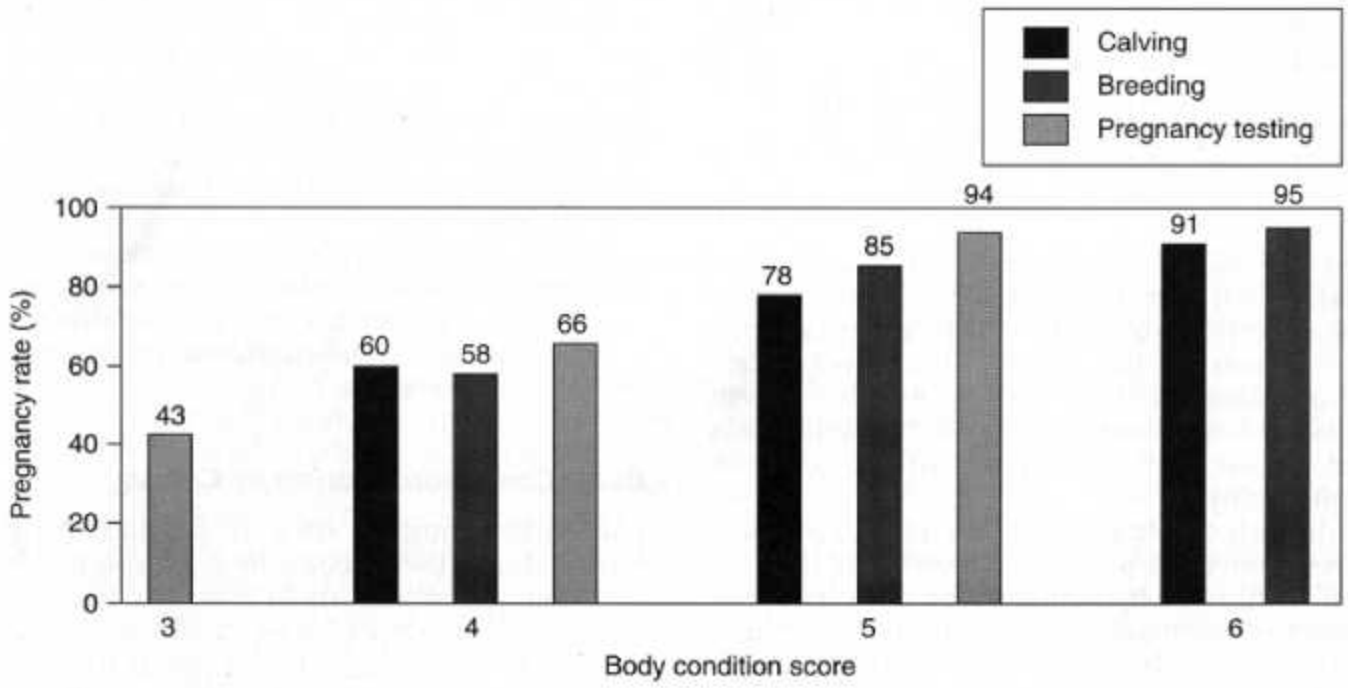

FIG. 13-5 Relationship between body condition score at different events and pregnancy rates.

Downloaded from Vet-e-Books.com

a BCS of 5. Assuming that this change in 1 BCS score represents an increased body weight (BWT) of approximately 70 lb, then these females will need to gain slightly more than 1 lb/day (0.45 kg/day) in the interim—a gain that must coincide with the period of maximum milk production. A disadvantage of conducting BCS at calving is that it necessitates either gathering cows with very young calves, which is often inadvisable, or using visual assessment from a distance in the pasture or paddock, which tends to cause errors.

Body Condition Scoring at Breeding

Assessment of body condition in females at breeding should provide the most accurate prediction of herd fertility, since it occurs just before the predictive event. The disadvantage is that there is little opportunity to correct significant shortfalls in time to affect the current breeding season, unless this is prolonged.

Body Condition Scoring at Pregnancy Checking

Assessment of body condition at the time of pregnancy checking has the advantage in that it can be done in concert with a routine, managerial procedure, thus not requiring a separate animal handling. It also allows considerable time to remedy obvious deficiencies before calving and then subsequent rebreeding. The disadvantage is that, although it can provide clues to explain current pregnancy patterns, it is too late to remedy them.

Mineral Supplementation

Mineral requirements are generally placed into two groups: major minerals (calcium, phosphorous, and salt) and trace minerals (or microminerals), which usually have much lower requirements. Table 13-16 shows minerals for which nutrient allowances for beef cattle have been established (calcium and phosphorus levels are shown in Table 13-14).

Several microminerals have been identified that can affect different reproductive functions in cattle, including cyclicity, fertility, and survival of early pregnancies. Both low copper and magnesium have been associated with increased services per conception as well as increased early embryonic death (EED) lactating dairy cows (Ingraham et al, 1987), whereas low copper and zinc levels have been associated with suppressed estrus expression (McDowell, 1992; Herd, 1994). Copper, zinc, manganese, and cobalt have all been associated with decreased postpartum cyclic activity (Doyle et al, 1999), whereas manganese deficiency in older females has also been associated with depressed conception rates, abortion, stillbirths, and low calf birth weights (NRC, 1996). In turn, elevated levels of manganese significantly reduced days to conception (Doyle et al, 1999), whereas application of phosphorus, copper, manganese, and zinc on native pasture improved reproductive performance in lactating beef cows, without evident change in body condition (Doyle et al, 1988). Iodine deficiency may have delayed effects such as irregular cyclicity, low conception rate, and retained placenta in females, as well as depressed libido and semen quality in bulls (NRC, 1996).

Male Nutrition

As with females, postweaning rate of gain influences both weight and age of puberty in bulls, with puberty often defined as the age at which the first ejaculate containing 50×10^6 sperm with a minimum of 10% motility (Wolf et al, 1965) is obtained. In general, low nutrition during this period will delay puberty in association with delayed testicular growth and sperm production (Bellows and Short, 1994; Swecker, 1997) although genotype-environment interactions occur with such relationships, particularly with *Bos indicus* genotypes in subtropical or tropical environments (Perry et al, 1991; Chase et al, 1997). Diets adequate in protein, vitamins, minerals, and energy appear to hasten the onset of puberty in beef bulls (Coulter and Kastelic, 1999), although high-energy diets for postpuberal bulls do not appear to be beneficial to some reproductive traits and may actually be harmful (Coulter and Kastelic, 1999). A multisire natural breeding study, in which calf crop was established by

Downloaded From Vet-eBooks.com

parentage, showed that increasing backfat thickness was associated with reduced fertility (Coulter and Kozub, 1989). The harmful effects of high-energy diets during the peripuberal and postpuberal periods may be long lasting and may affect sperm production, semen quality, and sex drive. The exact mechanisms for the deleterious effects of high-energy levels on sperm parameters is unknown, although adverse effects on testicular thermoregulation as well as stress-induced hormonal imbalances have been mooted (Coulter and Kastelic, 1999). In general, bulls should be in good, athletic condition at the start of the breeding season, with the expectation that an active, mature bull may lose 1 to 200 lb in body weight over the course of an intensive breeding season. Such loss of weight in mature bulls has not been shown to adversely affect sperm production, unless specific dietary deficiencies occur.

Specific dietary deficiencies that have been associated with bull infertility include zinc and selenium (Swecker, 1997). Gossypol, a component of cottonseed, can adversely affect both spermatogenesis and sperm morphology in bulls (Chenoweth et al, 1994), although the spermatoxic effects of gossypol may be countered with dietary vitamin E (Velasquez-Pereira et al, 1998).

Nutritional Effects on Immunocompetence

A general association between nutrition and health has been recognized for many years. For example, general malnutrition can cause reduced disease resistance by altering immune responses (Franco, 1998). A depressed immune system, in turn, causes increased susceptibility to disease, reduced immunological response to vaccines, and nonresponsive medical therapy (e.g., with antibiotics or anthelmintics). A functional immune system requires adequate energy, protein (or amino acids), minerals (calcium, phosphorus, iron, zinc, copper, cobalt, and selenium), and vitamins A and D (Doyle et al, 1999) to sustain its different mechanisms. The interaction between nutrition and immunity is complex and is complicated by a wide variety of both disease threats and disease types of immune response that may be evoked. This topic is covered in detail by Doyle et al (1999).

HEALTH AND PRODUCTION MANAGEMENT PROGRAM

A cost-effective and efficacious herd health and production management program is essential for the economic viability of most cow-calf operations. What such a program entails, however, varies with region, relative economics, perceptions, and opportunity. A good herd health program manages risk of disease and lowered productivity at a number of levels and reflects the complexity of maintaining immunocompetence in both individuals and groups. These levels include considerations of biosecurity, nutrition (both macro and micro), and the judicious use of biologicals such as vaccines. The term *immune system management* is used to describe this holistic view of herd health (Stokka and Faulkner, 1998). Here, both reproductive, nutritional, and health management overlap. For example, the adoption of a restricted breeding season (e.g., 40 to 65 days for cows and 30 to 45 days for heifers) is advantageous to herd health since it allows groups of animals to be managed and treated similarly.

The role of the herd health provider in developing herd health programs has a large educational component (Spire, 1988). Producers in the United States rely heavily on veterinarians for relevant information on herd health (NAHMS, 1994a). However, despite the privileged position of veterinarians as advisors on herd health, a considerable number of producers do not appear to have health programs that supply even minimum protection against common pathogens. For example, in a survey of 169 producers in northwest Kansas, Spire (1988) reported that the following vaccines were used in cows and heifers respectively: none (31.3%, 28.4%), *Campylobacter* (55.6%, 44.4%), *Leptospirosis* (62.1%, 53.2%), *Clostridia* (5.3%, 23.6%), IBR (11.2%, 19.3%), bovine viral diarrhea (BVD) (11.2%, 13.6%), and *Rotavirus-Coronavirus* (10.6%, 5.9%).

A more recent survey from a wider geographical sampling of cattle breeding operations in the United States (NAHMS, 1998a) indicated even less vaccination activity overall. The most common vaccination was calves for *Clostridial* diseases between 3 weeks of age and weaning (approximately 62% of operations), and this group also received most vaccinations against IBR, BVD, PI3, and BRSV. For cows, most vaccinations were against reproductive disease, such as *Leptospirosis* 28.5% of operation and *Campylobacter* 20.1%. Other vaccinations included bovine respiratory disease (BRD) and clostridia, both approximately 14%; *Escherichia coli*, 4.7%; *Rotavirus* and *Coronavirus*, 4%; and *Trichomonas foetus*, 1.1%. Bred heifers were generally not subject to as much vaccination as cows or heifers before breeding. For the latter group, vaccinations included leptospirosis, 18.0% and IBR and BVD, approximately 17%. Only 11% of heifers were vaccinated against *Campylobacter* before breeding, and 0.2% against *Trichomonas foetus*. A somewhat brighter picture emerged from a survey of 53 beef cow calf producers in the Rocky Mountain West (Sanderson and Gay, 1996), where considerably higher utilization rates were reported. Here, over 60% of producers vaccinated cows for *Clostridia*, 87% for *Leptospirosis* and 85% for *Campylobacter fetus* (79% heifers). However, even though this survey was conducted with progressive ranchers, it suggested that management practices were not adjusted for relative risk, especially when purchasing cattle of unknown origin. This was confirmed in survey data that showed that only a third of operations quarantined new additions to the herd (NAHMS, 1997b).

Although apparent opportunity exists for many producers to improve their levels of herd protection and biosecurity, producers themselves have nominated the following as serious disease concerns (NAHMS, 1994b): external parasites (67%), internal parasites (61%), females not breeding or breeding late (e.g., reproduction) (50%), pinkeye (41%), calf scours (31%), footrot (26%), abortion (14%), weak calves (22%), and calf pneumonia—shipping fever (23%).

MARKETING OF HERD HEALTH CONCEPTS

For many producers, the sheer number of potential disease threats, and the biological and therapeutic products available for their prevention or treatment on the market, is bewildering. Here, veterinarians can play a valuable role in simplifying and translating this information into effective, practical, cost-effective herd health programs. In the past such advice has been given freely, and veterinarians have relied on associated services and product sales as major income generators. This is changing as producers perform more and more services previously regarded as solely within the veterinary domain, and, at the same time, veterinarians are finding it increasingly difficult to compete with other sources for product sales. Over 15 years ago, U.S. veterinarians identified the growth of herd health management services as the area with greatest potential for revenue growth (Wise, 1987). Today this is still an area of largely untapped potential.

The problem is to identify ways for veterinarians to better market their health knowledge for cow-calf producers. Estimates of the value of herd health programs to producers are difficult to generate, although Toombs (1996) has estimated

higher returns of $5 to $20/cow when an effective vaccination program is used. Generic programs for all producers are of limited value. Each operation is a unique entity, with its own risk factors, economics, and priorities—factors that should be reflected in an individually tailored, documented, herd health program. Not only should each operation have a tailor-made herd health program, but it should be reexamined regularly (Gay, 1999).

Access to herds and the development of mutual confidence may be achieved by applying "marketable skills"; veterinary procedures or techniques that are of proven economic benefit (Chenoweth, 1989). A number of these exist, ranging from individual animal diagnosis and treatment to palpation skills, bull evaluation, financial management, and risk assessment. In the herd health context, appropriate marketable skills would include diagnostic and economic analyses, nutrition counseling, and data handling, including epidemiology.

For a particular herd, a starting point is to identify current production losses by comparing the performance of the herd with relevant benchmarks. These may be established for a given region, or from national surveys such as those obtained through SPA, which can also provide an economic estimate of losses. Table 13-17 gives an example of such benchmarks for the U.S. Midwest.

The next step is to conduct cost-benefit projections of different herd-health options. Final decisions depend on a number of factors, which may not all make perfect economic sense. However, decision making may benefit from use of "what-if" computer simulation software, such as DECI (Decision Evaluator for the Cattle Industry) developed by the USDA in conjunction with the National Cattlemen's Beef Association (NCBA) (Roybal, 1999), which can provide long-term estimates of the production and financial consequences of different managerial decisions.

Concurrently, veterinarians should work with clients to establish a list of disease threats to the herd and then rank them according to their potential to cause disaster. Richey (1991) described the process as follows:

1. Recognizing the disease challenge (diagnosis and surveillance)
2. Knowing when and why a particular challenge will occur (pathogenesis)
3. Lowering (or eradicating) the challenge (management)
4. Raising resistance both to the specific disease and in general (immune system management)

Identification of potential disease challenges for a beef herd in any region can be a challenge. As a starting point for North America, a list may be compiled as shown in Box 13-9.

Local knowledge and advice from producers, extension personnel, and diagnostic laboratories will help to narrow this list down to those most prevalent for each region. Once a list of potential pathogens is established for a region, the next step is to assign relative risk for each class of cattle most likely to be affected and when they are most at risk. For example, a list of the major pathogens associated with reproductive wastage in beef cows in North America, with relative risk for each gestational period, may be tabulated (Table 13-18). Such a list of infectious disease entities and their relative risk can be used to determine the cost-benefits of different approaches to herd protection, or, at least, risk reduction. Here, it is useful to consider the different components of herd health (after Richey, 1991).

A herd is "healthy" when its collective resistance is greater than the disease challenge. Effective herd health programs act to raise resistance, reduce the risk of disease challenge, or both. A challenge may occur when a pathogen is introduced to a susceptible population (or animal), or when an overwhelming infection occurs in a normally resistant population (or animal). Factors associated with changes in resistance and challenge levels can include those shown in Box 13-10.

Box 13-10 shows that a number of options exist to keep a herd "healthy" and disease free. To devise the "best" option for each situation requires the veterinarian to have a good understanding of the animal populations involved and their environment, plus management priorities and constraints.

The risk level of the herd varies according to its potential to be exposed to particular pathogens, with the terms "open," "closed," and "modified open" being used to describe degree of risk (see below).

Herd Health Calendar

The major disease risks for a given herd, and appropriate preventive measures, should be established in consultation with herd owners. For a given disease, the options may include the following: (1) ignore, (2) minimize risk managerially, or (3) use biologicals. If biologicals are being considered, veterinary advice should include the relative efficacy of different products, their formulation and duration of effect, handling and storage information, contraindications and cost effectiveness. A "good" vaccine should decrease the number of susceptible animals, increase the level of collective herd immunity, and have a minimum of deleterious effects (Spire, 1988).

The best times for herd intervention must be established. These will often coincide with other major managerial tasks, or events, for the cow-calf operation. One approach is to devise a herd-health "calendar" in which the health events are coordinated with major operational events. An example of such a calendar for a spring calving herd is given in Table 13-19.

The normal activities that occur during the course of 12 months in a beef breeding herd can be grasped easily if illustrated diagrammatically through a system of circles and windows (Richey, 1992). Such diagrams are also helpful with client communication. In Fig. 13-6, the cow year for a generic herd is shown as the major circle, with a smaller circle representing the breeding season (in this case, 90 days). Veterinarians should work closely with producers to develop such plans, since each operation is different. The health program should be designed to "fit the management" (Richey, 1992). In order to construct such a herd health program for a client, several key dates need to be obtained and inserted, as shown in Table 13-20, with the given dates used as examples only. Relevant information that may affect many of these considerations include breed types, normal herd working dates (cow and calf), calf weaning date, calf management (e.g., creep feeding), age of breeding of replacement heifers, source of bulls, and previous disease problems.

Inclusion of the above dates for the "Wildcat Ranch" would cause a cow-calf annual cycle as shown in Fig. 13-7.

Herd health procedures should be synchronized with major routine managerial events as much as possible to minimize herd disruption and labor costs. With the "Wildcat Ranch," coordination of health and managerial events may be achieved as shown in Fig. 13-8. Here, major herd health intervention opportunities are synchronized with managerial "events" as much as is feasible. Possible intervention opportunities are represented by numbers and small, dark circles and are discussed below.

Intervention windows of opportunity vary with different enterprises, and some may be combined (e.g., precalving and prebreeding). Similar "cycles," with inclusion of their own specific health intervention "windows," may be constructed for each class of cattle, such as heifers, bulls, and calves.

Notes to Accompany Cow-Calf Health Programs

Breeding Considerations

A restricted breeding season is advantageous to an effective preventive herd health program (PHHP) (Stokka and Faulkner, 1998). Here, as a general principle, heifers should be bred before the main cow herd and for a shorter period. This allows selection pressure to be exerted for fertility and allows particular attention to this group at calving time. This may, however, not be a practical option in a number of herds, particularly where genotypes or environments present difficulties in achieving target weights on schedule. Prescreening of bulls and use of good bull management principles optimize calf crops with use of fewer bulls. For AI programs, facilities and procedures should be established before the program begins, especially if estrus synchronization is planned.

Prebreeding vaccinations should be completed within 2 to 4 weeks of the start of breeding. The major diseases to consider here are campylobacteriosis, trichomoniasis, leptospirosis (five strains), IBR, and BVD.

Preweaning

Preweaning is an important intervention because it can help prepare calves for the stress of weaning and reduce the possibility that such stress will compromise the efficacy of biologicals. Common vaccinations here include the clostridials, BRD (IBR, BVD, PI3, BRSV plus *Haemophilus somnus* and *Pasteurella* spp.), and leptospirosis. For BRD vaccinations, only products licensed for suckling calves should be given. A broad-spectrum anthelmintic may also be given at this time to ensure that calves cause minimal pasture infestation.

Weaning

Good weaning management includes preparing calves by allowing them prior access to the weaning facility, feed, and water. It also entails weaning into a clean area, with fresh feed and water. At weaning, a second vaccination should be given for those products recommending two injections. Modified live viral products can be given at this stage. Another clostridial vaccination is not indicated if calves were previously vaccinated at working and preweaning. Implanting may be done here on animals not intended for reproduction. Parasite and grub control may be done here also, although timing should coincide with calendar recommendations for the latter. For areas where brucellosis is under regulatory control, heifer vaccination with either St19 or RB51 should be given within the age "window" stipulated.

Pregnancy Examination

Pregnancy examination should be conducted ideally as soon as possible after breeding, allowing for detection of those animals that got pregnant last. For practical purposes, this is probably 45 days or more after the end of breeding. For other operations, it may be more convenient to schedule the pregnancy examination to coincide with weaning.

This is an important intervention time. Here, cull females are identified. These include some or all animals that are classified as nonpregnant and those that qualify on the grounds of age, soundness, or disease. Veterinary procedures such as removal of squamous cell carcinoma of the eye (cancer eye) may be done, or scheduled, at this stage.

For pregnant animals, important information should be recorded on stage of pregnancy, age, parity, body condition, and lactation status ("wet" or "dry"). Other relevant information, and its analysis, is discussed earlier in this chapter.

Precalving

A precalving intervention may coincide with pregnancy testing, although the ideal time is about 1 month before calving. The vaccinations here are intended to protect the newborn calf through colostral transfer. Thus important antigens include those of the major clostridial diseases (particularly *Clostridium perfringens*), leptospirosis (5-way) as well as those for calf scour pathogens (*E. coli, Rotavirus, and Coronavirus*),

*Pre-breeding working opportunity may not be available, depending on breeding season length. Appropriate herd health procedures (particularly vaccinations) then should be given in the latter part of gestation. If so, avoid replicating virus vaccines, particularly infectious bovine rhinotracheitis and bovine viral diarrhea.

respiratory disease (IBR, BVD, PI3, BRSV plus *H. somnus* and *Pasteurella*) and redwater where these represent significant problems.

Replacement Females

Replacement females should be subjected to the same vaccinations as those given to females before breeding.

Bulls

In general, the bulls should be subjected to the same vaccinations as the cow herd, with several major exceptions. First, bulls should not be vaccinated for brucellosis. Second, the trichomonosis vaccine currently approved for use in the United States is not approved for bull use. Caution is advised with modified live virus (MLV) IBR vaccines, since bulls may recrudesce this virus and shed it in semen. Also,

TABLE 13-20

Dates for Major Cow Calf "Events" on the "Wildcat Ranch"

Event	Adult Cow Herd	Replacement Heifers
Start of breeding season	3/15/01	2/15/01
End of breeding season	6/14/01	5/17/01
Length of breeding season	91 days	91 days
Length of gestation (HxA)	283 days	283 days
Start of calving	12/13/01	11/15/01
End of calving	3/27/02	2/28/02

semen shipment to other countries may be jeopardized. Otherwise, recommended bull vaccinations include leptospirosis (5-way) and campylobacteriosis, in accord with recommendations for the cow herd.

CALVING MANAGEMENT

The endpoint of a cow-calf enterprise is the profitable production of calves. The goal is to obtain and maintain a live calf to weaning. Management of the calving season is critical to optimizing the weaned calf crop. According to the NAHMS *Beef '97* survey, 58% of calf mortality from birth to weaning occurred within 24 hours of birth, and 78% of calf mortality occurred within the first 3 weeks after birth. Total mortality from birth to 3 weeks of age was 3.3% and from birth to weaning was 5.5% (NAHMS, 1997b). These survey results are consistent with other research indicating 57% of mortality occurred in the first 24 hours and 75% within 7 days of birth (Patterson et al, 1987). Significant risk factors for increased calf morbidity are also active at the time of calving and can lead to increased death loss and decreased calf performance. Wittum et al (1994b) found a 16-kg reduction in weaning weight in calves that experienced a morbidity incident from birth to 45 days of age. These results highlight the importance of proper calving season management practices for optimum production. Current calving management performance and practices of U.S. cow calf herds as reported in the NAHMS *Beef '97* survey are summarized in Table 13-21.

Downloaded from Vet-eBooks.com

Target goals for calving management as reported in the literature are arbitrarily based on levels achieved by "good" producers (Spire, 1991). These serve as a good starting point for assessment of productivity but may not be the optimum level of production for the individual herd. Optimum production must be based on financial and economic inputs and returns for the individual herd. SPA has proved useful for identifying the optimum level of production (Hamilton, 1995). The key factors to control in calving management are shown in Box 13-11.

Dystocia Management

Calving difficulty, or dystocia, is the major cause of calf loss for cow-calf producers. Bellows et al (1987) attributed 50.9% of calf mortality to dystocia (406 of 798 mortalities). In another study, calves that experienced dystocia were 13 times more likely to die within 12 hours of birth and 4 times more likely to experience a morbid incident by 45 days of age than calves that did not experience dystocia (Wittum et al, 1994a). Producers in the *Beef '97* survey reported a dystocia incidence in heifers of 17%. The prevalence of dystocia in heifers calving at 2 years of age commonly ranges from 15% to 30%, causing significant financial loss. Dystocia causes increased perinatal calf mortality, morbidity, and decreased productivity in cow-calf herds. Increasing incidence of dystocia in a herd has been associated with increased incidence of calf morbidity and mortality in the herd (Sanderson and Dargatz, 2000). Dystocia incidence above 20% was associated with a fivefold increase in risk for high herd morbidity and mortality. Dystocia has also been associated with an increased incidence of mothering problems in all age dams. Once the effect of dystocia was accounted for, no effect of dam age was noted (Wittum, 1994a). In addition, pregnancy rate may be decreased in the next breeding season in the females that lost calves (Patterson et al, 1987), and prolonged parturition may cause depressed subsequent reproduction in beef cattle (Doornbos et al, 1984).

Dystocia is of primary concern in primiparous beef replacement heifers. In one study, for every 1% increase in the percentage of heifers calved in a herd, risk for high herd calf mortality increased 1.2 times (Schumann et al, 1990). Dystocia management in replacement heifers must begin with proper replacement heifer development (see "Replacement Heifer Development"). Fetal pelvic size incompatibility is a major contributing cause of dystocia. Calf birth weight, the size of the pelvic area of the dam, and the interrelationships of these two factors are major determinants of dystocia (Meijering, 1984; Anderson et al, 1993b). While the role of birth weight in dystocia is well established and likely most important (Anderson et al, 1993b), the role of pelvic dimension is less clear (Van Donkersgoed et al, 1990). The weight of the calf is a function of genetic and environmental factors. Genetic factors include sex, length of gestation, breed, heterosis, inbreeding, and genotype. Nongenetic factors include age and parity of the dam, nutrition of the dam during various phases of gestation, and environmental temperature. Dystocia is likely a threshold trait; that is, dystocia is not related to birthweight in a linear manner. Once a certain threshold birth weight is reached in a herd, dystocia rates may increase dramatically. Conversely, after decreasing birthweight to a certain level, further decreases have only a minimum effect on dystocia rates (Anderson et al, 1993b). Genetics for high growth rate after birth are expressed prenatally, so selecting for decreased birthweight also may select for lower growth rate postnatally. For these reasons minimizing birthweight may not be cost effective. Increase of birthweight to the threshold for the herd to optimize dystocia rates and growth rate is likely the best practice.

Efforts to manage dystocia level and moderate its effects must center on replacement heifer development, sire selection, and early dystocia intervention.

TABLE 13-21

Calving Practices in the United States

Management Practice

Replacement Heifer Development for Dystocia Management

Dystocia rates in beef heifers cannot be reduced by nutritional restriction during late pregnancy (Kroker and Cummins, 1979). In controlled feeding trials the restriction of energy intake in the bovine female to a level that maintains maternal body weight has little influence on the development of the fetus, even though maternal metabolism may be altered considerably by the level of energy intake (Prior et al, 1979). Within certain experimental limits, the level of maternal dietary energy intake does not influence fetal weight or composition (Prior and Laster, 1979). However, the loss of 0.5 kg/day during the last trimester of pregnancy in beef heifers is associated with weak labor, increased dystocia rates, reduced calf growth rate, prolonged

Downloaded from Vet-e-Books.com

postpartum anestrus, reduced pregnancy rate, and increased morbidity and mortality (Kroker and Cummins, 1979; Corah et al, 1975). These are not evident in heifers that are maintaining or gaining weight at a moderate rate during late pregnancy. It is recommended that heifers be fed to allow modest rates of body weight gain (0.5 kg/day) during late pregnancy. Protein malnutrition in late pregnancy has been associated with weak calf syndrome and may be a factor contributing to neonatal mortality in beef calves. Beef cows fed 0.37 kg of crude protein/day during the last 4 months of pregnancy had a decreased gestation period of 274 versus 282 days and decreased weight gains compared with controls fed 0.96 kg (Waldhalm et al, 1979). Calf mortality in the low-protein group was caused by dystocia or prematurity. Cow weight and weight loss are functions of the interactions within a herd. Genetic background, breed of cow, management, amount and quality of feed, and degree of shelter provided during cold and windy weather all contribute to body weight loss.

Measurement of the pelvic area of the dam to predict dystocia is used as a criterion for the selection of replacement heifers, even though pelvic area alone has been shown to explain only a small proportion of the variability in dystocia (Johnson et al, 1988). Pelvic area measurements before the breeding season or at the time of pregnancy examination have been used to estimate the pelvic area before calving. Those heifers with a small pelvic area before the breeding season may then be culled or selectively mated to easy calving bulls, and those with a small pelvic area at the time of pregnancy examination may be aborted, culled, or identified for careful observation at calving (Deutscher, 1985). Some on-farm studies have reported that pelvic measurements a few weeks before the breeding season and again at the time of pregnancy examination have poor positive predictive values and sensitivities in each herd (Van Donkersgoed et al, 1990). Although the mean pelvic area in the heifers with dystocia was slightly smaller than for those without calving difficulty, there was a large overlap in the distribution of their pelvic areas. Reasons for the inconsistent results among different observations include the definition of dystocia, the accuracy and precision of the measurement procedure, and the fact that calf birth weight in relation to the dam's pelvic area determines the degree of calving difficulty (Van Donkersgoed et al, 1990). Some evidence suggests than culling heifers with the narrowest pelvic width may be more effective than culling based on pelvic area (Anderson et al, 1993b).

Sire Selection for Dystocia Management

The use of pelvic area measurement to decrease the incidence of dystocia without using some method of controlling or predicting calf size would be ineffective. However, a combination of culling heifers with small pelvic areas and using bulls that sire calves with small birth weights might reduce dystocia significantly (Makarechian and Berg, 1983). Using only the sires' birth weight to control calf birth weight and dystocia is not effective. A large number of nongenetic influences affect birth weight, such as age of the dam, environment, and birth type. The ability to identify sires appropriate for use on replacement heifers has advanced significantly in recent years. The use of expected progeny differences (EPD) for birth weight is more effective than using only sire birth weight in selecting for acceptable birth weights. EPDs are reported in the units of the trait that they reflect (e.g., pounds for birth weight). Along with each EPD is reported an accuracy ranging from 0 to 1. The accuracy is a measure of the reliability of the EPD value, a statistical confidence in how accurately the EPD reflects the true effect of the bull. Higher accuracies indicate a higher level of confidence that the stated EPD truly reflects the bulls' effect. EPDs are most effective at comparing bulls rather than identifying the specific effect a bull will have on a herd. For example, a bull with a birth weight EPD of +4.0 would be expected to sire calves 6 lb heavier on average than a bull with a birth weight EPD of −2.0 when bred to the same set of heifers. An attempt should be made to identify bulls with low birth weight EPDs for use on heifers while maintaining at least moderate weaning and yearling weight EPDs. This is best achieved by the use of AI sires with high accuracy EPDs. EPDs can be calculated on yearling bulls with no progeny based on their performance and their pedigree performance, but the accuracy is low. Distributions of EPDs and mean values can be obtained from the respective breed associations to assess the ranking of bulls within the breed. Until recently EPDs were only useful in comparisons within breeds. Methodology for across-breed EPDs have been developed to allow estimation of the effect of bulls on different breeds. This is of particular use in selecting bulls to control dystocia in crossbreeding programs. Currently, adjustment factors between breeds are available to assess the effect of a bull in a crossbreeding system (Van Vleck and Cundiff, 1998). Two recent innovations in the use of EPDs for management of dystocia are the calving ease EPD and the maternal calving ease EPD. Calving ease EPD is related to birthweight EPD but may predict calving ease more effectively. Maternal calving ease is a measure of the effect of the maternal grandsire and the ease with which a bull's daughters will give birth.

Multiple factors influence calving ease, likely including ones not yet known. Calf birth weight is the most important factor in dystocia (Naazie et al, 1989), accounting for 30% to 50% of the variability in dystocia rates (Meijering, 1984). As the birth weight of the calf increases, the incidence of dystocia also increases. Calves with an inherent ability for growth exhibit that genetic potential in utero, and, although this may produce birth weights capable of causing dystocia, it also causes superior weaning weights. Calving difficulty is higher for male than female calves (McDermott et al, 1992). Cows that calve unassisted generally weigh more at calving than those with difficult births. Abnormal presentations of the calf accounted for 22% of dystocias and 4% of all births in one study (Holland et al, 1993). Most dystocias occur in primiparous 2-year-old heifers, and the frequency decreases with increasing age and weight of the cow. At least some studies have suggested that cows that had previously experienced dystocia were more likely to experience a subsequent dystocia (McDermott et al, 1992). Environmental effects may also have an effect on calf birth weight and dystocia. Cold weather may increase birth weights and subsequently increase the incidence of dystocia (Burns et al, 1979).

Early Intervention for Dystocia Management

Despite the best efforts to avoid dystocia, some episodes will occur. Indeed, as discussed previously, minimizing dystocia incidence may not be an economically justifiable goal. Early intervention in dystocia cases will work to minimize the effects of dystocia on calves. Dystocia can cause hypoxia, acid-base disturbance, and decreased vigor, leading to a delay in ingestion of colostrum and increased incidence of failure of passive transfer. In one study, approximately one third of the anatomically normal calves that died in association with a difficult calving had not been given assistance but had gross pathological evidence of parturition injury. The authors suggested that these deaths could have been prevented if surveillance and obstetric assistance had been provided (Bellows et al, 1987). Research indicates stage II labor

Downloaded From Vet-eBooks.com

should not exceed 1 hour in heifers and 30 minutes in cows (Doornbos et al, 1984). This same study showed that heifers that complete stage II labor within 1 hour do not have extended postpartum intervals. Heifers will need to be monitored regularly and provided with assistance promptly if stage II labor is not to exceed 1 hour. Data from the *Beef '97* survey showed that 39% of heifers were allowed to labor for 3 or more hours before assistance was given (NAHMS, 1997a). If heifers cannot be monitored regularly, bull selection should focus on minimizing birth weight at the expense of growth. The individual herd will need to identify the most economical level of dystocia and growth and select a bull to match. Producers must be well trained to intervene appropriately in dystocia and must recognize when to call the veterinarian. A general rule of thumb for the producer is that if they have not made significant progress in delivering the calf within 30 minutes, it is time to get help.

Passive transfer in calving management

Calves receive immunity passively from the dam through the ingestion of colostrum. The calf's immune system is immature at birth and dependent on acquisition of passive immunity for disease protection in early life. Immunoglobulin (IgG1 and IgM) and lymphocytes are absorbed directly across the gut into the calf's circulation to provide immunity. The ability of the gut to absorb these large molecules and cells is a transient phenomenon. Gut closure is complete by 24 hours and absorption has decreased significantly by 6 to 8 hr of age. Ingestion of adequate amounts of quality colostrum as early as possible after birth is important for calf survival and growth. Limited surveys of beef calves have shown a passive transfer failure rate of 11% to 30% (Perino, 1997). Calves with failure of passive transfer (FPT) are three to nine times more likely to become sick before weaning, and five times more likely to die before weaning compared with calves with adequate passive transfer (Wittum and Perino, 1995; Perino et al, 1993).

The relationship between dystocia and FPT has not been consistent in the literature. In a set of 73 crossbred 2-year-old heifers, an increase in calving difficulty score was associated with decreasing serum IgG1 and IgM levels in calves even though assisted heifers were milked out and calves force fed (Odde, 1988). Increased calving difficulty was also associated with an increased interval from birth to standing. Other studies have not shown significant differences in immunoglobulin levels between calves experiencing dystocia and those not when both groups were force fed an equal amount of colostrum (Stott et al, 1978) or when allowed to suckle (Perino et al, 1995). Postnatal respiratory acidosis resulting from dystocia has been associated with decreased colostral absorption despite adequate colostral intake (Besser et al, 1990). It seems likely that dystocia would have some negative effect on passive transfer.

The relationship between prepartum nutrition and FPT has not been firmly established. In 2-year-old heifers, BCSs at calving did affect calf serum IgG1 levels. Calves from heifers calving with a BCS of less than 5 had lower IgG1 levels than calves from heifers with BCSs greater than or equal to 5 (Odde, 1988). Other studies have not found a difference in calf immunoglobulin levels after restricted nutrition in the final trimester (Hough et al, 1990) Heifers fed a restricted diet do have decreased colostral volume but increased IgG1 concentration (Odde, 1988). Numbers of animals in most studies have been small, perhaps limiting the ability to detect the effect of prepartum nutrition. Despite the lack of clarity in the relationship between prepartum nutrition and FPT, a well-balanced ration should be provided to prepartum cows and heifers.

Mastitis in beef cows has been associated with decreased serum immunoglobulin levels (Perino et al, 1995). Mastitis has not been studied extensively in beef cows; however, available studies have found a prevalence of 9% (Perino et al, 1995) to 32% (Simpson et al, 1995). Poor udder conformation in beef cows has been associated with increased time spent teat seeking and time to first suckle in calves (Ventorp and Michanek, 1992), perhaps increasing the likelihood of FPT.

Management to minimize the incidence of FPT should emphasize dystocia management, proper nutrition, and intervention with calves at high risk for FPT. Cows that experience dystocia should be milked out immediately and the calf force-fed colostrum to ensure ingestion. Cows with poor udder conformation or mastitis should be milked and the colostrum fed to the calf to ensure timely intake. Colostrum supplements have not proved useful in controlled clinical trials in elevating serum IgG levels (Perino et al, 1995; Mihura et al, 1997). Vaccination of the cow before calving with pathogens causing enteric disease in calves may be a useful adjunct to good overall management in reducing morbidity (Cornaglia et al, 1992; Boland et al, 1995). Vaccination in both studies caused approximately 50% decrease in morbidity, although blinding was not practiced so treatment bias cannot be ruled out. Vaccination of cows prepartum against IBR (Mechor et al, 1987) and BRSV (Belknap et al, 1991) protected calves against experimental challenge. For optimum effect cows should receive their final booster vaccination 2 to 3 weeks before the onset of calving season.

Management of the Calving Environment

Research data on the optimum management of the calving season at the herd level are sparse, perhaps because of the difficulty in assembling large numbers of cooperator herds to provide a statistical basis for inference at the herd level. One such study examined risks for high herd mortality level using 56 herds in a case control design (Schumann et al, 1990). This study found a number of univariate associations of management practices and herd mortality incidence. In the final multiple logistic regression model, percentage of heifers in the herd (odds ratio 1.2), poor drainage in the calving area (odds ratio 1.4), and wintering cows and heifers on the same ground (odds ratio 6.4), were associated with increased risk for high herd mortality. For every 1% increase in the percentage of poorly drained calving area, risk for high herd mortality increased 1.4 times. Calving of cows and heifers together was associated with increased herd mortality in a univariate analysis. It was highly correlated with wintering cows and heifers together and was not included in the final multivariate model. Increasing calving area was associated with increased herd mortality, but the odds ratio was very small (1.001) and not likely biologically significant. Similarly, providing shelter in the nursing area was associated with decreased herd mortality of questionable biological significance (odds ratio 0.998). Dystocia incidence was not collected in the study, and odds ratio estimates might change significantly if it were included as a covariate. Season of calving may be associated with morbidity and mortality levels as well, likely through weather stress. One Canadian study found calves born from December to March were four times more likely to die within 24 hours and two times more likely to have diarrhea from 1 to 30 days of age than calves born in April and May (Ganaba et al, 1995). Provision of shelters that allow calves protection from the weather may be useful in decreasing stress and morbidity (Olson, 1986); however, good data to support this are not available. Care should be exercised when shelters are used for calves, since they concentrate calves in a

Downloaded From Vet-e-Books.com

small area and may increase infection pressure. Movable shelters may be best to allow their removal from contaminated areas on a regular basis. It may be useful to provide access to the shelters during inclement weather and to restrict access during good weather to minimize the buildup of pathogens. Calving later in the spring has been advocated as a way to match cow nutritional needs to forage resources, decreasing the amount of harvested feed fed to cows, and feed costs. Such a plan may also be useful in managing calf morbidity and mortality. The moderate weather of late spring is less stressful on calves, requiring less provision of shelter and subsequent population density. Increased solar radiation and decreased wet and muddy conditions may decrease the buildup of pathogens, causing decreased calf exposure. In addition, more moderate temperatures may decrease birth weight and dystocia incidence (Burns et al, 1979). Fall calving can provide similar benefits as late spring calving in relation to calf morbidity and mortality. In the United States, 64% of calves are born in February through April and 9% of calves are born in June through September (NAHMS, 1997a).

The purpose of environmental control emphasizes decreasing calf stress and infection pressure on the calf. Unfortunately, these two goals are somewhat antagonistic. Controlling calf stress centers on close confinement and observation of calving to ensure prompt dystocia intervention and the provision of shelter from inclement weather for calves. Close confinement to facilitate observation and provision of calf shelter increases population density and subsequently infection pressure on the calf. Balancing these two competing interests to optimize the calf crop is the objective of calving management. Unfortunately, good data on where the optimum combination may be are scarce. Clearly, dystocia is an important, perhaps the most important, risk for calf morbidity and mortality. Calving in confined conditions appears to be associated with increased morbidity, but population-attributable fractions suggest it is less important than dystocia (Sanderson and Dargatz, 2000). Data on the optimum square footage necessary for each cow or heifer in the calving pen are not available. Estimates vary from 1000 to 2000 sq ft/cow in the observation pen. From an infection pressure standpoint, the more space provided, the lower the infection pressure; however, monitoring becomes more difficult as the area increases. Current knowledge of proper management of the calving environment suggests the key areas discussed in Box 13-12.

BOX 13-12

Management of the Calving Environment

1. Calve cows and heifers separately. This provides the opportunity for increased observation of first calf heifers to ensure prompt dystocia intervention. There may be effects of decreasing exposure of heifers to pathogens.
2. Calve cows and heifers on calving grounds separate from the wintering grounds. Moving to fresh ground for calving decreases the accumulation of pathogens in the environment. Ideally, calving grounds should be left vacant the rest of the year to allow drying and solar ultraviolet rays to decrease the pathogen levels. Pens should be scraped and allowed to dry over the summer.
3. Ensure that calving pastures are adequately drained to avoid standing water and mud and/or manure buildup. Pathogen accumulation and survival are increased by providing a moist environment, causing increased infection pressure on the calf. Preferably, calving pens should have a slight slope to encourage runoff of water and a compacted surface to minimize the amount of water that is absorbed. Calving pastures should have good grass cover to minimize mud and be managed to maintain the grass. All calving lots or pasture should have a southern exposure to facilitate drying and maximize solar radiation.
4. Manage dystocia pens to minimize pathogen buildup and infection pressure on calves. Pens used for dystocias or mothering problems should be easily cleaned and not supportive of pathogen buildup. Concrete floors are ideal for cleaning but may not be economically practical in many instances. Compacted sand or gravel may be a useful alternative. Sand and gravel support minimal bacterial growth and can be scraped and replaced between calving seasons. Pens should be bedded, with the bedding material being replaced between calvings. An adequate number of pens is necessary to allow for time to dry out after cleaning and before being used again.
5. Consider calving at a time of year when weather factors are least stressful on calves and the environment is easiest to manage. This recommendation requires a comprehensive plan for marketing calves and an assessment of the economic effects of the calving season change in all areas of the enterprise. Such a change should not be entered into in a cavalier way but may be indicated in some situations.

Cow-Calf Pair Management

Physical-spatial management of the pregnant cow or heifer and the postpartum pair is an important component of calving season management. Again, hard data on optimum practices are scarce. Some reasonable practices can be recommended, however (Box 13-13). See Fig. 13-9 for an example facility for management of calving groups.

The most common cause of calf morbidity in the neonatal period is diarrhea. According to a major survey of U.S. beef producers, 80% of morbidity from birth to 21 days of age is due to diarrhea (NAHMS, 1997b). It is generally not possible to differentiate diarrheas associated with different etiological agents based on clinical signs. The age distribution of infection for the common etiological agents associated with acute undifferentiated diarrhea are summarized in Table 13-22. The difference in the age of calves affected can be helpful clinically in identifying likely agents involved. Cows and calves often serve as carriers of the common agents of diarrhea in calves. Mature cows commonly carry *Rotavirus, Coronavirus,* and *Cryptosporidia* and shed them to the environment particularly around calving time. *E. coli* and *Salmonella* may be commonly introduced to a herd by the importation of a shedding animal. Once calves are infected on the farm, they become multipliers of the infectious agent, causing a rapid rise in environmental contamination. *C. perfringens* is a ubiquitous organism in the environment. Control for pathogenic agents of neonatal diarrhea involves segregation of sick animals from the healthy nursery in order to decrease environmental contamination and transmission. In addition, *E. coli* and *Salmonella* control involves biosecurity rules to prevent the purchase and introduction of new calves or cows during the calving season. Once calves are identified as sick, they should be isolated quickly to prevent further environmental contami-

BOX 13-13

Physical-Spatial Management of the Cow-Calf Pair

1. Calve cows and heifers separately. This provides the opportunity for increased observation of first calf heifers to ensure prompt dystocia intervention. There may be effects of decreasing exposure of heifers to pathogens. For reproductive reasons heifers are often calved 3 to 4 weeks before the cows.
2. Calve cows and heifers on calving grounds separate from the wintering grounds. A move to fresh ground for calving decreases the accumulation of pathogens in the environment.
3. Two to three weeks before the onset of the calving season, cows and heifers should be moved from winter grounds to calving grounds.
4. Sort heifers and cows into management groups based on estimated calving date. This criterion for sorting can be provided from data collected at the time of pregnancy examination, when cows and heifers are grouped based on estimated gestational duration. Separation of the herd into management groups allows more concentrated observation of a smaller number of cows or heifers that are more likely to be calving and need intervention.
5. Ensure that cows and heifers accept and mother their calves. Heifers especially are at risk to reject their calves, subjecting them to increased risk for disease. If heifers do not accept their calves and allow nursing within a short time, they should be brought into the calving barn and restrained to allow the calf to suck. Heifers that experience dystocia and human intervention are at increased risk for rejecting their calves.
6. If cows or heifers experience difficulty in calving or mothering, move them to the calving barn for intervention and monitoring. Pairs entering the calving barn are at increased risk for disease because of dystocia, mismothering, or hypothermia and the exposure to the population dense environment of the barn. Once a pair enters the calving barn, they should not go to the general nursery pasture but to a separate high-risk nursery. Calves in the high-risk nursery can be monitored more intensively for morbidity and treated promptly. Segregation of these high-risk calves also avoids exposure of the rest of the herd.
7. Once cows or heifers have calved, move the pair out of the calving area to a nursery pasture within 24 hours. Once the pair has bonded and passive transfer has occurred, pairs should be moved to a nursery with decreased population density to minimize infection pressure.
8. Calves identified as morbid in the healthy nursery pasture should be removed and brought to the barn for treatment if necessary and placed in a morbidity nursery. Clinically ill calves can serve to multiply infectious agents and cause high levels of environmental contamination. One study suggested that quarantine of diarrheal calves and their dams from the rest of the herd decreased morbidity incidence.* The morbidity nursery may be combined with the high-risk nursery, but this will increase exposure of the high-risk calves to pathogens. Morbid calves should not be returned to the general nursery area.
9. Treatment equipment should be disinfected thoroughly between calves to avoid transfer of infectious agents from calf to calf.

*Clement JC, King ME, Salman MD, et al: *J Am Vet Med Assoc* 207:1334-1338, 1995.

nation of the healthy nursery. Once the environment is contaminated, moist cool conditions allow survival of infectious agents for an extended period. *Cryptosporidia* is especially suited to survival in the environment (Corwin, 1992), and prevention of contamination in the healthy nursery is especially important.

Commercial vaccines are available for *Rotavirus, Coronavirus, E. coli* K99, and *C. perfringens* types B and C. They are to be given to cows and heifers before calving to elevate specific immunoglobulin levels in colostrum. An initial vaccination and booster followed by a yearly booster vaccination is required. The booster vaccination should be given at least 2 weeks and not more than 6 weeks before calving. Clinical trial data are not consistent; some trials report no effect, whereas others report significant decreases in morbidity. Vaccination is likely a useful adjunct to proper management in controlling neonatal diarrhea. Vaccination does not lead to effective control when the level of management is poor. An oral modified live vaccine is available for administration to calves at birth. It must be administered at least 1 hour before colostrum ingestion. Clinical trial data have not supported its effectiveness.

The individual management of sick calves has been reviewed extensively elsewhere, and the reader is referred to those sources for recommendations on the treatment of individual calves (Radostits et al, 2000; Smith, 1996).

Veterinary Role in Calving Management

The veterinarian should be involved in designing and implementing management and environmental practices that control herd morbidity and mortality. The key areas and principles of management were summarized previously. If the opportunity arises to be involved in the design of calving facilities, these principles should be applied to design an optimum calving environment. Calving and nursery pens should be large enough to prevent buildup of pathogens and increased infection pressure. Proper drainage to avoid mud buildup in the calving or nursery pens is important. Drainage from the morbidity nursery to the calving pen or healthy nursery, or from the calving pen to the healthy nursery, should be avoided. Pens for assistance should be easily cleaned. Economic implications of recommendations should always be examined. An example of a calving facility is shown in Fig. 13-9.

Downloaded From Vet-eBooks.com

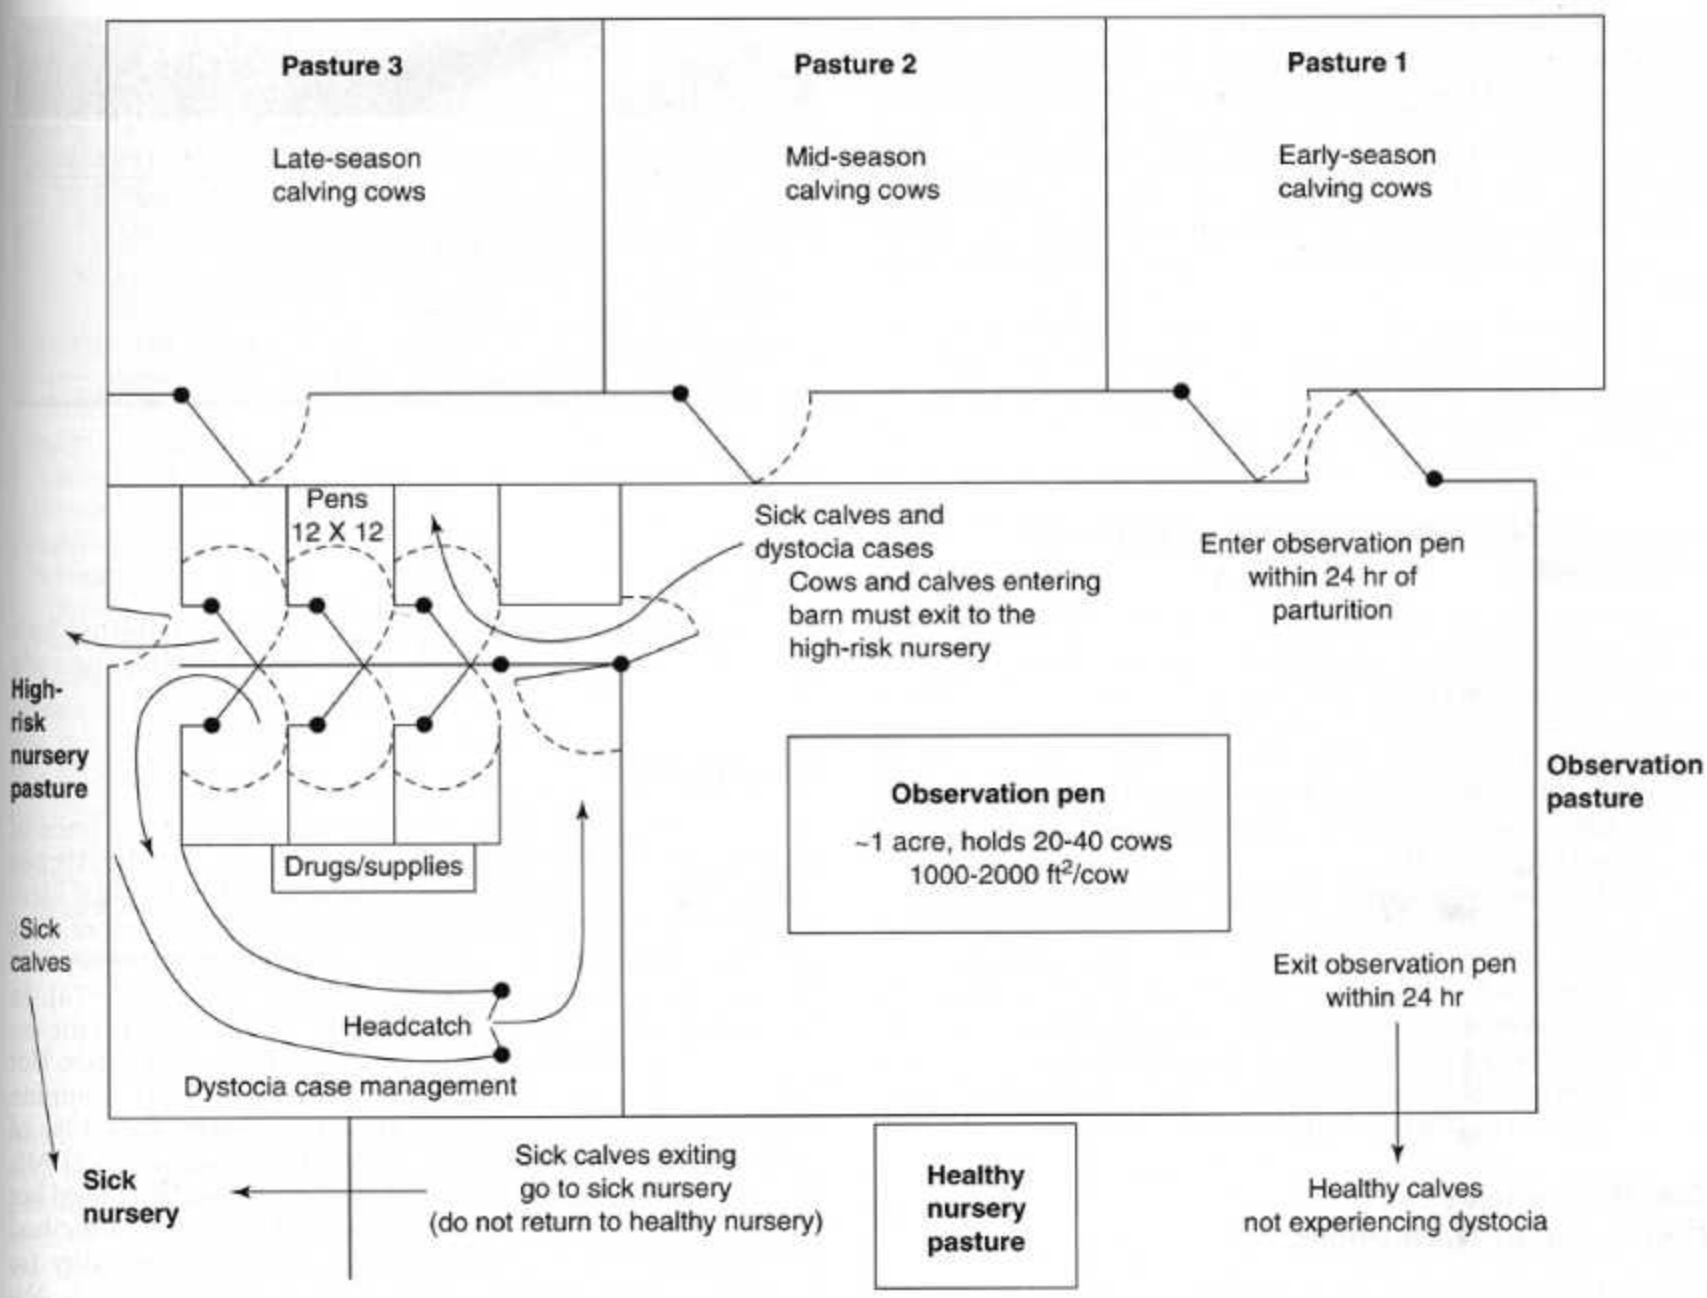

FIG. 13-9 Example of a calving facility.

The veterinarian should be able to assist the producer in selecting bulls to optimize calving ease and postnatal growth based on expected progeny differences. Ration formulation to provide proper nutrition is necessary for acceptable calving performance and subsequent calf health and performance.

A visit to the farm approximately 4 weeks before the onset to the calving season will provide the opportunity to evaluate the preparations made by the producer and to recommend any final changes. Proper dystocia intervention rules and procedures can be reviewed with the producer at this time, as well as rules for handling cow calf pairs after calving. Ideally, records on calving ease, and morbidity and mortality incidence will be kept to allow analysis of risks and risk groups. If an increased incidence of disease occurs, it will be easily detected and the management factors responsible more likely will be identified with good records. At least one additional visit should be made to the farm 2 to 3 weeks after calving has begun in order to assess the management and environment. The producer should be encouraged to contact the veterinarian promptly if any increased incidence of morbidity or mortality in the herd is noted.

TABLE 13-22

Age Occurrence of Common Enteropathogens Associated with Acute Diarrhea in Beef Calves

Enteropathogen	Age (days)
Enterotoxigenic *Escherichia coli*	<3
Rotavirus	5-15
Coronavirus	5-21

Cryptosporidium sp.	5-35
Salmonella sp.	5-42
Clostridium perfringens types B and C	5-15

Downloaded From Vet-eBooks.com

Morbidity and mortality incidence levels may be established above which the veterinarian should be called and a preliminary investigation begun. If computerized records on morbidity and mortality incidence are kept up to date, weekly incidence rates can be calculated to track a current measure of the effect of disease. If morbidity and mortality rates are indeed elevated, an investigation should be undertaken to identify the management factors contributing to the outbreak.

Calving management is a key area in controlling calf morbidity and mortality and optimizing the weaned calf crop (see Table 13-19). There are many opportunities for veterinary involvement in calving management that can be profitable to the producer and veterinarian.

BOX 13-14

Common Calf "Working" Tasks

Castration and dehorning
Identification (branding and tagging)
Implants
Vaccinations
Antiparasitics

CALF MANAGEMENT (BRANDING TO WEANING)

Whereas most calf mortality occurs before 28 days of age, the majority of growth occurs after 28 days. Management of calves to optimize growth during the summer grazing period is important to cow-calf productivity. Diarrhea remains an important cause of morbidity from 21 days of age to weaning, but infectious bovine keratoconjunctivitis (IBK) and respiratory disease become increasingly important at this time (NAHMS, 1997b).

The first opportunity to manage calves after calving occurs in many North American herds at the time of branding when the calves are aged 3 to 10 weeks. Cow-calf herds are then commonly turned out to summer pasture and not worked again until fall just before or at weaning time. Ideally, management practices implemented should be chosen to decrease morbidity and mortality or increase growth rate. Commonly recommended practices are listed in Box 13-14.

Calf Procedures

Castration and Dehorning

Castration of male calves in early life is likely to be less stressful to calves than castration performed later when testicular size is dramatically increased. In addition, early castration raises less concern about humane treatment. In the United States, 75% of producers that castrate calves do so by 3 months of age, but 25% of producers do not castrate any calves before sale. Large herds are more likely to castrate calves than are small herds (NAHMS, 1998b). A number of methods are available for castration, including the open surgical technique, the use of rubber rings, and the Burdizzo method. Calves castrated surgically initially exhibit more agitation compared with calves castrated with rubber rings, but both groups resume normal behavior soon after the operation is completed (Fell et al, 1986). U.S. producers most commonly castrate calves by open surgical removal of the testicles, with use of rubber bands next most common (NAHMS, 1998a). Castration of calves should be coupled with use of implants in the steer calves to improve weight gains.

Dehorning early in life is also less stressful than when performed later when horns have increased in size. In the United States, 28% of calves have horns and 62% of herds had at least one calf born with horns. Nationally, only 61% of horned calves were dehorned before leaving the ranch, and less than 50% of calves in south-central and southeast regions were dehorned before sale. Nationally, only 28% of horned calves were dehorned by 3 months of age, and 52% were dehorned after 5 months of age (NAHMS, 1997a,b) Horns are mostly a problem for the feeding period in which horned calves require more bunk space and may cause more bruising in penmates than in calves without horns. Such problems are best managed by polled breeding or early dehorning.

Identification

Individual identification of cows and calves is the basis of making selections based on performance. In the United States 52% of operations use no method of individual identification for calves, although herds with 300 or more cows were more likely to identify calves individually (78%) than herds with less than 50 cows (41%) (NAHMS, 1997a). In herds that did practice individual identification, plastic ear tags were the most common method in all sized herds. Hot iron branding and plastic tags were the most common methods of herd identification in U.S. herds, but 49% of herds used no method of herd identification (NAHMS, 1997a). Among herds with 300 or more cows, 90% used hot iron branding for herd identification. Branding as a method of identification is coming under increasing scrutiny for product quality and animal welfare reasons. The U.S. National Cattleman's Beef Association has supported a voluntary national cattle identification system to support value-based marketing. Commercial products are currently on the market that allow individual electronic identification. Such initiatives may eventually replace current identification systems.

Vaccination Procedures

Data on the effectiveness of individual vaccinations in decreasing calf morbidity and mortality are hard to obtain. According to NAHMS' *Beef '97* report, calves are not commonly vaccinated for respiratory pathogens from 21 days of age to weaning. The *Beef '97* data do not differentiate time of vaccination within this window of time, so it is impossible to know the frequency of administration at branding time as opposed to later in life. Calf vaccination practices in U.S. beef herds are summarized in Table 13-23.

Vaccines are available for viral (IBR, BVD, PI3, BRSV) and bacterial *(Pasteurella, Haemophilus)* respiratory pathogens. Residual passive immunity in young calves may limit the detectable antibody response to vaccination at an early age. Available evidence suggests that calves vaccinated at branding time will be sensitized to the antigens and respond with an anamnestic response when given a booster vaccine at arrival in the feedlot (Parker et al, 1993). Recommended vaccination programs include clostridial and viral respiratory vaccination at the time of branding. A number of "value-added" calf programs have been initiated, some of

Downloaded From Vet-e-Books.com

TABLE 13-23

Calf Vaccination Practices of U.S. Cow-Calf Producers

Vaccination	Percent of Producers	
	1-21 days of age	22 days to weaning

which require a vaccination program at branding time. No field trial data are available that assess the effect of vaccination at branding on the morbidity, mortality, or performance of suckling calves. Pneumonia incidence is typically low during the summer grazing period, and clinical effectiveness of a vaccination program against respiratory disease would likely be difficult to show. Primary sensitization to increase subsequent vaccination response preweaning may be the major benefit of such a vaccination program. A booster vaccination is often administered to calves before weaning for viral respiratory agents. Vaccination for *Pasteurella* has been recommended for inclusion in a preweaning or weaning vaccination program as well (Coffey et al, 1996). Available data suggest that calf buyers are willing to pay higher prices for calves that had undergone a preweaning health program (King et al, 1995, 1996, 1997). Unfortunately, field trial data on the effectiveness of respiratory vaccines in decreasing morbidity and mortality in weaned calves are lacking (Perino and Hunsaker, 1997). Field trials to evaluate the effectiveness of vaccination should include the following factors:

- Assessment of a clinically relevant outcome (morbidity, mortality, performance)
- Random assignment of calves to treatment and control groups
- Blinded assessment of clinical outcome (especially important for morbidity outcomes)
- Appropriate statistical analysis (correct application of statistical tests and control of herd clustering effects)

IBK is a significant problem in suckling calves, although control has proved to be difficult. Vaccination against IBK has shown variable results. Challenge with a homologous strain after vaccination may provide some level of control (Lepper, 1988), but challenge with a heterologous strain creates little protection (Smith et al, 1990). Some genetic resistance to IBK has been shown to occur in Hereford cattle with pigmented eyes (Pugh et al, 1986). In a Kansas survey, steer calves with a "bad eye" were discounted $8.35 and heifer calves $7.58/100 lb at market (Brazle et al, 1988). The face fly has been shown to be important in the transmission of this disease; therefore fly control is important, although difficult because the fly spends a limited amount of time on cattle. Dust bags and insecticide impregnated ear tags are only effective in reducing fly numbers by 50% to 70% (Mock, 1993). Feeding of a mineral supplement containing chlortetracycline (CTC) may decrease the incidence of IBK; however, the future use of feed grade antibiotics in food animals is in question. IBR may also cause ocular lesions or predispose calves to IBK (George et al, 1988). A proper vaccination program for IBR may be helpful. Table 13-24 outlines possible vaccination programs for calves.

Implant Strategies

Use of hormonal implants as a management practice for calves has been shown to increase weaning weights by 3% to 5% (Griffin and Mader, 1997). Economic returns are typically $5 to $10 for every $1 invested. Implants are available for calves over 45 days of age. Despite the clear value of implanting calves, the NAHMS *Beef '97* survey indicates that only a limited number of producers take advantage of this management technique. In the *Beef '97* survey 94% of producers reported that they did not implant replacement heifers and 82% reported that they did not implant any other calves (NAHMS, 1997b). Larger herds were more likely to implant both replacement heifer candidates and other calves than were small herds. Among herds of 300 or more cows, 29% implanted replacement heifers one or more times, and 59% implanted other calves one or more times (NAHMS, 1997b). All steer calves and heifer calves that are not candidates for breeding should be implanted. Implantation of heifers that may be kept for replacements is somewhat controversial. Fertility of implanted heifers may be decreased, but increased level of nutrition may overcome most of this depression. Heifers that may be replacement candidates should never be implanted before 45 days of age, and multiple implants should not be used. If calves are to be retained after weaning, they should be reimplanted to improve postweaning gains. Performance of implanted calves will be poor if adequate nutrition is not provided.

Parasite Control

The effect of treating for internal parasites in suckling calves has not been examined adequately. Egg burdens of calves are typically low at spring branding but may rise significantly by mid summer (Reinemeyer, 1997). Deworming of cows in late spring may cause increased weaning weights in calves (Boyd and Kniffen, 1992). Studies examining the effects of deworming calves only at branding have been few and results inconsistent, with some showing positive effects (Stacey et al, 1995) and others no effect (Stacey et al, 1997). Deworming of calves in addition to cows in late spring appears to confer minimal additional benefit (Stacey et al, 1996, 1997). Deworming of early weaned calves in mid summer caused a 10-lb increase in weaning weight in one study (Purvis et al, 1996).

External parasites of cattle are estimated to be an important cause of economic loss as well. Studies have generally shown a weight gain response of 10 to 20 lb in suckling calves (Quisenberry and Strohbehn, 1984) when fly control is provided, although not all studies agree (Gerhardt and

Shrode, 1990). The most common method for fly control is the use of insecticide impregnated ear tags. Maximum fly control probably requires application of two ear tags to each cow and calf. Cows are commonly the only animals tagged. With the widespread use of pyrethroid insecticides in ear tags, emerging resistance has become a problem. Alternation of insecticides from different chemical families has been recommended for control of emerging resistance. Resistant phenotypes decline rapidly when the pyrethroid exposure is removed (Krafsur et al, 1993). Current recommendations are to use organophosphate tags for 2 years followed by 1 year of a pyrethroid tag, forming a 3-year repeated cycle (Mock, 1993). Insecticide sprays and backrubbers can also be effective in controlling flies, but cattle must be forced to use them. Their use can provide the same level of control at a much-reduced cost compared with ear tags (Knapp and Webb, 1992; Sheppard, 1987). Application of pyrethroid sprays may select for fly resistance at a slower rate than use of pyrethroid ear tags (Sheppard, 1987).

Nutrition

Suckling beef calves are generally not supplemented during the summer grazing period, when milk and an increasing intake of forage provide their diet. Trace mineral deficiency may be a concern in some areas for calves. Proper trace mineral nutrition of the cow herd before calving provides the calf with adequate reserves at birth. Subsequent supplementation is difficult, since trace mineral mix intake is sporadic at best in calves. Creep feeding increases reliability of intake. Proper trace mineral nutrition is important for proper immune response.

Creep Feeding

Creep feeding in beef calves has been reviewed recently (Herd et al, 1998). Response to creep feeding has been highly variable, as has the economic return. Response is generally better when forage quality is decreased and calf gains are low. When forage quality and quantity are acceptable and cows are milking adequately, creep feed is an expensive substitute for available forage. When forage quantity or quality is limited, supplemental feed is used more efficiently by feeding calves than by feeding cows to produce milk for calves. Creep feeding causes decreased dry matter intake of forage, but milk consumption remains the same (Cremin et al, 1991). It may have a sparing effect on forage for use by cows but does not reduce lactation pressure on cows. Use of

Downloaded from Vet-e-Books.com

high protein, limited intake creep feeds can be efficient when forage is plentiful but of low quality. A summary of four studies using high-protein-limited feed creep on low-quality pasture showed a feed conversion of 2.6:1 (Herd et al, 1998). Consumption of high-protein-limited creep feeds should be controlled to 0.5 to 1 lb/head/day by mixing with salt. Creep feeding of potential replacement heifers should be avoided. Increased preweaning gains in heifers cause excess fat deposition in the udder, decreasing functional mammary parenchyma. Heifers appear to be most sensitive to the effects of fat deposition in the udder from 3 to 8 months of age. From 3 to 8 months of age, heifers gaining 2 lb/day showed decreased milk production and decreased calf-weaning weights compared with heifers gaining 1.2 lb/day. The result is cows with decreased milk production, decreased weaning weights, and decreased productivity (Johnsson and Obst, 1984).

The effect of creep feeding of calves on cow performance has been quite variable. Most studies have not shown a significant effect of creep feeding on production measures of cows the following year. Creep feeding for 3 to 4 weeks before weaning may be an effective way to reduce stress and disease at weaning. Calves will be acclimated to feed, achieve acceptable intakes quicker, and perhaps experience less morbidity from decreased stress at weaning. Small frame calves may show a depression in feed efficiency after weaning following creep feeding. Large-framed calves generally do not show depressed feedlot efficiency (Herd et al, 1998). Creep feeding may allow more calves to achieve choice quality grade by 14 months of age (Faulkner et al, 1994). It may have a sparing effect on BCS of cows and the amount of supplemental nutrition needed to get cows in adequate condition by calving.

Weaning

Weaning time is a particularly stressful time because the calf is removed from its mother and forced to adjust to a different diet; population density is increased, leading to potential for increased disease exposure and transmission. Management procedures should aim to minimize stress on calves while ensuring they are in sound condition nutritionally and immunologically. Proper cow-herd nutrition is important for the calf to begin its new life with adequate nutritional stores. By mid summer, calves are obtaining an increasing amount of feed from forage and may be consuming a limited amount of a trace mineral mix. A quality trace mineral mix should be available continuously for the cows and calves. Management practices that increase the stress on the calves should be minimized at weaning time. Castration and dehorning certainly should be performed well before weaning time. Ideally, vaccinations will be given before weaning to prepare the calf's immune system for increased exposure. Vaccinations given at weaning do not provide immunological protection during the period of highest risk immediately after weaning. In addition, immune response may be limited by the stress associated with weaning time. Completion of vaccination, deworming, and implant procedures before weaning allows calves to be weaned without handling. This serves to remove the stress of working through the chute and provides time for calves to respond to vaccinations before weaning.

Early Weaning

Early weaning of beef calves may be implemented when calves are 30 to 170 days of age. It may create more efficient use of feed resources by directly supplementing calves to maintain weight gain rather than supplementing cows to produce milk for calf growth. Weaning times as early as 30 to 60 days can increase reproductive performance of cows and heifers. Cows and heifers cycle and rebreed earlier in the calving season, and pregnancy rates are higher in a limited breeding season after early weaning at 30 to 60 days (Lusby et al, 1981; Guyer, 1983). Management requirements are increased greatly in calves weaned at this time. Nutritional needs of the weaned calves must be met carefully to ensure acceptable health and performance. When properly managed, postweaning weight gain of calves weaned at 30 to 60 days of age can equal the preweaning weight gain of calves weaned at 7 months of age (Lusby et al, 1981). Creep feeding the weaning ration to early weaned calves before weaning may be helpful to ensure early consumption after weaning. The postweaning ration should be balanced carefully to provide adequate nutrition to the calves. The final ration should provide 15% protein and 75% TDN and be balanced for vitamins, macrominerals, and microminerals.

Early weaning at 150 to 170 days of age decreases lactational stress on cows when forage resources are limited and causes improved cow condition. Reproductive performance in the breeding season is not affected by weaning at this time. When forage resources are limited, weaning calves to decrease the nutritional requirements of the cows will allow them to regain condition before winter with less or no supplementation. Calves can be supplemented more efficiently than cows. Depending on forage resources, feed costs, and market prices, early weaning may be an economic management consideration. Marketing of the calves should be thought out in advance. Direct marketing at early weaning would generally not be profitable, so plans should be made to retain calves and feed them until normal weaning time and weight (Table 13-24).

REPLACEMENT HEIFER DEVELOPMENT

Replacement heifer development programs generally commence at weaning as the heifers begin preparation for the breeding season. However, decisions relating to use of hormonal growth promoting implant programs for replacements must be made beginning at the spring working of calves at 2 to 3 months of age. Use of growth-promoting implants in heifer calves before 30 days of age may have severe effects on development of normal uterine function (Bartol and Floyd, 1996) and should not be practiced. Products are available for use in replacement heifer prospects from 45 days of age to weaning. Implants have been shown to increase weaning weight and frame score in heifers compared with nonimplanted control heifers. Pelvic area is increased in implanted heifers at 1 year of age, but most of the advantage over nonimplanted heifers is lost by calving and there is no difference in calving ease. The effect of implanting replacement heifers on their subsequent reproductive performance has been variable. In a review of the effect of implants on heifer fertility, application of a single implant caused an average depression in yearling pregnancy rate of 1% (range: +7% to −14%). Application of two or more implants caused pregnancy rate depressions as high as 42% (Deutscher, 1994). Some of the depression in pregnancy rate may be overcome by ensuring implanted heifers have sufficient nutrition to support a higher rate of gain (Deutscher, 1994). In general, reimplanting heifers at weaning, or after 6 months of age, is not recommended.

Heifers that calve at 24 months of age have increased lifetime production compared with heifers that calve first at 30 or 36 months of age. Heifers calving at 24 months of age produce an additional calf over their productive

Downloaded from Vet-eBooks.com

lifetime compared with heifers calving at 36 months of age (Lesmeister et al, 1973). Lehman et al (1993) used marginal cost analysis to assess the economic effects of calving *Bos taurus* heifers at 24 or 30 months of age. They calculated increased costs of calving 24-month-old heifers, including increased feed, increased dystocia and subsequent mortality, and decreased conception rates and weaning weights. This study found a $61/head advantage to calving heifers at 24 months of age even without including increased opportunity and inventory costs of calving heifers at 30 months of age (Lehman et al, 1993). When replacement heifers are managed properly, calving at 24 months of age is economical. Calving *Bos indicus* heifers at 24 months of age is possible but more difficult to achieve than with *Bos taurus* heifers and may not always be an economic proposition.

Heifer Selection

Selection of replacement heifer prospects begins at weaning time when the heifers are typically 6 to 8 months old. Selection at this point is based on birth date, conformation, frame score, and dam production records. Selection of heifers born early in the calving season leads to replacement heifers that are older and heavier at the start of the breeding season. Puberty is an age- and weight-dependent characteristic, so older heifers more easily reach target age and weight by breeding and nutritional supplementation cost may be less.

Conformation of replacement heifers is important for longevity of the cow herd. Heifers that remain in the herd longer have more productive years and provide increased return on their development costs. Heifers should be evaluated for conformation of their feet, legs, and udder. Unacceptable conformation in any of these areas should disqualify a heifer as a replacement prospect. Age-adjusted frame score can be used to estimate the mature size of prospects. It places some objective criteria on the selection of replacements to maintain a constant cow size designed to fit the environment and feed resources. Retention of the largest heifers each year causes the average cow size in the herd to increase over time. In addition, some evidence suggests that increasing weaning weights in heifers is associated with decreasing weaning weights in their offspring (Johnsson and Morant, 1984). As described in the section on summer calf management, average daily gain (ADG) of 2 lb in Hereford heifers before weaning may cause decreased milk production, although subsequent fertility may be improved (Johnsson and Obst, 1984). If available, dam production records can be used to select heifers from highly productive cows. However, in a study of cow-calf producers in the northwestern United States that regularly used a veterinarian for herd work, only 23% of herds kept cow-family production records (Sanderson and Gay, 1996).

Once potential replacement heifers are selected at, or after, weaning, a nutrition and vaccination program should be instituted in preparation for breeding. The design of the nutritional program depends on the breed and weight of the heifers and the time available before breeding. If heifers are to calve by 24 months of age, they must be bred by 15 months of age. This establishes the time available to prepare heifers for breeding. For optimum fertility heifers should weigh approximately 65% of their mature body weight by 12 to 13 months of age. Pregnancy rates are generally poor if heifers are bred on their puberal estrus, but they are significantly better when heifers are bred on the second or third estrus. For this reason, heifers should be developed to reach puberty at least 3 to 6 weeks before the breeding season. A ration must be balanced to provide the required rate of gain to meet the target goal of 65% of mature body weight in the time available. Specific requirements vary with the weight and breed of the heifers and the amount of time available before breeding. However, target or critical mating weights have been established for different breeds based on optimum growth rates (Table 13-25). Such lists should be used with caution because strong genotype-environmental interactions occur. However, to achieve such weights for breeding as yearlings requires target gains of 1 to 1.5 lb/day (0.5 to 0.7 kg/day). Periodic weighing of the heifers is useful to ensure that gains are progressing at an acceptable rate and allow for needed adjustments.

Excessive weight gains over the prebreeding period can be detrimental to heifer fertility (Utter et al, 1994; Minton et al, 1994). Recent evidence suggests that maintaining heifers at a low rate of gain for the first two thirds of the development period followed by a high rate of gain for the last one third may be more cost efficient. Heifers that gained 0.1 to 0.5 lb/day over the first 112 days of the development period followed by 2.4 to 2.8 lb/day for the last 56 days had similar reproductive performance as heifers that gained 1.1 to 1.3 lb/day over the entire development period (Lynch et al, 1997). The goal of the nutritional program is to develop fertile heifers that will breed early in their first breeding season. Heifers that calve early in their first calving season have greater lifetime production than heifers that calve late (Lesmeister et al, 1973).

Incorporation of ionophores into rations for replacements can decrease age and weight at puberty and decrease the feed:gain ratio (Purvis and Whittier, 1996). They have no effect on fertility of replacement heifers but may cause increased pregnancy rates in the first 20 days of the breeding season because of increased numbers of heifers exhibiting estrus. Ionophores can be included at 200 mg/head/day from weaning to breeding but will not be useful if the heifer ration is not balanced to provide a gain of approximately 0.75 lb/day (Floyd et al, 1995).

The effect of exposing heifers to bulls before breeding has been inconsistent (Roberson et al, 1987, 1991) but may decrease age at puberty. Heifers with an increased rate of gain may be more responsive to the effect of bull presence (Roberson et al, 1991).

TABLE 13-25

Reproductive tract scoring (RTS) systems have been developed to assess the maturity of the reproductive tract in heifers (Anderson et al, 1991). They are typically performed 30 to 60 days before the breeding season. The score is based on the size and tone of the uterus and the size and structures on the ovaries. Heifers with more mature tracts have increased pregnancy rates to synchronization than heifers with immature tracts. In one survey of well-developed replacement heifers, culling rate for immature reproductive tracts was very low (8 of 1489), suggesting the technique may be of limited use in properly developed replacement heifers (Spire and Holtz, 1995). It may be useful in late maturing or underconditioned replacement heifers to assist in culling heifers that will be unlikely to respond to synchronization (Spire, 1997), thus saving drug, semen, and labor costs.

The pelvic area of replacement heifers is commonly measured at 30 to 60 days before breeding. Pelvic area is not an effective predictor of future calving difficulty. On-farm studies have reported that pelvic measurements a few weeks before the breeding season and again at the time of pregnancy examination have poor positive predictive values and sensitivities in predicting dystocia (Van Donkersgoed et al, 1990). Mean pelvic area in the heifers with dystocia was slightly smaller than for those without calving difficulty, but there was a large overlap in the distribution of their pelvic areas. Pelvic measurement of replacement heifers is likely most useful for identifying heifers with small or abnormally shaped pelvises for culling. Minimum pelvic areas for yearling heifers of 150 cm^2 (Larson and Moser, 1998) and 160 cm^2 (Spire and Holtz, 1995) have been suggested as a culling criterion. Selection for increased pelvic area also leads to selection for increased mature cow size and increased birth weight. This effect can be minimized by using frame scores for selection criteria to stabilize cow size.

Heifer Vaccination Program

The vaccination program for replacement heifers should be designed to provide them optimum protection from reproductive diseases. Pathogens for which vaccinations exist, and estimates of the percent of heifers vaccinated, are summarized in Table 13-26. Vaccination for reproductive pathogens is common in herds in which a veterinarian is involved in management (Sanderson and Gay, 1996) but are considerably less common in a random sample of U.S. herds (NAHMS, 1998a). The program should include vaccination for *Brucella abortus*, IBR, BVD, *Campylobacter*, and *Leptospira* (Table 13-26). *Brucella* vaccination is carried out according to state or provincial regulations. Modified live vaccines for IBR and BVD may give the broadest immunity to strain differences especially for BVD. Modified live IBR and BVD should be given twice to ensure a high level of immunity. Some evidence suggests that modified live BVD and IBR may transiently infect the ovary and cause decreased fertility. For this reason, the second vaccination should be given at least 1 month before breeding. A vaccine containing *Campylobacter fetus* and five strains of *Leptospira* is given twice before breeding. Vaccination of heifers with *Trichomonas* vaccine has been shown to increase calving rate and decrease duration of infection in infected herds, but it does not prevent infection (Kvasnicka et al, 1992; Hudson et al, 1993). A vaccine for trichomonosis may be useful in infected herds or herds that are at high risk for infection, but it may not be economical in herds in which risk for infection is low.

Once the heifers are nutritionally and immunologically prepared for breeding, a synchronization program can increase the number of heifers that are bred early in the breeding season. In addition, AI allows the use of high-quality bulls with high-accuracy EPDs for birth weight. It is generally recommended to begin breeding heifers 3 to 4 weeks before the cow herd. This allows the heifers to calve early, be more closely observed, and have additional time to recycle and rebreed with the cow herd for their second calf. Advance planning is necessary to ensure adequate time to follow synchronization protocols before the desired breeding date. The heifer-breeding season should be limited to 45 to 60 days to place some selection pressure on early fertility and provide pregnant heifers with a reasonable chance to rebreed with the cow herd the following year. In synchronized herds, each heifer can have three opportunities to be bred in a 45-day breeding season.

Nutritional development needs to continue through the second breeding season. Heifers should be managed separately from cows until after they are bred for their second calf. Target weight for the first calving is 85% of mature body weight. Heifers that calve below target weight and in poor BCS have a longer postpartum interval, and lower pregnancy rates, and postpartum weight gain does not completely overcome this depression (Bell et al, 1990). Nutritional management from first breeding to second breeding is critical to optimizing the number of heifers that remain in the herd as productive cows. In herds in which replacement heifer development is suboptimum, heifers drop out at a high rate after their second breeding season and before the cost of developing them has been recaptured.

Commercial replacement heifer development enterprises are available to cow-calf producers. These development centers provide custom heifer development or development of heifers for sale. If the level of labor, management, or resources precludes proper heifer development, custom

heifer development may be an economical alternative. Selected heifers may be sent to the development center for nutritional and immunological development and for breeding. Heifers are generally returned to the herd after breeding. For herds involved in a terminal sire-breeding program designed to produce slaughter calves, development centers may provide a source of quality heifers for replacement. Similar to bull test programs, replacement heifer development test programs are being developed by state beef improvement associations and university extension (Table 13-27).

Calving as Two-Year-Olds

The advantages of calving 2-year-old heifers include improved lifetime efficiency of 2-year-olds versus 3-year-olds, reduction of age of cows at culling through an overall reduction of herd average age, more effective use of pasture with all age groups contributing to net reproductive rate, and increased genetic progress in the herd for those characteristics under selection through generation intervals. Reasons given by some producers for not adopting 2-year-old calving compared with 3-year-olds include a greater incidence of dystocia, rearing of lighter calves, reduced reproductive performance subsequent to their first calving, and lighter weights when culled for age at 8 to 10 years of age. These particular reasons against 2-year-old calving are no longer valid. The major causes of dystocia are understood and can be managed practically and economically, the lighter weight of calves reared is not significant, and subsequent fertility is not reduced if heifer breeding is managed adequately. The lifetime calf crop from 2-year-old calvers can be expected to be equivalent to an extra 0.7 calf compared with 3-year-old calvers.

Heifer Breeding Management Models

A model has been developed for heifer breeding management (Mossman and Hanly, 1977). Here, a herd of 100 well-grown cycling heifers in excellent body condition is mated to proven bulls at a bull-to-female ratio (BFR) of 1:33 for 105 days. It is proposed that each 21 days, 60% of eligible heifers become pregnant. The theoretical conception rate in 100 heifers over 105 days is shown in Table 13-28.

The total number of services required to get 100 beef heifers pregnant at a 60% conception rate is 164—that is, 1.64 services/heifer. It takes 105 days to get 100% heifers pregnant. If breeding is terminated at Day 42, 84% are pregnant; at Day 45, 85% to 86% are pregnant. Another 60 days are required to get the remaining 14% to 16% in calf.

If the veterinarian assumes 100 days are needed after calving for an average first-calf heifer to return to heat, then the time to the second breeding (second breeding year) is 380 days (280 + 100). When the heifer returns to heat, she requires 1.64 services, on average. Therefore, for a heifer to become pregnant again, another 0.64 of a service, or 0.64 of a 21-day cycle, is required—13.4 days. The time of the first conception to the second conception (the calving interval) is now 393.4 days (280 + 100 + 13.4). Therefore the average heifer takes 393 days from first conception to second conception, which means that she is 28 days behind starting her lifetime production of one calf/cow/year. Thus, theoretically, heifers should be bred 28 days ahead of cows.

The theoretical heifer calving pattern over 105 days (in 21-day periods) is shown in Table 13-29 and Fig. 13-10.

If the heifers are first bred at the same time as the mature cows, the average calving interval will be 393 days. From the 100th day after calving, it takes 105 more days (Table 13-23) to get all the heifers pregnant again—a period of 485 days (280 + 100 + 105). It is impossible to get heifers pregnant again (within 365 days) that were not pregnant by the 62nd day of their first breeding period, because the calving index is greater than 455 days. If a mating period of 63 days is planned for the herd, then heifers not pregnant by the 45th day of their breeding period do not become pregnant during the herd-breeding period. This theory for reproductive failure is the basis of a limited heifer-mating period (42 to 45 days) 28 days ahead of the cow herd, in which a minimum of

85% of heifers are pregnant and pregnancy-tested 6 to 8 weeks after the end of the breeding period. The use of real-time ultrasound for pregnancy testing is highly accurate as early as 26 to 28 days of pregnancy, and it could be used to test much earlier than 6 to 8 weeks after the end of the breeding period. The remaining 15% are the animals potentially not pregnant, and these could be culled and sent for slaughter. This would depend on current and predicted market prices and on the availability and costs of feed.

The calving pattern for the remaining 85% of heifers from the 100 heifers that were examined for pregnancy 6 to 8 weeks after mating is shown in Fig. 13-11.

If the postpartum interval for first-calf heifers could be shortened to 80 or 90 days using good prepartum and postpartum nutrition, it would cause increased conception rate as well as a concentrated calving season and pattern, which are all highly desirable. With a concentrated breeding period, heifers can calve in the spring on selected calving grounds with more control over feed intake before and after calving. This leads to large savings in feed, which is virtually impossible with a 90-day calving period. Another major economic advantage of concentrated calving is that the labor and surveillance required at calving time can be intensified and thus be more effective. It is more cost effective and beneficial to be watching several animals calving through the night than it is to watch one animal every night or every other night for 90 days.

Replacement Heifer Management

In order to optimize lifetime production, calving heifers at 2 years of age have become a widely accepted practice among beef producers. If a heifer is to calve at 24 months of age, she must be cycling and fertile at 15 months of age. However, many 15-month-old heifers have not reached puberty. Puberty in heifers is influenced by age, growth rate, breed, and level of nutrition. Age at puberty, date of conception, and conception rate are largely determined by the management of heifers during the winter period immediately after weaning. Reproductive performance is enhanced if heifer calf replacements are fed to gain weight at a rate of at least 0.5 to 0.75 kg/day from weaning to breeding so that they reach target weight. Thus replacements should gain approximately 100 kg from weaning to breeding. Winter weight gains may be more beneficial than gains during the breeding season (Lemenager et al, 1980). Where approved for use, ionophores such as monensin and lasalocid in the diet of heifer replacements fed harvested forage increase weight gain and improve feed efficiency (Sprott et al, 1988). Ionophores do not alter fertility but may decrease age at puberty in the female (Sprott et al, 1988).

A management system for replacement heifers from weaning through breeding is shown in Box 13-15.

Heifers should be well developed at the time of first breeding, and their management during gestation must ensure their continued growth. Pregnant heifers should be separated from the main cow herd at the time of pregnancy testing after their breeding season and maintained separately until reentry into the breeding herd after their first calving. This ensures that adequate nutrition and management levels are met. Such management may increase calf birth weight, but most of the increase is in soft tissue and skeletal structure and should be more than offset by the increased size and vigor of the heifers. Sires used with year-

ling heifers should be selected to minimize the probability of excessive birth weights when combined with the genetic makeup of the heifers. If close supervision is practiced at calving, a bull should be selected based on calving ease, but the same breed should be used as that used on the cow herd. If the heifers are calved on the range with minimum supervision, a breed of bull should be chosen to minimize calving problems. If there is any doubt about the heifer's ability to calve unassisted or if calving seems prolonged, obstetric assistance should be provided as soon as possible to minimize calf and dam injury, possibly death, and the problems of subsequent reproductive performance. Heifers should be bred ahead of the main cow herd. This ensures that any increase in the postpartum anestrus period after their first, perhaps difficult, calving does not compromise their chances for cycling and rebreeding with the main cow herd.

Maternal Nutrition and Subsequent Performance

Nutritional management of the beef herd is the main limiting or controlling factor for reproduction. Insufficient energy intake resulting from dietary quality or quantity delays puberty, lengthens postpartum anestrus, and causes anestrus in cows or heifers that are having estrous cycles (Short and Adams, 1988; Richards et al, 1989a,b).

The effect of winter weight loss in beef cows on subsequent reproductive performance has been documented

BOX 13-15

Management System for Replacement Heifers

1. Select the largest and oldest heifers, and select 20% to 30% more than required. The largest heifers may be older and reach puberty quicker, they are probably faster growing, their dams were probably good milk producers, and they are easier to get to breeding weight. Selection of 20% to 30% more than required allows some culling for quality, development, pregnancy, and production. A guiding principle is to "select on performance and cull on fertility."
2. Feed heifers from weaning through to breeding for them to gain 0.5 to 0.75 kg/day. They should continue to gain weight throughout the breeding season. Weighing calves at weaning and subtracting weaning weight from the target breeding weight allow an estimate of the ADG required to reach the critical minimum weight for breeding to be made.
3. Vaccinate heifer replacements for those diseases that can cause abortion (e.g., infectious bovine rhinotracheitis, vibriosis, and leptospirosis), depending on the occurrence of these diseases in the area.
4. Provide suitable and permanent identification.
5. Weigh heifers 3 weeks before breeding to determine the critical minimum, or target, weight. The weights shown in Table 13-25 are those established for different breed types (all *Bos taurus*) of well-grown heifers to reach puberty in a temperate climate.

Excessive weight loss in 2- and 3-year-old cows causes delayed onset of estrus after calving and an increase in the percentage of nonpregnant animals and late calvers. Mature cows may reproduce satisfactorily on diets that are unsatisfactory for younger cows. Thus young cows respond favorably when fed a diet higher in energy than that fed to cows (Davis et al, 1977).

The nutrition of the pregnant beef cow, particularly the first-calf heifer, can have a marked influence on the subsequent reproductive performance of the cow and on the viability and health of the calf from birth to weaning. Undernutrition during pregnancy in first-calf heifers commonly leads to an increased incidence of dystocia because of lack of weight and size (Makarechian et al, 1982; Wiltbank and Remmenga, 1982), weakness at the time of parturition, insufficient colostrum, weak calves at birth, and a high incidence of prolonged postpartum anestrus, which leads to a high percentage of nonpregnant animals that may have to be culled. If they are left in the breeding pasture to be bred over a period of 3 to 6 months, a high percentage ultimately conceives but they are late calvers in the next season. The high rate of culling of nonpregnant animals and late calvers among young beef heifers and cows is a major cause of economic loss in beef breeding herds. The effects of undernutrition on reproductive performance are greater in first- and second-calf heifers and cows than in older cows. Thus pregnant heifers should be fed and managed separately from cows and should be on a higher plane of nutrition than cows.

GENERAL HEALTH MANAGEMENT CONSIDERATIONS

Herd health is dependent on a number of factors that act to maintain collective immunocompetence. For many infectious diseases the greatest risk for initial introduction into a herd is with the purchase of subclinically infected animals that are carrying the infectious agent. The herd risk level for introduction of disease is thus related to the amount of contact that occurs with "outside" animals, with some risk also attributable to wildlife carriers. Potential sources of infection may occur with herd additions, or through advertent or inadvertent movements and contacts. Herds may be classified as "open," "closed," and "modified open," based on their potential for pathogen exposure (Spire, 1988). This classification may then be used to help plan the herd health program, as explained below.

Closed herds restrict the introduction of animals (probably only breeding bulls) as well as contact with other herds and animals, whereas modified open herds may replace animals from outside sources on a limited basis and allow other controlled contacts, such as at livestock exhibitions. In general, any incoming animals should be subject to the same herd health program as the regular herd. It is preferable to obtain these from herds whose herd health history is known and to have a record of vaccinations and treatments. It is also wise to quarantine newcomers while appropriate tests, observations, and vaccinations are performed. For pubertal bulls, such tests should include tests for campylobacteriosis and trichomonosis.

At the other end of the spectrum, open herds represent high risk for the introduction of pathogens. This risk occurs through such practices as regular introduction of purchased replacements (especially from commingled sale groups), direct introduction of stressed stocker calves (especially into high population densities), and mingling of animals of different backgrounds, through either cooperative breeding programs or poor herd biosecurity.

Situated between these two categories, modified open herds are characterized as those that limit the introduction of new animals and other animal movements and that have adequate herd biosecurity. In general, sound herd health management should include separating all purchased or introduced animals from the home herd for a reasonable observation period (e.g., 4 weeks) and for them to undergo the same health procedures as the home herd. If the origin of the newcomers is unknown, it is wise to test them for bovine leukosis, Johne's disease, and BVD (Stokka and Faulkner, 1998). Pubertal bulls should be tested for trichomonosis and vibriosis.

For AI programs, only semen should be used that was processed by an approved AI center with a comprehensive health program for minimizing the risk of transmission of venereal (and other) diseases through frozen semen. In North America, such assurance is obtained from AI collection centers that are affiliated with Certified Semen Services (CSS), the industry group that establishes guidelines for both bull health and semen quality control (see below).

Vaccinology

Although they form the basis of many herd health programs, vaccines vary widely in their efficacy. This variation occurs even when they are used properly (Gay, 1999). Improper use, including errors in storage, dosage, and site of administration, add to the probability of vaccine failure. Knowledge of factors such as appropriate vaccine choice, handling, and administration is more important than the actual vaccination schedule (Randle, 1993). In developing production

Downloaded from Vet-eBooks.com

medicine programs for cattle breeding herds, veterinarians need to advise on such aspects as replicating versus nonreplicating vaccines, number of doses required for effective protection, best timing of administration, storage and mixing of vaccines, location and route of administration (Randle, 1993), and withdrawal constraints. The effectiveness of any vaccine is dependent on a healthy immune system in the recipient. Overreliance on vaccinal protection can be mistaken if these considerations are not addressed.

Infertility Diseases

Although infertility is a major cause of loss to cow-calf producers, it is often insidious in nature and difficult to detect. True infertility is something that occurs before fertilization, such as when females are not cycling (or if cycling, not becoming pregnant). Although this definition differentiates infertility from disease entities that cause embryonic or fetal loss, this is often more difficult to do in practice. However, if this definition is accepted, then infertility in mature (postpuberal) female cattle is usually due to one or more of the factors listed in Box 13-16.

The presentation here does not describe each of these conditions in detail but briefly reviews the infectious causes of infertility from the diagnostic and managerial perspectives.

Trichomoniasis

Trichomoniasis is a contagious venereal disease (caused by *Tritrichomonas* [or *Trichomonas*] *foetus*) that is apparently widespread in beef herds (8% of bulls in Oklahoma and Florida, 15% in California herds), in which it is capable of causing significant economic loss through both delayed breeding and gestational loss (Rae, 1989).

In bulls *T. foetus* occurs on the penis and prepuce, localizing within epithelial crypts and smegma such that older bulls (4 years and older) tend to become chronic carriers. However, no clinical or pathological signs are reported in bulls. In females the organism colonizes the vagina, uterus, and oviduct. It produces vaginitis and endometritis with mild discharge. It does not interfere with fertilization but either directly or indirectly (through endometritis) starts to adversely affect the fetus from about 50 days' gestation, with death and subsequent resorption occurring around 100 days. Pyometra and abortion may occur, although they are rare. Infertility is a common sequel, probably resulting from initial fetal death and subsequent failure of conception or implantation. This infertility commonly lasts 2 to 5 months after which cows may regain fertility with some immunity. It is possible, however, for females to retain infection throughout pregnancy, although most will eliminate the organism at the first or second postpartum estrous cycle.

BOX 13-16

Causes of Infertility in Beef Herds

Nutritional problems (± suckling/lactation)
Bull infertility
Vibriosis (campylobacteriosis)
Trichomoniasis
Other infectious causes (e.g., *Ureaplasma*, infectious bovine rhinotracheitis, *Haemophilus somnus*)?

The most obvious sign in the herd is often females returning to estrus 3 to 4 months after they were bred. This may not be noticed with restricted breeding seasons such that first sign may be a lowered calf crop. Sometimes, the first indication may be an increased number of pyometras at pregnancy test. *T. foetus* can survive freezing and thus be transmitted with AI. It can also exist for varying periods on bedding. It is very contagious (80% to 90% of females bred to an infected bull will contract the disease). A tentative herd diagnosis for trichomoniasis may be obtained from analysis of herd pregnancy diagnosis records, which can provide important clues such as strung-out conception patterns or increased numbers of open females. Calving analyses can also provide similar information, only later. Increased pyometras and midterm abortions are also useful clues. However, the definitive diagnosis depends on identification of the causal organism. This is best done from the prepuce-penis of mature bulls (Rae et al, 1999), using a technique such as the "In-pouch," or Diamond's media, as the preferred culture media. Such preparations should be maintained at 37° C and examined microscopically at 24, 48, and 72 hours.

Risk factors for trichomoniasis in herds include commingling of cattle from different herds or backgrounds, failure to limit breeding season length, use of older bulls, failure to screen introduced bulls for trichomoniasis, poor fencing, and the continued presence in the herd of older or cull females (Gay et al, 1996). In bulls, carrier status appears to be related to the development of crypts within the penile and preputial epithelium. Such development is largely age related, although breed differences occur in the age at which some bulls may become carriers. For example, in the study by Rae et al (1999), several 2-year-old bulls were diagnosed as infected.

Losses resulting from *T. foetus* in cattle breeding herds may be substantial. In Oklahoma, annual calf loss in 1979 was estimated at $2.5 million (Wilson et al, 1979). A simulation model (Rae, 1989) estimated a reduction of 14% to 50% in annual calf crop when bull prevalence was between 20% and 40%, with net return per exposed cow being reduced by 5% to 35%. In large herds in which bull prevalence was up to 35.9%, cow performance measures were adversely affected by large numbers of infected bulls (Rae et al, 1999).

When trichomoniasis is diagnosed in a herd, a number of options exist. These range from doing nothing and living with the economic consequences, or the following:

1. AI with semen from an accredited AI center (AIC)
2. Vaccination (females only)
3. Culling of open cows and older bulls
4. Institution of "clean" versus "dirty" herds
5. Avoiding public grazing lands that are shared with other herds
6. Testing and removal of positive bulls and prevention of positive bulls from entering the herd

The last option, which depends on a reliable testing method and good animal identification and control, was used successfully in an extensive beef herd in Florida (Rae et al, 1999). Here, the mean prevalence of *T. foetus* infected bulls was 11.9%. Test sensitivity of the in-pouch diagnostic system was estimated for consecutive tests as follows: 73%, 90%, 96%, and 99%. Although this was lower than other published estimates for this technique (Skirrow et al, 1985; Kimsey et al, 1980; Gay et al, 1996), it is similar to AI industry estimates of average diagnostic sensitivity for trichomonosis (Monke, 1998). Reasons for lowered test sensitivity for trichomonosis are many. False positives are considered rare when experienced laboratory personnel are involved (with the possible exception of confusion with *Trichomonas enteris*, as below); false negatives are a possibility that can

Downloaded From Vet-e-Books.com

occur despite the effectiveness of the culture medium itself. Some possible reasons for this follow.

Restraint and Sampling. A preputial smegma sample should be obtained from the region of the glans penis and the adjacent preputial membrane. This should be as free from contamination as possible. These conditions are not always easy to fulfill, especially when fractious bulls are examined in poor facilities. Bulls that have recently completed natural or artificial vagina (AV) service may have a reduced population of *T. foetus* and a minimum 4-day interval without sexual activity before sampling has been advised. In bulls with large sheaths, standard insemination pipettes may not be sufficiently long to reach the preferred sampling site.

Transport and Culturing. The temperature of the transport-culture media should be as close to ideal culture temperature (37° C) as possible. Where this cannot be ensured, samples should be transported to a laboratory incubator as rapidly as possible. Temperature extremes, contact with atmospheric oxygen, and contamination should be minimized.

Interpretation. Technicians need to be trained to identify the telltale movements of *T. foetus* (best seen at a magnification of 100×) and to be diligent in searching for them. Cultures should be monitored regularly to detect overgrowth that can cause death of *T. foetus*, leading to a false-negative result. On occasion, confusion may be caused by the presence of an enteric trichomonad (*T. enteris*), which can resemble *T. foetus*. Here, definitive diagnosis is dependent on use of electron microscopy, or specific staining, to define fine structures.

Vaccination of cows and heifers against *T. foetus* is an option when disease is detected, suspected, or threatened (Kvasnicka et al, 1999). In the United States, this is achieved with a killed *T. foetus* product that significantly reduces abortion losses in challenged females and limits the duration of infection, although it does not prevent infection (Kvasnicka et al, 1999). The vaccine requires two administrations, 3 weeks apart and about 1 month before breeding, with an annual booster. Timing of the vaccination is important, with reports of diminishing effectiveness with increasing interval between vaccination and breeding.

Vibriosis (Campylobacteriosis)

Bovine vibriosis is a true venereal disease that is common in beef herds worldwide, where it is mostly associated with infertility. The causative agent, *Campylobacter fetus* var. *venerealis*, survives on the penis and prepuce of the bull, specifically within mucosal crypts, and within the female reproductive tract. It can also survive freezing so that it can be transmitted in frozen semen. Antibiotics are added to extenders to avoid this. It may also be transmitted from animal to animal through unsanitary AI practices.

In females, infected bulls deposit *C. fetus* in the vagina. After 1 to 2 weeks, organisms are throughout the uterus and can reach the oviduct (25%) within the same period. A progressive endometritis ensues, which reaches its peak at about 8 to 13 weeks after infection. Initially, fertilization may occur, but the embryo will either not survive for long, leading to a prolonged return to estrus, or later abortion can occur. If initial fertilization did not occur, a temporary failure of fertilization may occur due to failure of gamete transport. Normal cyclicity may be evident except at the first cycle, which can be prolonged. Abortions occur in a minority of infected females (3% to 5%), usually after 5 months gestation but sometimes earlier (2 to 3 months). Immunity usually develops after 4 to 6 months following initial infection. The duration of this immunity varies but it usually is minimal after approximately 4 years. Some females remain carriers.

In bulls, *C. fetus* localizes in the epithelial crypts of the penis and prepuce. Carrier status thus depends on the development of these crypts, usually in mature bulls (4 years or more). Younger bulls tend to have transitory infections. Mechanical transmission is very rare. However, bulls may become infected by contact with infected material. No clinical or pathological evidence of infection occurs in bulls.

In herds the most common sign of the disease is extra breeding activity and a "strung-out" calf crop resulting from the variable recovery periods of individuals and their initial susceptibility. Thus either heifers or first-calf females may show the worst effects—whichever group is first exposed to infected bulls. Bulls may become fatigued because of increased workloads.

A tentative diagnosis of the disease can often be made with the use of good herd records in conjunction with an understanding of disease patterns (although it may be difficult to differentiate between vibriosis and trichomoniasis). Valuable circumstantial evidence for the presence of either vibriosis or trichomoniasis in the herd can be gleaned from analyses of herd pregnancy diagnosis records. Samples may be taken from the vagina or cervix of selected females and cultured in special media. *C. fetus* is difficult to culture. Thus, at least 10 to 20 open, cycling females should be selected—excluding vaccinates and those that have aborted. Identification of *C. fetus* in one or more females is proof of herd infection. Laboratory methods of diagnosis are covered elsewhere. A sample may be taken from the bull's prepuce using a pipette or scraping device, with this being placed in a transport medium. However, bulls are generally not good candidates for isolation of *C. fetus*. The "gold standard" is to test breed a group of heifers with a suspect bull and then sample cervical mucus just before first estrus. Serology has been used as a herd-screening test, although this has severe problems and must be interpreted in light of vaccinations and other records. The mucus agglutination test is regarded as being more useful for herd screening.

Treatment options for females have been inadequately studied because of spontaneous recovery within 6 months. In bulls, carriers can be treated with antibiotics (e.g., local treatment with neomycin-erythromycin). Vaccination, using high antigen mass, has also been reported to clear bull infections.

Bacterins are commonly used for control, in either an oil (longer duration, bigger lumps) or aluminum hydroxide (shorter duration, smaller lumps) adjuvant. *C. fetus* vaccines are often combined with *Leptospira* (5 way) and, sometimes, with *T. fetus*. Effective protection is relatively short (4 to 8 months). Best protection is when vaccination is completed around 2 to 4 weeks before breeding. All breeding bulls and females should be vaccinated annually.

Management procedures may also be used to control or prevent vibriosis. Here, use of AI with semen from an accredited AI center is a safe option. Another option is to breed virgin bulls with virgin heifers to build up a "clean" herd. The judicious culling of open and late-pregnant females, as well as the use of young bulls, can reduce the deleterious effects of vibriosis to low levels. Vaccination of bulls alone is used by many producers, and this can be effective when herd biosecurity is ensured.

Ureaplasmosis

Ureaplasmas are common inhabitants of the respiratory and reproductive tracts of cattle, and they have been implicated in a number of reproductive syndromes (Sanderson and Chenoweth, 1999). They are assumed to cause considerable

Downloaded from Vet-eBooks.com

loss under certain conditions, which have yet to be specified. The causative agent, *Ureaplasma diversum*, has been implicated in a variety of reproductive tract disorders, including granular venereal disease, early embryonic loss, weak calf syndrome, abortion, and seminal vesiculitis in bulls. After experimental inoculation, granular vulvovaginitis occurred in 3 to 6 days followed by endometritis and salpingitis. Female susceptibility to *U. diversum* seems to vary, with heifers appearing to be particularly susceptible. CTC has been used in feed, with mixed results, to prevent or reduce the adverse effects of *U. diversum*.

Health Standards for Artificial Insemination Centers

A number of diseases have been shown to be transmittable in frozen semen. For this reason, the biosecurity and health programs of AICs are relevant to this discussion of cow-calf health. In the United States, most AICs are affiliated with the National Association of Animal Breeders (NAAB), and with its subsidiary, Certified Semen Services (CSS). CSS establishes rules and procedures for the certification of businesses that process livestock semen. These include requirements for testing both bulls and mount animals before entering isolation, during isolation, and while in residence at the bull stud. They also include general sanitary procedures and requirements for the addition of appropriate antibiotics to semen and extender to control specific microorganisms, particularly mycoplasmas, ureaplasmas, *H. somnus* and *C. fetus* subsp. *venerealis*. At present, the recommended antibiotics for this purpose are gentamycin, tylosin, and Linco-Spectin. Comprehensive standards are provided for those diseases known or suspected to be sexually transmissable. The underlying goal is to protect the herd into which the semen is being introduced. Thus use of semen from CSS-approved AICs is recommended, at least in the United States. Such semen is certified as CSS "Health Certified Semen" and will have the CSS logo imprinted on semen packages. Further information on CSS procedures and recommendations may be found at http://www.naab-css.org.

BULL SELECTION, ASSESSMENT, AND MANAGEMENT

Beef cattle numbers in the United States have remained relatively stable over the past quarter century, with the predominant breeding system being natural breeding at range or pasture. Since reproductive performance is the most important single economic trait in the cow herd, the reproductive capabilities of breeding bulls assume great importance. The best single assurance that a bull is likely to be fertile is for him to pass a breeding soundness evaluation (BSE).

In 1997 approximately 55% of U.S. beef *operations* had bulls semen tested before purchase, lease, or loan, with SC measurement being performed on 44%, up from 31% in 1993 (NAHMS, 1998b). Previously, 57.2% of respondents indicated that bull SC was either extremely or very important in bull selection, with 19.2% regarding it as not important at all (NAHMS, 1994a). In this survey, the three major bull selection criteria were breed, temperament, and structure-appearance. Paradoxically, infertility and physical unsoundness were the most important culling criteria for bulls.

The numbers of *operations* using bull assessment *before sale*, although not particularly high, contrasted with those that assessed bulls *before breeding*. Here, not only are estimates disappointingly low, but surveys indicate an overall decrease between 1993 and 1997 in both semen testing (18.3% and 17.0%, respectively), and SC measurement (10.8% and 8.9%, respectively). For actual *bull numbers* (in contrast to operations), the percentage of bulls subjected to a prebreeding semen test in 1997 was 30.1%, with SC being measured on 17.7%. Together, these data indicate several trends. One is for bulls to be assessed at only one time in their breeding careers (e.g., before sale, lease, or loan). In general, larger operations more commonly use bull reproductive exams than do smaller ones (NAHMS, 1998a). Despite this, bull management was identified as a prime area for increased veterinary involvement in major cow-calf regions of the United States where cow herd sizes were larger than average (Sanderson and Gay, 1996). An apparent decrease in use of a prebreeding bull BSE by industry between 1993 and 1997 (NAHMS, 1998b) may reflect a trend to reduce veterinary inputs at times of low calf prices.

Relationships Between Bull Breeding Soundness Evaluation and Fertility

There is a considerable amount of supportive evidence that links the BSE and/or its components with bull fertility. An earlier study (Cupps et al, 1959) concluded that impaired breeding efficiency occurred when sperm motility was below 37% and normal sperm morphology below 65%. In Nebraska, a natural breeding study found that bulls classified as satisfactory, questionable, and unsatisfactory obtained average pregnancy rates of 75%, 52%, and 12%, respectively, although individual bulls varied within categories (Wiltbank et al, 1965). The conclusion was that the average fertility of categorized bulls could be predicted with some reliability, although individual bull fertility prediction was less reliable. The most predictive aspect of semen quality was percent abnormal sperm followed by sperm motility. In Texas trials, cows were mated with bulls having 80% or greater normal sperm, or with unselected bulls. Subsequent pregnancy rates were 93% and 87%, respectively (Wiltbank and Parish, 1986). In a second trial, heifers were bred to bulls of three sperm morphology categories; 80% plus normal sperm, 70% plus normal sperm, and unselected controls. The respective pregnancy rates were 90%, 91%, and 85%. The conclusions were that bulls preselected for good sperm morphology (70% or 80% normal) could achieve 5% to 6% more pregnancies than unselected bulls, and that 70% normal sperm was a reasonable threshold.

In an attempt to increase breeding pressure on bulls, and thus accentuate differences in male fertility traits, several trials used bulls with groups of heifers that had been treated to synchronize estrus. In one such series (Mateos et al, 1978), "satisfactory" BSE bulls obtained a pregnancy rate advantage of 10.5% over those categorized as questionable (actual pregnancy rates of 53.6% and 43.1%, respectively). Here, each of three major components of the BSE (SC, sperm motility, and percent normal sperm) were associated with pregnancy rate (all $p < .05\%$). In a similar study, satisfactory bulls obtained a pregnancy rate advantage of 6% to 9% compared with questionable bulls (Farin et al, 1989). Another approach has used blood-typing technology to determine calf parentage, and thus the fertility of bulls in multi-sire breeding herds. In one study the most important bull factors were found to be large SC, low numbers of primary sperm defects, and lesser amounts of backfat (Coulter and Kozub, 1989). Also in Canada, prior BSE screening of bulls in a large herd caused increased pregnancies (3.5%) in a shorter breeding season while using less bulls (BFR went from 1:20 to 1:30) and increased calf weaning weights (Prince et al, 1987). This last observation indicates that females became pregnant earlier in the breeding season, causing older, and heavier, calves at weaning.

Studies in tropical and subtropical regions have shown encouraging results for the BSE and/or its components. In a

Downloaded From Vet-eBooks.com

study in Northern Australia (Bamualim et al, 1984), BSE score had some ability to predict a bull's fertility over the subsequent breeding season ($p < .01$) and also over the bull's lifetime ($p < .05$). Here, semen quality was positively associated with pregnancy rate. In a similar environment, a study in which bulls were examined at various intervals from 11 months before mating found the most important factors in bull fertility "indexes" to be testicular volume, sex drive, induced luteinizing hormone (LH) levels, and body weight (Perry et al, 1990). Age and dominance value (a measure of social dominance) also played a role in the derived indices that were highly related to pregnancy rate. A study with Brahman bulls in a more extensive beef region of Northern Australia (McCosker at el, 1989) exploited calf blood-typing to determine major influences on bull fertility in multisire herds that had BFRs of 1:20 to 1:33 and a breeding season of 124 to 190 days. Here, low and variable bull fertility was associated with bulls that had low BSE scores. Bull SC and BSE score influenced bull fertility (both $p < .05$), as did dominance value. The use of only sound bulls caused substantially higher pregnancy rates at lower BFRs (1:33 versus 1:20). Most recently, a large-scale study (12 sites, 245 bulls) in North Queensland used DNA parentage technology to determine the major effects influencing fertility in *Bos indicus* derived bulls (Fitzpatrick et al, 1998). Here, highest calf crops were obtained from bulls with more than 70% normal sperm, whereas bulls with less than 50% normal sperm sired relatively few calves. The conclusion was that "semen quality, particularly percent normal spermatozoa, was consistently related to calf output." Important relationships at different sites were obtained between bull fertility and percent normal sperm, dominance, sex drive, SC, and sperm motility. The summation was that "these results confirm that semen examination, including sperm morphology, should be standard procedure when assessing bulls for reproductive soundness."

In the United States, bull influences on conception rates were studied over a number of years in both *Bos taurus* and *Bos indicus* cattle at USDA-STARS, Florida (Larsen et al, 1990). Significant effects on conception rate were associated, positively or negatively as expected, with the prevalence of normal sperm ($p < .01$), proximal droplets ($p < .01$), and percent "primary" abnormals ($p < .01$). Here, bull age, sex drive, and length of breeding season also influenced fertility parameters.

From the studies just mentioned, which embrace a variety of regions, genotypes, and managerial conditions, the resounding conclusion must be that the bull BSE, an otherwise quick and inexpensive screening procedure, is a highly effective tool in reducing the uncertainty associated with bull purchase and usage. Thus a "rough" estimate may be made of a 6% or greater fertility advantage for bulls passing a BSE or semen quality thresholds over unselected bulls, with larger differences possible when satisfactory bulls are compared with those that fail the BSE. Additional benefits accrue through increased weaning weights of older calves at weaning.

Bull-to-Female Ratios

Studies indicate that traditional recommendations of BFRs between 1:25 and 1:30 for herd bulls often lead to underuse of competent bulls. For example, one study comparing single and multiple sire of Hereford bulls in natural breeding herds at BFRs of 1:25, 1:44, and 1:60 concluded that "the fertility, libido and mating ability of each sire was more important than the BFR or the matter of single- vs multiple-sire breeding systems" (Rupp et al, 1977). Similarly, in Northern Australia, there was no difference in reproductive rates between single- and multi-sire herds studied over a period of 18 years (Bamualim et al, 1984). In Colorado, yearling Hereford bulls were compared at BFRs of 1:20 (single sire) and 2:40 (multisire) with synchronized crossbred heifers (Farin et al, 1982). Here, with the exception of number of services per heifer, bull-mating performance and pregnancy rates did not differ between BFRs of 1:20 and 2:40. Since considerable bull overlap occurred in multi-sire groups, it was concluded that single-sire mating was inherently more efficient. Comparison of a variety of single-sire BFRs (1:7 to 1:51), also with females subjected to synchronization treatment, found that BFR was not a limiting factor to fertility, even at higher levels of breeding stress (Pexton et al, 1990). Rather, bull age and fertility appeared to be most important. In these trials bull service activity increased with stimulus pressure, such that upper recommended limits for BFRs "may not be justified." In Northern Australia, no difference was observed in herd fertility when reproductively sound Brahman bulls were used at BFRs of either 1:17 or 1:40 (Fordyce et al, 1998). As previously noted, two studies in vastly different environments showed that use of bulls that had been prescreened with a BSE increased both BFRs (1:20 to 1:33) and herd pregnancy rates (Prince et al, 1987; McCosker et al, 1989).

Thus it is apparent that sound bulls that have passed the BSE can handle considerably more females in a generic breeding season than would be suggested by traditional recommendations. It is also evident that most producers have yet to take full advantage of these findings. For example, surveys indicate that cow-calf operations overall use yearling bulls at 1:17.5 and mature bulls at 1:25 (NAHMS, 1998b). A survey of cow-calf producers in the Rocky Mountain West revealed a mean BFR of 1:21, with 25% of herds using a BFR of less than 1:18 (Sanderson and Gay, 1996).

Bulls are a major cost item for most cattle breeding operations. Exploitation of the BSE can reduce bull numbers while enhancing fertility rates. It would be difficult to find a better example of a procedure guaranteed to improve the "bottom line" for cow-calf producers.

Genetic Considerations

Although the heritability of reproduction in cattle is generally regarded as low, a number of traits associated with bull fertility are relatively highly heritable. SC in bulls is a major example, with this trait being moderately to highly heritable in beef bulls (approximately 50%) and is favorably related to seminal traits. In general, as SC increases in young bulls, so do sperm numbers and aspects of semen quality (Coulter, 1994). Genetic correlations between SC measures and growth traits are generally favorable for young beef bulls (Coulter and Kastelic, 1999), although some variations occur. Lack of a significant relationship between birth weight and SC suggests that selection for SC can be achieved without increasing dystocia rates. There are suggestions that selecting bulls for larger SC will enhance growth characteristics, as well as their maternal value (Coulter and Kastelic, 1999). Importantly, studies indicate strong links between SC in young bulls and age at puberty in related females, and favorable relationships have also been reported with other female reproductive traits in cattle (Coulter and Kastelic, 1999). Heterosis also benefits both bull SC and heifer age at puberty (Gregory et al, 1991). Selection using SC EPDs was shown to be more effective than phenotypic selection in reducing age at puberty in daughters (Moser et al, 1996). Bull SC is an accurate predictor of bull puberty (Lunstra, 1982), with remarkable agreement between breeds in pubertal SC. With females, earlier age at puberty has been associated with improved lifetime fertility and pounds of calf produced (Brinks, 1994).

Downloaded From Vet-eBooks.com

One possible caveat occurs with selection for SC, with particular reference to selection for extreme growth. Here, anecdotal evidence suggests that spermatogenesis may be affected adversely in young bulls with extremely large testicles. Further work is needed to clarify this observation. Testicular tone, as measured with a tonometer, has also been shown to be moderately heritable and associated with semen quality (Coulter et al, 1976).

A number of positive genetic relationships occur with BSE traits in beef cattle. Thus use of BSE criteria to select bulls for scrotal circumference (and associated improved semen traits) can help to improve immediate and future herd fertility and production through a number of mechanisms.

Bull Fertility Assessment

Bull fertility is influenced by a number of traits, including semen quantity and quality, libido and mating ability, and social interactions (dominance effects) within the breeding pasture (Chenoweth, 1994b). In addition, bull performance is limited by the fertility threshold of the female herd (Saacke et al, 1991), and it can be complicated by the size and terrain of the breeding pasture as well as by the presence of infertility disease.

Thus herd fertility is influenced by a number of factors that may, or may not, act in tandem. This consideration helps explain why avid pursuit of single trait relationships with fertility is often destined to give disappointing results. Despite this, both reason and scientific evidence support the pivotal role of bulls in herd fertility. Bulls differ markedly in their reproductive capacities. Conservative estimates indicate that at least 20% of unselected bulls are relatively infertile. Procedures used to evaluate bulls have been shown to be effective in identifying many of these infertile bulls. For these reasons, bull evaluation represents an important "marketable skill" for veterinarians. The procedures involved in such evaluations are remarkably consistent throughout the world. In North America these have been formalized by the Society for Theriogenology into a standardized form that has been modified over time as knowledge has accrued (Chenoweth et al, 1992). This procedure (Chenoweth et al, 1993) is described in detail below. Standards for bull evaluation have also been published separately by the AACV (Anon, 1995), as well as the Western Canadian Association of Bovine Practitioners (Barth, 1993).

Bull Breeding Soundness Evaluation

The BSE represents a relatively quick and economic procedure for screening bulls before sale or use. It aims to place bulls into different categories, which generally perform as predicted. It is most effective in identifying bulls at the lower end of the potential fertility spectrum. However, this in itself represents good infertility "insurance" and can be useful in helping to improve "genetic" fertility of the herd. The BSE, however, is relatively less effective in its ability to accurately predict individual bull fertility at the upper end of the spectrum. Reasons for this include the following:

1. Fertility is a complex trait that is influenced by both male and female traits as well as by extraneous factors.
2. The BSE is a relatively quick and simple screening procedure that does not attempt to comprehensively assess all aspects of male fertility.
3. The BSE aims to identify bulls that are satisfactory (not necessarily those that are superior).
4. Knowledge and understanding of male fertility keep increasing and changing.

This last factor, in particular, provided the impetus for the American Society for Theriogenology to revise their recommended bull BSE procedures, which had been in effect since 1975. This new system (Chenoweth et al, 1993), in concert with general principles of bull evaluation, is described below. Forms and background information for this procedure may be obtained by members of the American Society for Theriogenology at 530 Church St., Suite 700, Nashville, TN 37219.

Timing of the BSE. Veterinarians should conduct a BSE on all pubertal bulls before sale or purchase. In addition, since many problems can occur over a 12-month period, it is recommended that bulls undergo a BSE every year, preferably before breeding. The optimum time to perform this procedure in relation to start of breeding usually involves a compromise. Predictability of the test increases when it is performed close to the start of breeding. However, it is often necessary to provide enough latitude in timing to allow for retesting (and perhaps treatment) and for identification and screening of replacements. Because of these considerations the BSE is often conducted within 2 to 4 weeks of the start of breeding.

General BSE Procedures. The primary mission of the natural breeding bull is to efficiently impregnate all available females as early in the breeding period as possible. To achieve this he must possess the physical and reproductive necessities to perform this task. These include good eyesight and musculoskeletal conformation as well as the necessary reproductive equipment and sex drive to produce and appropriately deliver sufficient numbers of fertile spermatozoa. To adequately assess all of these aspects within a short period is a tall order. The routine BSE attempts to achieve this through the following steps:

1. Physical examination
2. Reproductive examination (including measurement of scrotal circumference)
3. Collection and examination of semen

In addition, a libido-mating ability test may be included, as may special tests for diseases (e.g., vibriosis or trichomonosis). These procedures will add predictive value to the assessment process and may be indicated specifically in some situations, but they are not part of the routine BSE.

It is very important to inform clients not only of the advantages of the BSE but also of its limitations. With the latter, it is sobering to consider the inherent difficulties of trying to predict future performance based on historical events. With semen characteristics it may take weeks or even months before the effects of spermatogenic insult may be fully reflected in the ejaculate. Limitations of the BSE include the following:

- Results are most valid at the time of examination only
- The system works best to identify infertile bulls
- It is not designed to predict the precise fertility of individual bulls
- Unless specifically included, there is no assessment of bull libido and mating ability
- Unless specifically included, there is no testing for infertility diseases

Restraint Considerations. A safe, secure bull restraint system is most important for this task. The examiner should have safe access to both the rear end of the bull and his underbelly without undue fear of injury. The bull should also be unable to injure himself. Head catches should ensure that bulls do not injure, or even kill, themselves if they collapse in the chute or crush. Some bulls (e.g., many *Bos indicus* types) are more tractable if their head is not restrained during the BSE. Squeeze chutes, especially hydraulic ones, are effective in constraining excessive bull movements. If a bar or chain is placed behind the bull to prevent rearward movement, then palpation of the testicles should always be conducted below this device. Secure footing should be provided

Downloaded from Vet-e-Books.com

for the bull in the chute. Here, a backstop for the hind feet can be useful for bulls undergoing electroejaculation (EEJ).

Identification and Ownership of Bulls. It is important to establish permanent and unique identification of each bull as well as the establishment of ownership. It is a sound practice to also identify all samples, slides, and worksheets with the bull identification number.

Body Condition and Other Body Measures. The body condition (or degree of fatness) of bulls is relevant to their reproductive assessment. Excessively fat or thin bulls may have problems with semen quality, libido, or mating ability as well as bull fertility in general (Coulter and Kozub, 1989). Poor body condition may also reflect health problems apart from poor nutrition.

Bull pelvic size in bulls is related to pelvic size in their daughters, which may be an important consideration in dystocia management. This information may be recorded.

Structure, Conformation, and Movement. Ideally, the bull should be allowed to move freely so the veterinarian can observe gait and movement. Once in the chute or crush, the veterinarian should pay close attention to limbs, joints, and claws. The bull should have good, symmetrical musculoskeletal formation, and he should walk with a smooth action. Asymmetrical or overgrown claws and swellings over lower limb joints are common abnormalities and may reflect poor conformation, pathological conditions, or both. Conditions such as chronic lameness, sole abscesses, arthritis, severe quarter cracks, interdigital fibromas, and footrot can adversely affect mobility, mating ability, and libido as well as contribute to testicular degeneration if the bull is semirecumbent. High body temperatures associated with footrot, or pyrexia from any other cause, can also cause spermatogenic dysfunction. Since the hind limbs are most important in supporting bulls during service, hind limb and joint structure should be examined most critically. Poor conformation (e.g., "post legs," "cow hocks") is highly heritable in bulls (McNitt, 1965) and contributes to bull breakdowns in the breeding pasture. Back problems, particularly spondylosis-spondyloarthrosis of the lumbosacral joint, are not uncommon in bulls, even those relatively young, and contribute to service disabilities and loss of libido.

Physical and Reproductive Examination

For a bull to be a functional breeder, he must be able to eat, see, and move about without discomfort. Thus a thorough physical examination is indicated. A systematic approach should be used that emphasizes those aspects most important for breeding success.

Once in the chute or crush, the bull's eyes should be examined for any indication of impaired vision. This is particularly important because bulls use vision as their primary sense in detecting estrus females. Examination of the bull's teeth allows verification of age and helps to ensure that dentition is adequate for foraging.

The sheath of the bull should be inspected and palpated. The penis is palpable within the sheath, although it is often most convenient to examine it when extended during EEJ. On palpation, it should be symmetrical, freely moveable, and have no associated abnormal masses.

Scrotal conformation should be evaluated, since this can influence testicular development and function (Coulter, 1994). Optimum spermatogenesis occurs at 4° to 5° C below internal body temperature. This temperature gradient is maintained through a complex system that entails mechanisms to raise and lower the scrotum and testicle and to transfer heat from the pampiniform plexus to the external environment through the scrotal neck. Any factor that interferes with any of these mechanisms can lead to defective scrotal thermoregulation, with resultant deleterious effects on semen quality and sperm production. Studies using thermography indicate that abnormal scrotal temperature gradients in bulls can provide indirect evidence of potential fertility problems (Lunstra and Coulter, 1993). Optimum thermoregulation of the testicle occurs when the scrotum hangs vertically, and the scrotal neck is distinct (Coulter, 1994).

Although some variation in size between the two testicles in the bull is common, significant differences in the size and shape of either testicle should be cause for further evaluation. A disparity of more than 25% in the size of either testicle should be regarded with suspicion. The most common cause of marked scrotal asymmetry is unilateral testicular hypoplasia—a condition that might be presented as a putative "undescended" testicle. It is relevant to note here that definitive diagnosis of testicular hypoplasia necessitates use of testicular histological methods. Practitioners should be cautious when using this term without such evidence. A variety of congenital, traumatic, or infectious conditions may also lead to reduced testicular size, with testicular degeneration and aplasia being most common.

Testicles should be palpated for hardness and resiliency; a normal testicle should be firm and resilient (similar to a new tennis ball). A tonometer developed for bull testicles has been used with a spectrum of results. "Soft" testicles often reflect testicular degeneration and are found more often in older bulls and in bulls that have undergone thermal stress. This latter often includes bulls that spend a lot of time lying down. "Hard" testicles usually reflect fibrosis, which is often a result of testicular degeneration, but they may also occur with acute orchitis in which increased heat and other signs of inflammation can usually be detected. Recent developments in both diagnostic ultrasound and thermography hold promise for improved diagnostic capabilities in relation to dysfunctions of scrotal contents and the testicular parenchyma.

The epididymides (head, body, and tail) should be palpated. Problems detectable here can include inflammation, fibrosis, abscessation, hypoplasia, or aplasia.

To complete the examination of the external genitalia, the penis of the bull should be exteriorized, with this examination often performed during EEJ.

A per-rectal examination of the bull is an essential step to enable evaluation of internal reproductive structures. This examination normally includes identification and palpation of (in order) the pelvic urethra, prostate gland, vesicular glands, ampullae, vasa deferentia, and internal inguinal rings. The most common abnormality encountered is often that of accessory genital disease, which is most readily recognized as seminal vesiculitis. Segmental aplasia-hypoplasia of the embryonic Wolffian duct system may also be detected, although this is relatively rare.

Scrotal Circumference. SC measurement is an important part of the bull BSE, because testicular size in bulls is positively associated with sperm production and semen quality as well as with the age at puberty of related females (Brinks et al, 1978). Genetic correlation estimates have been obtained between SC in yearling bulls and age of puberty in half-sib heifers of −0.71 and −1.07 (Brinks et al, 1978; King et al, 1983). In turn, age at puberty in heifers is favorably associated with lifetime reproduction and production traits (Brinks, 1994). Adjustments for SC based on dam age and that range from 0.025 to 0.032 cm/day have been suggested for use of SC as a selection criterion with yearling beef bulls (Brinks, 1994), with the adjustment factors shown in Table 13-30.

The measurement of SC is simple and repeatable and does not require expensive or highly technical equipment to

Geske GM, Schalles RR, Zollner KO: Yearling scrotal circumference prediction equation and age adjustment factors for various breeds of beef bulls. Proceedings of the Cattleman's Day Report, Kansas City, 1995, Kansas State University.

perform. The approved technique is to snugly apply a tape around the greatest circumference of both testicles, which should be manipulated to ensure that they are as close to the bottom of the scrotum as possible. A reliable procedure is to take two measurements to ensure accuracy, with two consecutive measurements not varying by more than 1.0 cm. Although this technique is easily learned, variations in results between evaluators led to development of a spring-loaded tape that was precalibrated to provide standardized results (Coulter and Kastelic, 1999).

Several studies have examined the relationships between prepuberal and subsequent SC (Pratt et al, 1991; Geske et al, 1995). The possibility of being able to use SC as a selection or screening criterion in prepubertal bulls poses considerable economic advantage. Both studies confirmed that bulls with small prepuberal testes were unlikely to develop large testes after puberty. In the latter study, SC was measured on 329 bulls, representing different beef breeds, at the start of a 140-day gain test and at 365 days of age. Threshold SC at start of the gain test, to achieve 30 cm by 365 days of age,

TABLE 13-32

Minimum Thresholds for Bull Scrotal Circumference

Age of Bull (mo)	Minimum SC (cm)
≤15	30

was 23 cm for Angus, Simmental and Zebu-derived breeds and 26 cm for other continental breeds and Polled Shorthorn bulls. In Kansas, Geske et al (1995) determined that a scrotal circumference of approximately 21 cm was necessary at 205 days of age for British and European-breed bulls to achieve 32 cm at 1 year of age, with adjustment factors being calculated for the different breeds studied (Table 13-31). Scrotal circumference thresholds recommended by the Society for Theriogenology for a "satisfactory" breeding bull are shown in Table 13-32.

The thresholds just described represent minimum standards designed to have wide application as well as acceptability for bulls of diverse genotypes and raised in a variety of environments to be classified as "satisfactory prospective breeders." On a regional basis, veterinarians are urged to work with breed associations, breeders, and sales organizations to elevate these standards where data are supportive. Here, data can be used to fine-tune the system to reflect different biological types of cattle; they can also be used where nutrition is consistent. For example, minimum standards have been established for different genotypes raised under similar conditions (grain fed in pens) in Western Canada (Table 13-33). Also, higher standards may be used where the objective of the evaluation is to identify "superior," rather than "satisfactory," prospective breeders.

Semen Collection

Semen can be collected from bulls by a variety of means including per-rectal massage, use of an AV and EEJ. The latter method is the one most commonly used with range-type bulls, and it is highly efficient in obtaining a representative semen sample from pubertal bulls. Such samples are comparable with those obtained with an AV in terms of semen fertility and freezability (Singleton, 1970). Modern machines and probes cause much less physical reaction in bulls than did earlier machines (Ball, 1986). Welfare aspects of this procedure are addressed later in this chapter.

Electroejaculators and Probes. Commercially available electroejaculators are available with power provided by AC current, by internal rechargeable batteries, or by 12-volt automobile batteries. Effective EEJ necessitates the stimulation of pelvic nerves controlling not only the emission of semen into the penile urethra but also those controlling erection

Downloaded from Vet-eBooks.com

TABLE 13-33

Recommended Minimum Scrotal Circumferences (in centimeters) for Grain-Fed Bulls in Western Canada

Barth AD: Bull breeding soundness evaluation, Western Canadian Association of Bovine Practitioners, Saskatchewan, Canada, 1992, Western College of Veterinary Medicine, University of Saskatchewan.

and ejaculation. Newer probe designs have full-length longitudinal electrodes that stimulate all functions simultaneously and cause considerably less muscle contraction than earlier probe designs, such as those using bipolar ring electrodes (Ball, 1986). Available machines vary in control mechanisms and features, with several being capable of preprogrammed stimulation regimens. Variations on stimulus patterns occur with different machines and operators. However, an overriding consideration should always be the welfare of the animal. Stimulation should be discontinued if either undue stress is being caused or physical injury to the bull might occur.

Preparation and Stimulation. The bull's rectum should be emptied of feces before the probe is inserted. The lubricated probe is inserted so that the anal sphincter closes behind the main body of the unit. Procedures for EEJ of bulls are described elsewhere (Chenoweth et al, 1992). However, an important consideration is to ensure that a representative semen sample is collected. Failure to collect a representative ejaculate can lead to errors of interpretation of the spermiogram. This is because the initial portion of the ejaculate may contain large numbers of degenerating spermatozoa in bulls that have not been recently sexually active. Similarly, if an ejaculate shows substandard motility in the absence of an obvious physical cause, a second sample collected within a short period of time (e.g., 5 to 10 minutes) can often show improvement in this trait.

Another important consideration is that, unless the penis is exteriorized for examination, difficulty exists in ensuring that it is problem free. Penile conditions that may be observed at this time include adhesions, phimosis, paraphimosis, fibropapilloma, persistent frenulum, hair rings, and some circulatory disorders of the corpus cavernosum. The approach to be taken with penile frenulums is subject to debate. Many of these can be separated relatively easily while the bull is still under the influence of the electroejaculator, and this is the routine approach often taken. Despite this, there is evidence that the condition can be highly heritable (McNitt, 1965). Further complication arises from evidence that many bulls evidently undergo natural separation of weak attachments before the BSE. The best advice for purebred breeders should be to select against persistent penile frenulums where practicable. Another caveat occurs with deviations of the bull penis. Here, although deviations of the penis may occasionally be observed at the time of EEJ, definitive diagnosis should await their observation during actual breeding attempts. This is because the fibrous architecture of the bull penis is such that it has a natural tendency to spiral, and EEJ can override normal control mechanisms. In fact many bulls will "corkscrew" during the ejaculatory process (Seidel and Foote, 1969).

Collection Devices. Semen should be collected into a prewarmed insulated or jacketed tube. All surfaces coming into contact with semen should be clean, warm, dry, and free of spermatoxic agents. Because "cold shock" causes irreversible damage to spermatozoa, efforts to maintain semen at 30° to 35° C until the "on-site" evaluation procedures are complete are important considerations for successful semen assessment.

Semen Evaluation

Initial Impressions. Volume, density, and gross characteristics of the ejaculate are not "front-line" BSE assessments because they have not been shown to be directly related to fertility. However, the recording of such information might be useful under some circumstances. Likewise, the assessment of spermatozoal concentration is not a routine part of the BSE because the measurement of scrotal circumference provides a better estimate of sperm production in range-type bulls that are subject to infrequent examinations. However, informal recording of such information may help to monitor the success of semen collection and to interpret gross motility estimation.

Other gross characteristics that may be noted include evidence of contamination, hemorrhage, or inflammatory material. If the ejaculate contains sufficient purulent material for this to be obvious to the naked eye, then that bull should not be classified as satisfactory at least until a benign cause is found. Debris or contamination from the sheath may be regarded as being less serious unless it represents active infection.

Sperm Motility. Sperm motility should be assessed microscopically. Two methods of assessing sperm motility are traditionally used: gross motility (or mass activity) and individual motility (or percent progressive motility). It is worthwhile to use both methods because they can differ somewhat in interpretation and precision. With all motility

Downloaded from Vet-e-Books.com

estimations it is important to protect semen against adverse effects (e.g., cold shock) and to do the estimation as soon as possible after semen collection.

Gross motility, or the amount of swirling (or wave motion) present in an undiluted semen sample, is a function of both sperm concentration and individual motility. Under field conditions, gross motility is typically assessed by placing a drop of raw semen on a warmed slide and observing it at 100 magnification (103 eyepiece and 103 objective). With the condenser properly adjusted, mass action or "swirl" can be observed in samples that have a sufficient concentration of motile spermatozoa to produce this effect. The rankings for this estimate are shown in Table 13-34.

Individual progressive motility of spermatozoa is assessed under a brightfield or phase-contrast microscope, preferably equipped with a warm stage or other means of preventing cold shock of spermatozoa. Cover-slipped specimens are usually examined at a total magnification of 400×. In dense samples (milky or creamy) the sample should be diluted for proper observation of individual spermatozoa, as it is common for operators to make the error of overestimating sperm motility in dense samples. Sodium citrate- or skim milk-based semen extenders are serviceable diluents; physiological sterile saline (PSS) may be used, although readings should not be delayed when it is used. The percentage of active, progressively motile cells is estimated. This procedure takes more practice than does the gross motility estimation but is probably more accurate in experienced hands. Individual motility ratings are shown in Table 13-35.

Observation of the semen sample at 400× can also help to identify the presence of other cells (e.g., squamous epithelial, inflammatory, or spermatogenic cells) within the sample. When these occur in numbers such that more precise identification is needed, other staining procedures should be considered. The identification of aberrant cellular material can benefit from the staining of a semen smear with Dif-Quik, New Methylene Blue, or other differential blood cell stains, whereas bacteria may be categorized using a Gram stain.

TABLE 13-34

Rankings of Gross Motility

Mass activity (gross motility)	Rating
Rapid swirl	Very good
Slower swirl	Good
General oscillation	Fair
Sporadic oscillation	Poor

TABLE 13-35

Individual Motility Ratings

Progressive motility	Rating
≥70%	Very good
50% to 69%	Good
30% to 49%	Fair
<30%	Poor

Morphology. Morphology of spermatozoa (differential counts of normal and abnormal cells) is assessed either by phase-microscopy with "fixed" semen preparations (using formol-buffered-saline or PBS-glutaraldehyde, for example) or by using brightfield microscopy of stained smears. Common stains used for this purpose include nigrosin-eosin, William's stain, and modified Giemsa. The Society for Theriogenology recommends use of the nigrosin-eosin stain for its combination of ease and utility. Although this stain may also be used as a "supra-vital" stain (i.e., sperm that are "alive" at staining will not absorb stain, whereas those that are "dead" will partially or completely absorb the red eosin color), here it is primarily used for its ability to depict sperm morphology only.

Brightfield microscopy of stained smears is best done at 1000× plus using an oil immersion lens. At least 100 spermatozoa should be observed in different fields and classified for normality or abnormality. To achieve a "satisfactory" BSE category, bulls should have at least 70% normal sperm. This threshold applies regardless of the types of sperm abnormalities involved.

In some evaluation systems, sperm abnormalities are placed into different categories that reflect either their presumed origin or their significance regarding fertility. One widely used system classifies sperm abnormalities as being either "primary" or "secondary" (Blom, 1950), on the assumption that primary abnormals (considered to be caused during spermatogenesis) were more serious than secondary abnormalities (caused subsequent to sperm release into the extragonadal system). Even though this system presents problems in interpretation, it has been retained as the reference point in the present system. Although total abnormalities only are used as the threshold in the new BSE system, "primary" and "secondary" abnormalities can be collated to arrive at this number. The recording of such information can also be useful for decisions on prognoses, and for monitoring progress, in problem bulls (Box 13-17).

The final step of the BSE is to place bulls into one of three categories, as follows.

Satisfactory. These bulls equal or surpass the minimum thresholds for scrotal circumference, sperm motility, and sperm morphology and do not show genetic, infectious, or other problems or faults that could compromise breeding or fertility.

Unsatisfactory. These bulls are below one or more thresholds and are highly unlikely to ever improve their status. Also included are bulls that show genetic faults or irrevocable physical problems (including infectious disease) that would compromise breeding or fertility.

Classification Deferred. Any bulls that do not fit into the above categories and that could benefit from a retest should be scheduled for a retest. This category would include bulls with an "immature" semen profile* as well as any bulls whose semen is substandard but considered capable of improvement. Also in this category are bulls from whom a satisfactory ejaculate could not be obtained for reasons unknown as well as bulls with treatable problems such as seminal vesiculitis or footrot. In general, if any doubt exists about a bull fitting into either the satisfactory or unsatisfactory categories, he should be considered as a candidate for a retest and placed into the "classification deferred" category.

*It is not uncommon for yearling bulls to exhibit higher levels of certain types of spermatozoal abnormalities that are associated with immaturity. Such bulls will usually require a second examination before being classified as a satisfactory potential breeder.

Behavioral Aspects of Bull Fertility

Bull Libido–Serving Capacity. The ability of a bull to produce good semen does not necessarily guarantee that he has the urge and ability to deliver this where and when necessary. Thus much work has been done to define the role of bull sex drive in relation to bull reproductive performance. Sexual behavior in the bull includes behavior associated with the detection and service of estrus females. Libido, or sex drive, is the "willingness and eagerness" of a bull to attempt mounting and service. Mating ability refers to the ability of the bull to complete service. Serving capacity is a measure of the number of services achieved by a bull under stipulated conditions and thus includes aspects of both libido and mating ability.

Assessment of Sex Drive in the Bull. Libido is a measurable behavioral trait (Box 13-18). Testing procedures that have been developed for bulls have generally exploited several or more of the following findings (Chenoweth, 1997):

1. Libido in bulls has a significant genetic component
2. Bulls are polygynous and tend to distribute their services among receptive females.
3. The greatest single stimulus for bulls to attempt mounting and service is an immobile object that resembles the rear end of a female
4. Prestimulation of bulls increases their sexual response
5. Competition among bulls can increase their sexual response

Methods. Many procedures have been used to assess sex drive in bulls and other male livestock. Although the easiest method would seem to be observations in the breeding pasture or paddock, in practice this approach has been disappointing, at least in terms of repeatable, quantitative results. In the absence of successful indirect testing methods, the generation of such results at present requires use of a structured, pen-type testing regimen. Several such systems for the assessment of sexual behaviors in the bull are described in Box 13-18. With the libido score test, prestimulated bulls are introduced to the pen containing mildly sedated, restrained females at a BFR of 2:2 and observed for 10 minutes. Eleven categories have been described (Box 13-19).

Fertility Relationships. Cattle fertility is a multifactorial trait, influenced by both male and female factors. From the male aspect, there is good evidence that bull libido is one of the more important contributing factors. For example, in one study, better first-cycle pregnancy rates were obtained in heifers mated with higher-serving-capacity bulls than in those mated with bulls of low serving capacity (Blockey, 1978b). More recently, differences in pregnancy rates were demonstrated between high-, medium-, and low-serving-capacity Hereford bulls (Blockey, 1989). Other studies have shown advantages in herd fertility for bulls with higher sex drive (Chenoweth, 1997). Close relationships were reported between bull rankings for fertility, libido score, and testosterone response to GnRH (Post et al, 1987). In Texas one study showed that bull libido assessment provided greater prediction of bull fertility than did semen assessment alone (Smith et al, 1981). With the use of multi-sire mating and progeny identification by blood typing, the number of services performed in libido–serving capacity tests was positively correlated with fertility up to a certain level (approximately four services), above which fertility actually declined with subsequent services (Coulter and Kozub, 1989).

However, other studies have revealed poor or inconclusive relationships between bull libido–serving capacity assessment and herd fertility or pasture performance

BOX 13-17

Sperm Morphology Categories

PRIMARY SPERM ABNORMALITIES
Head abnormalities
Midpiece abnormalities
Proximal droplets
Strongly coiled tails
Double heads–midpieces
Acrosome abnormalities

SECONDARY SPERM ABNORMALITIES
Loose normal heads
Loose, folded acrosomes
Abaxial tails
Simple bent tails
Distal droplets

OTHER CELLS IN SEMEN
Epithelial cells
Erythrocytes
Medusa cells
Sperm precursors
Double heads and midpieces
Round cells
White blood cells

The minimum recommended threshold for bovine sperm morphology is 70% normal cells.

BOX 13-18

Assessment of Sexual Behaviors in the Bull

REACTION TIME
Reaction time is defined as the time elapsed between male cognition of an appropriate stimulus and the first copulation, or ejaculation.*

SERVING CAPACITY
Serving capacity is a test procedure that involves the testing of groups of prestimulated bulls with restrained, nonestrus females, at a bull-to-female ratio of 5:3 or 5:4. The number of services achieved by an individual bull within a prescribed period (10 to 40 min) is recorded as his serving capacity score.†

LIBIDO SCORE
A scoring system has been developed that describes increasing levels of sexual activity of bulls under specified test conditions, usually within a pen or dry-lot. These conditions have varied from use of unrestrained, estrus-induced females, to restrained, nonestrus females.*

BOX 13-19

Libido Score and Sexual Behavior

Libido score	Sexual behavior
0	No sexual interest
1	Sexual interest shown once only
2	Sexual interest shown more than once
3	Active pursuit–persistent interest
4	One mount or attempt; no service
5	Two mounts or attempts; no service
6	Three mounts or attempts; no service
7	One service; no further sexual interest
8	On service; continued interest
9	Two services; no further sexual interest
10	Two services followed by further sexual interest, including service

Chenoweth PJ: *Theriogenology* 16(2):155-177, 1981.

(Chenoweth, 1997). In some studies, although higher-libido bulls serviced more often and serviced more females than did lower-libido bulls, more pregnancies did not result (Boyd et al, 1989; Farin et al, 1989; Godfrey and Lunstra, 1989).

Such apparently contradictory findings may occur due to differing approaches and methodologies. In some trials, bulls were not placed under sufficient breeding stress to demonstrate differences, which may have been more apparent with use of higher BFRs or shorter breeding periods. In addition, bulls of potentially low fertility were excluded from cooperative breeding trials. Factors associated with BSE (scrotal circumference, sperm motility, and sperm morphology) can separately influence fertility and are apparently not linked with sex drive. Even though bulls may be superior in one trait, their fertility can be compromised by a deficiency in another. This was illustrated in one study (Farin et al, 1989) in which 92 beef bulls were placed both into satisfactory and questionable BSE categories, as well as into high (score 9 to 10) and medium (score 7 to 8) libido categories before single-sire mating with groups of estrus synchronized heifers. Here, pregnancy rate was 9.1 percent higher for satisfactory BSE bulls compared with those in the questionable BSE category, but it did not differ between bulls of high and medium libido score even though high libido bulls serviced more females and served more times than did medium libido bulls. This paradox apparently occurred because a lower percentage of serviced females in the high libido group became pregnant than in the medium group. Here, differences between bulls in sex drive were clearly masked by differences in their BSE components.

The ability of bulls to service females is related not only to their inherent sex drive but also to their mating ability. Problems in mating ability may be due to a number of physical and pathological causes, including skeletal and penile abnormalities (Chenoweth, 1983). Here, a libido–serving capacity type of test procedure can be a valuable tool in helping to detect such problems.

Factors Influencing Bull Sexual Performance

Age and Rearing Effects. Age and/or experience of bulls can influence their mating ability and thus their perceived level of sex drive. Mating ability appears to have a learning component in bulls. In young, tropical beef bulls, libido score increased with bull age between 16 and 31 months of age (Perry et al, 1990). Bull age affected sexual behavior traits in crossbred bulls, with yearling bulls showing lower libido and a higher proportion of mounts than did older bulls (Coulter and Kozub, 1989). In Florida, sexual performance assessments generally increased with age in young (12 to 24 month) *Bos taurus* bulls, although not in *Bos indicus* bulls (Chenoweth et al, 1996). The latter group, however, displayed a lower level of sexual activity than did the former. More information is needed to differentiate the effects of age and experience on bull sexual behavior from those resulting from environmental and managerial influences. In this respect, prolonged nursing was considered to retard, or compromise, the expression of normal sexual behavior in Angus bulls (Couttie and Hunter, 1956), as has feeding high concentrate levels in crossbred bulls (Hentges, 1967). Negative relationships have been obtained between sex drive and production traits (ADG and final test weight) in yearling beef bulls in one study (Ologun et al, 1981), whereas underfeeding had no adverse effects on bull sexual behavior in another (Wierzbowski, 1978). Zebu bulls raised on open range exhibited slower sexual responses compared with those reared more intensively (McFarlane, 1974), although no permanent sexual inhibitions have been attributed to rearing methods in bulls. It is, however, possible that temporary sexual inhibitions in bulls may compromise pregnancy rates in herds that have restricted breeding seasons (Chenoweth, 1981).

Social Effects. Social ranking of bulls within groups can influence their sexual activity (Chenoweth, 1997). Social dominance was positively associated with calf crop in several multi-sire breeding studies in northern Australia in which paternity was established (McCosker et al, 1989; Holroyd et al, 1998). Social dominance is expressed more strongly and linearly in older bulls (e.g., those 3.5 to 4 years of age or older) and appears to be more related to seniority than to age or body weight (Blockey, 1979). It has been suggested that the effect of social interactions among bulls on herd fertility may be greater when BFRs are low and competition for females is high (Blockey, 1979).

Dominance rank was negatively correlated with sex drive in one study with yearling bulls (Ologun et al, 1981). If dominance and sex drive are different traits, then the dominant bull (or bulls) could impair herd fertility both through failure to service females and also by preventing less dominant bulls from serving. This apparently occurred in at least one study (McCosker et al, 1989). Such effects are probably most evident when older and younger males are combined in the breeding pasture (Blockey, 1979), although mixing different bull genotypes may cause similar effects (Chenoweth, 1991).

Social effects may benefit bull sexual behavior. Such an effect was observed in one study in which greater sexual activity occurred when young, inexperienced bulls were tested in groups (three to five) than when tested individually. Similarly, yearling bulls of higher serving capacity achieved more services in double-sire tests than when tested alone (Godfrey and Lunstra, 1989). Beneficial social effects on bull sex drive expression include the observations that both prestimulation of bulls can positively affect sperm harvest (Chenoweth, 1983), and both prestimulation and competition can positively influence libido test results (Chenoweth, 1994b).

Downloaded from Vet-e-Books.com

Genetic Effects. Bulls of dairy breeds may be more sexually active than those of beef breeds, and *Bos taurus* bulls generally show higher, and less variable, levels of libido in test settings than do those of *Bos indicus* breeds (Chenoweth, 1997). A number of such breed differences are probably attributable either to genotype-environment influences or to breed variability in response to testing procedures. In studies in northern Australia, Brahman and Brahman crossbred bulls obtained the lowest libido scores, Africander bulls and their crosses achieved the highest, and European bred bulls were intermediate (Chenoweth and Osborne, 1975; Perry et al, 1991). In U.S. studies, higher sex drive scores were also obtained with *Bos taurus* bulls than with *Bos indicus* bulls (Hardin et al, 1981; Randel, 1994). Despite such results, a comparison of trials in which bulls were placed with estrus synchronized females indicated that *Bos indicus*–derived bulls were as efficient as European breed bulls in detecting, serving, and impregnating estrus females, despite a lower service rate (Chenoweth, 1994b). This discrepancy may be explained in part by observations that *Bos indicus* bulls tend to be selective and shy breeders, and that they generally do not perform well in pen tests to assess sex drive (Chenoweth et al, 1996), even though they can be very active and efficient detectors of estrus in the pasture. In Florida *Bos taurus* (Angus, Hereford) bulls obtained superior results in sex drive tests compared with tropicalized *Bos taurus* (Senepol, Romosinuano) bulls, with *Bos indicus* (Brahman, Nellore × Brahman) bulls generally obtaining the worst results (Chenoweth et al, 1996). Here it was suggested that commonly used testing procedures for sex drive may disadvantage *Bos indicus* bulls. Modifications that have been suggested in attempts to improve the performance of such bulls include the use of unrestrained estrus females and the avoidance of extraneous distractions during the test (Chenoweth, 1986).

A number of studies indicate that strong microgenetic influences occur with bull sex drive. In Scandanavia monozygous twin bulls raised on differing nutritional regimens displayed greater similarity in mating behavior and temperament within pairs than between pairs (Bane, 1954), suggesting strong genetic influences on these traits. Paternal half-sibs of Swedish bulls differed significantly in libido with greater variation between sire-son groups than within them (Hultnas, 1959). Studies showing that cross-bred bulls generally exhibited higher sex drive in pen-tests than did their parental purebreds indicate that genetic effects, in this case heterosis, influence bull sex drive (Chenoweth and Osborne, 1975; Perry et al, 1990). In Colorado, line of breeding (inbred lines or crosses among inbred lines) was an important source of variation in bull sex drive, indicating that lines had been selected or differentiated previously on the basis of sexual behavior (Chenoweth et al, 1977). Similarly, differences in libido scores were observed between breeding lines and sires-within-lines in young bulls of British breeds (Ologun et al, 1981). Here, high sex drive was not synonymous with either superior production traits (ADG or final test weight) or high social ranking. Sire strongly influenced serving capacity in young Angus bulls (Boyd and Corah, 1988). A number of studies have indicated that measures of traditional breeding soundness criteria, such as scrotal circumference and semen traits, are not significantly correlated with sex drive estimates in bulls (Chenoweth, 1997), which suggests that these are separate traits. A heritability estimate of 0.59 ± 0.16 was obtained for serving capacity in a study of 157 paternal half-sib bull groups in Australia (Blockey, 1978a). In this study the inclusion of bodyweight as a covariate did not alter the result, and serving capacity was not associated with temperament rating.

Pitfalls in Testing Bull Sex Drive. Successful testing of bulls for libido and mating ability requires careful planning. The following list represents some of the pitfalls that may be encountered in testing procedures that use restrained, nonestrus, females:

1. Testing of bulls that are excessively apprehensive or agitated. Precautions should be taken to handle cattle quietly and to avoid unnecessary distractions during the test.
2. Testing of bulls immediately following their subjection to other procedures such as EEJ, vaccination, and parasite control measures.
3. Testing under adverse weather conditions, such as in extreme heat, cold, or inclement weather.
4. Testing of bulls in groups in which one or more bulls are markedly dominant, such as with mixed-age groups of bulls. The exposure of only two bulls to test at a time, and subsequent retesting with a different bull, helps to minimize this problem. It should be noted, however, that a dominant bull can exert an inhibitory effect from a distance (e.g., from an adjacent pen). It is also recommended that stimulus females be located at an appropriate distance from each other (5 m or more).
5. Use of inadequate stimuli. Restrained females should be incapable of excessive movement, or some bulls may be deterred. Overly restless or agitated females should be replaced. The service crates used should not impede mounting and service.
6. Spreading of venereal diseases. Every precaution should be taken to ensure that diseases such as vibriosis and trichomonosis are not transmitted by such procedures.

Welfare concerns with such tests have been expressed, especially in instances where they have been conducted without due care. Guidelines for conduct of libido–serving capacity testing of bulls are discussed in the section on welfare considerations. In addition, research is ongoing into alternative ways of obtaining comparable information.

Alternative Assessment Procedures. The indirect determination of bull libido (e.g., through blood hormone levels) is an attractive proposition, since it could reduce or eliminate the time, labor, and esthetic or welfare concerns that might occur with current methods of assessing sex drive in bulls. It would also allow assessment of bulls that, for inexplicable reasons, do not give a good response in such tests. However, attempts to link either sporadic or sequential LH or testosterone (T) levels with bull sex drive have been generally disappointing (Chenoweth, 1997), probably because of the episodic nature of hormone release and the inhibiting effects of handling or restraint of the animal. By inducing LH or T release with parenteral administration of gonadotropin-releasing hormone (GnRH), there is potential to avoid some of these difficulties. In one study (Post et al, 1987), a significant relationship occurred between induced T levels and bull fertility; in another (Perry et al, 1990), positive relationships were obtained with induced LH levels. However, other studies have obtained disappointing results when attempting to relate GnRH induced levels of testosterone or LH with bull sex drive (Byerley et al, 1990; Chase et al, 1997).

Composite Assessment Systems for Bulls. A number of factors influence bull fertility, including BSE values and behavioral factors such as dominance and libido, and these do not always complement each other. Attempts have been made to combine a number of these factors to best predict bull performance. Perry et al (1990) assessed a number of traits in young tropical beef bulls at varying intervals from single-sire matings. The traits assessed included BSE values, sex drive (libido and serving capacity), production traits (ADG and body weight), and LH and T

Downloaded From Vet-eBooks.com

responses to GnRH. A stepwise regression procedure was used to select the most suitable combinations of traits highly correlated with pregnancy rate. Fertility indexes were calculated from this analysis. The fertility indexes so obtained were, in general, highly predictive of pregnancy rate, even at 11 months before mating. The lowest correlation was the one obtained at the examination just before breeding ($r = 0.45$, <0.05) when the only trait included in the index was libido score. Genotype differences had little influnces on these indexes. Overall, the most important measures were GnRH–induced LH levels, testicular volume, libido, and body weight. Interestingly, these factors are derived from separate entities known to influnce bull reproductive performance (e.g., sex drive, endocrine status, and sperm production).

Coulter and Kozub (1989) used a regression model to predict bull fertility in multisire breeding in which paternity was determined by blood typing. Best relationships with fertility were obtained with scrotal circumference, backfat, sperm morphology (particularly primary abnormalities), and sex drive. In yearling bulls the model accounted for 37% of the variance in bull fertility; in 2-year-old bulls it accounted for 22%. A study conducted in northern Australia also used paternity estimates to predict the fertility of bulls in multisire breeding systems (Holroyd et al, 1998). Here, the most "successful" predictors of calf crop were percent normal sperm and social dominance, with scrotal circumference and an assessment of sexual behavior (mounts plus services) also showing some predictability. Thus it seems as if the best prediction of bull fertility is obtained when bulls are assessed for a number of traits, including sex drive. The development of fertility indexes, which combine a number of important traits, should improve predictive ability. Recommendations for bull assessment and management are shown in Box 13-20.

ARTIFICIAL INSEMINATION AND ESTRUS SYNCHRONIZATION PROGRAMS

AI is a proven tool for promoting genetic progress in livestock. With cattle, the dairy industry has adopted this technology wholeheartedly, whereas the beef industry has been less receptive (at least in the Americas and Australasia)—despite evidence that many economically important traits in beef cattle are relatively highly heritable, and that AI is the best means to rapidly exploit genetically superior sires (Patterson, 1999). It is also despite evidence that an effective genetics program, managed with AI, is cost effective, with an estimate of $7 to $30 increased returns per cow (Toombs, 1996). In the United States, the percentage of beef operations using AI has increased slightly from 5.4% in 1992 and 1993 to 7.1% in 1997 (NAHMS, 1998b). The reasons for this relatively low adoption rate vary. However, contributing factors include unwillingness to change management practices, fear of the unknown, and a perception that an unacceptable amount of effort is involved. A certain amount of effort is, of course, necessary. This includes attention to aspects such as identification and management of adequate numbers of "eligible" females, animal confinement, estrus detection, breeding facilities, time constraints, and AI technique (Chenoweth et al, 1980). At least some of these constraints may be countered with estrus synchronization. However, producers still have reservations about the cost and effectiveness of AI-synchronization programs, particularly in commercial herds run under extensive conditions. Examples of failed programs are common. This section outlines a number of options available for synchronization programs in beef cattle, as well as managerial precautions to help prevent failure. Veterinarians should consider planning programs with their clients well ahead of breeding. For larger beef operations, particularly those that are conducting AI programs (either with or without synchronization) for the first time, prior training of personnel in all aspects of such programs is strongly recommended. Preliminary planning should commence well before the breeding season in question. As well as personnel training, facility suitability and estimated numbers of eligible females should be considered. Semen should be ordered early, and from a reliable source, as should liquid nitrogen equipment and synchronization products. If necessary, frozen semen should be checked by a competent laboratory before the commencement of breeding. Related considerations include the following topics.

BOX 13-20

Recommendations for Bull Assessment and Management

- Select sound bulls with good expected progeny differences
- Perform breeding soundness evaluation of all bulls every year
- Conduct a libido–serving capacity test where feasible
- Test older bulls for vibriosis and trichomonosis before breeding
- Vaccinate all bulls before breeding; use homogenous groups of 2- to 3-year-old bulls
- For yearling bulls, use a higher bull-to-female ratio (1:15-20)
- Regularly monitor bulls in breeding pasture

General Considerations

Female Selection

Animals selected for AI-synchronization programs should be those that are good candidates for successful breeding. For heifers, this means those that have achieved target weights for their breed type and those that are cyclic. Use of reproductive tract scoring (Anderson et al, 1991) is effective in determining the latter. Cows require an adequate postpartum interval, which varies with nutritional status, as previously discussed. In addition, some breed differences occur, with *Bos indicus*–type cattle often requiring a longer interval than *Bos taurus* cattle. Several stratagems to help reduce this interval may be considered. These include weaning stratagems such as temporary calf removal and once-a-day suckling as well as biostimulation (Chenoweth and Spitzer, 1995; Spitzer, 1998). Females that are poor candidates for AI-synchronization include those in poor body condition, those with calving problems, and those that have suffered setbacks or illness.

Herd Health

AI programs, with or without synchronization, should only be attempted in herds that have a good herd health program. The best breeding programs will be unsuccessful if they have to compete with infertility diseases such as vibriosis and trichomonosis. Protection should be provided against abortion-causing diseases such as leptospirosis, IBR, and brucellosis (where applicable). Herd health considerations extend to the source of semen. Semen, whether frozen, chilled, or fresh, should come from sires of known herd health and from an organization that maintains good health

Downloaded from Vet-eBooks.com

and sanitary requirements. In the United States, this is ensured by using frozen semen from organizations affiliated with CSS.

Facilities

Effective artificial breeding programs require good facilities, including those for congregating cattle, feeding them if necessary, observing estrus, and breeding. For breeding, an enclosed breeding chute or crush has advantages in reducing animal stress. For synchronization programs, prior calculation should be made of the maximum number of animals that can be handled (i.e., bred) during the breeding "window." Protection from the elements while handling semen and breeding is also an important consideration.

Animal Identification and Records

Implementation of AI on beef operations often mandates an upgrading of record keeping on the property, as well as improvement in animal identification systems. Animal identification should be read easily from both sides at a distance and be unambiguous. A number of effective identification systems are available, varying from electronic chips to legible ear tags and paint marks. Record-keeping systems should keep tabs on which females were bred to which bull and when. Other information, such as estrus signs, ease of AI, and any other relevant comments are also helpful.

Stress Reduction

Stress reduces reproductive success, with this probably playing a greater role with AI/synchronization programs than with natural breeding. Stress is increased by environmental factors, such as excessive heat, cold, and unstable weather. It is also increased when animals are handled roughly, such as when they are driven a long distance and subjected to dogs, whips, and electric prods. Stress is reduced when animals are conditioned to the facilities, they are handled gently, and breeding is performed in an enclosed breeding box.

Technicians-Inseminators

Technicians-inseminators are a potential problem area with beef artificial breeding programs, since technicians vary in experience and technique. For synchronization programs, the inseminator should have had recent experience in successfully breeding large groups of females within a restricted period. Owner-inseminators who have had limited experience under such conditions may be disappointed with their results.

Estrus Detection

Cowboys (and stockmen) are often surprisingly unaware of the finer details of effective estrus detection, in contrast with their dairy colleagues. Here, some prior sensitization might be in order, whether or not estrus detection aids are used. People delegated to observe estrus should be both knowledgeable and motivated. Estrus detection is best observed in smaller groups of animals in a confined area such as a feedlot or trap. Best time to observe is first thing in the morning and late afternoon-early evening. At least 30 to 60 minutes of uninterrupted time should be devoted to this task on each occasion. Estrus detection aids add to the efficiency of estrus detection in most types of programs. These run the spectrum from tail paint to K-Mar heat mount detectors and Heat-Watch (electronic pressure-activated devices that transmit data to a recording device). They may be used with teaser bulls or, equally effectively, with androgenized cows (Burns and Spitzer, 1992).

Calving

Calving after a successful synchronization program should occur within a compressed time period. If all females are bred on the same day, most calves will be born over a 2-week period, with a 4- to 5-day period of maximum activity. Preparations should be made for an adequate calving watch over this period, with personnel and facilities being made adequate to handle emergencies. It is helpful if sires used for heifer breeding are selected for calving ease.

Synchronization Programs

Synchronization makes more cows available for AI, shortens the period of AI, reduces estrus detection effort, allows more efficient scheduling of breeding and calving, and can allow females to get pregnant earlier. However, although hormonal means to effectively group estrus in beef females have been marketed for some time, beef producers have been slow to adopt (Patterson, 1999). Selection of a "best" method for a particular operation depends on a number of factors. Product cost is important, but other considerations include overall duration of program, number of cattle handling opportunities, and cost of semen.

Early methods to control the bovine estrus cycle used exogenous progesterone to prolong the luteal phase of the estrous cycle or to establish an artificial luteal phase (Patterson, 1999). These programs suffered from variable and poor results. When prostaglandin (PG) became available, this rapidly became the preferred product for synchronization programs. Administration of PG alone causes lysis of the corpus luteum (CL) in cycling females, with subsequent estrus. However, this method is ineffective in females that do not have an active CL. Absence of a CL may occur in animals that are acyclic, and in those at the "wrong" phase of the estrous cycle when PG is administered. A single injection of PG into a group of females that are all cycling causes an approximate 75% to 80% estrus response rate. Several approaches have been used to improve this response. For example, the "Moody system" is a single-injection system that has some advantages for beef producers (Chenoweth et al, 1980). This works as follows:

Days 1 to 5: Conventional AI program of heat detection and insemination.

Day 6: At this juncture, a decision can be made whether to proceed depending on whether detected estrus has been satisfactory over the past 5 days. If so, the remaining unbred females can be given an injection of PG.

Days 6 to 11: Breeding of estrus females.

Days 27 to 33: Rebreed synchronized females that did not settle on the first heat.

This system has the advantages that animals require only one PG injection, and it incorporates a "fail-safe" feature if results are not promising after the initial breeding period.

Compared with a single injection of PG, a two-injection regimen of PG given 11 to 13 days apart increases estrus response rates such that virtually all females should show heat within a 5-day period. Heat detection, however, is still required.

A system that allows breeding either at detected or timed heat is the Syncro-Mate B program (SMB) or Crestar. This

Downloaded From Vet-eBooks.com

combines the use of a progesterone and estrogen in an ear implant, usually left in place for 9 days, in conjunction with an injection of estrogen at implant insertion. This system has the advantage that it may be used with all cycling females, regardless of where they are in their estrous cycle, and it may also stimulate cyclicity in some subcyclic females. If implants are inserted on Day 0, and removed on Day 9, most responding females will show heat between Days 10 and 13. For fixed-time insemination the best time is 48 to 54 hours following implant removal. In lactating females, calf removal between implant removal and start of breeding (48 hours) can improve estrus and pregnancy responses. However, this product is not currently available in the United States.

Controlled Intravaginal Drug Releasing and Progesterone-Releasing Intravaginal Devices

Both controlled intravaginal drug releasing (CIDR) and progesterone-releasing intravaginal devices (PRIDs) are controlled, internal, drug-releasing intravaginal devices used to synchronize estrus in cows and heifers. The CIDR contains 1.2 g of progesterone, whereas the PRID contains 1.55 g progesterone plus 10 mg of estradiol valerate. A common protocol is to insert the CIDR, give an injection of PG on Day 6, and remove the device on Day 7. Following removal of the CIDR, estrus should lead to responding females within 1 to 3 days. Breeding is conducted in conjunction with estrus detection. This method has shown some ability to stimulate cyclicity in acyclic females also. PRIDs are generally left in for 12 days, although this can be shortened to 8 days if a PG injection is given on Day 7. Neither product is presently available in the United States, although CIDRs are undergoing the regulatory process.

Melengestrol Acetate/Prostaglandin

An inexpensive and useful synchronization system that has particular advantages for heifer synchronization in range-type herds is a system that uses melengestrol acetate (MGA) in conjunction with PG. MGA, a progestogen that can be administered as a top dressing or mixed in feed, prevents estrus. Cessation of feeding causes cyclicity, although the first resultant estrus is relatively infertile. Thus breeding is usually delayed until the second cycle, which is further synchronized with PG. A common protocol is to feed MGA for 14 days, as follows:

Days 1 to 14: Feed 0.5 mg MGA/head/day.
Day 15: Stop feeding MGA. Responding females should come into heat over the next 7 days.
Day 31: Inject PG. Responding females will come into heat over the next 5 days.
Days 32 to 38: Inseminate according to estrus.

This system (without the use of PG) has also been used effectively with natural breeding (Patterson et al, 1990).

Ovsynch, Cosynch, and Select Synch

Programs have been devised that use various combinations of GnRH with PG, in attempts to synchronize follicular dynamics, and that facilitate fixed-time insemination. Different variations on this theme have been termed *Ovsynch, Cosynch,* and *Select Synch* (Patterson, 1999). For postpartum beef cows, Cosynch and Select Synch have received most attention, whereas Ovsynch has been used most with dairy cows. With Cosynch, GnRH is given on Day 1, PG on Day 7, and then GnRH is given on Day 9 to coincide with AI breeding. Select Synch is a program that uses conventional estrus detection. GnRH is given on Day 1, PG on Day 7, followed by estrus detection and AI. Results with these programs exceed those obtained with a two-injection PG program (Patterson, 1999).

Synchronization Programs with Natural Breeding (Bull-Synch)

A number of producers are successfully using estrus synchronization programs in conjunction with natural breeding. Successful Bull-Synch has been used with PG, SMB, and MGA programs. Although Bull-Synch does not confer the genetic advantages of using superior AI sires, it does have other advantages, such as less overall effort and cost than AI-synchronization programs, including delegation of estrus detection duties to the bull. Such programs can be useful as an interim step toward a full AI-synchronization program by facilitating animal grouping and by refining synchronization protocols (Pexton et al, 1989). For some, this represents a useful heifer-breeding program in its own right. A successful program will achieve results at least as good as for AI (Pexton and Chenoweth, 1977), with most breeding occurring over a 2- to 3-day period. During that time, an active bull will serve many times (e.g., an average of 55 times in 30 hours in the Colorado trials). Such work rates emphasize the importance of using sound, agile bulls that have passed a breeding soundness examination. Some programs have achieved good results by removing females after they have been serviced once, although optimum fertility usually requires several services.

Guidelines for the successful conduct of a Bull-Synch program include the same as those for a conventional AI-synchronization program, with the addition of the following considerations;

1. Bulls should be preassessed for breeding soundness. A libido–serving capacity test may also be useful in selecting the best bulls for this task (Farin et al, 1989).
2. Breeding is best done in a small pasture or lot.
3. BFRs may be between 1:10 and 1:30, although 1:20 is advised (Patterson, 1999).
4. Single-sire breeding is preferable.
5. The breeding "season" should be regularly monitored.

Economics of Artificial Insemination Breeding Systems

The cost of an AI breeding system is determined by a number of factors, including the number of times cattle are worked (thus influencing labor costs), the cost of the synchronization products, and the cost of semen. Benefits include genetic improvement plus improved management spin-offs such as earlier, more concentrated calving. Costs are also associated with natural breeding. A comparison between different systems has been made based on 1998 U.S. prices (Table 13-36) (Hogan, 1998).

Biostimulation

Biostimulation is a term used to describe the stimulatory (positive) effects of a male-on-female reproductive behavior or response. This can include effects on estrus, ovulation, or pregnancy. Although best recognized in species such as sheep, it is evident that biostimulatory effects also occur in cattle. A number of studies have shown positive effects of bull presence on interval to estrus following parturition in cows, whereas inconsistent results occur with such effects on heifer puberty (Chenoweth and Spitzer, 1995; Spitzer, 1998). With the latter, interactions appear to occur with nutrition and other environmental factors, as well as unknown factors. The mechanism(s) for biostimulation is/are largely unknown. However, it is not restricted to males only since androgenized females can be equally effective (Chenoweth and Lennon, 1984; Burns and Spitzer, 1992). With postpartum cows biostimulation appears to be most effective before Day 60 after calving. It thus appears to have particular

Relative Cost of Natural Versus Artificial Breeding

Method	Natural Breeding*	Cosynch	Syncro-Mate B7	Traditional Artificial Insemination (AI)
Bull cost	$2750	—	—	—
Cost/Pregnancy	$39.35	$34.67	$25.42	$45.00

Based on 60% AI success.
*Bull bred with 30 females at 92.5% pregnancy rate. Bull costs include salvage, depreciation, maintenance, and opportunity costs. AI-synchronization costs include product and labor.

advantages for use with late-calving cows and for use in conjunction with AI programs (Spitzer, 1998).

RECORD COLLECTION AND MANAGEMENT

To achieve optimum performance, both production and financial, records of production and costs are necessary. In the United States, a large proportion of cow-calf producers report that they keep some sort of records, but most are hand written. Computer records were not commonly kept except in herds greater than 300 head (NAHMS, 1997a). In a survey of producers in the Northwest that regularly used a veterinarian for herd services, 64% reported that they kept production records. However, when asked for specific production or health measures, they were only able to provide estimates, which suggested that their records were not in an accessible form (Sanderson and Gay, 1996).

Hand-written records have limited use because of the difficulty in summarizing and analyzing them. In and of themselves, records are data on the productivity of the farm. They must be summarized and analyzed in order to turn the data into information useful for guiding management decisions. Analysis of data is accomplished most efficiently with the use of a computer. Once hand-written records are collected, half the work is done and entry of the data into a computer database will dramatically increase its use. Day-to-day recording of data is best collected in a pocket diary. Daily births, morbidities, mortalities, and treatments can be recorded and entered into the computer database later. Data from pregnancy examination may be collected directly into the computer database at "chuteside." Future improvements in data acquisition may increase the ability to input data directly to the computer at the time of the management event.

Quality databases are currently commercially available for cow-calf record management and analysis (e.g., Cow-Calf 5, Cowsense, or CowBoss). These may be purchased by individual producers to keep records on their own herds or by veterinarians to keep records in multiple herds. In either case the veterinarian should be involved in the analysis and interpretation. Anonymous comparison of production data and costs among herds in a practice or region may be useful in identifying production inefficiencies and opportunities. Summary data on production and economic measures in cow-calf herds are available (e.g., CHAPS, SPA) (Spire, 1991). Identification of "production practices" that are profitable for cow-calf producers must be measured at the herd level and thus will require production data on a large number of herds. The current move in the U.S. cow-calf industry toward production-marketing alliances may provide an opportunity for comparison of production information on large numbers of herds. With additional training in database management and data analysis and interpretation, veterinarians could play an important role in this expanding area.

Opportunities for veterinarians to assist producers with production and financial records are extensive. SPA data highlight the importance of controlling costs in beef cow-calf herds for profitability (McGrann and Wikse, 1996). Indiscriminate cost cutting has the potential to decrease production return more than the cost savings and to decrease net return. Informed decisions to optimize production level and maximize net income can only be made on the basis of records to identify input costs and production response for the individual herd. Whereas generic regional production and financial data provide a good starting point, actual optimum production level is unique to each herd because of differences in input costs and environment.

The ideal record system for the cow-calf enterprise facilitates collection of the necessary data to allow informed decision making. It does not collect excessive, unnecessary data that waste time, cost, and effort without improving decision making. The proper balance between these two principles is sometimes difficult to achieve, and it differs between herds. Guiding principles in deciding what records to keep on an individual ranch should include the following:

1. Ability to articulate the proposed utility of the data to be collected. If you cannot state for what the proposed data will be used, it is probably not worth the time and expense to collect it.
2. The desire of the producer to keep and use records. Recording a small number of the "most" important records may be helpful and effective in showing the producer the value of records. Overwhelming the producer with too much "paper work" will likely doom the record-keeping effort to failure.

Four questions are helpful in identifying the record-keeping needs of the operation:

1. What are the sources of revenue for the operation?
2. What are the sources of expense for the operation?
3. What are the suspected biggest sources of lost revenue (failure to conceive, low rates of gain, marketing errors, health losses)?
4. What are the suspected biggest sources of excess cost (wasted or spoiled winter feed, wasted or ineffective vaccine or antibiotics, machinery purchase and maintenance)?

Quantification of answers to the third and fourth questions is the purpose of record-keeping systems. Ranchers and the veterinarians who serve them would do well to write out the answers to these questions, then write out the components of their production system directly related to each

Downloaded From Vet-eBooks.com

question. At that point, they are ready to begin evaluating record-keeping packages for how well they satisfy their specific needs. Financial and economic records collection has been covered in the section devoted to standardized performance analysis and is not covered here. This section concentrates on production records.

The economic level of record keeping at which cost of record keeping equals the economic return is unknown and likely variable from ranch to ranch. Considerable research is needed on the economic value of particular production records. The goal of the record-keeping system should be to identify and quantify sources of income as well as expense for the operation. Once these records are in place, practitioners can begin to identify the areas of significant lost revenue resulting from decreased production or excess cost. Records kept should be evaluated in light of these goals.

The records that we keep are primary source data or the raw data of the operation as it occurs. This primary source data would include, for example, the pregnancy status of the individual cow or the treatment of the individual calf. From this primary source data, we calculate useful indices of production that can inform decision-making. These production indices would include pregnancy rate, morbidity rate, calf crop, etc. The primary source data must be collected in a reliable way to ensure its utility. This requires that the database information system be structured in a way that reflects the production process.

A minimum production database of records should provide the ability to track production indexes at the herd level. The minimum collection of primary records would include the following:

1. *Number of cows and heifers in the herd at the beginning of the fiscal year.* For any record system an accurate inventory of production units throughout the year is essential. Without accurate inventories, the calculated production indexes are meaningless.
2. *Number of cows and heifers exposed to be bred.* This is the number of cows and heifers supported in order to produce the weaned calf crop.
3. *Transfers of pairs or pregnant females in or out of the herd.* Transfers must be accounted for to keep inventories correct and to make calculated production indexes meaningful.
4. *Total number of calves weaned.* This is the aggregate calf production of the herd.
5. *Total pounds of calf weaned.* This is the aggregate production of the herd in pounds.
6. *Total price received for weaned calves.*
7. *Total acres used for grazing and raised feed.*
8. *Treatment and processing records of groups to facilitate quality assurance.* These records are essential to ensure that chemical and physical defects are avoided. These records should include the date of procedures performed, products used, lot number, administration route and site, and frequency of needle changes (see Fig. 13-12 on p. 572). Records kept here will be defined by the goals of the quality assurance program designed to meet the requirements of the operations customers.

These records allow the calculation of herd production levels of the following:

1. *Calf crop.* Total number of calves weaned divided by the number of cows exposed to be bred. Calf crop includes losses from infertility, early embryonic death, abortion, stillbirth, and calf death from birth to weaning. As such, it identifies depressed production without identifying the specific cause. Identification of the specific cause requires additional primary records targeted to each area of loss.
2. *Pounds of calf weaned per cow exposed.* Total pounds of calf weaned divided by the cows exposed to be bred—another important calculated production index. Pounds weaned per cow exposed include loss from all areas included in calf crop and losses resulting from depressed weight gain in calves.
3. *Pounds of calf weaned per acre of land used for grazing or feed production.* Total pounds of calf weaned divided by total acres used for grazing or raised feed—a measure of the efficiency with which grazing and forage producing land is used.

Additional primary source data allow more exact tracking of production level and specific causes of production depression and inefficiency.

1. *Individual cow and calf identification.* The basis of tracking individual performance of cows in the herd and culling based on that performance.
2. *Individual cow and heifer pregnancy status.* Pregnancy percentage provides an index of the breeding efficiency of the herd. It includes failure to conceive, early embryonic mortality, and, depending on the time of pregnancy examination, early- to mid-term abortions. Along with BCS at breeding and pregnancy, it provides an estimate of nutritional effects on fertility.
3. *Cow BCSs or cow weights.* Ideally at the time of pregnancy examination and before calving. They help identify potential nutritional effects on reproductive performance and groups of cattle that may need separate nutritional management.
4. *Calf birth date/Calving date.* Identify early born calves and early calving cows. When categorized by 21-day periods during the calving season to produce a calving histogram, it provides an index of fertility over the course of the breeding season.
5. *Calf birth weight.*
6. *Calving ease score.* A measure of the incidence and severity of dystocia. Along with calf birth weights, this can effectively guide the use of expected progeny differences for sire selection to control dystocia rates and optimize calf growth.
7. *Calf vigor score.* Scored at birth. It may reflect the effects of dystocia, nutritional deficiency, and infectious disease on the calf.
8. *Date of all calf deaths.* Along with calf birth date, this allows assessment of when mortality is occurring. Analysis can assess rates of stillbirths, deaths from birth to 24 hours, 1 to 28 days of age, and 28 days of age to weaning. Provides detail on when losses are occurring to guide intervention resources and efforts.
9. *Individual calf weaning weight.* Assess the production of individual cows.

A comprehensive production management information system includes additional elements such as the following:

1. *Date and diagnosis of morbidity in calves and cows.* These data allow calculation of disease-specific incidence rates. This provides additional detail on the time of losses and the effect on production to effectively guide the rational allocation of resources to prevention. Record of disease-specific rates require training of producers to validate case definitions to allow useful interpretation of the data. If rates are to be compared across herds, each producer needs to be using the same case definition—that is, all producers have to agree on what a sick calf is.
2. *Date and treatment of morbidity in calves and cows.* Useful in assessing response to treatment and providing quality assurance validation. If treatment response is to be measured recovery, retreatment and final disposition dates of all cases need to be tracked also.

The collection and tracking of calf morbidity data allow the assessment of the effects of morbidity on calf performance and the costs associated with each morbidity incident.

Downloaded from Vet-eBooks.com

Once these values are known, an appropriate amount of resources can be allocated to optimize net income. Current record-keeping databases for cow calf production are limited in their ability to track morbidity incidence but will likely improve over the next few years.

Commercially available record management programs provide "canned" reports of certain production indexes. In addition, the database can be queried to provide additional indexes that may be useful in addressing production. Proper design of the database is necessary for full use of the collected data. If the program design does not reflect the relationships inherent in the production system it models, it will sometimes fail to allow the needed analysis for decision making. The program should also be able to write records data to a file for importation into software that allows for more sophisticated analysis.

The record system chosen should be based on the desire of the producer and the level of information needed to make decisions. Collection of primary source data on an individual animal basis allows much greater flexibility in identifying areas of production depression and the likely causes of it. Financial and economic data must be kept as well in order to assess the effect of production changes on net income. Standardized performance analysis for assessment of financial and economic performance has been dealt with in more detail elsewhere in this chapter.

BEEF QUALITY ASSURANCE

Hazard analysis of critical control points (HACCP) is a process control method to identify hazards or dangers that may occur during production and identify ways to prevent them from happening. The focus is on prevention of problems rather than on detecting and removing problem animals. Beginning in January 1998, HACCP became the method of ensuring food safety in all large U.S. beef slaughter plants. By January 2000, all U.S. beef slaughter plants were required to have a HACCP plan in place. With the establishment of HACCP programs in slaughter plants, much attention has been focused on extending the concept back to the production phases of the beef industry. To some extent this is already being done at the feedlot level, although not yet by government regulation. It is only a matter of time before it is extended to the cow-calf and stocker sectors.

HACCP is a process control method developed by the Pillsbury Company in the 1960s. When NASA was planning the space program they were confronted with the problem of ensuring food safety for the astronauts during their trips. Every meal could not be tested because the very nature of the testing could cause contamination. They developed the HACCP concept to prevent food safety problems and to ensure a safe product.

The first step in implementing a HACCP program is hazard analysis (Box 13-21). This involves a thorough study of the product (beef, in this case) and the conditions, inputs, and management practices of production, distribution, and processing. Hazard analysis is used to identify the areas where something could go wrong and a food safety or quality problem could occur. Once these areas are identified, they become the guides for implementing critical control points to prevent food safety and quality problems. Management practices and activities are implemented to prevent the hazard from occurring. Finally, the critical control points are monitored to be sure the management changes are controlling risk. If the critical control points are working, the final product is very likely to be safe. This process is in place for the majority of beef slaughtered in the United States at this point. Preliminary data suggest it has been effective in reducing the incidence of *Salmonella* on ground beef by more than one third (USDA:FSIS News Release, March 9, 1999).

The concern here is the application of the program's principle to preharvest production. The feedlot industry has already begun implementation of an HACCP-like program called quality assurance critical management points (QACMP) (Box 13-22), sometimes just referred to as beef quality assurance (BQA). The feedlot industry has focused its efforts in three areas that may cause a food (beef) to be unsafe or of reduced quality: bacterial contamination, chemical residues, and physical defects. A similar approach may be useful for the cow-calf sector.

Problem Categories

Bacterial Contamination

At this point there are no known critical management points for bacterial contamination at the preharvest level (Hancock, 1997). Bacterial agents of concern include *Salmonella, Campylobacter* sp., *E. coli* O157:H7, and *Listeria*. The ecology of foodborne pathogens in the production environment is not known well enough to clearly identify any points at which the hazard could be prevented. Available evidence suggests that food and water may be impor-

BOX 13-21

Identifying Potential Safety or Quality Hazards

Identify Critical Management Points (CMPs): Points at which potential problems can be controlled or eliminated.
Establish critical limits for CMPs: Determine how to identify when a management activity is not being conducted correctly.
Establish CMP monitoring procedures: Ensure that CMPs stay within established limits.
Establish corrective actions: Corrective action to be taken when critical limits are exceeded. Includes what to do to prevent the problem from happening again.
Establish verification procedures: Testing monitoring to ensure that the system is working.
Establish record keeping procedures: Document the system is working.

BOX 13-22

Five Preliminary Steps to Quality Assurance Critical Management Points (QACMP)

1. Assemble a QACMP team and resources.
2. Describe what you raise and how it is distributed
3. Identify who buys your cattle and communicate with them
4. Develop and verify a process flow diagram (all the production steps)
5. Meet requirements for good management practices for beef quality assurance

Downloaded From Vet-eBooks.com

tant reservoirs for transmission of these agents both within and between farms. Clearly, prevention of fecal-oral transmission by ensuring clean water and feed are good management practices, but their validity as critical management points is unknown. Development of water sources to minimize fecal contamination may be useful, but the economic cost:benefit ratio cannot yet be assessed. Use of equipment for cleaning pens or corrals and then deliverance of feed without a thorough cleaning between should not occur. Further research on the ecology of foodborne pathogens may identify critical control points. Competitive exclusion or inhibition therapy and dietary modification may prove to be useful critical control points with further research. Current recommendations for prevention of bacterial defects are summarized in Box 13-23.

Chemical Residues

The beef industry has a history of dealing effectively with chemical residues, such as antibiotic, anthelmintic, and pesticide residues. Fed beef cattle accounted for 2% of violative chemical residues in 1996 (Paige et al, 1999). Control has been achieved by record keeping of individual animal treatments to facilitate adherence to withdrawal times. In the United States, use, records, and withdrawal time of all drugs must conform to Animal Medicinal Drug Use Clarification Act (AMDUCA) guidelines. The primary cause of violative residues for all classes of animals was failure to follow established withdrawal times, followed by inadequate animal identification and inadequate medical records (Paige et al, 1999). The cow-calf industry is somewhat insulated from chemical residue concerns by their temporal distance from entering the food chain. However, certain antibiotics and pesticides may lead to residues extending into the slaughter phase, most significantly gentamicin. Cull cows, however, may be slaughtered promptly after sale, increasing the risk of violative residues. Cull beef cows accounted for 10% of residues in 1996 (Paige et al, 1999), highlighting the need to increase producer and veterinary vigilance to decrease the violation rate (Table 13-37).

Drug withdrawal times should be completed before sale or shipment, or the purchaser should be notified of remaining withdrawal constraints. The Nebraska Beef Quality Assurance program prohibits the use of aminoglycosides because of their extended withdrawal time, and the American Association of Bovine Practitioners has instituted a voluntary prohibition of aminoglycoside use. Aminoglycoside withdrawal time may exceed the life of the calf even when given early in life.

Pesticide residues may occur through contamination of feeds, necessitating that feedstuffs be free of contamination. This requires records of pesticide use and adequate time before harvest to allow feedstuff residues to decline. Cooperation from suppliers is essential. Suppliers must have procedures in place to ensure residue-free product and must provide documentation. Withdrawal times following pesticide exposure may be extensive and on occasion may force euthanasia and disposal of animals. Topical organophosphate antiparasitics and pesticides should be stored securely away from all feedstuffs to avoid inadvertent contamination. Contaminated feedstuffs must be discarded.

Nonperforming cattle ("chronic poor doers") are animals requiring particular vigilance with regard to chemical residues (Box 13-24). At the cow-calf level, cull cows need to be monitored carefully to ensure drug clearance before slaughter. These animals may have metabolic abnormalities, such as liver and kidney dysfunction, that will dramatically extend withdrawal times. Screening for residues before shipment is prudent.

BOX 13-23

Prevention of Bacterial Contamination

- While no specific critical management points exist for bacterial contamination, good management practices to minimize fecal oral transmission of potential pathogens are prudent.
- Avoid fecal contamination of feedstuffs. Use separate equipment for cleaning pens and loading feed, or thoroughly wash bucket, tires, and undercarriage before using on feed.
- Regularly clean water troughs to minimize fecal contamination.
- Buy feeds from reputable suppliers; some may have quality control testing programs that may include organisms like *Salmonella*.

TABLE 13-37

Number and Percent of Residue Violations by Class of Slaughter Animal In the United States (1996)

Slaughter Class	No. of animals	Residues (%)
Bob veal	941	47
Cull dairy	647	32
Market hogs	49	2
Beef cows	191	10
Sows	8	0.4
Steers	45	2
Other	111	6

BOX 13-24

Prevention of Chemical Residues

- Establish a treatment protocol book that includes appropriate withdrawal times.
- Record all processing and treatment of animals and the associated withdrawal times. Follow Animal Medicinal Drug Use Clarification Act guidelines for drug use.
- All withdrawal times should be checked before shipment.
- Nonperforming "realizer" animals should be tested for residues before shipment.
- Store herbicides and pesticides separately from feed.
- Buy feed from reputable suppliers with quality control procedures in place.
- Collect and save a representative sample of all feeds.

Physical Defects

Injection site lesions, bruises, hide defects from brands and parasites, and needles broken off in the muscle are examples of physical defects (Box 13-25). Significant progress has been made in injection site lesions. In 1991 the National Beef Quality Audit found that 21.6% of all top butts in fed cattle had injection site lesions. By 1997, top butt lesions had decreased to 5.6% (National Cattleman's Beef Association, 1997). Responsibility for prevention of injection site lesions extends back to the cow-calf producer. Injections given early in life cause detectable changes in muscle tissue at slaughter that reduce tenderness (George et al, 1997). In 1994 76% of cow-calf producers and 65% of veterinarians were still administering intramuscular injections in the hindquarters (NAHMS/CHAPA, 1994c). Injection site lesion data suggest this may have improved. Nonfed beef (cull beef and dairy cows) remains a problem regarding injection site lesions. To continue to control injection site lesions in all classes of cattle, products should be chosen that can be given subcutaneously in the neck area.

Any intramuscular injections should be given in the neck, never in the hind quarter, shoulder, or loin. The neck muscle is a lower-priced cut of meat, commonly ground into hamburger, and it seems less reactive to injections.

An additional physical defect is broken needles left in muscle. Animals with broken needles cannot be shipped to slaughter. Metal hubbed needles should be used and changed every 10 head or less. Bent needles should be changed immediately, rather than straightened and reused. Broken needles must be removed or the animal euthanized and disposed.

Bruising is another cause of quality defects in carcasses. One study of cull cows found bruises on 48% of cull cow carcasses, with 17% of the bruises being considered major and requiring extensive trimming (Hoffman et al, 1998). Cows originating from livestock markets conducting first point testing for brucellosis had a greater number and severity of bruises, suggesting a role of increased handling in bruise incidence. Another study suggested that rough handling in the feedlot caused increased incidence of bruising at slaughter (Grandin, 1981). Proper handling procedures and safe facilities are necessary to prevent bruising in cattle.

Role of Veterinarians in Beef Quality Assurance

The veterinarian's role in BQA is to assemble and coordinate a team to establish QACMP procedures on the ranch. This requires careful analysis of the management and procurement procedures on the ranch in order to identify any practices that could cause a quality or safety defect. The veterinarian should be pivotal in the establishment of management practices to reduce the risk of defects. This requires that the veterinarian serve as an educator to teach producers the importance of management practices to decrease quality defects. This includes proper injection procedures and sites, proper handling of cattle, and proper records and observance of withdrawal times. An emerging role for veterinarians will be in practicing, and educating producers on, prudent use of antibiotics.

A record-keeping system to monitor control points and verify their effectiveness is essential. This may include processing diagrams to indicate products used and location of administration (Fig. 13-12), as well as recording and checking of all withdrawal times before shipment. Residue data suggest that improved animal identification and records to ensure compliance with withdrawal times are still required. Veterinarians should be pivotal in continuing to educate producers and implement proper records and withdrawal plans. Management practices for storage and use of pesticides to ensure feedstuffs do not become contaminated are necessary. Animal-handling education and guidelines as well as safe and functional facilities are necessary to control bruising. The veterinarian should be involved in monitoring the QACMP plan to ensure goals are being met. Periodically the plan should be reevaluated to ensure the critical management points are effective and useful. As new information becomes available, management will need to change to most effectively control safety and quality risk.

No quality assurance program can work without the cooperation of labor and management. A key factor in the successful QACMP plan is the education and motivation of the workforce. Workers should be trained in the requirements and necessity of the components of the quality assurance plan. Managers should be made responsible for compliance with the QACMP plan and asked to sign off on records for a set of cattle before shipment. The veterinarian is essential in the training of workers to appreciate the importance of the plan and to carry it out effectively.

The beef industry is aggressively working to build an effective system of ensuring beef quality and safety. The future of the industry depends on consumers' having confidence in the safety, quality, and consistency of beef. Veterinarians should have an important role in this system that will benefit all. It is a natural extension of herd health and record keeping related to production in which veterinarians are already involved. If veterinarians choose not to coordinate quality assurance programs, someone else will fill this important niche, to the detriment of both the veterinary profession and the cattle industry.

BOX 13-25

Prevention of Physical Defects

Do not use injections behind the slope of the shoulder (never in the hip or leg).
Select subcutaneous and intravenous injections whenever possible.
Use the neck when intramuscular injections are required.
No more than 10 ml/injection site.
Use appropriate sized, metal hub needles for injections.
Change needles every 10 head; immediately change the needle if it becomes bent or burred.
Remove horns.
Avoid side brands.

ANIMAL WELFARE CONSIDERATIONS

The beef cattle breeding industry, at least in the United States, has been the subject of less animal welfare concerns than other segments of the livestock industries, possibly because it most closely approximates the social ethic of animal husbandry, and because most ranchers have genuine regard for their animals (Rollin, 1995). The veterinary profession has made major, although largely unheralded, contributions to animal health (and thus animal welfare) by reducing or eliminating disease effects that otherwise would cause untold animal suffering. Although such considerations are important and often neglected, concerns have been raised about a number of animal welfare issues in the cow-calf sector of the cattle industry. These may be of a

Code of Ethics

Provide the food, water, and care necessary to protect the health and well being of their animals.
Provide disease prevention practices to protect the health of the herd, including access to veterinary care.
Provide livestock facilities that allow safe, humane, efficient movement and restraint of animals.
Use humane and legal methods when disposal of animals becomes necessary.
Provide personnel with a working knowledge of proper handling and care techniques.
Make timely observations of all animals to ensure their basic needs are being met.
Provide transportation for cattle that avoids undue stress caused by overcrowding, excess time in transit, or improper handling during loading and unloading.
Do not tolerate persons who willfully mistreat animals.
Keep updated on advancements and changes in the industry and make decisions based on sound production practices and consideration to animal well-being.
Realize that the owner-manager of beef cattle is ethically and financially responsible for providing proper care to his or her livestock and for producing wholesome, quality beef and beef products.

perceptual nature only, and resolvable with good communications, or they may raise valid questions about traditional procedures.

The emergence of questions about traditional procedures has prompted cattle producers to articulate general recommendations for the care and handling of cattle. In Australia, codes of practice have been developed for different industries in a process of consultation by interested parties (Penson, 1998). The Code of Cattle Practice, for example, attempts to meet three general objectives as follows:

1. To promote humane and considerate treatment of cattle and the use of good husbandry practices to improve the welfare of cattle in all types of cattle farming enterprise
2. To provide information concerning their obligations and responsibilities to all people responsible for the care and management of cattle
3. To set an industry standard by defining acceptable cattle management practices

A representative "code of ethics" has been developed by cattlemen in Nebraska (as with a number of cattle organizations), as shown in Box 13-26.

Agriculture Canada has published a "Recommended Code of Practice for the Care and Handling of Food Animals: Beef Cattle" (Hurnik, 1991) that covers a wide spectrum of topics from shelter and housing to commercial transportation, and the Federation of Animal Science Societies in the United States produces a useful compendium that covers welfare considerations for a number of species including beef cattle (Federation of Animal Science Societies, 1999). Proceedings of relevant conferences include those on "Grazing Animal Welfare" (Moore and Chenoweth, 1985) and "Food Animal Well-Being," hosted by the USDA and Purdue University in 1993. Readers interested in this topic might consult relevant sections in the text edited by Temple Grandin (1993) and that written by Bernard Rollin (1995).

Some specific welfare issues have been raised in relation to the cattle breeding industry. These include branding, castration, spaying, weaning, dehorning, cattle handling and transport, EEJ, serving-capacity testing, adverse environmental effects, treatment of cull cows, and surgical preparation of teaser bulls. Veterinarians should be aware of these questions and be prepared to provide informed, objective responses when they are raised. There are good reasons for most procedures in the cattle industry, and those that might appear to be inhumane to those outside the industry can often be justified on good grounds that include sound welfare considerations. However, procedures that cause unnecessary pain or suffering should be scrutinized closely. Those that are unjustifiable should be discarded, and viable alternatives should be investigated for others. A full discussion of all welfare topics deserves its own chapter, or even book; Rollin (1995) presents relevant arguments. This section focuses on several issues of recent concern that relate to topics discussed elsewhere in this chapter.

Bull Electroejaculation

Welfare concerns relating to bull BSE in bulls have mainly focused upon the use of EEJ to obtain semen. The development of effective EEJ first allowed routine testing procedures with unhandled range beef bulls as well as from wild and endangered species. Such animals cannot be collected safely by traditional means, such as with an AV. In bulls, studies have shown that a representative semen sample obtained by EEJ is comparable in most important respects with that obtained with an AV (Singleton, 1970). Not only does EEJ permit range-type bulls to be evaluated, but it allows semen to be collected from bulls whose physical or other impairment rules out AV collection. Despite this, the EEJ process does cause some discomfort to bulls, if not distress, although constant improvement in probe design and machine circuitry have led to a marked reduction of such signs. One study ascertained that bull heart rates were less when an epidural was given before EEJ, although no comparison was made with other activities, either painful or pleasurable (Mosure et al, 1998). In rams, based on relative aversion, EEJ was considered no more aversive than part shearing (Stafford, 1995). Ram blood cortisol levels were shown to be similar for shearing, EEJ, and lateral restraint (Stafford, 1995). Other work has indicated that, although blood cortisol levels were elevated with bull EEJ, these were not as high as those caused by restraint alone, or by per-rectal palpation (Welsh and Johnson, 1981). In addressing this issue, relevant questions might include the following: Does EEJ fall within the category of routine, necessary managerial procedure? If so, does it cause more distress than other routine, necessary procedures? Does it cause unnecessary pain or harm? In other words, do the costs in term of animal distress outweigh the benefits? Here, the debate may be different between those countries or regions that have predominantly range- or pasture-based natural breeding systems (e.g., the Americas and Australasia), and those in which AI predominates, as in Europe where several countries have banned this procedure in unanesthetized animals. Although male fertility is important in both cases, it is usually assessed with unhandled bulls in the former case, compared with bulls that are used to handling and AV collection in the latter. For unhandled bulls, the choice is either to use a method of semen collection that poses minimal danger to both man and beast (e.g., EEJ) or to avoid semen assessment altogether. As discussed previously, the second approach would lead to infertility in breeding herds, adding extra economic burdens to producers and added stress to natural resources. If it is conceded that EEJ represents a

BOX 13-27

Australian Association of Cattle Veterinarians Guidelines

The service crates used should be designed properly for adequate restraint of previously unhandled females.
Bull groups should be managed so that a number of bulls do not simultaneously compete for a single female.
Significant size disparities between males and females should be avoided, as should be the conduct of tests in which there is uneven terrain or unsound footing.
Females of suitable temperament should be selected where possible. Mild sedation should be a routine option.
Females showing signs of agitation or distress should be replaced expeditiously.
Stimulus females should undergo regular application of lubricant to their vulvas and posterior vaginas.
Females that have been serviced a number of times should be monitored subsequently for untoward sequelae and treated accordingly.

useful, routine managerial tool, then it is still valid to ask whether or not the pain outweighs the gain. Here, although objective studies are lacking, observations indicate that this procedure is no more distressful than other accepted procedures such as restraint, vaccination, or palpation, although the degree of distress is probably influenced by probe design, restraint method, and experience of the operator (Stafford, 1995). Thus bull EEJ may be considered an essential, routine, managerial task that causes no more distress than other tasks in this category. However, it should be conducted as humanely as possible.

Bull Libido–Serving Capacity Testing

The use of restrained nonestrus females as stimuli for bull sex drive testing, a feature of a number of published procedures, has led to understandable concerns for the welfare of the females so utilized. These concerns have led to the development of the guidelines shown in Box 13-27 for the proper conduct of such tests (Anon, 1998).

Consideration should also be shown for the welfare of the bulls being tested. Some appropriate precautions are as follows:

1. Do not congregate groups of bulls in yards or pens any longer than necessary, since such congregation increases the chances of bull injury. This is particularly true for older bulls, but it also applies to mixed age bull groups.
2. Separate any bulls that are showing aggressive behaviors that threaten other animals.
3. Avoid using service crates that have projecting edges or other design features that may injure animals.

Cull Cow Management and Handling

Welfare aspects of cull cow management and marketing have received attention for several reasons. Firstly, cull cows often represent a vulnerable group of animals. Survey data in the United States indicate that a large number of U.S. cull animals have a number of defects in health, quality, or both (Executive Summary, 1994). Indications are that many of these animals are sent to market with little concern for the health and well-being of the animal, or public concerns about food health or quality (Spire, 1997). In addition, these defects were estimated to cause industry-wide losses of $32.34/head.

Problems encountered included animals in which debilitating disease or infirmity was well progressed (obviously unhealthy animals are severely discounted), extensive bruising, injection-site lesions, and poor body condition.

Veterinarians can play an important role in ensuring that the culling process meets welfare as well as production needs. First, they can educate clients of the need to identify potential problems early. This allows timely shipment or intervention. With the latter the decision to intervene medically or surgically as well as product choice and route of administration also influences the marketability of animals that are sold subsequently. Good records of all such interventions and products should be maintained. In a number of cases, the best option may be to maintain the cull animal on an appropriate nutrition program until they are in suitable condition for market. This may also allow time for markets to improve.

Cull cows are often old, sick, injured, or diseased. Welfare codes for injured, sick, and disabled cattle have been developed by different organizations, with the following examples from guidelines produced by Agriculture Canada (Hurnick, 1991):

- Only cattle fit to travel should be considered for transportation, unless special precautions are taken to ensure the animal does not suffer
- An animal that becomes injured, sick, or disabled during transit must be taken to an appropriate place for treatment; special precautions must be taken to minimize its suffering
- An animal that becomes injured, sick, or disabled in transit should be kept separate from other animals

A prominent welfare issue associated with transportation and marketing is that of bruising. Research indicates that presence of horns (tipped or not) as well as class of cattle (bull, steer, cow, calf) are important determinants (Wythes et al, 1985), with temperament also playing a role (Fordyce et al, 1985). Cows were most likely to suffer bruising, as were animals in poor condition or dehydrated. Movement through saleyards, distance traveled, rough handling, and multiple loadings and unloadings also contributed to increased bruising (Hoffman et al, 1998). Many of these determinants have particular significance for cull cows. Practitioners are advised to handle cows with more care than other classes of livestock and to subject them to less handling and "strenuous" schedules (Wythes et al, 1985; Hoffman et al, 1998). These factors all have relevance for cull cow welfare.

VETERINARY RESOURCES

A number of resources are available to assist veterinarians in effectively implementing herd-health and production programs. These resources fall into two general categories: those associated with education and training and those associated with implementation.

Education and Training

Veterinarians seldom have all of the tools necessary to implement herd-health/production programs when they first graduate from veterinary school. This is understandable,

Downloaded from Vet-eBooks.com

since the standard veterinary educational process is often overstretched in providing the essential basics upon which the production-oriented veterinarian can later build. This education provides the basis for a majority of veterinarians who provide competent medical and surgical services for companion- and food-animal clients. However, a career in production medicine generally requires training or education beyond basic veterinary education and an emphasis on populations of animals rather than on individuals. Production medicine has many facets, with differing requirements, and preparation for a career in this field varies accordingly. Veterinarians who are successful in this area have arrived at this point through a variety of pathways. In general, however, veterinarians aiming toward a successful cow-calf–oriented, production medicine career are first advised to become knowledgeable concerning the industry, its procedures, terminology, constraints, and applicable production medicine concepts. The development of "marketable skills" (Chenoweth, 1989), such as pregnancy testing or bull evaluation, provides an opportunity to gain access to producers, to gain their confidence, and to use this as a basis to develop more comprehensive programs while acquiring relevant knowledge and skills. On-the-job training with one or more cooperator herds can be invaluable. Enhanced capabilities in reproduction, nutrition, epidemiology, financial management, data handling and analysis, risk analysis, agricultural engineering, personnel management, and communication skills are all highly relevant to such a career. These capabilities may be developed in a number of ways, including formal postveterinary education (such as with an MS or Ph.D.) or continuing education programs. In the latter category programs include the "Beef Cattle Production Management Series," conducted by the Great Plains Veterinary Educational Center, part of the University of Nebraska (Lincoln). This program aims to train veterinarians to use tools to evaluate and monitor production-management strategies and integrate the many factors involved in decision making to optimize productivity and improve financial success for beef cattle producers (Hamilton, 1997). The program is multidisciplinary and interactive, consisting of seven 3-day sessions conducted at the Center over a 12- to 15-month period, with an emphasis on problem solving at whole-farm and industry levels. Topics include financial management, nutrition, preharvest food safety, epidemiology, data handling and analysis, and communication skills. At Colorado State University, the Integrated Livestock Management Program offers a coordinated approach for both continuing education and graduate level training. The University of California-Davis offers a Master's program with a strong epidemiological emphasis in Veterinary Preventive Medicine, whereas the University of Guelph (Ontario), which also has a strong epidemiology program, offers a Doctor of Veterinary Science program. Although this program has a clinical emphasis, it may be tailored toward production medicine interests. In Australia, advanced training in tropical veterinary medicine is available at the James Cook University of North Queensland, while a Master's program in production medicine is offered by the Pastoral Veterinary Center of the University of Queensland. In Victoria, the Mackinnon project at the University of Melbourne offers post-DVM training in production medicine for food- and fiber-producing animals (Caple et al, 1998). Relevant training could also be obtained through less traditional routes, such as with a Master's of Business Administration (MBA). No doubt there are a number of other opportunities for veterinarians to develop expertise relevant to production medicine.

BOX 13-28

Steps to Implement a Production Medicine Program

Establish goals for operation
Establish a herd data base
Identify areas of production inefficiency
Identify areas of financial deficiency
Identify areas for improvement
Establish a plan and timetable
Implement and monitor plan and progress
Document and evaluate outcomes

Implementation

Implementation of effective production medicine programs involves a systematic approach that might include some or all of the steps in Box 13-28.

Although veterinarians often have the training, farm access, and credibility to capably implement such programs, they do not necessarily have expertise in all appropriate areas. In fact, the list of appropriate expertise for all facets of such programs is beyond the resources of most individuals. Fortunately, resources are often available to help in many such areas, including nutrition, finances, and agricultural engineering. Extension personnel, diagnostic laboratories, regulatory agencies, and veterinary colleges all provide a wealth of pertinent information, as do many sites on the World Wide Web.

The formation of teams, or task forces, that combine appropriate expertise for a specific industry problem or sector, has received considerable attention. One such example is that of integrated resource management (IRM), which was conceived by extension specialists in conjunction with the NCBA (formerly NCA) as a national beef educational effort in the United States. Out of this initiative came the guidelines for SPA, as discussed previously in this chapter. Other IRM concepts are expressed in terms of workshops, financial and production analysis programs, development of educational materials such as CD-ROMs, and on-farm problem analysis using multidisciplines. All of these activities benefit from veterinary involvement, particularly on-farm problem solving by teams of expert advisors, such that IRM concepts are now being taught in some U.S. veterinary colleges. Related initiatives include the development of focus teams for different sectors of the animal industry in Missouri, with the beef focus team utilizing veterinary expertise as well as that in areas of economics, forage systems engineering, nutrition, and environmental regulation. In Texas a partnership has been established among veterinarians, extension personnel, producers, and a large pharmaceutical company to help cow-calf producers improve both productivity and profitability through a series of continuing education programs (Wikse et al, 1998). In Australia the development of advisory teams to investigate and solve producers' problems has also met with success (Withers, 1984; Sykes and Stafford, 1984). Such examples illustrate the growing complexity and sophistication of animal agriculture and the need to approach problems from a broad perspective. Today this perspective may include not only whole-farm, or even industry, considerations, but aspects such as international trade, environmental concerns, and animal welfare perceptions (Box 13-28).

CHAPTER 14

Health and Production Management in Beef Feedlots

ROBERT A. SMITH, GERALD L. STOKKA, OTTO M. RADOSTITS, and D. DEE GRIFFIN

A beef feedlot is a place where young growing cattle are fed a high-energy diet to produce marketable beef at the lowest cost and in the shortest time possible. Depending on the starting body weight and age of the cattle, the period of confinement and feeding varies from 60 days to 12 months.

Beef feedlots have evolved from small family farm lots, in which 25 to 100 head of cattle were finished annually, into large, capital-intensive enterprises that market thousands of finished cattle annually. In the family farm feedlot the calves were born and reared on the home farm, weaned at 6 to 8 months of age, fed a growing ration until they were 1 year of age, and then finished on a high-energy ration, usually grains, until they reached marketable weight at 18 to 24 months of age. Health and production problems were minimal, and expansion of this kind of enterprise was limited only by the capital investment and the desire, knowledge, and labor necessary for expansion.

In North America, expansion of these farm feedlots has been limited when compared with the proliferation of the capital-intensive enterprises that feed and market thousands of cattle annually. Beginning in the 1950s, economic forces led to the development of a large feedlot industry. Feedlots may purchase and own cattle exclusively, custom feed cattle for absentee owners, or a combination of both. In these enterprises cattle are obtained either as weaned calves 6 to 8 months old or as yearlings 12 to 14 months old; they are placed in the feedlot and fed for periods ranging from 60 days to 12 months, depending on initial age and weight. The animals are obtained and transported long distances from many different genetic, nutritional, and geographical backgrounds and are commingled in the feedlot. Net profit in these intensive feedlots depends not only on good animal management and animal health, but also in large part on the purchase and selling prices of the cattle. The cattle are fed primarily on an ad libitum basis, and the aim is to produce a wholesome product for consumers as efficiently and economically as possible with a minimum occurrence of the common diseases that affect feedlot cattle. Feedlot owners have long believed that if cattle are bought right, a profit can be made. However, a number of other factors affect profitability: fed cattle prices, feed conversions, daily gains, interest rates, and even seasonality (Jones and Mintert, 1997). In some cases the occurrence of disease may have a major economic impact on net profit in the feedlot, but in other cases, if the selling price of cattle increases markedly during the finishing period, disease may play only a minor role in net profit. Unexpected fluctuation in the prices of feed and cattle can lead to large financial losses.

In North American feedlots the male castrate (steer) is the predominant animal, but heifers, cull cows, and bulls are also fed for beef production. Young bulls convert feed energy and protein to lean beef more efficiently than do steers (MacNeil et al, 1989; Steen, 1994). Carcasses from bulls slaughtered at traditional weights and ages are leaner than carcasses of contemporary steers. However, lean beef production from young bulls remains an available production system that is currently not exploited. Cattle feeders may be reluctant to feed young bulls in feedlots because of the perceived liabilities and management problems that result from their agonistic behavior. The successful feeding of yearling bulls in the feedlot may depend on the use of management and feeding techniques that reduce the length of the feeding period and the adverse consequences of agonistic behavior (MacNeil et al, 1989).

Energy use in agriculture in general and in beef production in particular has been the topic of much discussion. The added energy inputs, which were substituted for the labor of humans and horses into agriculture, has certainly been a large contributor to the increased production of agriculture (Heitschmidt et al, 1996). Total energy used in the various steps of the beef production system, under conditions of cow-calf production on a range in Colorado with yearling steers fed a high-concentrate diet, is shown in Table 14-1 (Ward, 1980).

Cow-calf production involves support of cows, including their winter feed. Transport of personnel and supplies to the

TABLE 14-1

Distribution of Energy Consumption in Average Beef Production

		Percent
Cow-calf production		21.2
Stocker (180 to 320 kg)		16.0
Feedlot (320 to 500 kg)		62.8
	Total	100.0
ENERGY CONSUMPTION IN THE FEEDLOT		
Feed production		86.4
Feed processing		3.5
Feed operation		10.1
	Total	100.0

pastures represents the largest single energy input. The feedlot phase represents 60% of the total energy use, of which more than 80% is allocated for feed production. Despite heavy mechanization, feed processing and feedlot operation constitute a small percentage of the total. The fact that so much of the energy input is in the form of feed means that growth promotants that increase feed efficiency make an important contribution to energy conservation. Allocation of energy by system of production tends to favor the feedlot system over higher roughage–based systems because of increases in efficiency. Total energy required per pound (kilogram) of meat produced is reduced by 37% to 40% when increasing amounts of feed energy are obtained from human edible sources (Council for Agricultural Science and Technology, 1999). In addition, significant energy savings in beef production can be obtained by reducing the days on feed for heavy feedlot cattle. This can be achieved by eliminating the additional feeding time for cattle that have reached an optimum endpoint. Ten percent of the total energy for finishing an animal is used during these 2 weeks to produce an additional 2.2 lb (1 kg) of protein along with about 8.8 lb (4 kg) of largely undesirable fat.

The extensive use of hormone implants and feed additives to promote growth and improve feed efficiency has been economical and has had an impact on reducing the costs of feeding high-concentrate grain diets. The major benefactor of reduced input costs has been the consumer.

Because of the high cost of grain in some parts of the world, there has been considerable research activity on a global basis to find inexpensive alternative feeds for all parts of the cattle production cycle. Developments in forage production and quality show promise for decreasing costs associated with growing cattle. Wheat pasture, alfalfa, fescue, and other tame pastures offer great potential for grazing cattle. In addition, grazing crop residue (plant material left in the field after harvest) offers real potential to reduce maintenance costs.

By-product feeding—that is, the feeding of feedstuffs that have been processed for alternative purposes—is a major component of feedlot diets in many parts of the world. Wheat middlings, the by-product of the flour milling industry, corn hominy, potato-processing residue, bakery waste, and other by-products of food-processing industries can replace some of the grain portion as an energy source for growing and finishing beef cattle. In addition, by-products of the ethanol industry, brewing industry, and sweetener industry (e.g., corn gluten feed, steep liquor, barley products) are used extensively in the growing and finishing cattle industry.

Major changes occurred in the beef cattle feedlot industry during the 25 years between 1958 and 1983 (Koch and Algeo, 1983). In the 1960s the commercial and custom cattle-feeding industry in the United States underwent a dramatic shift in numbers, geographical location, and technological handling of cattle and commodities. Large-scale custom feeding operations developed in which the operators of the feedlot did not own the cattle but instead fed and handled them on consignment for absentee owners. Large-scale modern abattoirs were built in the beef-producing areas. Growth promotants came into general use, providing an economic benefit to the consumer. Research into grain processing led to increased efficiency in feed use, and many changes occurred in the marketing and processing of beef cattle.

During this same period there was a major drive in the beef-cattle industry to produce a superior carcass (Berg and Walters, 1983), characterized by a high proportion of muscle, a low proportion of bone, and an optimum level of fatness. The resulting changes included a decrease in fatness at an acceptable slaughter weight and an increase in growth rate accompanied by larger mature sizes. Changes in body form accompanied the changes in growth rate and composition. All of this has led to major changes in the grading systems for beef in North America (Bredenstein and Carpenter, 1983). The use of crossbred cattle selected for growth and leanness has been a major factor in the changes in animal product composition and has implications for animal production systems.

It is clear that the efficiency of beef production has been improved steadily by applying new knowledge of nutrition and breeding (Trenkle and Willham, 1977). Advances in nutrition, management, reproduction, genetics, animal breeding, and meat processing have been significant but not significant enough to make beef cattle production and beef processing routinely profitable. To increase the efficiency of beef production, additional advances must occur in genetics and animal breeding, management, nutrition, reproduction, growth biology, marketing, meat processing, and meat merchandising. The beef industry is fortunate that its primary end product not only is very nutritional but also is enjoyed by consumers. Consumers will continue to demand both highly palatable beef products that are competitively priced with other animal protein sources and composition that leads to optimum nutritional value.

The beef feedlot industry in the United States and Canada developed as a result of the surplus of grain and the demand for beef from the North American public. In Europe, where land and feed are expensive, intensive beef feedlots are rare, and dual-purpose cattle are customary. In most European countries, beef and veal production is a by-product of milk production, and consequently production levels are dependent mainly on changes in dairy cow numbers 1 to 2 years earlier (Allen et al, 1982).

ECONOMICS OF THE FEEDLOT

There are two important economic factors that determine the profitability of a feedlot operation:

1. Cattle increase in weight, and the cost of the gain in weight must be less than the value of the weight. However, this factor is not sufficient in itself, because it is often not possible to make an adequate profit out of a simple gain in weight.
2. The quality of the entire animal is changed so that the entire carcass increases in value per pound (kilogram) of body weight, and this "margin" is the basis of profitability for the feedlot system. The margin varies, because the demand for feedstuffs and available feeder cattle is variable enough that prices for them fluctuate continuously. What makes the system work is the demand for a continuous supply of meat of uniform quality and tenderness at all times of the year.

The principal factor that affects the cost of growth and finishing of cattle in the feedlot is the cost of feed. Other input costs include capital cost of the lot and labor included as a component of yardage costs, interest costs, processing, and veterinary costs (Jones and Mintert, 1997). The longer the animal remains in the lot to reach a specified gain in weight, the less economically efficient the system becomes. Thus there is an incentive to feed out cattle quickly. On the other hand, very heavy feeding may go beyond the point of optimum conversion, and therefore both weight gain per day and feed conversion efficiency must be kept in view as criteria of efficiency. The rate of gain per day increases as the proportion of grain in the diet increases, whereas under normal conditions the efficiency of conversion increases at the same time. Increasing the intake of roughage generally has the opposite effect, and therefore a decision on the optimum proportion of grain and roughage is critical to

Downloaded From Vet-e-Books.com

profitability. This decision must also take into account the relative costs of grain and roughage. There are also limitations on the amount of grain that can be fed safely. High-grain diets must be managed correctly to avoid digestive upsets and clinical cases of acidosis.

Rate of gain in body weight and feed conversion efficiency are both strongly inherited, and the purchase of efficient animals can make a considerable contribution to profitability.

Another important factor in determining profitability is disease. The failure to adequately control disease at an economic level can cause complete loss of profitability and the loss of part or all of the asset invested in the cattle. The spectrum of diseases that occur will vary considerably, depending on the management system and the geographical location of the lot. These diseases will be discussed in a later section on the causes of economical loss in the feedlot.

Of great importance in maximizing the profitability of a feedlot is the number of throughputs that can be managed in a year. The capital investment is often such that it is necessary to maintain the lot as close to maximum capacity as possible to spread depreciation and other operating costs, including labor, over as many animals as possible.

EFFECTS OF GENETICS ON BEEF PRODUCTION IN THE FEEDLOT

The increase of the efficiency of beef production systems by genetic methods primarily involves two procedures: selection within breeds to enhance critical characteristics and selection among combinations of breeds to produce individuals that better fit production conditions and resources (Long, 1980). Crossbreeding for beef production has become a generally recommended and accepted practice (Gregory and Cundliff, 1980). The current recommendations for crossbreeding can be explained in terms of heterosis for traits usually considered desirable in terms of profitability. Beef production consists of two phases: the cow herd phase, in which reproduction, or increasing the number of cattle, is of primary importance; and the growth and fattening phase, in which weight increase is of primary importance. The characteristics critical to efficiency during the growth and fattening phase include the postweaning average daily weight gain, yearling weight, postyearling weight gain, feed conversion, and carcass characteristics. Crossbreeding improves each of these characteristics to varying degrees. The effects of management must be considered when assessing the economic impact of crossbreeding (Long, 1980).

Much higher levels of heterosis have been observed in crosses of *Bos indicus* and *Bos taurus* cattle than in crosses of *Bos taurus*. Much of this higher level of heterosis may result from less common gene frequency within *Bos indicus* versus *Bos taurus* cattle. This causes a greater amount of heterosis effect. The crossbreed is a genetic intermediate that may be better adapted than the parental pure breeds, both to the climatic environment and for meeting beef production requirements in moderately intensive beef production systems. A disadvantage of *Bos indicus* cattle and its crosses is one of decreased meat quality as it relates to beef tenderness (O'Connor et al, 1997).

VETERINARY MEDICINE IN THE FEEDLOT

The veterinarian must be a competent gross pathologist, a clinical diagnostician, and an epidemiologist, and he or she must have applied knowledge of feedlot production and nutrition, economics and marketing, and computer-based record keeping.

The role of the veterinarian in the feedlot has changed from the traditional emphasis on the diagnosis and treatment of individual sick animals to that of a professional adviser (Jim and Guichon, 1989; Lechtenberg et al, 1998). Advice on animal health and how it affects animal performance is based on the clinical and pathological examination of animals and on the records of animal health and performance. The details of these procedures are presented later.

Compared with other specialties in veterinary medicine (small animal practice and dairy herd health), feedlot health management has been slower to develop as a recognized specialty with a reliable body of knowledge. This is the result of at least two factors: a lack of knowledge and comfort with the management of feedlots, and practical application of the concepts of population medicine. At the same time, veterinarians have been slow to abandon comfortable areas of large animal practice such as reproductive programs and surgery.

There is a continuing need for the collation of a reliable body of knowledge in feedlot animal health that can be put to use successfully and economically by veterinarians working in feedlots. This body of knowledge should be epidemiologically based and computer generated to maintain animal health at a level that yields optimum feedlot beef cattle performance.

TYPES OF FEEDLOTS

The end product of all feedlots is beef and the resulting by-products of the industry. The major variations among feedlots are the types and quality of cattle that are fed, the feeds used, and the length of the feeding period. A brief description of the characteristics of the common feedlots follows.

North American Feedlots

The primary objective of the North American permanent feedlot is to control the social and nutritional environment of the animals and to produce a wholesome product that meets the needs of the consumer. The types and weights of cattle purchased may vary depending on the market. Every action is conducted in such a way as to achieve the optimum animal and financial advantage.

The cattle and facilities may be totally owned by the owner of the feedlot, who buys and sells the cattle and assumes total responsibility for the management of the production and health of the cattle. In "custom" feedlots, the owner of the cattle makes a contract with the owner of the feedlot, who assumes total responsibility for managing the production and health of the cattle for a predetermined fee. The owner of the feedlot does not participate directly in any profit or loss.

The modern feedlot in North America has become a highly mechanized, well-organized, highly financed enterprise. Capacities range from 1000 to 130,000 head and higher, with at least two throughputs per year. Feed processing and feeding systems are highly mechanized, automated, and computerized, and rations can be changed on short notice by on-site feed mills. Specialized personnel process the feed, pen checkers monitor the animals regularly for illness, and a treatment crew is responsible for treatment of sick animals and the processing of cattle on arrival. Certain pens are allocated for new arrivals, and hospital pens are available for segregation of sick animals. Detailed records are kept of morbidity, mortality, treatments given, and production performance. Detailed financial records of each item of production are kept so that aberrant variations can be examined and corrected if possible (Brennan and Hoffman, 1989; Lechtenberg et al, 1998).

Downloaded from Vet-e-Books.com

There must be a variety of options in the manner in which feedlots are operated, depending on availability of cattle and feed; the options may vary in a particular locality from time to time. However, the final stage in any beef feedlot operation is a period of intensive feeding on a carbohydrate-rich diet to finish the cattle with a light cover of fat on the carcass and deposition of fat in the muscle tissue itself (marbling).

The traditional permanent feedlot has a number of options. Cattle are bought at various ages, and the economics of the various situations are different. Young cattle may be bought at 6 months of age, immediately after weaning, when they may weigh 400 to 700 lb (180 to 320 kg); they are either fed intensively until they weigh 1200 lb (550 kg), usually at 14 to 16 months. Alternatively, they may be fed roughage at slightly above maintenance levels through the winter months (stocker phase), then placed on pasture until they are about 14 months old and weigh 750 to 900 lb (340 to 400 kg), when they are put onto heavy grain feeding. In areas where wheat pasture is available, economical gains can be achieved through the fall and winter months.

When older cattle are brought in—usually yearlings weighing 600 to 900 lb (275 to 400 kg) at 12 to 18 months of age—they are normally stepped up to the final finishing rations within 2 to 3 weeks of arrival and may spend from 90 to 150 days on feed. The objective in the feeding strategy program is to achieve a growth rate of 3 to 4 lb/day (1.4 to 1.8 kg/day), which adds 300 to 600 lb (135 to 273 kg) of body weight. In terms of feed the objective is to put on these weights using 5 to 7 lb (2.3 to 3.2 kg) of ration on a dry matter basis per pound of weight gain. Levels of concentrate in the finishing diet will vary from 75% to 90%.

In heavy grain feeding programs, special disease problems are related to abnormal digestion, especially lactic acid indigestion and bloating. Careful feeding management is necessary to avoid losses from these diseases.

The key to managerial success in feedlot feeding is being able to get cattle onto full feed quickly without causing losses from lactic acid indigestion. Details of recommended feeding programs are given later in the section on disease prevention. Because of the pressure to improve the economy of lot feeding, there is a constant search for low-priced, carbohydrate-rich feeds. As a result the use of by-products, particularly corn by-products, in the rations of feedlot cattle has dramatically increased.

Farm Feedlots

Small farm feedlots that feed between 100 and 1000 animals annually still account for a significant part of the feedlot industry in North America. Cow-calf enterprises with between 100 and 300 to 500 cows may retain some steers and heifers and feed them to finish for market directly on the farm. In some cases the owners will purchase between 50 and 300 to 500 feedlot calves from public sales yards and add them to the farm feedlot. The feeds used include cereal grains and corn silage, and mixtures of a variety of roughages depending on availability. The animal health management needs of these farm feedlots are similar to those of larger feedlots, although they are not of the same magnitude.

Backgrounding for the Feedlot

Backgrounding is a feeding enterprise in which recently weaned calves are grown to yearling feeder cattle weight, usually in a smaller feedlot. The principal objective is to prepare cattle to adjust to a high-energy finishing ration in a feedlot with minimal health problems. This is achieved by feeding the calves a growing diet that yields rapid, efficient body weight gains without fattening. Maximum use is made of roughage-type diets. The spectrum of diseases that occur in backgrounding enterprises during the first 45 days after arrival of the calves depends on whether the calves originate from one or many different sources and on whether they have been preconditioned or immunized before arrival.

Beef Feedlots in Australia

Beef feedlotting in Australia has begun to develop and resemble that of North America (Moore, 1990). Capacity growth since the late 1960s has been generated primarily because of demand for beef from Japan and, more recently, Korea, from major supermarket stores domestically, and from the hotel and restaurant trade. Until relatively recently, the scale of operations in Australia has been smaller than that in North America, but many of the principles have been the same. These include facilities located in grain-growing areas; preference for low rainfall areas; facilities located within a reasonable distance of abattoirs; and good water as an essential element. The feedlot industry developed as a way to ensure consistent quality of beef for domestic use, but the dependency on pasture-fattened cattle was a problem because of the vagaries of Australian weather patterns, particularly drought; the ready availability of grain; and the ability to meet market demands. Feedlot capacities have grown from a range of 1000 to 8000 head to greater capacities of 30,000 to 60,000 today. The current capacity for Australian feedlots is somewhat greater than 750,000 head of cattle.

"Barley-Beef" Units in the United Kingdom

In the British system cattle are introduced to the units when they are 3 months old and weigh 200 to 220 lb (90 to 100 kg). The objective is to market them at 800 to 900 lb (360 to 400 kg) before they are 12 months old. The capitalization per place in the unit is very small. Because the units are relatively small and house relatively few animals (about 50 to 100 head), little money is spent on sophisticated machinery, milling, or feeding out. Feed is provided by private feed supply companies, which have grown enormously in the United Kingdom since the 1960s. They provide custom-mixed rations, and therefore the feed is a much greater expense than in the United States. The other noticeable difference between the barley-beef and the American "permanent" feedlots is the need in the latter to push animals through an intensive feeding period quickly to utilize highly capitalized cattle space to the fullest. Therefore in these lots there is an average of 2.5 throughputs, whereas in a barley-beef unit, where the pressure of capitalization is not nearly as great, one throughput per year is the average.

A similar system is common throughout eastern and western Europe and in Japan. The number of animals in an individual unit is usually quite small, and the intensity of the feeding program is usually inversely proportional to the number. Male castrates of the local indigenous, dual-purpose breeds are used and are allowed to grow as heavy as 1500 lb (680 kg) on very heavy grain rations, supplemented with a great variety of additional growth stimulants, including beer. Particular emphasis is placed on maximizing the amount of lean meat in the carcass. The

Downloaded From Vet-e-Books.com

animals are maintained indoors in small groups for the feeding period, with manure and urine disposed of through a slatted floor or by way of a deep litter system (Allen et al, 1982).

OBJECTIVES OF A HEALTH MANAGEMENT AND PRODUCTION PROGRAM IN THE FEEDLOT

The general objectives of a planned animal health and production program in a feedlot include the following (Church, 1980):

1. Rapid growth rate, minimum of fat at an acceptable slaughter weight, and moderate size at maturity. This is achieved by purchasing cattle with the genetic potential for rapid growth and leanness.
2. Maximization of feed conversion efficiency through the use of growth promotants, formulation of economical rations, effective feeding techniques, effective parasite control, and culling of animals with chronic diseases that are refractory to treatment.
3. Reduction in morbidity, mortality, and culling rates. This requires the purchase of cattle in good health by cattle buyers who know what they are buying. It also requires an effective processing and introductory system that minimizes the incidence of disease as well as animal attendants who can detect and treat clinically affected animals in the early stages of disease. In most instances it requires a reliable record-keeping system using a computer that provides useful information on a daily basis and a simple protocol for the clinical management of sick cattle.
4. Optimization of expenditures for biologicals and antimicrobials used for the control and treatment of disease. This can be done by avoiding unnecessary use of vaccines, anthelmintics, and prophylactic antimicrobials and by treating sick animals as early as possible with the most cost-effective drugs. Long-acting antimicrobials may be used when the morbidity rate is increasing in a new pen of cattle. Treatment response and relapse rate should be monitored and changes made in treatment protocol while avoiding unnecessary treatment and educating animal attendants on the proper use of vaccines and drugs used in the feedlot. In refractory cases, treatment should be discontinued and the animals culled.
5. Maintenance and improvement of employee motivation to provide good animal management and early detection and treatment of sick animals. Animal attendants must be made to feel that they are part of an important team providing animal health care. Such care should be evaluated regularly and the results shared with the attendants; education and communication are vital.
6. A profit commensurate with other investment opportunities. The veterinarian must be aware of the degree of risk aversion in the client.
7. The production of wholesome beef free of chemical residues. This requires reliable individual animal identification, reliable record keeping and cross-referencing before shipment, limited extra-label drug use, and use of drugs with a short withdrawal period on animals near slaughter weight.
8. Because of the large number of animals in a feedlot, a well-operated program with a good record system allows the veterinarian to conduct clinical research on a variety of drugs, particularly antimicrobials and vaccines. Manufacturers of drugs and vaccines view the feedlot as an excellent opportunity and facility in which to conduct clinical research on new products, which is needed for licensure for sale.

STANDARDS FOR HEALTH AND PRODUCTION PERFORMANCE IN THE FEEDLOT

The major factors that influence profit or loss in the feedlot are the price of the purchased cattle, the total cost per unit of body weight gain, and the selling price of finished cattle. There are fluctuations in the costs of feed, which may affect net profit, but major fluctuations in the costs of feeder cattle and the selling price of finished cattle lead to major changes in profit and loss. The individual feedlot operator has no direct control over the price of cattle, and net profit depends on a gross margin that is large enough to offset costs. A decrease in the selling price of cattle can lead to major economic losses; in these conditions, even the very best health and management program cannot lead to a profit, but it can reduce the magnitude of the losses. Conversely, a marked increase in the selling price of cattle usually causes large increases in net profit in spite of an unusually high incidence of disease and mortality in a particular group of cattle. In such cases, disease appears to be insignificant. In fact, in most well-managed feedlots, the waste resulting from disease appears to be relatively small compared with that from other causes. Some of the factors that affect the occurrence of disease and profit are presented in the discussion on the epidemiology of diseases of feedlot cattle. These factors are generally well known to feedlot managers. As a consequence the veterinarian serves as an advisor on the treatment and control of disease, with feedlot-specific advice and implementation. Because management, nutrition, environment, and economics have a close interrelationship with disease, the veterinary consultant to a feedlot must be familiar with each of these disciplines. If veterinarians become involved to a large degree, they may find themselves fitted for the role of manager. This has actually happened in some of the very large feedlots. The most important factor governing the efficiency and success of a feedlot herd health program is the veterinarian's depth of knowledge regarding the managerial factors that form the basis for good cattle health.

Other factors that affect the herd health service include not only the efficiency of the feedlot employees, but also the degree to which they can be motivated by management and the veterinarian. Reliable identification of animals as groups and accurate identification when they are treated—preferably by ear tag—are important. Keeping the cattle together as groups so that their subsequent performance can be traced back to their origin and to their handling during the conditioning period is also important. Proper hospital yards and chutes are needed to permit adequate handling for prophylactic and therapeutic procedures.

Production and Disease Targets in the Feedlot

There is only a limited amount of published, documented information available on the standards of health and performance that should be expected and aimed for in a well-managed commercial beef feedlot. Most feedlots record the details for their cattle on a group or pen basis. These data (pen closeouts) usually include the total weight and costs of cattle going into the pen, the total amount and costs of the feed consumed, the total number of animals (live and dead), the total costs of prophylaxis and treatment, and the total weight and selling price of cattle leaving the pen for market. From these records it is possible to assess the health and production performance. The standards for health and performance and the definitions of morbidity and mortality rates that

Downloaded from Vet-eBooks.com

are set out below are guidelines only; these will have to be modified according to the prevailing conditions in each feedlot.

Assessment of General Efficiency

Average daily gain

= (Total weight gained by group (kg)/Number of cattle)/Days on feed

= Not less than 1.2 kg/Day (2.7 lb/day)

Efficiency of feed conversion

= Total feed to group (kg)/Body weight gained by group (kg)

= <7.0

Costs per kilogram of body weight gain are variable, but in the United States they vary from $1.00 ($0.45/lb) to over $1.45 ($0.65/lb) of gain.

Definition and Assessment of Disease Statistics

Case Definition. A review of the literature regarding the methods by which the feedlot industry calculates and reports the occurrence of disease reveals that case definitions are often poorly defined and mostly are based on chemotherapeutic treatment as a criterion. If the animal was identified as being ill and was treated, it was included as a case for calculation of the morbidity rate (Kelly and Janzen, 1986). Thus "treatment" was used as a case definition, and the morbidity rates calculated could be called "treatment rates." Case definitions should always be stated clearly (Kelly and Janzen 1989; Perino and Apley, 1998). However, even though a case definition may be stated clearly, it may not be diagnostic. For example, a case definition for undifferentiated bovine respiratory disease in feedlot cattle may be any animal that appears depressed, has an increased respiratory rate, is removed from the pen, and, on cursory clinical examination, has no evidence of nonrespiratory disease and a body temperature of more than 40° C (104° F) and, is treated with an antimicrobial. Thus it will become part of the morbidity statistic, but it should really be part of the treatment rate. This case definition is not diagnostic, and one or more signs and symptoms may be used as treatment criteria. This means that a depressed animal may be counted as a case the same as an animal that exhibits all of the signs and symptoms. While this definition is clear enough and may be used for comparison from one day to the next, comparisons between feedlots using these criteria may have some agreement but should not be assumed to be exactly alike.

Morbidity and Mortality Rates

There is considerable misuse of morbidity and mortality statistics in North American feedlots (Kelly and Janzen, 1986). The simplest way is to calculate the incidence (cumulative) rate of morbidity in a group of animals. This is done by counting the animals that develop an illness over a period of time (cases) and dividing this number by the total number of animals in the group at the start of the time period. If the population at risk changes, an average may be used for the denominator. The cumulative incidence measures the chance of a randomly selected animal contracting disease during a specific period. Alternatively, the incidence rate is calculated as the number of new cases during a certain period divided by the sum of the time units at risk. The result is a measure of the rate at which the group became ill (e.g., the number of animals sick/animal-week at risk) (Noordhuizen et al, 1997).

The mortality incidence rate is similar, but deaths are counted as cases. The population at risk should be measured precisely, and only those animals that are biologically capable of suffering the disease should be included in the denominator. Because of problems with relapses, when an animal becomes ill with disease, it is conventionally considered to be no longer at risk. The period of observation must be either stated or incorporated into the rate units as above. The principle of using the precise sum of animal-time at risk can be used to any degree of precision (e.g., daily tally intervals instead of weekly) (Kelly and Janzen, 1989). The method is of special relevance to veterinary epidemiology, because large changes in population are common in farm animal situations, and precise records of the changes are often available because of the importance of head counts in agriculture.

There are wide variations in the record-keeping systems used by different feedlots. Most custom feedlots use their records primarily for accounting rather than to evaluate disease. The following definitions can be used to record disease on a monthly basis:

Disease Incident Rate. This incidence describes the number of new cases in a population over a specified period: (number of new clinical disease cases during the month/the number of animals at risk of developing disease during the month) × 100. For example, cattle are at the greatest risk for developing respiratory disease during the first 3 to 4 weeks after arrival, thus cattle received during the month of interest would be included in the denominator. The consultant is interested in the yearly cumulative morbidity rate, and this rate can be found by adding each month's cumulative incidence over a year's time. Alternatively, the total number of pulls (years' time) divided by the total number of received cattle for the year also gives this number. In addition, it is usually of value to know the disease incidence rate by pen.

Death Rate. Death rate can be expressed through this equation:

(Number of animals that died during the month / Average number of animals on feed during the month) × 100

Culling Rate. This is the percentage of animals culled because of chronic illness or inferior performance before the fattening period was completed. It will usually be approximately the same as the annual mortality rate. Culling rate can be expressed through this equation:

(Number of animals culled during the month / Average number of animals on feed during the month) × 100 (Frank et al, 1988)

The system should allow the development of a validated baseline of animal health data for feedlots.

The peak incidence of disease in feedlots in North America occurs soon after the calves arrive in the feedlot. Between 15% and 45% of incoming calves require treatment, and from 1% to 5% die (Kelly and Janzen, 1986). In yearling cattle these numbers will range from 5% to 11%, and death loss will be from 0.5% to 1% (Edwards, 1996).

Annual Population Mortality Rate. The annual population mortality rate is the percentage of the entire population in the feedlot that died during the year. A common standard is 1% or less, with a feasible target of 0.5%. Mortality rates less than this in the feedlot are uncommon because high-energy diets contribute to digestive disturbances and losses, but the rates are accepted as a trade-off for improved performance. Some feedlots report losses of 3% to 4% annually. However, the losses depend primarily on the age and kind of cattle that are purchased and fed. Annual population mortality rates may reach 5% when feeder calves 6 to 8 months old and weighing an average of 500 lb (225 kg) are placed in the feedlot. The population mortality rate for yearling cattle placed in the feedlot and weighing an average of 800 lb (375 kg) is as low as 1%.

Downloaded From Vet-e-Books.com

Relapse Rates. The total number of animals that became ill after one or more courses of treatment and the number of times they relapsed should be calculated separately. The relapse rate varies from 5% to 50% but will often be 15% to 20%.

Epidemic Curves. A graph showing the changes in morbidity or mortality rate with time is called an epidemic curve. It displays the dynamics of disease activity in a population and provides a basic epidemiological description (Kelly and Janzen, 1986). The regular occurrence of a disease peak soon after cattle arrive at a feedlot suggests a point source factor, such as stress induced by transportation, feed or water deprivation, the effects of mixing, and fatigue. This is in contrast to a propagated epidemic associated with a contagious disease in which new cases are spread out over a much longer period.

Health and Disease Costs. These are the total costs of health and disease, including the value of dead animals and the costs of prophylaxis and treatment. The total health and disease costs are expressed as a percentage of the total costs per unit of body weight gain per day.

CAUSES OF ECONOMIC LOSS IN THE FEEDLOT

The causes of economic loss in the feedlot vary considerably. The broad factors that influence optimum production and cause economic loss when unsatisfactory include those found in Box 14-1.

The veterinarian will have more impact on health management and disease losses in the feedlot than other areas; therefore this area deserves the most discussion. A thorough understanding of the impact of disease on animal performance and economic loss is essential in order to make cost-effective recommendations to feedlot managers. In 1968, Pierson said, "The hidden loss (due to shipping fever) sometimes exceeds the calculable loss. The hidden loss refers to the chronic poor doers that fail to gain and take much longer to grow to marketable size" (Pierson, 1968). This is still true today. The cost of death loss, chronic cattle marketed prematurely at a discount, and treatment costs are obvious and easy to calculate. Hidden costs, such as reduced performance and lower carcass quality, are often overlooked.

Mortality is an important economic loss in feedlots. Mortality rates can be expressed in two ways: as a percentage of monthly inventory (occupancy) and as a percentage of cattle received. The latter figure is calculated at "close-out," or when the cattle are sold. Calculating the mortality rate each month as a percentage of average inventory allows timely monitoring of trends in mortality. When the monthly mortality rate increases, management adjustments can be made more quickly than when mortality is monitored only at the end of the feeding period, or at "close-out." Mortality expressed as a percentage of inventory is lowest during April, May, and June and highest in November and December. On average, 0.268% of cattle die each month in feedyards; in other words, an average of 27 out of each 10,000 on feed die each month. Most death loss is caused by respiratory disorders and ranges from 0.072% in April to 0.234% of inventory in November. Digestive death losses are highest in November, December, and January, and average 0.061% of monthly inventory. Miscellaneous, or "other," death losses average 0.078% of monthly inventory (Vogel and Parrott, 1994).

The death rate for Holstein feeder steers is higher than beef breeds of cattle. In one report, the monthly mortality rate for Holstein steers averaged 0.419% of inventory compared with an average of 0.268% for beef cattle. A higher proportion of deaths in Holstein feedlot cattle, compared with beef cattle, is due to digestive disorders.

When calculated at "close-out," annual population mortality in well-managed feedlots feeding mostly low-risk cattle ranges from 0.57% to slightly over 1.0% of cattle received (Edwards, 1996). Higher rates are frequently seen (Kelly and Janzen, 1986). Age, size, source of cattle, previous management, and amount of commingling have a great influence on the health problems and the death rate that cattle will experience at the feedlot. About 60% of the deaths occur after cattle have been on feed greater than 45 days. Whereas deaths early in the feeding period are caused primarily by respiratory diseases, those occurring after 45 days on feed are more likely caused by digestive disorders (Edwards, 1996). Mortality rates in smaller feedyards are higher than in large (40,000+) feedyards (Vogel and Parrott, 1994). The reason for this is unknown but is possibly related to type of cattle received (low versus high risk), average number in each group received, labor availability, and location of smaller yards as compared with large feedlots.

Treatment costs are another source of economic loss. Factors influencing the average cost include the morbidity rate, retreatment rate, cost of the drug(s), combination versus

BOX 14-1

Causes of Economic Loss

MARKETS
The cost of cattle and the selling price have the most dramatic effect on the profit or loss resulting from feeding cattle.

NUTRITION
The quality and adequacy of the feeds and feeding systems used have a major impact on growth rate and feed efficiency.

TYPES OF CATTLE FED
Prior nutrition, genetic background, weight, age, and sex of the animals fed influence growth rate, feed efficiency, and carcass quality.

ENVIRONMENTAL EFFECTS
Because feedlot cattle are usually kept in confinement, often with a high stocking density, the effects of environment may interfere with optimum production. Weather impact on performance is greatest during a very cold, wet winter.

MANAGEMENT EXPERTISE
As in any livestock enterprise, the level of management is important. Most of the success of a herd health program depends on the people feeding the cattle, early identification and treatment of sick cattle, and accurate record keeping of daily activities. In large, modern feedlots, management of personnel becomes one of the highest priorities.

DISEASE
Disease may cause economic loss through mortality, treatment costs, or effects on productivity. The impact of clinical and subclinical disease on productive efficiency and economic returns may be greater than the losses associated with mortality.

Downloaded from Vet-eBooks.com

single antimicrobial therapy, whether or not adjunct therapy is used, labor, and feedlot markup on the products used. Many feedlots also charge for a chute fee for treating the cattle. Treatment costs are frequently $21 to $23 (U.S. dollars)/animal treated. The morbidity rate has the strongest influence on the average treatment cost for all cattle in the pen. When metaphylaxis is used to manage bovine respiratory tract disease (BRD), it must be added to the total medical cost for the pen.

Respiratory disease has a dramatic effect on the performance of feedlot calves. The reduced daily gain, and subsequent lower market weight, are not obvious to the observer but rather must be measured. Many studies have reported an association between BRD and losses in daily gain. Unfortunately, less is known about the impact of disease on feed efficiency because of the impracticality of measuring it in most field trials. Loss of daily gain after respiratory disease is greatest in the 28- to 30-day receiving period. These differences tend to narrow as days-on-feed increase, but treated calves seldom achieve daily gains of penmates that were not sick. During the first 28 to 30 days on feed, calves with clinical BRD will gain from 0.30 to 0.50 lb (0.14 to 0.23 kg)/day less than penmates that remain healthy (Bateman et al, 1990; Van Donkersgoed et al, 1993; Smith, 1997). At "closeout," differences in gain range from 0.14 to 0.56 lb/day (0.06 to 0.25 kg/day) (Bateman et al, 1990; Texas A&M Ranch to Rail Summaries, 1992-1999).

When cattle relapse with BRD and require a second or third course of therapy, the impact of disease on daily gain is much more significant than the initial episode. At 90 days on feed, a Canadian feedlot study (Morck et al, 1993) showed that cattle sick and treated for BRD once gained 0.39 lb (0.18 kg)/day less than healthy penmates, whereas those that had relapsed gained 0.73 lb (0.33 kg)/day less. Other studies have shown similar effects (Van Donkersgoed et al, 1993). The loss of daily gain associated with BRD results in less saleable weight at the end of the feed period. The economic loss is significant and is magnified if there is an accompanying loss of feed efficiency.

Cattle that are sick and treated return $49.58 to $118 (U.S. dollars) less than cattle that remain healthy throughout the feeding period. The losses include medical costs, reduced performance, increased death loss and culling rate, and reduced carcass quality grade. Based on arrival weight into the feedlot, cattle that become sick are worth from $8.65 to $19 (U.S. dollars) per hundredweight less than cattle that remain healthy (Texas A&M Ranch to Rail Summaries, 1992-1999).

Buying "bargain cattle," such as bulls instead of steers, heifers of unknown pregnancy status, or cattle that have been severely malnourished for an extended period, can cause further economic loss to the cattle owner. These higher risk and often poor performing cattle may provide a good economic return if sufficient purchase discounts are applied. The veterinarian must be able to provide science-based advice on the true value of higher risk cattle. Management of bulls and pregnant heifers is discussed elsewhere in this chapter.

EPIDEMIOLOGY OF DISEASES IN FEEDLOT CATTLE

In its broadest terms a study of the epidemiology of diseases of feedlot cattle would include a description of disease statistics (e.g., morbidity, case fatality, and population mortality rates); the prevalence of the major diseases; the age and seasonal incidence of the economically important diseases; and the epidemiological determinants such as the characteristics of the host, the environment, and the causative agent leading to subclinical or clinical disease. The economic losses associated with feedlot disease include losses from deaths, costs of treatment of animals with clinical disease, potential decrease in carcass of quality grade, and losses from suboptimum performance resulting from both clinical and subclinical disease.

Only a small amount of documented information is available on the epidemiology of feedlot diseases. More knowledge is needed regarding the frequency, epidemiological determinants, and economics of feedlot disease in order to develop animal health management programs that are geared toward the most economically important diseases.

The morbidity rate, case fatality rate, and population mortality rate associated with disease in feedlot cattle vary among feedlots and depend on several factors. Mortality rates are higher in beef calves 6 to 8 months old (2% to 4%) than in yearling cattle (0.5% to 1%). Seventy percent of the morbidity occurs within the first 45 days in the feed lot, whereas only 40% of deaths occur during that same period (Edwards, 1996).

A graph illustrating the changes in morbidity or mortality rate with time is called an epidemic curve (Fig. 14-1). Such a curve displays the dynamics of disease activity in a population and provides a basic epidemiological description. This information is valuable in a feedlot because it allows the veterinarian to formulate control and treatment strategies for some economically important diseases (e.g., respiratory disease). For example, it was thought for many years that shipping fever occurred in feedlot cattle 7 to 14 days after arrival. This was generally true if the affected cattle were shipped directly from the ranch to the feedlot. However, with auction market-derived calves, the epidemic curve for shipping fever shifts left, and the peak occurrence of respiratory disease is much earlier, as early as 4 to 6 days (Fig. 14-2). This suggests that auction-market calves are in the incubation stages of the disease when they arrive in the feedlot because they have been subjected to weaning, transportation, mixing, and feed and water deprivation, in contrast to calves received directly from the ranch that require several days to become ill. When antimicrobial metaphylaxis is used at arrival processing, peak occurrence of clinical respiratory disease in high-risk calves shifts to the right, usually to between 10 and 15 days after arrival (McClary and Vogel, 1999).

The most economically important diseases of feedlot cattle are infectious diseases and diseases associated with intensive feeding of high-energy diets. There are several epidemiological determinants that are usually associated with diseases of feedlot cattle. The animals are usually young (7 to 15 months old) and often have originated from several different sources and thus have unequal acquired resistance to infectious disease, especially respiratory disease. Respiratory disease accounts for 75% of illnesses and 45% to 55% of the population mortality in large feedlots (Edwards, 1996).

The incidence of fatal fibrinous pneumonia is strongly associated with the number of calves per farm on each truckload arriving at the feedlot. This is commonly referred to as commingling or pretransit mixing (Alexander et al, 1989; Ribble et al, 1995b). A high percentage of calves in North America are produced on smaller farms and ranches. When taken to auction markets, calves are sorted by gender, weight, type, and quality before being sold. This further increases the amount of commingling necessary in order to assemble truckload lots of uniform calves.

Season of year is correlated with respiratory morbidity and mortality rates. The highest occurrence of fatal fibrinous pneumonia is in November and December. During the fall season there is also an increase in the number of calves at

Downloaded from Vet-e-Books.com

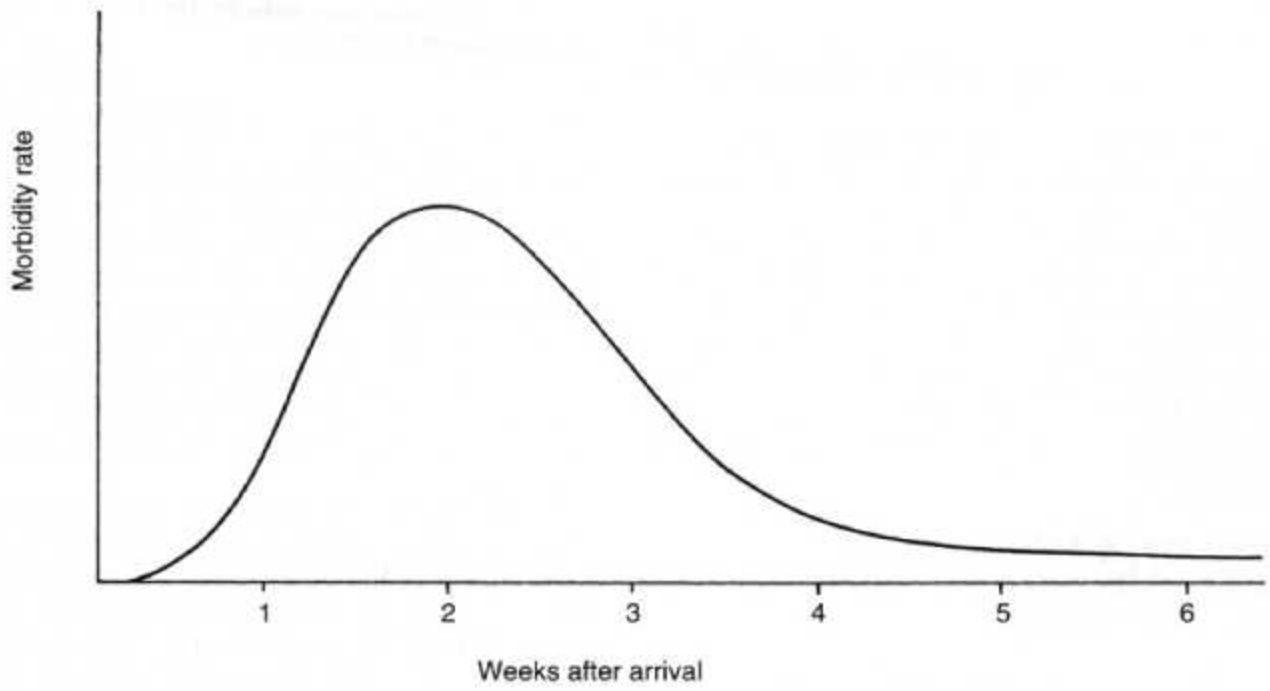

FIG. 14-1 Epidemic curve.

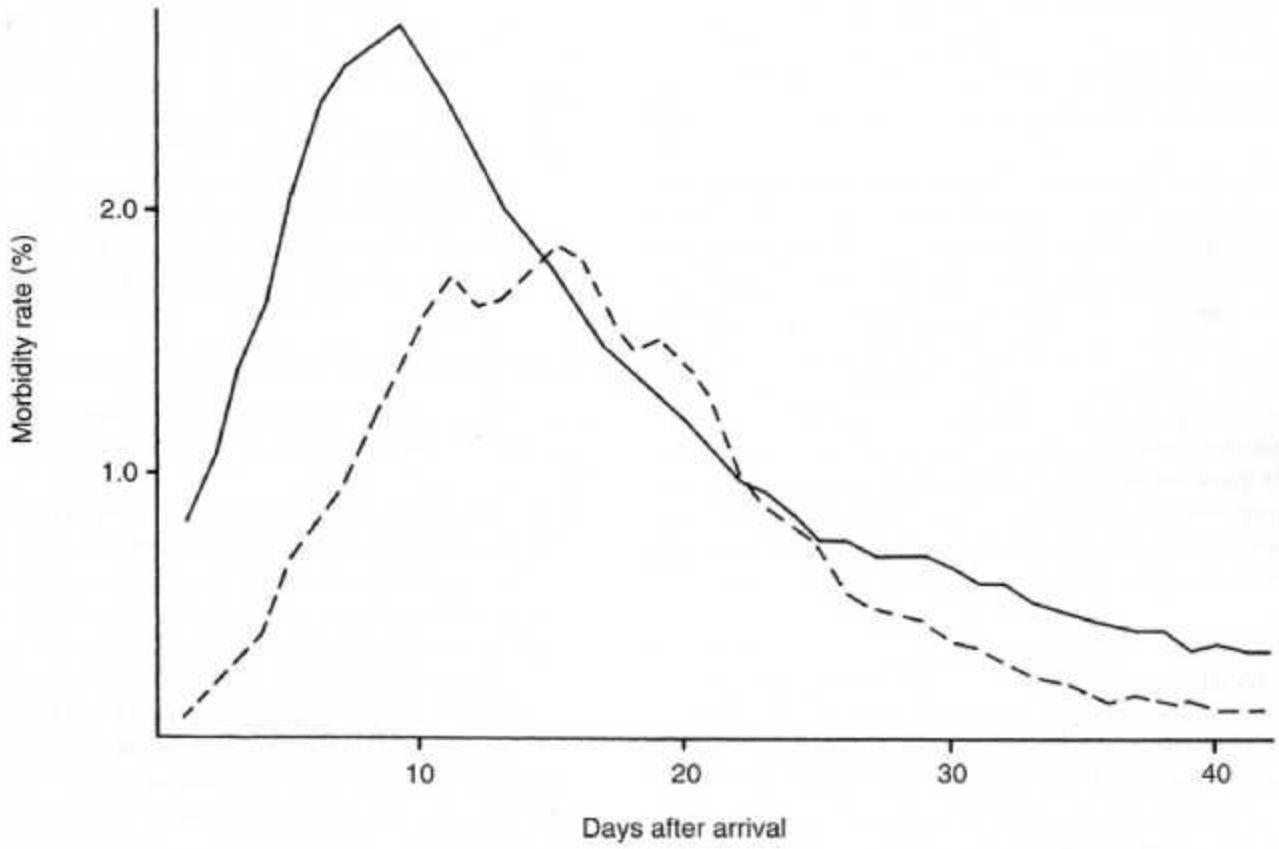

FIG. 14-2 Summary of epidemic curves for 74 groups of auction mart–derived calves (solid lines) and 23 groups of ranch-derived calves (dashed lines). (From Kelly AP, Janzen ED: *Can Vet J* 27:496-500, 1986.)

the auction markets and feedlot receipt of calves' peaks. During this period, feedlot hospitals become crowded and acute cases of respiratory disease are exposed to chronic cases (Ribble et al, 1995a; Vogel and Parrott, 1994).

The incidence of respiratory disease is higher in auction-origin cattle than in ranch source cattle (Wilson et al, 1985). This difference is magnified in the fall of the year when a greater proportion of calves enters the feedlot. The incidence of respiratory disease is higher in steers than in heifers. Heifers that are pregnancy checked are at greater risk of respiratory disease than those not palpated (Alexander et al, 1989). The reason for this is unclear; perhaps the stress of handling and palpation increases susceptibility to respiratory disease, or, more likely, feedlots are more likely to pregnancy-check groups of heifers that are at higher risk of developing respiratory disease.

Other minor diseases of the respiratory tract that occur in feedlot cattle include atypical interstitial pneumonia in yearling cattle (Jensen et al, 1976a), bronchiectasis in yearling cattle (Jensen et al, 1976b), brisket disease in yearling cattle

Downloaded from Vet-eBooks.com

that had previously grazed on mountain ranges (Jensen et al, 1976c), embolic pulmonary aneurysms in yearling cattle (Jensen et al, 1976d), diphtheria, and tracheal edema, or "honkers."

Bulling among steers, an abnormal behavioral trait, is a common health and economic problem in feedlot operations. Riders simulate males, and bullers simulate females. Bullers sexually attract the riders, which repeatedly mount and physically injure the bullers. Although this behavior may continue until the bullers become exhausted, collapse, and die, the main economic loss results from physical injury, stress to both buller and rider, and the necessity of early isolation of the affected animals. The prevalence of bullers generally averages 2% to 3% of a feedlot population (Taylor et al, 1997; Edwards, 1995).

COMPONENTS OF A HEALTH MANAGEMENT AND PRODUCTION PROGRAM IN A FEEDLOT

The continued profitable success of a modern feedlot is dependent on the right combination of good management, a favorable economic climate, and relative freedom from unfortunate occurrences such as epidemics of disease or unexpected increases in the costs of inputs (e.g., feed) or decreases in the price received for the final product. Success is heavily dependent on the cattle buyer, the animal attendants, the nutritional consultant, the veterinarian, and the manager of the feedlot, each assuming his or her individual responsibilities and doing the best work possible. In recent years, feedlot veterinary medicine has become a specialty discipline.

Veterinary medicine has been slow to meet the challenge of the feedlot industry. One major reason has been its preoccupation with the diagnosis and treatment of individual sick animals. As feedlots became larger and more sophisticated, it became obvious that knowledgeable animal attendants could successfully and economically diagnose and treat the common diseases of feedlot cattle. Veterinarians were thus used less routinely and were called only when alarming epidemics occurred that did not respond to the usual treatment procedures or in which the feedlot personnel could not make a diagnosis. This has changed, and more feedlots are recognizing the value of constant surveillance by a veterinarian who has specialized in feedlot veterinary medicine.

The successful feedlot veterinarian has a broad concept of disease in the feedlot and does not restrict the definition simply to sick animals. The concept of disease should include all of the identifiable factors that cause suboptimum performance: inadequacies in feeds and feeding systems, the purchase of undesirable types of cattle, and clinical and subclinical disease. The overwhelming majority of the veterinarian's continuing education efforts must be directed toward topics that directly benefit feedlot clients.

Relationship Between Veterinarian and Feedlot Personnel

The respective roles of managers, animal attendants, and the veterinarian must be understood, agreed on, and respected by each party.

Responsibilities of the Feedlot Manager and Animal Health Technician

The responsibility of the feedlot manager is to coordinate the animal health and production activities of the feedlot, using advice obtained from the veterinarian, the nutritional consultant, and any others deemed necessary. The manager must supervise animal health personnel, whose major responsibilities include the identification and treatment of sick animals and the processing of new arrivals.

Close surveillance of all animals in the lot must be maintained once daily (or, in recently introduced animals, twice daily) to detect illness in the earliest stage possible, when therapy is more likely to be successful. Without efficiency in this activity, the remainder of the program is largely pointless. The people who work all day in the feedlot know the cattle and are good livestock personnel. They become very efficient at identifying sick animals. The consulting feedlot veterinarian must remain as good as or better at disease detection than the crew he or she is responsible for training.

Segregation and treatment of sick animals are necessary. The number of diseases likely to be seen in any one feedlot is relatively small, and many of them can be identified easily by a watchful livestock attendant, especially if he or she has been trained properly by the veterinarian. The manager must stay alert for an unusual increase in the incidence or manifestation of a disease.

Managers must supervise the feeding procedures to be used throughout the feeding cycle, especially during the 3-week induction period—a period directed at preventing disease—after the cattle come into the lot. The manager is also responsible for supervising the buying and selling of the cattle and the purchase and processing of feeds and other necessary supplies. Most important, the manager must communicate effectively with the animal health personnel, the veterinarian, and any other consultants. Effective communication is essential to solving problems.

The design of the data collection system and the recording of all health and production performance data are the combined responsibilities of the animal health personnel, the feedlot manager, and the consulting veterinarian.

Responsibilities of the Consulting Veterinarian

The veterinarian is responsible for maintaining optimum animal health through the following activities (Janzen, 1990i):

1. Makes regularly scheduled visits to the feedlot, is punctual, and stays as long as necessary for adequate consultation. The frequency of visits depends on the size of the feedlot, the time of year, the expertise of the feedlot personnel, whether animals have recently arrived, and the degree to which the veterinarian is contractually responsible for the total animal health program.
2. Is available for emergency visits to the feedlot when disease epidemics occur unexpectedly.
3. Performs necropsies during the visit and trains feedlot personnel to do necropsies at other times.
4. Examines sick animals with the treatment crew to ensure that reasonably accurate diagnoses are being made and rational therapy is being given according to the previously provided treatment protocol (Janzen, 1990d).
5. Regularly examines, analyzes, and interprets animal health and production data and periodically makes recommendations in a written report. The effectiveness of detection of sick animals, based on response and relapse rates and case fatality rates, should be determined, and the effectiveness of the processing program for new arrivals, which includes the vaccines used and the medications given, should be examined and analyzed regularly. The veterinarian is responsible for selecting and prescribing all drugs used in the lot, giving specific advice about the use of drugs, and establishing a drug residue avoidance program in the lot.

Downloaded from Vet-eBooks.com

6. Discusses overall animal health and production performance with the feedlot manager and other consultants. He or she coordinates the advice of other specialists, sets animal health and production goals, and monitors achievement.
7. Performs benchmarking with other operations. Produces a monthly report that compares processing costs, treatment costs, and death loss by arrival weight and days on feed for clients in the consultants practice (Miles, 1998).
8. Takes an interest in all aspects of the feedlot operation and makes an effort to be aware of new developments in the feedlot industry (Janzen, 1990c,e,g).

Involvement of the Local Veterinarian

In some cases the veterinarian providing consulting services to a feedlot may live a long distance away. When the consulting veterinarian is not readily available, the local practitioner can serve as a valuable resource for the feedlot. Serving as part of the feedlot's health care team, the local veterinarian can make significant contributions to the animal health program. Advantages to involving the local veterinarian include the following (Schwenka, 1998):

1. Availability on a day-to-day basis
   - Focus on the individual animal
   - Help troubleshoot any problems that arise immediately
   - Use consultant's suggestions and provide follow-up
2. Diagnostics
   - Perform necropsies or assist crew with necropsies as the need arises
   - Collect and prepare tissue for proper diagnostic evaluation
   - Advise as to the proper diagnostic test and laboratory work for various problems
3. Processing
   - Assist with developing a processing program that fits the regional area
   - Provide training for the processing crew
   - Provide a processing crew on a contractual basis
4. Treatment program
   - Assist with developing a treatment program
   - Provide follow-up for the treatment program
   - Provide day-to-day monitoring and training for the crew
5. Drug sales
   - Have opportunity to supply drugs
   - Write prescriptions or provide prescription drugs
6. Pregnancy checking

Adversarial relationships between the consulting veterinarian and the local veterinarian must be avoided. The team approach to providing veterinary services is beneficial to all parties involved.

Implementation of a Feedlot Medicine Program

It is a major challenge to implement a feedlot health management program. According to Jim and Guichon (1989), the critical areas that must be considered in the implementation of a successful production-oriented veterinary service to large feedlots include identification of appropriate clientele, acquisition of extensive industry knowledge, a fundamental change in the traditional veterinarian-client relationship, establishment of a framework for program evaluation, and a well-constructed action plan. The client served must want to be involved in profit-oriented feedlot production. The veterinarian must be knowledgeable about the daily operation of a feedlot; this knowledge includes an understanding of cattle procurement, marketing strategies, allocation of personnel, and performance parameters. The veterinarian must also be able to integrate that knowledge with knowledge of clinical medicine, pharmacology, pathology, and economics.

The principal objective of a feedlot health management program is to optimize production and maximize profit, which includes reducing death loss and drug expenditures. In the traditional system of veterinary practice the veterinarian did best financially when the morbidity and mortality rates were so high that the diagnosis could be made, the treatments given, and the drugs dispensed at a profit. Thus there was a potential for conflict of interest. A veterinarian consultant is paid to keep animals healthy. Under a consulting system, the veterinarian directs the animal health program and is paid for professional services in one of several ways. A common method to charge for consultation services is to charge a monthly fee, with both the veterinarian and the feedlot manager agreeing on the frequency of visits, the length of each visit, and the services to be provided. A second method of remuneration is to charge for professional services according to the number of animals in the feedlot over a certain period. With either of these two billing methods, the veterinarian becomes more intimately involved with the health and production problems of the feedlot. There is no time pressure because the charges are based on a preset amount and level of service. Some veterinarians charge for consultation services on an hourly basis. An inherent disadvantage of being paid by the hour is the tendency to rush through the consultation activities, trying to complete tasks as quickly as possible so as not to be perceived as taking advantage of the system. A consultant must have the freedom to use all the time necessary to evaluate the cattle and feedlot operations, to interact with feedlot personnel, to evaluate records in order to determine trends and possible problems, and to train people. Another disadvantage of this billing method is that the costs of consultation services are not predictable for the feedlot.

Most feedlot consultants do not dispense drugs. Many feedlot managers view dispensing as a conflict of interest and prefer that the consultant provide prescriptions (purchase orders) as part of their consulting service, freeing the feedlot to purchase animal health supplies elsewhere. If the consulting veterinarian chooses to dispense animal health supplies, he or she must be extra cautious when recommending products in order to avoid the perception of having an overly vested financial interest.

Program in Action

Constant Surveillance

Constant surveillance by both feedlot personnel and the veterinarian is required. The frequency of veterinarian visits to the feedlot will vary from daily to weekly or monthly, depending on the size of the lot, the management capabilities, the expertise of the animal caretakers, the type of cattle fed, and the nature and prevalence of diseases encountered. A veterinarian can provide several components of a feedlot health and management service; the details of each of these are described.

Regular Inspection

Regular inspection of all areas of the feedlot for possible sources or causes of health problems should be included in a feedlot health service. Errors in animal husbandry should be noted and recorded for discussion with personnel. Attention should be given particularly to the delivery of feed and water, the general well-being of cattle, and any unusual characteristics of each feeding pen. Many feedlot health problems can be attributed to errors in management.

Downloaded From Vet-eBooks.com

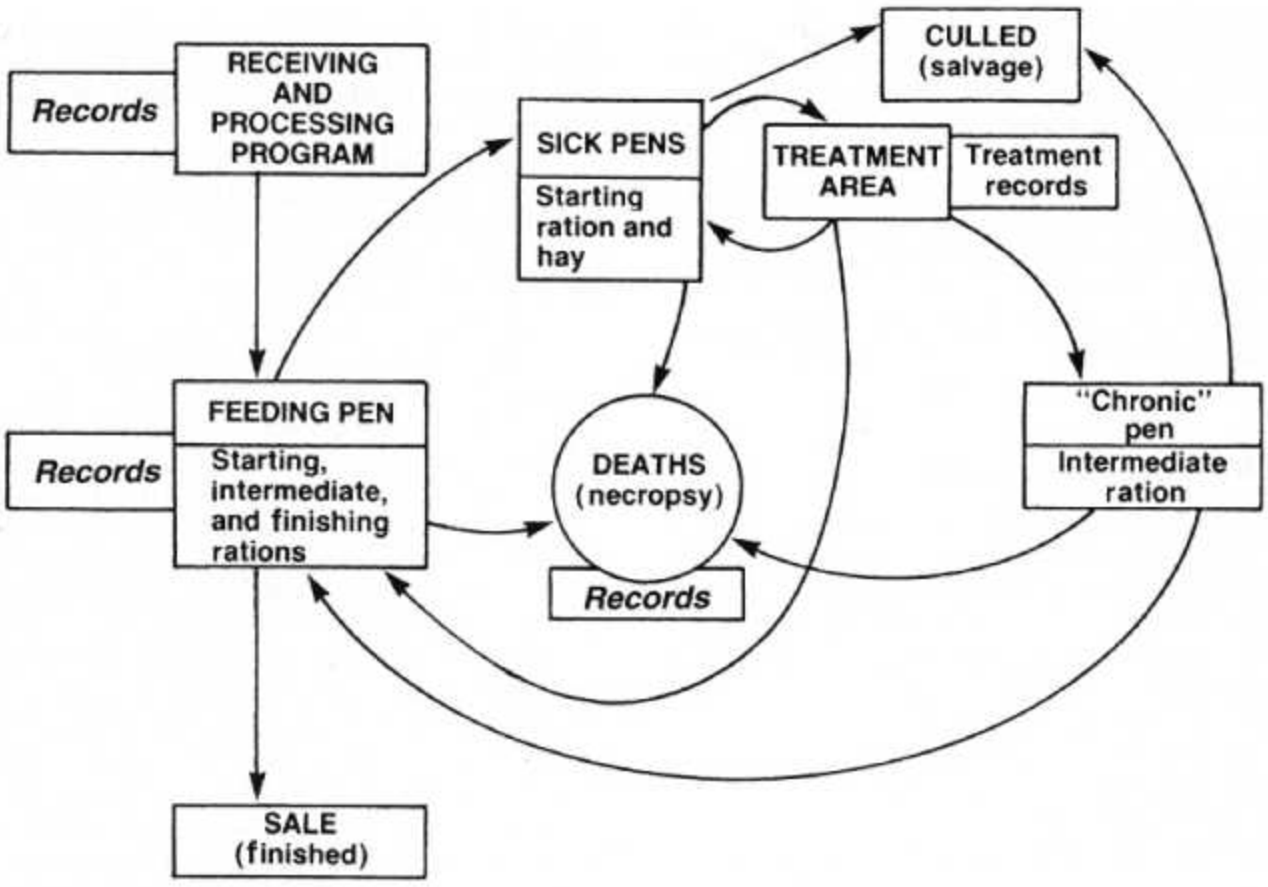

FIG. 14-3 Typical flow pattern of cattle in feedlots.

Disease Surveillance

Continued disease surveillance through regular necropsy examination of all dead cattle and regular observations of sick cattle are necessary. In areas with colder climates carcasses may freeze solid during the winter months before the veterinarian is available. Conversely, in areas with warmer climates, carcasses may decompose beyond usefulness during the hot seasons of the year. When distance prevents the consulting veterinarian from performing a necropsy on every animal that dies, the owner should be encouraged to employ a more accessible veterinarian to conduct regular necropsies. In many cases feedlot personnel can be trained to recognize many common postmortem lesions. Advantages include identification of diseases; confirmation of the clinical diagnosis; evaluation of the effectiveness of the various personnel involved with the health of the cattle, such as the buyer, truck driver, processing crew, pen checkers, treatment crew, feeders, manager, and veterinarian; and evaluation of the effectiveness of specific disease prevention programs and any necessary changes.

An often overlooked method of disease surveillance is monitoring of cattle in the packinghouse. One pharmaceutical company monitors the liver abscess rate for feedlots as a value-added service. The consulting veterinarian can further expand disease surveillance by establishing a relationship with packinghouse management and the government food inspectors so that they will understand the goals and objectives of the visit. When conducting routine packinghouse inspections of cattle for a client's feedlot, it is important to thoroughly understand the "do's and don'ts" allowed in the packinghouse. The primary mission of the packer and the inspectors is to produce wholesome and safe food. The consultant's activities must not and cannot compromise this. Griffin (1994) has described the conduct of routine inspections in a packing plant in detail.

A focal point in the management of disease in the feedlot is fast, accurate diagnosis. This requires a good surveillance system, a careful full-time search for sick animals, appropriate facilities for examination and treatment of sick animals, accurate identification of animals, and appropriate laboratory facilities, especially a necropsy service. A typical flow pattern in a feedlot is illustrated in Fig. 14-3.

Emphasis should be placed on training and supervising feedlot employees in the detection and early treatment of sick cattle. Employees should be given regular instruction in the clinical signs of common diseases. It is the manager's responsibility to ensure that adequate personnel are available to thoroughly inspect each pen at least once and preferably twice daily. It is the veterinarian's responsibility to ensure that these personnel are adequately trained and to monitor or design monitoring systems in order to ensure individual competence.

Surveillance Method (Pen Checking or Pen Riding). Pens of low-risk cattle must be checked at least once daily. Cattle classified as being at high risk of developing respiratory disease should be checked at least twice daily for the first 2 to 3 weeks following arrival into the feedlot. This enables detection of new cases as early as possible, when they are most responsive to treatment. Surveillance can be done from horseback or by walking through the pens, but it is essential to be close and able to move the cattle apart, although this should be done slowly and with the least possible harassment. Pen checking is a skill that requires constant practice and attention to small details.

Method for Checking a Cattle Pen. Once a pen checker knows for what signs to look, he or she needs a system for finding sick cattle and must look at all the cattle in the pen (Fig. 14-4). Experienced feedlot personnel know that sick cattle tend to drift away from healthy animals, and any "loner" deserves some special attention. Sick cattle often can be found around the outside edges of the pen and must be spotted before the checker goes into the pen. Fig. 14-4, *A*, shows how the pen checker can start to identify sick cattle. The most common mistake among pen checkers is to recognize a few sick cattle on the edges and then, instead of

Downloaded from Vet-eBooks.com

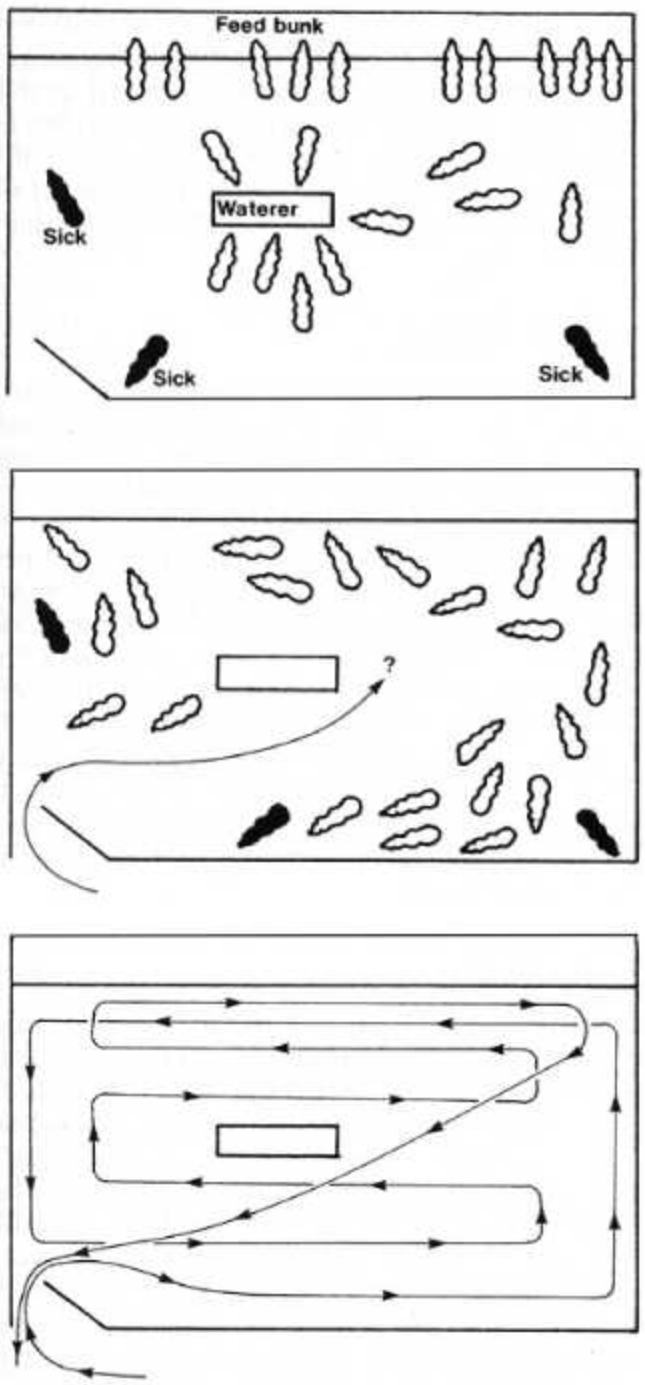

FIG. 14-4 How to walk a pen. **A,** Typical pen. **B,** Wrong approach. **C,** Better method. (From Duff RO: *Cattlemen* September:30-34, 1980.)

marking the animals immediately, to go directly to the center of the pen to stir up the other cattle. This causes the sick and healthy cattle to mix, with the checker usually losing the sick cattle that were on the outside edges (Fig. 14-4, *B*).

The best method of working through the pen is shown in Fig. 14-4, *C*. Note that this gives the pen checker a chance to quietly mark or pull the sick cattle on the outside edges when he or she first enters the pen. Then the pen checker can go on to check the rest of the cattle. By using the pattern shown in Fig. 14-4, *C*, the checker has an opportunity to see all of the cattle from both sides and also can check the waterers, the feed bunks, and any other potential problem areas. The pen checker's list should include the following:

1. Brand or ear tag identification on cattle in the pen: Are there strays? Have cattle been mixed?
2. Conditions in the pen: Are there mudholes that need filling? Is fresh bedding needed?
3. Conditions at the feed bunk: Are feed trucks overrunning high-energy diets at the end of the bunk so that new cattle in the next pen can get to it? What is the condition of the feed in the bunk? Does the bunk need cleaning? Are the water tanks full and operative? Has feed been spilled? Has feed been mixed and the wrong ration fed to the cattle? A pen checker should learn to recognize each diet coming out of the feed mill by sight. Suspicious findings should be reported immediately to personnel responsible for feed preparation and delivery.

The pen checker should be aware of the following:

1. The "loner" animal deserves special attention. However, in certain cases, a sick animal may not be a loner. Nervous system diseases may cause an affected animal to lose its eyesight. When this happens, the animal will actually seek the security of being close to the bodies and sounds of its penmates.
2. The left flank should be observed for fullness. Gaunt, "hollow" animals that are not "filled up" are abnormal. An animal that is not gaining weight or keeping up with its penmates, and any animal that lacks appetite, should be pulled.
3. Some feedlots rotate pen checkers through various sections of the lot. This makes it more difficult to become familiar with the cattle. Pen-checking assignments should be fixed, with each checker assigned to certain pens and having the sole responsibility to check those pens every day. In this way checkers can become familiar with the history of the cattle in these pens and can learn their habits. Fixed assignments also help management. The death loss from certain pens and the response of cattle to treatment allow management to identify efficient pen checkers, as well as individuals who may need extra training.
4. Dark-haired cattle need extra attention. Dark color often masks fine gradations of color that indicate disease in light-colored cattle. Bloody diarrhea is more difficult to spot on a dark animal, especially if the animal is wet. Eye inflammations and tear staining on the face are also more difficult to see.
5. Pen checkers should study the ground, since the character of feces is revealing. Close observation of the rumps helps identify affected cattle.
6. The checker should get the cattle up. The animal that rises, stretches, and defecates is normal, but an animal that does not do these is not necessarily abnormal. However, lame cattle or uncoordinated animals cannot be identified while they are recumbent.
7. Checkers should use other senses in addition to sight. They should listen for labored breathing, groaning, grunting, snoring, sniffling, or coughing. Some abnormal conditions can be detected by smell, such as metritis.
8. Cattle should be observed from a distance. When working a pen, the checker should look at the cattle in the pen behind or ahead. The cattle will be undisturbed and quiet, and sick animals can often be more easily identified from a distance.
9. Checkers should work cattle slowly. Excitement can elevate temperatures by 1° to 2° F, giving the treatment crew an abnormally high temperature reading. When a calf that needs to be pulled is cantankerous and refuses to be separated from its penmates, a second pen checker should be summoned to help in order to reduce the likelihood of injury or additional stress.
10. If a checker is unsure whether an animal is sick, mild exercise may exaggerate symptoms sufficiently to remove doubt.
11. When cattle are found dead in the pens, pen checkers should observe the necropsies, with the veterinarian reviewing the fundamentals of pen checking. This is an opportunity to correlate clinical signs with pathological lesions.

Downloaded From Vet-eBooks.com

The selection of pen checkers is important. They need to be keenly observant, knowledgeable, and trustworthy. A good pen rider can maintain surveillance for 5000 to 10,000 head of cattle. When a larger proportion of high-risk cattle are in the feedlot, pen checkers must be assigned fewer cattle because the time to check each pen and pull sick ones is increased.

The signs of ill health that are used to determine the presence of illness are shown in Box 14-2 (Griffin, 1996; Radostits et al, 2000).

Cattle showing these or other obvious signs of illness are examined more closely in the hospital area and, if necessary, treated. In some feedlots, treated cattle are immediately returned to their original pens, whereas in others cattle are kept in hospital pens until recovered. Recovered animals are then put back into their original pens. Most animals that do not recover or that relapse after the first treatment are retreated, although this decision depends on the nature of the disease. The criteria on which further decisions are based are obscure. There comes a time when the expenditure of more money on an animal that is going to be unprofitable is unwarranted. The decision on what course to take depends on whether the animal's life is in danger or the animal is simply doing poorly. If the animal's life is at risk, there is the potential loss of capital invested and all efforts are directed toward avoiding this. If the animal can still be sold and chances of recovery are slim, it is usual to cull it after two or three courses of treatment. This decision is based on the fact that it costs a great deal more, in terms of labor, to keep an animal in the hospital than in the feeding yards, and treated animals should be returned quickly to their own pens or culled. In some feedlots it is the practice to make up a pen of slow gainers, but this can be a nuisance; in most cases the rate of gain is not sufficient to justify the effort.

It is important to closely observe the pens from which sick animals are taken. It is imperative that a potential epidemic be identified early so that pen-level intervention can be considered.

Despite the importance of pen checking, it is not highly reliable for the detection of sick feedlot animals, particularly calves in the first week after arrival. It is difficult to distinguish tired, gaunt calves that may have been weaned a few days earlier from calves affected in the early stage of acute undifferentiated respiratory disease. In some cases up to 50% of animals pulled from a pen of recently arrived calves will not show clinical signs based on measurement of body temperature and a cursory clinical examination. However, more than half of the animals may be febrile at the peak of an epidemic, but less than 20% will display signs of illness. This suggests that the selection of sick feedlot animals based on visual appraisal from a distance may be a random event.

BOX 14-2

Signs of Ill Health

Anorexia: a reluctance to come up to the bunk or a gaunt appearance
Depression: reluctance to rise or move; dropped head and ears; arched back
Lameness or abnormal gait, such as knuckling or dragging of the toes
Stiff movement
Soft coughing; nasal and ocular discharge
Increased breathing rate
Crusted muzzle; sunken eyes
Rough, ungroomed, dry-looking haircoat
Loose or extra-firm feces
Abnormal abdominal fill
Straining; grunting; tail switching

Treatment Protocols

The veterinarian must specify procedures for the clinical management of sick cattle and provide a standard protocol that outlines specific treatments for disease syndromes, including dosages, treatment intervals, routes of administration, and withdrawal times (Janzen, 1990a). The protocol should be followed strictly by all personnel so that the success or failure of therapy can be evaluated accurately and to minimize chances of creating food safety hazards. The effectiveness of the treatment protocol should be evaluated regularly by determination of the response rates for the various treatment regimens. The failure of feedlots to use regular, competent veterinary supervision and to analyze treatment protocols often leads to the use of many different drugs indiscriminately, which leads to treatment overexpenditure and often an increase in the case fatality rate.

Feedlot Records

Records are essential to monitor the incidence of disease, response to treatment, and production performance, and they should be analyzed regularly by the veterinarian and feedlot manager. A wide variety of record-keeping systems are available and are often customized to a particular feedlot (Church, 1980; Janzen 1990b,c,e-g). Records can be maintained manually or by using commercially available computer software.[1-6] Either method is acceptable and has its own advantages and disadvantages. With a manual record system, there is no investment in software or computers, therefore the initial investment is less. Less training of personnel is required, but more time and labor is necessary to initiate, maintain, and analyze records. When records are maintained on a computer, health and feeding software can be interfaced with feedlot accounting software, making billing more timely, efficient, and accurate. Computerized records make the analysis of the animal health program by the consulting veterinarian easier and quicker than manual records.

The necessary input records include the lot description, processing record, lot update, sale information, animal identification, and feed and animal health products purchases. The necessary output records include the numbers of animals pulled from each pen daily, from which an epidemic curve can be drawn; the treatment response report according to pen or drug used; the percentage of pulled

animals that had a fever, which is an indication of how many are probably affected with an acute respiratory disease rather than a noninfectious disease such as grain overload; the daily mortality report, which should include the list of animals that died, along with their arrival dates, the dates of treatment, and the causes of death; a case abstract of the treatment history of each individual animal; and a close-out summary, which includes all of the costs of production, the health and production performance of the lot or pen of cattle (including morbidity, mortality, ratio of feed conversion to body weight gain, average daily gain), the costs of gain per unit of gain, the number of days on feed, and the profit or loss.

The following text outlines the use of manually generated records. Although most large feedlots have computerized record systems, a discussion of manual records best illustrates the principles of record-keeping, records that are necessary to generate reports, and analysis of records.

Individual Treatment Record (Fig. 14-5). Each animal treated should be individually identified, if this had not been done on entry, and this information recorded on the treatment card. The treatment crew should record the feeding pen, lot number, body temperature, body weight, disease suspected, treatment given, and disposition of the animal after treatment (e.g., which hospital pen). The severity of the illness should be assessed to properly evaluate response to treatment. Late treatment in advanced stages of disease, particularly respiratory disease, is a major cause of failure to respond, even when the treatment of choice is instituted. A card is filled out for each animal that is treated, and all subsequent treatments are recorded on the same card. The cards are filed and retrieved for animals that relapse or die. The cumulative information on the card can be used to decide whether an animal should be culled for chronic or recurring illnesses that are refractory to treatment, to decide on alternative treatments, to explain reasons for death, and, of major importance, to evaluate the effectiveness of the treatments recommended. Some feedlots, especially if they have computerized health records, record animals that are pulled but sent back untreated ("no treat") because they failed to meet the temperature criterion in the case definition for a given disease. This information can be of value if the animal is pulled again or dies. Information on the proportion of pulls that are "no treats" can be used to evaluate pen-checking effectiveness or to let the veterinarian know how a pen of cattle looks to the pen checkers.

Daily Morbidity and Mortality Record (Fig. 14-6). These data should be kept in a central location and updated daily by the pen checkers. This record simply contains the number of treated cattle by pen and lot number, the disease diagnosed, and the date. It provides both the manager and the veterinarian with a rapid assessment of the location of disease problems in the feedlot. It is based on what some call the "daily pull sheet" and contains information on the number of pulls and the number of "no treats," and then classifies those treated according to diagnosis and whether they are a relapse or new case. By using this report in conjunction with an inventory report showing filling dates and numbers added to the pen on those dates, it is possible to generate epidemic curves.

Morbidity and Treatment Analysis Record (Fig. 14-7). This record is an aggregation of data to summarize the morbidity rate, the relapse rate, and the death rate for a lot or pen of cattle. It is especially important as a tool to evaluate the overall effectiveness of the treatment program for various diseases; the relapse rates and death rates are compared with goals set for the feed and with benchmarks published in the literature. The disposition summary alerts the feedlot manager and consulting veterinarian when the chronic or culling rates are abnormally high, which can lead to significant economic losses. A quick glance at the completed form provides information needed for more in-depth diagnostics, training of feedlot personnel, and possible changes in the treatment protocol for specific diseases. The accuracy of the analysis may be improved by correlating the clinical response rate with the results of necropsies and drug sensitivity testing of bacteria isolated from affected animals before treatment (Martin et al, 1983).

Mortality Analysis (Fig. 14-8). The causes of death as determined by necropsy should be summarized on a regular basis. A mortality analysis includes the number of days the animal was in the feedlot, any observed premonitory signs, and treatment of the animal (diagnosis, drug used, and when treated). The location of the animal in the feedlot at the time of death should also be considered. Thus the mortality analysis is based on the individual treatment record and the individual mortality record.

Deaths may be classified as preventable or nonpreventable. Preventable deaths are those that result from inadequacies in management or in the techniques of feedlot personnel. In a large commercial feedlot that purchases cattle from a variety of sources, the personnel that may contribute to feedlot deaths include the veterinarian, pen checkers, feedlot manager, treatment crew, processing crew, feed mill and feeding system personnel, the truck driver who delivered the cattle, and the livestock buyer commissioned to buy the cattle. A regular summary of the possible relationship between death and feedlot personnel allows the manager to institute any necessary changes in management. For example, an unexpected high mortality rate as a result of pneumonia in recently arrived cattle may indicate that the animals were affected with acute or chronic respiratory disease at the time of purchase.

Feedlot Performance Summary (Fig. 14-9). Most feedlots complete a close-out summary for each group of cattle that have been finished and shipped to market. The performance record and feeding summary sections include average daily gain in body weight, total feed consumption, feed conversion ratios and cost per unit of body weight gain, mortality rates, culling rate, and medical costs. The financial summary provides the profit or loss on an individual and lot basis. When the feedlot finances the feed or the cattle, the interest is included in the customer's costs. When comparing costs among feedlots, it is important to know if and how interest is reported in the closeout summary (e.g., whether it is included in the cost of gain).

Vaccination Protocols

An important component of feedlot health programs is the planning of vaccination programs. The necessary vaccines and the vaccination schedule vary depending on the prevalence of disease both in the feedlot area and in the area from which the cattle originated. There is a tendency for feedlots

Downloaded From Vet-eBooks.com

to use too many vaccines in the hope that common infectious diseases will be controlled at a low level. This usually leads to both overexpenditures and less-than-satisfactory disease control. The kinds of vaccines used and the vaccination schedule should be based on the expected incidence of the disease, the cost of the disease when it occurs, the cost of the preventive procedure (vaccine plus labor), the field efficacy of the vaccine, and other available control procedures. All of these factors are based on sound statistical epidemiological data obtained from the disease records kept at the feedlot or at other similar feedlots, continued scrutiny of the scientific literature, and ongoing clinical trials conducted by the veterinarian in these feedlots.

Nutritional Advice

Feedlots frequently consult a qualified nutritionist to assist in the formulation of cost-effective diets. The veterinarian should communicate regularly with the nutritionist to be aware of the composition of the diets and any changes that are being planned. Because feed is the major portion of the cost per unit of body weight gain, it is imperative that the diet be the lowest-cost diet possible while providing nutrients that allow optimum growth and finishing. Most of the emphasis in feedlot nutrition has been on the development of cost-effective diets that support a maximum growth rate without any deleterious effects. Considerable information is available on the nutrient requirements for feedlot cattle and on the feeds and feeding systems used.

The precise specifications of the diets are the responsibility of the nutritionist, but the feedlot veterinarian frequently is in a position to evaluate the quality of the feed delivery system. This means checking to determine whether cattle are fed on time, whether the feed is mixed properly, and whether the feed intake is intermittent because of inclement weather or muddy ground surfaces. Any deviations should be communicated to the consulting nutritionist.

Nutritional deficiency diseases are uncommon in feedlot cattle, because cattle usually receive a diet that contains the nutrients required for maintenance and promotion of rapid growth. Diets prepared according to the Nutrient Requirements of Beef Cattle (National Research Council, 1996) should meet all the requirements under most conditions.

Specific nutrient deficiencies are extremely rare, because diets are prepared every few days or daily and it would be highly unusual for a feedlot to use a feedstuff deficient in a specific nutrient for a prolonged period. However, such a situation may occur in a small farm feedlot that prepares its own feedlot diet with little or no attention to the necessity

for supplementation of homegrown feeds. Thus there are only a few nutrition-related diseases that may affect a well-managed feedlot, but these diseases may cause large economic losses when they occur. They include the following:

- Carbohydrate engorgement (grain overload or D-lactic acidosis)
- Feedlot bloat or ruminal tympany
- Feeding errors (i.e., accidental incorporation of an excessive amount of a feed additive, such as monensin or urea, or sudden unintended changes in the ingredient composition of the diet)

Investigation and Clinical Management of Disease Epidemics

In spite of good management, unexpected disease epidemics occur in feedlot cattle. When feeding accidents occur, many animals can be affected suddenly, within 1 or 2 days. In outbreaks of acute infectious diseases, such as infectious bovine rhinotracheitis (IBR), pneumonic pasteurellosis, or *Haemophilus meningoencephalitis*, the first few cases will be followed by a steady increase in the morbidity rate for several days and then a decline as the outbreak subsides 10 days to 2 weeks after the index case.

In some cases, the diagnosis may be obvious (e.g., carbohydrate engorgement caused by a feeding error). However, in infectious diseases of the respiratory tract, the diagnosis may not be readily obvious, and a detailed epidemiological, clinical, and laboratory investigation may be required. A complete investigation may necessitate the involvement of specialists in several disciplines. Every effort should be made to determine the specific source of the disease, since this not only improves the efficacy of treatment and control but also usually generates new knowledge about the disease that may be applicable to future outbreaks.

For most outbreaks of disease in feedlot cattle, more than one method is usually available for the clinical management of the problem and the veterinarian must make decisions that have major economic consequences. The best decision will be made when the most information is available.

The objectives of an investigation are to determine the specific origin and extent of the disease, to take immediate corrective action, and to make recommendations to prevent occurrences (Kahrs, 1978). These objectives are best achieved by systematically delineating the characteristics of affected and unaffected animals within the study population and by observing, recording, and analyzing the distribution of the disease with respect to time, place, and a variety of exposure factors and environmental influences. This analysis must be correlated with thorough physical examination, necropsy findings from representative cases, and appropriate laboratory results.

After completing a general description of the problem, the next step is to confirm whether a problem exists based on the objective information available (Janzen and Ribble, 1990). This can be achieved by answering the following questions:

1. What is the problem, and what percentage of animals are affected? This is the case definition and is vital to the investigation.
2. Who is affected? Defining the group may give a clue to the cause. Recently arrived calves are more susceptible to acute respiratory disease than are animals that have been in the lot for some time.
3. When did the disease occur relative to other recent events in the feedlot? How soon after arrival in the lot did the animals become ill?
4. Where did the disease occur?
5. Why did the disease occur? Hypotheses about the possible causes are formulated on the basis of the observations and data collected.

A complete history should be summarized, including details on the first (index) case, index date, total number of sick animals, treatments given, case fatality rate, population

mortality rate, and vaccination history. The origin of the cattle should be determined if possible, and the length of time the cattle have been in the lot may give some clues to a diagnosis. The composition of the feed and whether any recent changes have been made in feeding practices should be determined. A sample of the feed consumed by the affected animals should be obtained and either analyzed or stored for future analysis.

An adequate clinical examination should be performed on several representative affected animals and on some

normal in-contact animals. Often there is evidence of early stages of disease in animals that appear normal on distant examination. In cases of infectious disease, appropriate samples (e.g., nasal swabs, blood samples, cerebrospinal fluid samples, and feces) should be taken from affected animals and submitted to the laboratory. Samples for bacterial culture and antimicrobial sensitivity testing should be taken from acute, non-treated cases. Necropsies should be performed on dead animals as soon as possible after death, before postmortem decomposition makes diagnosis difficult.

After the diagnosis has been determined, the rationale for treatment is then outlined. Emergency slaughter for salvage may be the most economical method for the clinical management of diseases such as grain overload. Cattle affected with common infectious diseases (e.g., pneumonic pasteurellosis, *H. meningoencephalitis*) cannot be slaughtered for salvage, and treatment is necessary.

When outbreaks of infectious disease are encountered, the intensity of surveillance must be increased to detect new cases in the early stages of disease when response to treatment is usually good. Detection of clinically affected cattle in the early stages of disease is difficult and requires considerable dedication on the part of pen checkers. Approximately 20% of the cattle that die from pneumonic pasteurellosis are found dead without any premonitory clinical signs; this occurs even in well-managed feedlots.

All of the details of the outbreak should be listed in chronological order and then analyzed and interpreted. Correlations can be made between exposure factors and the occurrence of new cases during the course of the outbreak. Often epidemiological determinants that explain why the disease occurred can be identified. This information can be used to control future occurrences. A detailed report of the outbreak, outlining the conclusion and recommendations, should be prepared and submitted by the veterinarian to the owner.

Undifferentiated Bovine Respiratory Disease

Undifferentiated bovine respiratory disease (UBRD), also known as cattle shipping fever, is the most important disease complex affecting cattle in North American feedlots. The term *undifferentiated fever* (UF) is now considered more appropriate than *bovine respiratory disease* for describing feedlot cattle that are febrile with a lack of abnormal clinical signs referable to a body system other than the respiratory tract (Booker et al, 1997, 1999).

Etiology. The most common pathogen isolated from the lungs of feedlot cattle that die from UBRD is *Pasteurella haemolytica*, biotype A, serotype 1 (Confer et al, 1988). *Pasteurella multocida*, Heddleston type 3, is isolated to a lesser extent. It is generally agreed that *P. haemolytica* is the most important pathogen in fatal pneumonic pasteurellosis, accounting for the majority of cases of UBRD (Haziroglu et al, 1997). However, several viruses, including IBR, parainfluenza type 3 (PI3), bovine respiratory syncytial virus (BRSV), and the bovine viral diarrhea virus (BVDV), can be isolated from the tissues of the respiratory tract of feedlot animals that have died from respiratory disease. A common enteric virus, bovine coronavirus has also been implicated as having a role in BRD (Carman and Hazlett, 1992). *Mycoplasma bovis*, *Mycoplasma dispar*, and other species have also been isolated (ter Laak et al, 1992). It is believed that one or more of these pathogens may play a contributing role in the origin and pathogenesis of the disease in some affected animals (Virtala et al, 1996). According to Yates (1982), lesions virtually indistinguishable from those of shipping fever in the field can be produced experimentally, but the relationship between naturally occurring disease and experimental dosages of viral and bacterial respiratory tract pathogens and the challenge exposure methods used is unknown. Experimentally, *P. haemolytica* A1 is capable of causing the disease as a primary pathogen if the animals are susceptible (i.e., nonimmune) and if the organisms are in the logarithmic growth phase and administered into the trachea or lungs in sufficient numbers (Shoo, 1989b).

Seroepidemiological studies of UF in feedlot calves in western Canada found evidence of exposure to *P. haemolytica*, *Haemophilus somnus*, bovine herpes virus-1, GIV-glycoprotein, bovine viral diarrhea virus, *Mycoplasma bovine* and *Mycoplasma alkalescens* (Booker et al, 1999).

BRSV is widespread and has been implicated as a predisposing factor in fibrinous pneumonia and as a cause of interstitial pneumonia (Collins et al, 1988a,b). In feedlots 92% or more of unvaccinated cattle may be seropositive for BRSV and BVD and PI3 viruses. If cattle enter the feedlot without antibodies to these viruses, they may undergo seroconversion while in the feedlot, even without clinical evidence of disease. Range cattle have more varied exposure to BRSV; the overall prevalence in adult beef cows is about 70%.

Two studies have noted an association between high BRSV serum antibody titers on arrival at the feedlot and a reduced risk of subsequent respiratory disease (Martin and Bohac, 1986; Caldow et al, 1988). Field trials to evaluate immunization of beef cattle before weaning, at weaning, or immediately on arrival at the feedlot with a commercial BRSV vaccine demonstrated a small reduction in treatment rate for respiratory disease that may not be significant (Van Donkersgoed et al, 1990; Hansen et al, 1992). There is a possibility that the disease may be immune mediated and that there may be a relationship between the presence of antibodies acquired from natural infection and the effects of vaccination.

Atypical interstitial pneumonia (AIP), also known as acute interstitial pneumonia, has occurred in association with epidemics of BRSV infections. The pathological findings in cattle with AIP are similar to those reported for acute cases of naturally occurring BRSV infection (Collins et al, 1988a). Recently, experimentally induced BRSV infection has been demonstrated to cause the severe form of disease sometimes observed after natural (Wollums et al, 1999). In acute, fatal, naturally occurring cases of BRSV pneumonia, the principal lesions consist of acute or chronic bronchitis and bronchiolitis in the cranioventral portions of the lungs, combined with widespread emphysema and edema throughout the lungs (Kimman et al, 1989a). It has been suggested that BRSV infection in the cranioventral portion of the lung and the accompanying cytopathological findings are not sufficient to explain the widespread edema and emphysema in the entire lung; an immune-mediated mechanism may also play a role. Such a pathogenic mechanism has been proposed by Kimman et al (1989a,b). During an outbreak of BRSV, calves with or without maternal antibodies are exposed to the virus for the first time. Ciliated and nonciliated epithelial cells in the airways and alveoli in the cranioventral portion of the lung become infected and injured. This process is accompanied by inflammation and repair. The infected cells have altered surface characteristics that activate complement, which may contribute to lysis of these cells and cause the influx of neutrophils. The primary immune response is first detected 8 to 10 days after infection, which may explain the two stages of the disease that are sometimes observed. Activated complement may reach the cranioventral portions of the lung by way of the bloodstream, exerting its spasmogenic effect on smooth muscle and inducing the release of mast cell mediators, which causes severe edema and emphysema in the entire lung, clinically recognized as respiratory distress. There is indirect evi-

Downloaded from Vet-e-Books.com

dence for implication of immunoglobulin E (IgE) in BRSV infection (Stewart and Gershwin, 1989). There is also evidence that BRSV infection with 3-methyl-indol intoxication causes more severe lung disease (Ellis, 1998a).

When *H. somnus* was first recognized as a pathogen in feedlot cattle, the most common associated disease was thromboembolic meningoencephalitis. However, fewer cases of the nervous form of the disease are currently being reported, and other disease manifestations are being identified. The *H. somnus* disease complex, also known as hemophilosis, includes several different syndromes and lesions. The respiratory form of the infection has been gaining in importance, and the organism has been associated with laryngitis and tracheitis in feedlot cattle. In recent years, *H. somnus* has been isolated with increasing frequency from the lungs and pleura of feedlot cattle dying with lower respiratory tract disease, and it is currently thought that this organism may be an important contributor to fatal feedlot fibrinous pneumonia (Harris and Janzen, 1989). In case-control studies the organism has been found in pure culture in up to 28% of the cases' pneumonic lungs (Groom, 1989). However, isolation of the organism varies widely on incoming cattle (Van Donkersgoed et al, 1994; Haziroglu et al, 1997). Previous treatment with antibiotics and freezing of the tissues reduce the isolation rate of the organism. Experimentally, *H. somnus* can produce a suppurative pneumonia that resembles the naturally occurring pneumonia thought to be caused by the organism (Jackson et al, 1987; Potgieter et al, 1988). Three new *H. somnus* syndromes are thought to be the result of septicemia occurring without the nervous form of the disease. Acute fibrinous pleuritis in the absence of pneumonia is becoming more prevalent in laboratory submissions (Groom, 1989). Affected animals are found dead without previous evidence of illness or a history of ineffective response to treatment for pneumonia. At necropsy, there is extensive fibrinous pleuritis with mild to moderate pulmonary congestion.

Myocarditis caused by *H. somnus* is being recognized with increasing frequency in feedlot cattle. Affected animals usually die suddenly. At necropsy the typical lesion consists of a darkened, necrotic area with a pale border at the base of the papillary muscle in the left ventricular wall (Guichon et al, 1988). The lesions measure up to 1 × 2 cm in diameter, and small abscesses may be evident when the ventricular wall is sectioned. The cause of death is acute heart failure. Acute pulmonary congestion and edema causing sudden death are also thought to be a form of *Haemophilus* septicemia. Virulence differences exist among strains of *H. somnus,* which may account for the different clinical manifestations (Groom et al, 1988).

Epidemiology. In a 12-month survey of diseases in a large Colorado feedlot, lower respiratory disease accounted for approximately 46% of the total cost of disease and 60% of the cost of the 10 most prevalent diseases (Frank et al, 1988). The incidence of the disease varies widely, but on average, approximately 30% of calves 6 to 8 months old develop the disease 7 to 14 days after arrival in the feedlot (Martin et al, 1988) or after being subjected to stresses such as weaning, commingling, shipment over long distances, and rapid fluctuations of environmental temperature. Within a defined group of cattle, the epidemic curve peaks at 7 to 21 days after arrival and then declines toward no morbidity after Days 21 to 28 (Martin and Meek, 1986). However, some calves are affected with the disease on arrival in the feedlot or become affected within a few days of arrival. Often these animals are of auction mart origin and may have been weaned several days earlier. The epidemic curve suggests that BRD is the result of a point source cause, even though the incubation period may vary. Field observations by feedlot managers and veterinarians suggest that in a large pen containing animals from many different sources, there is a buildup of the number of cases, followed by a decline, known as a propagated outbreak, suggesting animal-to-animal transmission of the responsible pathogens (Wilson et al, 1985). The hypothesis that the disease is communicable within large pens containing animals from different sources seems to have played a major role in the development of control measures such as prophylactic medication and the use of vaccines for immunization against the pathogens. However, there is no evidence that the clinical disease in one individual increases the risk of disease for other cattle in the same pen (Martin et al, 1988).

The possibility that infection with several different viruses and *Mycoplasma* may predispose feedlot cattle to acute pneumonia has been the subject of intense research activity (Perino, 1989). Ample evidence demonstrates that most of the putative pathogens spread rapidly when cattle are assembled at sales yards and feedlots. Direct contact is the most common method of transmission; however, airborne transmission of BHV-1, BVDV, and BRSV is possible (Mars et al, 1999). *P. haemolytica* has been shown to rapidly transfer to susceptible calves even under nonstressful conditions (Briggs et al, 1998). A comparison of the distribution of serological titers of cattle on arrival in the feedlot—with the distribution of seroconversion 28 days later in animals treated for respiratory disease, and with controls not treated—revealed that IBR virus, PI3 virus, BVDV, and BRSV were present, active, and associated with respiratory disease (Martin and Bohac, 1986). The presence of antibody indicates current or recent exposure to the virus but does not indicate resistance. Cattle with low titers to IBR or BRSV were at increased risk for subsequent treatment for respiratory disease. Treated cattle also had greater responses to PI3 or BVDV antibody titers than did control calves. Serologically there is evidence of a high prevalence of *M. bovis* and *M. dispar* infection in feedlot calves (Rosendal and Martin, 1986), but there is insufficient evidence to support an etiological role for the organisms (Martin et al, 1989).

Seroconversion to *P. haemolytica* cytotoxin, BRSV, and BVDV was predictive of respiratory disease, explaining 69% of all respiratory disease cases in small groups of feedlot calves (Martin et al, 1989). In another study incoming calves carried high antibody titers to *Haemophilus* at the feedyard, and high titers were associated with a reduced risk of developing BRD (Martin et al, 1998a). An investigation of the statistical relationship between titers and the health status of feedlot calves at the group level revealed that seroconversion rates to *M. dispar* and BVDV were predictive of increased respiratory disease rates, and seroconversion rates to *P. haemolytica, P. haemolytica* cytotoxin, *M. dispar,* and PI3 were predictive of decreased weight gains (Martin et al, 1990). In a Canadian study, 82% of calves had antibody titer to bovine coronavirus; however, titer change after arrival at the feedlot was not related to the development of BRD or weight gain (Martin et al, 1998b).

Regarding the roles of multiple pathogens in the pathogenesis of bovine respiratory disease, Martin et al (1990) stated the following:

In attempting to understand BRD, it seems sensible to accept that infections involving multiple agents are the rule rather than the exception. Debate may occur about the relative importance of each agent, about the causal structure, and about the best way to break the causal chain/web. However, there should be little doubt that many putative pathogens are active in both individuals and groups during BRD outbreaks, and their effects may go far beyond morbidity and mortality. The apparent effects of these agents should be interpreted in the light of the outbreak situation and the presence of other, non-infectious causes of respiratory

Downloaded from Vet-e-Books.com

disease. Until their role is clearly understood, we believe there is much benefit to be gained from studying the presence and activity of microorganisms in "healthy" herd-mates, not just in diseased individuals, and in using groups, such as pens, as the unit of analysis when possible.

Although they are accepted as etiological agents of UBRD, the pathogens described previously are more difficult to manage and cause more severe disease when additional stressors are placed on cattle. Market origin and feeding management can affect the levels and distribution of respiratory disease. In one study of Alberta feedlots, cattle purchased from auction marts and started on high levels of grain were determined to be 6.3 times more likely to be treated for any disease, 4.9 times more likely to be treated for respiratory disease, and 12.7 times more likely to die from respiratory disease than the group made up primarily of farm-assembled heifers and started on a 10% grain ration with time allowed for adjustment to grain (Wilson et al, 1985). This indicates that auction market-derived calves are at greater risk than calves received direct from the ranch, and that certain strategic measures may be necessary to manage and control disease in auction-mart calves. Risk factors affecting morbidity and mortality have been identified previously and include the following (Ribble et al, 1998):

- Mixing of animals from different groups
- Number of calves passing through auction markets
- Time of year when calves are placed in the feedlot
- Weather conditions around the time that calves arrive at the feedlot

The risk factors identified for lower respiratory tract disease in a cohort of feedlot cattle indicated that the disease was more common in steers than heifers; mixing cattle from different sources increased morbidity, and checking heifers for pregnancy within 30 days of arrival was detrimental (Alexander et al, 1989). An increase in the concentration of 2- to 3-μm airborne particles along with wide-ranging daily ambient temperatures enhanced the association between particulate exposure and the incidence of pneumonia (MacVean et al, 1986). The incidence of pneumonia was greatest within 15 days after arrival at the feedlot and during the autumn.

Factors that are known to cause immunosuppression are thought to be contributors. There is strong evidence that a primary postnatal infection of cattle with the BVDV can cause transient immunosuppression, sufficiently enhancing the effect of other pathogens to cause bovine respiratory disease (Potgieter, 1997).

Clinical Findings. The clinical findings of the disease have not been well defined because feedlot cattle with suspected clinical illness are usually not examined thoroughly. Usually there are many animals to be examined, and it is not cost effective to have a veterinarian clinically examine each animal using several diagnostic techniques to improve the accuracy of the diagnosis. Thus the examination is usually superficial. Sick animals are usually detected in the pen, from which they are "pulled" and examined quickly, usually in less than 1 minute in the chute. The emphasis is on measuring the body temperature with a thermometer. Affected cattle are usually depressed and anorexic, may have a gaunt abdomen or may move slowly because of thoracic pain, and commonly have an ocular and nasal discharge. The respiratory rate is sometimes increased, and depending on the stage of the disease, respirations may be shallow and apparently effortless or deep and labored. Coughing may or may not be present. The body temperature is usually elevated to between 39.5° and 41.0° C (103° and 106° F). Although not usually performed in large commercial feedlots, auscultation of the lungs reveals varying degrees of abnormal lung sounds such as loud breath sounds, crackles, and wheezes, suggestive of pneumonia. Lung sounds are usually muffled in cases with a pleural effusion. Some animals may be found dead without any previous sign of illness. Affected animals usually respond to treatment with common antibiotics, but a small percentage do not respond to treatment and relapses sometimes occur after successful therapy.

The clinical findings of pleuritis may vary depending on whether the disease is associated with fibrinous pneumonic pasteurellosis or *Haemophilus* septicemia. Affected cattle are usually chronically ill with fever, dyspnea, and painful respirations. Cattle affected with myocarditis may be found dead without any previous history of treatment for disease. Acute interstitial pneumonia is characterized by severe dyspnea, perhaps mouth breathing, normal body temperature or fever, loud breath sounds on auscultation of the lungs, and a history of nonresponse to treatment.

The details of the clinical findings and differential diagnosis of pneumonic pasteurellosis are given in Radostits et al (1994).

Pathology. Necropsy of individual dead animals in a feedlot is an important means of obtaining daily information on the occurrence of specific diseases and on the efficacy of the animal health management program. The differential diagnosis of feedlot pneumonias has been reviewed by Wikse (1985). The feedlot pneumonias can be categorized according to epidemiology, etiology, clinical findings, and lesion type. This approach enables the clinician to make immediate useful recommendations based on evaluation of the epidemiological, clinical, and pathological findings. The most common pathological findings are bronchopneumonia, fibrinous pneumonia, coagulation necrosis, and varying degrees of the common complications such as pleuritis and pulmonary abscesses (Andrews and Kennedy, 1997). One of the major problems in the diagnosis of feedlot pneumonia has been the assessment of the age of the lesions. Determination of the age of a bacterial pneumonia with some accuracy helps management to assess whether the pneumonia was already present in the animal on arrival or whether treatment failure resulted from late detection or inadequate drug therapy. In one study the degree and extent of necrosis and fibrosis was found to provide the best assessment of the age of the pneumonia (Daoust, 1989). In acute interstitial pneumonia the lungs are diffusely reddish tan, enlarged, and do not collapse. All lobes are rubbery, wet, and heavy. Emphysema is present, primarily in the diaphragmatic lobes, and there is white froth in the trachea. In fibrinous pleuritis there are thick sheets of fibrin over the visceral and parietal pleura. The thorax contains fibrin and straw-colored fluid. In caudal venal caval thrombosis the lungs contain pulmonary arterial aneurysms and abscesses. Blood clots are present in the airways, and a liver abscess near the vena cava contains a thrombus.

Computer imaging technology can now be used to facilitate the capture of feedlot necropsy data. A digital camera is used to capture necropsy images. Subsequently, the images are electronically transferred to a central site for veterinary interpretation and diagnosis (Wildman et al, 2000).

Treatment and Clinical Management. Pen checkers should record pertinent information on cattle presented to the hospital for treatment. At a minimum, this should include pen of origin, tag numbers, color or description of the animal, and a tentative diagnosis. This pull sheet serves as a valuable mechanism for communication between the pen checkers and hospital personnel. This is especially useful when morbidity rates and hospital activity are high. Hospital personnel should observe cattle pulled for treatment while they are still in the holding pens; this provides an opportunity to evaluate the cattle and to observe for clinical signs before they enter the chute, thereby allowing confirmation of the diagnosis made by the pen checkers.

Downloaded From Vet-eBooks.com

Once each calf is restrained in the chute, calf identification (pen, lot, tag number[s]) should be entered into the computer or recorded on the treatment card. At a minimum, the date, rectal temperature, clinical diagnosis, drug(s) used, and dosage should be recorded. Body weight and clinical illness score are useful to assess response to therapy.

The treatment regimen should be developed and monitored by the consulting veterinarian. The focus of the treatment program must be on the therapeutic management of BRD. Four methods are commonly used to select the antimicrobials to be used for treatment of BRD (Smith, 1996b):

- Antemortem testing
- Postmortem testing
- Literature (field trials)
- Evaluation of clinical response

Antemortem culture and antimicrobial sensitivity testing (e.g., minimum inhibitory concentration [MIC]) of acute, febrile, untreated cases provide the best information for determining etiological agent, the bacterial susceptibility, bacterial resistance, and the appropriate antimicrobial dosage. Caution must be exercised when trying to interpret culture and antimicrobial sensitivity data from chronic cases, since these are not representative of the bacteria that initiated the disease.

Necropsy examination of dead calves is an important means of conforming or refuting the clinical diagnosis. Concurrent conditions that may hamper treatment response can be identified. The necropsy also provides an opportunity to show pen checkers and hospital personnel the correlation among disease processes, lesions and the clinical signs. The utility of culturing the lungs of chronic, heavily treated calves is suspect at best.

Published field trial results can provide information critical to the antimicrobial selection decision. To be useful the trial must be properly designed, conducted, and subjected to statistical analysis. A description of the type cattle used in the study, management conditions under which the antimicrobial was evaluated, case definition, and time-event relationships are important information to be included in the paper. Proper statistical analysis helps rule out interactions that tend to mask true differences in the efficacy of products being evaluated. Although field observations are important, differences defined in controlled field trials help the practitioner make the antimicrobial selection based on science rather than just a "gut feeling."

Determination of clinical response to treatment is the final method available to select the antimicrobial to treat BRD. Treatment records should be analyzed in each feedlot on a regular basis to determine the overall effectiveness of the treatment program, including response to first treatment, relapse rate, chronic rate, case fatality rate, and cost of treatment. Results are compared with goals established for the feedlot, which are influenced by the background of cattle received, age of the cattle, feedlot personnel, facilities, diet, and weather.

Suggested guidelines for evaluating the clinical response of cattle treated for BRD are shown in Table 14-2. A reasonable goal for response to first therapy is 70% to 80%. An extremely high first-treatment response rate, coupled with corresponding low case fatality and chronic rates, does not always indicate that the treatment program for BRD is successful. A first-treatment response rate of 90% or higher suggests that many calves without bacterial BRD are being treated, which is not cost effective. When faced with this situation, the consulting veterinarian should perform a physical examination of several of the representative calves. Based on the physical and laboratory findings, the proper course of action should be outlined and feedlot personnel should be

TABLE 14-2

Suggested Guidelines for Evaluating the Subpopulations of Cattle Being Treated for Bovine Respiratory Tract Disease (BRD)

If		
BRD Case Fatality*	**First Treatment Response†**	**Consider**
1%-2%	90+%	Too many false positives in the treatment mix
5%-10%	75%-80%	Might be close to the right treatment mix; however, do not rest. There could still be room for improvement in the number of PTLs and false positives in the mix.
Significantly >10%	Around 60% or less	Too many PTLs. Keep in mind that some cattle may be PTLs when they are unloaded.

From Apley M: *Vet Clin North Am Food Anim Pract* 13:549-574, 1997.

PTL, Pulled too late.

*Defined as total BRD mortalities divided by cases receiving therapy for BRD.

†Defined as cases receiving therapy for BRD minus both mortalities and those requiring additional BRD therapy within 21 days of initial therapy.

trained to respond to the calf's needs accordingly. A first-treatment response rate lower than the goals and expectations for the treatment program should be of even greater concern than one that is too high. A low first-treatment response rate is often associated with a high case fatality rate, high chronic rate, and high treatment costs. Poor initial treatment response forces the use of several courses of antimicrobial therapy, increasing the risk of antimicrobial resistance.

When the first-treatment response rate is poor, the consulting veterinarian must perform a systematic evaluation of the cattle and the health program. The treatment of cattle with advanced lung lesions is the most common cause of poor first-treatment response rates. This can be due to receipt of cattle's incubating disease or being sick on arrival ("stale" cattle), as well as cattle's being pulled too late by pen checkers. Concurrent diseases, especially those that are immunosuppressive (e.g., coccidiosis, salmonellosis, BVD), negatively affect the response to therapy. Proper hospital management is absolutely necessary for treated cattle to recover from disease.

It is tempting to blame a low first-treatment response rate on the antimicrobial being used. Often feedlot personnel go from drug to drug without improved success. The antimicrobial selected is only one component of the success or failure of the treatment program. In an Oklahoma study (Smith et al, 1994), a significant difference in response rate was seen between groups of calves received during the same period, treated with the same antimicrobial regimen, housed in the same feedyard, fed the same ration, and managed by the same people. One group had an 86.1% response to first therapy, whereas calves from a different origin had a 54.9% response rate. The latter group was lower priced, took longer to assemble, and was "stale" on arrival.

In another report, calves that relapsed after first treatment were treated significantly earlier after arrival than those that did not relapse. Relapse is 3.5 times more likely in a calf treated during the first 4 days after arrival than in one treated more than 4 days after arrival. The response, relapse, and case fatality rates showed greater variability among feed lots than among antimicrobials (Bateman et al, 1990).

Combination antimicrobial therapy is often used with hope of improving the response to treatment; this is done mostly without scientific merit. The intent of combination antimicrobial therapy is to "extend the spectrum of activity," which usually suggests a lack of confidence in a single antimicrobial program. In reality, the spectrum of activity of modern antimicrobials is more than sufficient to treat the common BRD pathogens, including mixed infections. A common practice is to use a less costly antimicrobial in combination with a newer generation, more expensive product. There is no rationale for including a product in the treatment regimen that will not stand on its own. Using some antimicrobials in combination can be antagonistic (Apley, 1997b), causing efficacy for the drug combination that may be less than expected from either drug by itself.

Florfenicol is superior to tilmicosin for the treatment of UF in calves that have previously received tilmicosin metaphylaxis on arrival because of the lower chronicity, wastage, overall mortality, and BRD mortality rates (Jim et al, 1999).

Adjunct or ancillary therapy has been commonly used in many feedlot treatment programs. The use of ancillary therapy has been reviewed (Apley, 1997a). There is little scientific evidence to support the use of ancillary therapy in BRD treatment programs. Much of the reasoning to support their use has not come from controlled field trials, but rather from interpolation of human literature and ill-advised logic. Newer generation nonsteroidal antiinflammatory drugs (NSAIDs) show some promise as ancillary therapy (Hellwig et al, 1999), but at this time the field trial data are yet inconclusive.

When a favorable treatment response is lacking, hospital management must be evaluated. Some feedlots have successfully used a treat-return system, whereby cattle are treated and then returned to the home pen on the same day. This greatly reduces the hospital population but poses more challenges for the pen checker because, in the same pen, there are healthy cattle, treated cattle that are recovering, treated cattle that need additional therapy, and first time pulls. Other feedlots have been equally successful when placing sick cattle in the hospital system until they have recovered satisfactorily.

When hospitals are used to house sick cattle, it is beneficial to pen cattle by day of treatment. By doing this, cattle are more apt to "eat alike" and "look alike." Small cattle should be penned separately from larger, more aggressive cattle. Most feedlots do not have adequate hospital space to house cattle during the fall and winter months when morbidity is high. An aggressive effort to continually return recovered cattle to their home pen is essential to avoid overcrowding, which must be avoided because transmission of enteric diseases, especially salmonellosis, is not uncommon when pens are unsanitary. Ideally, 150 square feet of space/head should be provided. Pens should be scraped frequently, and water tanks should be washed twice daily. In northern feedlots windbreaks provide relief from the stress of cold wind, whereas in southwestern feedlots, shades may be necessary to provide relief from extreme heat.

Expectations for the treatment program should be realistic, accounting for the background and age of the cattle, time of year, and feedlot staffing with adequate numbers of trained and motivated people. Goals can be based on past experience (e.g., reducing death loss by a given percentage as compared with last year), published health performance figures, and comparison with other feedlots in the region (benchmarking).

Death loss is largely a function of the morbidity rate. If the pull rate is low, death loss as a percentage of cattle received is generally low; conversely, death losses are higher when morbidity is high. The range of case fatality rates in the literature is from 1.3% to 15.0% (Bateman et al, 1990; Smith et al, 1994; Gorham et al, 1990). A reasonable target for the case fatality rate is 6.0% (Apley, 1997b; Hoar et al, 1998). The case fatality rate, which is defined as the number of deaths in a given period divided by the number of diseased animals in the population in the same time period, is the most useful figure to assess the overall effectiveness of the treatment program, since the relationship between morbidity and mortality is objectively defined.

Control. Satisfactory and economical control of disease depends on successful integration of management techniques and the possible prophylactic use of biologicals and antimicrobials. It is unrealistic to depend on a vaccine, an antibiotic, or a single management technique to control the disease. Successful control begins with the adoption of good management techniques when the calves are still on the farm or ranch, the judicious use of efficacious vaccines, and care in handling and transportation of cattle to the feedlot. The established structure of the feedlot industry in North America often prevents vaccination of cattle before arrival in the feedlot. Epidemic curves of treatment rates of BRD in North American feedlots demonstrate that the greatest percentage of morbidity occurs within the first 2 weeks after arrival, before a vaccine given on arrival can take effect.

Because disease commonly occurs at the time of shipment from the farm or ranch to the feedlot, much attention has been given to reducing the incidence of disease at this time. In North America, this led to the development of the concept

Downloaded From Vet-eBooks.com

of preconditioning. The objective of preconditioning was to prepare the weaned calf for the feedlot environment by vaccinating it for all of the common diseases before weaning and by distributing all stressful procedures (e.g., castration, dehorning, branding, and deworming) over a period of time rather than concentrating them at weaning time. Weaning at least 2 weeks before shipment was also considered desirable, although it now appears that a longer weaning period is beneficial. It was hoped that a weaned calf would adjust quickly to the feed bunks and water tanks in a feedlot. Preconditioning has not been accepted widely because its economic value has not been proven. Nevertheless, it appears to positively promote health and thus can be recommended, even though its economic value remains to be determined. Preconditioning is discussed briefly later in this chapter.

Management. The majority of calves produced in North America are produced on smaller farms and ranches. Because cattle are shipped to feedlots in truckload lots, most farms and ranches do not have sufficient numbers of calves of similar quality, weight, and sex to sell in truckload lots. As a result, most cattle are sold through public livestock auctions or sales yards. This has necessitated the development of conditioning procedures in which, after arrival, the cattle are individually identified, treated with a residual insecticide, given an anthelmintic, sometimes injected with a long-acting antimicrobial, and vaccinated for clostridial and respiratory diseases. Some limited field trials indicate that processing may be delayed for up to 3 days after arrival if the workload prevents earlier processing. Delays of 6 days or more may be detrimental (Lofgreen, 1988).

The feeding and nutritional status of newly arrived cattle must assume some importance, but there are little scientific data with which to formulate a sound economic feeding program to promote rapid recovery from shipping stress. Lofgreen (1988) claims that good results are achieved when stressed calves are fed a receiving ration consisting of 50% to 75% concentrate plus native grass hay, both provided on a free-choice basis for 1 week, followed by removal of the hay and continuation of the milled feed for another 2 to 3 weeks, depending on the performance and appearance of the calves.

Enhancement of Immunity by Vaccination. *Pasteurella* bacterins and respiratory viral vaccines have been used extensively in attempts to control BRD (Cardella et al, 1987). Many veterinarians and feedlot owners maintain that vaccination against respiratory disease is an essential component of their disease prevention programs, both to prevent specific diseases of the respiratory tract, such as clinical IBR, and to reduce losses resulting from respiratory disease in the first few weeks after arrival. However, reviews of the literature on the efficacy of available vaccines for the control of BRD concluded that there are little documented data to support their use under feedlot conditions (Martin, 1983; Perino and Hunsaker, 1997). (Efficacy refers to the ability of the vaccine to reduce overall treatment rate or to increase weight gains.)

Recommendations for a vaccine to control UBRD in feedlot cattle are not possible based on the currently available efficacy information. The vaccines are used widely and many anecdotal claims regarding their effectiveness have been made, but there is little scientific evidence based on properly designed field trials that the vaccines are effective and economical in reducing the incidence or the consequences of respiratory disease (e.g., suboptimum weight gains) (Perino and Hunsaker, 1997). Vaccine manufacturers have not conducted studies to evaluate the efficacy of the vaccines against naturally occurring disease in the field using vaccinated animals with unvaccinated animals as concurrent controls. In most cases the vaccines were approved for sale based on tests for animal safety and for potency as measured by a serological response to the vaccine or an experimental challenge in animals in the laboratory.

Because of the paucity of information from properly designed field trials, the practitioner currently must do a risk assessment to determine the need for a particular vaccine and then evaluate efficacy of the vaccine based on published laboratory challenges (Smith, 1992). This is not the most satisfactory way to select vaccines, since laboratory testing does not realistically mimic feedlot conditions. The cost of preventive measures should not exceed the cost of the disease; risk assessment will help the practitioner make the economic decision.

Vaccines to Control Acute Undifferentiated Respiratory Disease. Because fibrinous pneumonia caused by *P. haemolytica* is the most common lesion associated with BRD in feedlot cattle, much of the emphasis has been on the development of effective vaccines for bovine pneumonic pasteurellosis (Mosier, 1997). Based on immunological and microbiological findings in both naturally occurring and experimentally induced pneumonic pasteurellosis, artificial immunization of cattle appears possible. High levels of naturally acquired antibody to *P. haemolytica* have been associated with protection against the disease (Jericho, 1987, 1989).

Calves that recover from experimentally induced pneumonic pasteurellosis possess increased resistance to subsequent experimental challenge. Calves that have been naturally exposed to *P. haemolytica* or exposed by vaccination also develop antibodies. Protection afforded by antibodies is dependent on the presence of specific antibodies. Leukotoxin antibodies are most closely associated with protection against disease. Certain outer membrane protein antibodies also offer some degree of protection against *P. haemolytica* infection (Confer and Fulton, 1995; Confer et al, 1988).

The vaccine has been evaluated in field trials in feedlots in Canada, with varying results. In one trial, the vaccine was used on arrival in fall-placed calves; the pull rate was reduced by 4%, the first relapse rate by 11.9%, and the second relapse rate by 18.7% (Jim et al, 1988). There was an 8.2% decrease in the mean number of treatment days, overall mortality was decreased by 49%, and the mortality rate resulting from fibrinous pneumonia was reduced by 50%. It appeared that vaccinated animals also responded to treatment more favorably than did nonvaccinated animals. Vaccination of recently shipped nonpreconditioned calves in Ontario caused a slight decrease in morbidity, a slight improvement in response rates, and a possibly significant reduction in relapse rates (Bateman, 1988). When the vaccine was combined with an intramuscular (IM) modified live IBR/PI3 virus vaccine, the morbidity rate was increased, the response rate was decreased, and the mortality rate was increased in some groups. More recently, at least two combinations of modified life virus vaccine and *Pasteurella* vaccine have been approved in the United States by the U.S. Department of Agriculture (USDA).

Pasteurella vaccine has been evaluated in a field trial comparing its efficacy in calves vaccinated at the ranch 3 weeks before shipping to the feedlot, in ranch calves vaccinated on arrival in the feedlot, and in auction market calves randomly assigned to either receive or not receive the vaccine on arrival at the feedlot (Thorlakson et al, 1990). The vaccine did not effect a change in morbidity rates or weight gain. Total mortality rates increased significantly, and mortality rates from respiratory disease tended to be increased in ranch calves that were vaccinated at the ranch. In auction market-derived calves the relapse rates were significantly lower in vaccinated calves. The source of calves was a major factor affecting the incidence or effects of BRD. Calves transferred

Downloaded From Vet-e-Books.com

directly from ranches to feedlots, regardless of vaccination status, had lower morbidity and mortality rates and better weight gains than calves purchased from auction markets.

Based on the observation that previous infection of the respiratory tract with either IBR or the PI3 virus may predispose cattle to pneumonic pasteurellosis, the vaccination of beef calves 2 to 3 weeks before weaning and of feedlot cattle 2 weeks before shipment to a feedlot has been recommended as part of a preconditioning program. The results vary, but vaccination of calves at 3 to 6 months of age with an intranasal modified live IBR/PI3 virus vaccine has provided protection against experimental pneumonic pasteurellosis induced by aerosol challenge with the IBR virus, followed 4 days later by an aerosol challenge with *P. haemolytica*. It is important to vaccinate calves at least 2 weeks before they are weaned, subjected to stress, or transported to a feedlot. Vaccination on arrival, although commonly done, is not reliable and in one study was associated with increased mortality. An intranasal modified live virus vaccine given to feedlot steers does not cause transmission of the vaccine virus to nonvaccinated comingled animals (Baker, 1989). A *Pasteurella* vaccine combined with an *H. somnus* bacterin and intranasal modified live IBR/PI3 vaccines and administered to beef calves 3 weeks before weaning and shipment did not prove beneficial (Martin et al, 1984). An *H. somnus* bacterin evaluated in a large number of feedlot cattle had no effect on the overall crude mortality rate; however, vaccination appeared to reduce the incidence of fatal disease and the mortality rate during the first 2 months in the feedlot, when the risk of fatal disease onset is highest (Ribble et al, 1988). Crude mortality and incidence of fatal disease onset during the second week were reduced significantly in vaccinated steers. It was concluded that about 17% of fatal respiratory disease in unvaccinated steers could have been prevented by vaccination with the *H. somnus*–bacterin (Ribble et al, 1988). In U.S. trials the use of *H. somnus* bacterins to control BRD have not always produced positive or logical results. Reports on three studies by one research group have shown positive, neutral, and negative outcomes after vaccination with *H. somnus* bacterin (Amstutz et al, 1981; Morter et al, 1982; Morter and Amstutz, 1983). Some challenge studies have been performed using a systemic challenge (Stephens et al, 1984), whereas others have used a respiratory challenge (Groom and Little, 1988). In western Canadian feedlots, *H. somnus* infection is implicated in 40% of all mortality (Guichon et al, 1996), which makes attempts at controlling the disease through vaccination very appealing. The lower incidence of *H. somnus*–related diseases in U.S. feedlots makes the use of the vaccine questionable.

Studies evaluating the usefulness of BRSV vaccine in prevention of BRD have produced mixed results. In a western U.S. field trial, auction origin calves vaccinated with BRSV vaccine were two times less likely (odds ratio = 2.0) to require treatment for BRD than unvaccinated calves (Hansen et al, 1992). Groups of calves with low morbidity did not benefit from BRSV vaccination. A modified live virus BRSV vaccine given to beef calves before weaning, at weaning, or immediately after arrival in the feedlot was associated with a significant reduction in the treatment rate in one of three groups immunized before weaning and in calves immunized after arrival in the feedlot (Van Donkersgoed et al, 1990). The vaccine had no significant effect on the treatment rate in calves immunized at weaning, in calves immunized after arrival in a bull test station, or in yearlings immunized after arrival in the feedlot. Several other trials have failed to show benefit from using BRSV vaccine.

When BVDV and BRSV virus infections occur simultaneously, the respiratory tract disease is much more severe than a BRSV infection alone (Kelling et al, 1995). BRSV infection alone produces mild signs. When mixed infections occur, the value of vaccination with BRSV vaccine may be greater than that demonstrated in field trials. There is more benefit from vaccinating calves entering the feedlot than yearlings.

Some feedlot veterinarians recommend that feedlot cattle be vaccinated on arrival with the *P. haemolytica*, IBR/PI3, *H. somnus*, and BRSV vaccines. In many cases the BVDV vaccine is also used, because some veterinarians feel that the virus is part of the respiratory disease complex. It is believed that control will be achieved if the animals are vaccinated against all of the common pathogens that contribute to lesions of bovine respiratory disease. However, there is little, if any, published evidence based on controlled field trials to justify such action. It is obvious that vaccines are only one of the tools used to reduce the risk of BRD and cannot by themselves predictably control BRD.

Metaphylaxis. Antimicrobials have been used extensively for many years to control pneumonic pasteurellosis in cattle that have just been introduced into a feedlot. The challenge has been to know which groups of animals benefit from metaphylaxis and to know when to administer the drug.

When considering metaphylaxis as a management tool in feedlots, it is necessary to establish objectives for its use. Objectives of antimicrobial metaphylaxis include those found in Box 14-3 (Smith, 1996a).

Obviously, not all groups of newly arrived feeder calves benefit from metaphylaxis. Cattle that have been properly backgrounded and immunized experience morbidity rates that are too low to justify the expense. Lighter-weight, multiple-origin calves are at greater risk of developing BRD than heavier, yearling cattle. Other risk factors for the development of BRD have been reviewed (Young, 1995).

Metaphylactic use of antimicrobials should adhere to the following principles (Young, 1995): (1) the risk of infection is sufficient to warrant the use of antimicrobials, (2) organisms that are involved in the infection should be known or accurately predicted (a logical corollary would follow that the selected antimicrobial has demonstrated efficacy against the organism or organisms), (3) the antimicrobial should be delivered and distributed to the site of infection before the onset of infection, (4) the selected antimicrobial should pose minimum risk of adverse effects, such as tissue damage, (5) the metaphylaxis protocol should be cost effective, and (6) only products labeled for cattle with an established preslaughter withdrawal should be used.

Criteria useful for determining whether to use antimicrobial metaphylaxis on a particular group of newly received calves are shown in Box 14-4 (Smith, 1996a).

Currently, two routes of administration are available: oral and parenteral. Oral medications can be delivered through the water or the feed or as boluses. A disadvantage of administration of antimicrobials through the feed or water is the uncertainty of individual animal intake, since dosage is measured on a pen basis. Administration of products through feed or water offers advantages of minimal cattle handling and less labor and eliminates the likelihood of injection blemishes. The use of boluses is somewhat laborious and time consuming. When boluses are administered to large numbers of calves, such as at processing, the risk of pharyngeal injury is increased. Parental administration of antimicrobials is a viable option in a metaphylaxis program. Products selected should be efficacious, have an established preslaughter withdrawal, and should be tissue friendly. Those with smaller dose volumes are more easily administered (Pollreisz et al, 1991).

One of the first attempts to prevent new cases of respiratory disease was through the administration of sustained-release oral sulfamethazine boluses or benzathine-procaine penicillin to animals after arrival in the feedlot. In the case of

Downloaded from Vet-eBooks.com

the penicillin compounds, the results varied; sometimes the short-acting component was effective if the animal was in the early stages of the disease, but the long-acting component was ineffective because the serum concentrations of the drug were not high enough to be effective over the critical period.

In other earlier studies, oxytetracycline at dosages of 5 mg/lb (11 mg/kg) of body weight IM daily for 3 days, followed by oral sulfadimethoxine (68 mg/lb, or 150 mg/kg body weight) on the third injection day reduced the number of treatment days per calf by about 80% compared with controls. The use of long-acting oxytetracycline reduced the treatment days per calf by 90%. Furthermore, administration of long-acting oxytetracycline (9 mg/lb, or 20 mg/kg body weight IM) to feedlot cattle on arrival can reduce the morbidity and mortality from respiratory disease (Albak et al, 1986). IM administration of two different formulations of oxytetracycline to high-risk feedlot calves on arrival reduced the morbidity from respiratory disease during the first 2 weeks on feed and for the entire feeding period by 15% to 19% and also reduced the incidence of fatal fibrinous pneumonia by 67% and 84% (Harland et al, 1991). Long-acting oxytetracycline can reduce the isolation rate of *P. haemolytica* from nasopharyngeal swabs by about 30% during the first week after treatment (Shoo, 1989a).

More recently, two newer antimicrobials, tilmicosin and florfenicol, have been approved for metaphylactic treatment of BRD. Because it has been on the market longer, more data are available from studies using tilmicosin for metaphylaxis than florfenicol. In a summary of 15 trials, Guthrie et al (2000) reported that the use of tilmicosin in high-risk calves at arrival reduced the morbidity rate by 53%. The overall mortality rate was significantly less in calves treated at processing, and gain was improved by 8.4% during an average study period of 60 days. The morbidity rate was reduced in all 15 trials. Differences in mortality and daily gain were less consistent. Delaying the use of tilmicosin metaphylaxis until 72 hours after arrival does not offer any advantages over treatment at arrival (Schumann et al, 1991).

The practice of using rectal temperature as a determinant for metaphylactic therapy has long been debated. If rectal temperature is a useful predictor of illness, fewer animals would be treated at processing, decreasing input costs and antibiotic usage. This concept has been researched but with contrasting outcomes. In the first temperature-based metaphylaxis study, Galyean et al (1994) divided 511-lb (232-kg) high-risk calves into three treatment groups: nonmedicated controls; complete metaphylaxis with tilmicosin at processing; and a temperature-based group where only those calves with a rectal temperature exceeding 39.7° C (103.5° F) were treated with tilmicosin. At 56 days after arrival, calves in the temperature-based and complete metaphylaxis groups gained 0.30 and 0.33 lb (0.14 and 0.15 kg)/day more than the controls, respectively. Feed efficiency was significantly improved in both treated groups. Morbidity was high (44%) in the nonmedicated control group, but it was reduced to 12% and 13% in the complete and temperature-based metaphylaxis groups, respectively. In this study, there were no significant differences in gain, feed efficiency, or morbidity between the two medicated groups; both medicated groups performed better than controls. Temperature-based metaphylaxis returned $3.21 more/head than complete metaphylaxis (Smith, 1996a).

In a larger study (Vogel et al, 1998) calves not medicated at processing experienced a 58.7% morbidity rate and 4.5% death loss during a 211-day feeding period. Calves in a temperature-based metaphylaxis group were treated with tilmicosin at processing if the rectal temperature was 40° C (104° F) or higher. In that group, 49% were treated for BRD and 2.9% died. When all calves were treated metaphylactically, regardless of rectal temperature, the morbidity rate was 34.5% and the death loss was reduced to 1.7%. When performance was calculated on a "deads in" basis, daily gain and the feed/gain ratio of calves in the complete metaphylaxis group were superior to those in the other groups. Dry matter intake was similar in all treatments.

When adequate highly skilled labor is available, temperature-based metaphylaxis can be successful. However, when trained people are in short supply, large numbers of high-risk cattle are received, hospital facilities or space is inadequate, or weather is severe, complete metaphylaxis of high-risk calves is more cost effective.

BOX 14-3

Objectives of Antimicrobial Metaphylaxis

Reduce morbidity. Historically, this has been the most common objective.

Reduce mortality. When research trials are being reviewed, mortality differences are difficult to measure statistically; however, overall, if morbidity is significantly reduced, mortality will also be lower.

Improve performance. It is difficult to justify the cost of metaphylaxis without an improvement in daily gain and feed efficiency.

Improve facilities management. The use of metaphylactic antimicrobials should reduce hospital crowding. This is especially important in the fall of the year when receipts of high-risk cattle are higher and morbidity rates are at their annual peak.

Overcome personnel shortages or inexperience. Antimicrobial metaphylaxis reduces the number of cases of BRD that must be treated on an individual basis. With fewer cattle becoming clinically ill, chances of "missed pulls" are decreased and more time is available to treat individual sick calves.

Improve profits. To be profitable, antimicrobial metaphylaxis should reduce morbidity and individual animal treatment costs, reduce the number of calves that die or must be culled, and improve cattle performance.

BOX 14-4

Criteria for Choosing Antimicrobial Metaphylaxis

Clinical appearance and past history. If the calves look sick or "stale," or if records show that cattle from this source historically have high morbidity rates, metaphylaxis may be indicated.

Morbidity patterns. If the bovine respiratory tract disease (BRD) morbidity rate exceeds 10% on 2 consecutive days, metaphylaxis may be indicated. It is also indicated if the expected BRD morbidity rate exceeds 20% to 25%.

Feed consumption patterns. A decrease in feed intake often precedes a respiratory disease break by about 24 hours.

Rectal temperature. A sampling of the rectal temperature of calves before processing may be helpful. If the percentage of calves with an elevated temperature is excessive, metaphylaxis is indicated.

Downloaded From Vet-eBooks.com

Calves treated with tilmicosin at arrival processing have reduced treatment rates as compared with calves receiving preshipment metaphylaxis (McClary and Vogel, 1999). Preshipment metaphylaxis has been used by many auction markets and order buyers in an attempt to reduce postshipment sickness rates. However, when calves are purchased within a 3-day period and shipped by Day 4, arrival metaphylaxis is superior to preshipment programs and equal to combined preshipment and postshipment metaphylaxis. When metaphylaxis is performed at the feedlot, the consulting veterinarian and feedlot staff have control of the total BRD treatment program, thereby ensuring that proper records are completed and that the Beef Quality Assurance and Residue Avoidance Programs are being followed.

Medication of feed and water supplies is an alternative to metaphylaxis through the use of injectable products. In large feedlots, medication of the water supply is not practical because most have automatic watering systems without the capability to meter medication into the water. Medication of feed is a practical method for metaphylactic treatment of BRD. Chlortetracycline offered at 10 mg/lb (22 mg/kg) of body weight for 5 days has been shown to reduce morbidity to a similar level as tilmicosin (Kreikemeier et al, 1996). Feed intake, both on a pen basis and individual basis, should be considered when making the decision whether to treat by injection or in the feed. Metaphylactic treatment using injectables is preferred when calves become ill with BRD in the immediate postarrival period and before they are eating a normal amount of ration. The antimicrobial susceptibility of the microbes causing BRD should always influence product selection.

Metaphylaxis is not indicated for all groups of newly arrived cattle. It should not be used as routine practice, but rather each group of cattle should be considered on its own merit. Metaphylaxis can be a useful management tool, but alone it cannot solve other management problems that affect health and performance of feeder cattle.

CONTROL AND PREVENTION OF DISEASE IN FEEDLOT CATTLE

Successful and economical control and prevention of disease in feedlot cattle depends on purchasing healthy animals; providing a transportation system that minimizes stress, a comfortable feedlot pen environment, and an adequate feeding system; providing a good surveillance system; and judiciously using vaccines and, when necessary, antimicrobial agents.

Feedlot Facilities

Large commercial feedlots that purchase and market large numbers of cattle have the usual facilities for unloading and loading and for weighing and sorting cattle. Some feedlots have starting or introductory pens that are equipped for easy observation and removal of sick cattle. The cattle are fed in these pens until they have adjusted and been processed; then they are sorted and grouped according to size and condition and placed in finishing pens. However, in other feedlots, there are no introductory pens, and the finishing pens are filled to capacity as the cattle arrive. Adequate treatment facilities and hospital pens should be easily and efficiently accessible (Janzen, 1990g). Some feedlots treat sick cattle and immediately return them to their home pen, whereas others choose to hospitalize cattle until they are fully recovered and competitive.

One of the most important considerations in the construction of a feedlot is landscaping to promote good drainage (Janzen, 1990c). The pens and alleyways should be well drained and easily accessible for scraping the ground surface as necessary. Good drainage requires a 6% slope. To avoid overstocking, each animal should be provided with 18 m^2 of space in well-drained land and 9 m^2 in a paved lot.

Cattle and feed need protection from wind, rain, snow, excessive heat, and sunshine. In northern feedlots, snow fences should be constructed with 20% openings and located so that snowdrifts accumulate outside the pens and alleyways. Trees are planted as windbreaks, and buildings and fences are placed so that the wind is not deflected into feeding areas or sheds. An open-front shed provides protection for cattle from winter storms and hot summer sun. Each animal needs about 1 to 1.5 m^2 of cover. The shed should be open to the south or southeast, and the front should be high enough so that the sun strikes the ground at the back on the shortest day of the winter. The back of the shed should be at least 2.5 m high. A covered feed bunk protects feed from weather damage and affords cattle added comfort when eating. Feed remains dry and palatable, and waste is reduced. In southern feedlots, snow fences, windbreaks and sheds are not cost effective because of typically mild winters. Shades to provide relief from extreme summer heat are useful in feedlots in the extreme southwestern United States.

Feedlots and Environmental Pollution

Environmental concerns about feedlot operations have greatly increased in recent years. In the early days of feedlot development, managing the environment to control mud was based primarily on cattle performance and footrot concerns. Dust during the dry season was considered a part of cattle feeding. Environmental management now has increasing priority. Muddy cattle are discounted because of contamination, partly because the abattoirs refuse to pay for the weight added by the mud and manure, but also because of the increased costs to clean the animal before the hide can be removed. Food safety concerns are foremost in the minds of abattoir operators and government inspectors. Foodborne illnesses, particularly those caused by *E. coli* O157H:7 and *Salmonella*, have forced the meat-packing industry to change the way beef carcasses are processed. The packing industry has placed pressure on feedlots to provide animals that are as clean as possible. In addition, stricter environmental laws require that all feedlot waste and run-off be contained in approved lagoon systems. Pollution prevention plans must be on file with the appropriate government agency. Monitoring, testing, and record-keeping requirements vary from country to country and from state (province) to state.

The control of flies is a major concern in many communities. This is generally solved by timely scraping of pens, proper management of stockpiled manure, use of insecticides, and use of wasps that feed on fly larvae. A great deal of money is spent on managing the feedlot environment, especially scraping pens and disposal of animal waste. These costs will continue to escalate with increasing societal concerns over the environment, food safety, and animal welfare.

Transportation of Cattle to the Feedlot

Transportation, or shipping, of cattle has long been associated with increased BRD in the feedlot, hence the term "shipping fever." Today, however, roads are better and trucks are faster and more reliable than those in the 1950s, causing greatly reduced transient times to deliver cattle to their destination. Under the current transportation system, there is not a correlation between the distance cattle are shipped and the risk of fatal fibrinous pneumonia in the feedlot (Ribble et al, 1995c). Apparently other factors such as level of immunity,

Downloaded From Vet-eBooks.com

commingling, and other stressors are more important in the risk of BRD than distance shipped.

Obviously, unnecessary stressors should be avoided when transporting calves. Cattle should be handled with a minimum of excitement; this is particularly important for newly weaned calves. Careless handling and transportation of weaned calves can negate any effort the producer may have made to produce healthy preconditioned calves.

Cattle lose considerable weight within the first 24 to 48 hours after weaning, during shipment, and after deprivation of feed and water. This loss in body weight is known as *shrink*. Shrink varies from a minimum of 4% in cattle deprived of feed and water for 24 hours up to 9% in animals that are transported long distances over a period of 2 to 4 days. Some of the shrink is caused by the normal loss of fluids and electrolytes from the digestive tract without normal replenishment. Excitement during handling and transportation increases the total amount of shrink. Most of the fluid and electrolyte shrink can be restored within a few days if the animals begin to eat and drink normally. Tissue shrink also affects cattle subjected to long transportation or excessive handling. Shrink exceeding 7% has been associated with increased animal health problems. The total loss in body weight may not be restored for up to 3 weeks.

Transportation equipment and facilities should meet local standards and be able to transport cattle comfortably regardless of the season of the year. When long trips of more than 24 hours are necessary, calves should be unloaded, fed some good quality dry hay, allowed to drink water, and rested for several hours before continuing the trip. Some countries prohibit the transport of cattle over a certain length of time without unloading for rest, feed, and water. The optimum number of cattle that should be loaded per truck depends on the size of the animals, the size of the vehicle, and legal weight limitations.

On arrival at their destination, the cattle should be examined carefully for evidence of clinical disease or injury. Provision of fresh hay and water can help detect those that are anorexic and should be examined more closely. This is particularly important if unexpected delays in transportation have occurred that increase the level of stress in the animals.

Cattle Purchase and Introduction to a Feedlot

The purchase of cattle and their introduction to a feedlot has been a controversial issue in beef production since the development of commercial feedlots. Commercial feedlots attempt to purchase the most inexpensive cattle that will perform the best and provide maximum economic returns (Van Donkersgoed 1990a,b). However, infectious diseases of the respiratory tract, particularly "shipping fever" pneumonia caused by *Pasteurella* spp., are major causes of morbidity and mortality during the first 30 to 45 days after arrival in the feedlot. Digestive diseases, especially carbohydrate engorgement, in cattle placed on a high-energy diet within 30 days after arrival in the feedlot are a major potential threat but can be controlled. The acute respiratory disease complex is much more difficult to control in feedlot cattle, even under good management conditions.

Epidemiological observations over many years indicate that several factors cause stress, which contributes to the pathogenesis of acute respiratory disease complex in feedlot cattle. The routine process of weaning beef calves at 6 to 8 months of age in North America is often followed by respiratory disease. Any factor that causes additional stress at weaning time leads to an increased incidence of disease. Transportation delays, such as mechanical problems or severe road conditions that slow the trip, are often followed by a herd problem. Rapid changes in weather and unexpected snowstorms at the time of shipping may lead to outbreaks of shipping fever. Recently weaned beef calves 6 to 8 months old that are placed into the feedlot have much higher morbidity and mortality rates than do older yearling cattle. Presumably this is because of the higher level of acquired immunity in older cattle. Mixing or commingling of calves from multiple sources into truckload lots is positively correlated with the risk of fatal BRD (Ribble et al, 1995b). The stress of handling recently weaned beef calves is also considered to be a major factor contributing to shipping fever pneumonia. Cattle are often vaccinated, dehorned, castrated, branded, implanted, and injected with vitamins and antibiotics within a few days after their arrival in the feedlot. The acute respiratory disease complex may remain a major source of economic loss in the feedlot industry if the industry continues the common practice of introducing stressed cattle from different sources, with different immunological backgrounds, into populations of cattle in which disease is endemic.

The major objective is to get the cattle onto a high-energy diet—which will result in rapid growth—as soon as possible, usually within 21 days, while minimizing the morbidity and mortality associated with acute respiratory disease, other common infections (e.g., *Haemophilus* septicemia), and digestive diseases associated with adjustments to high-energy diets. All of these objectives should be achieved as economically as possible.

Origin and Purchase of Cattle

Origin and purchase of cattle is an important phase of feedlot operations. The type of cattle fed are influenced by the cost and availability of feeder cattle, ration cost, expected performance of the animals, and anticipated net financial returns. In North America both calves and yearling cattle are commonly fed. Only a small number of bulls are fed because of the lower market price and the problem of managing bulls in the feedlot. The decision on what kind of cattle to buy and where to buy them is largely a matter of risk aversion. How much risk is the feedlot operator willing to take? It is possible to buy groups of uniform feeder calves or yearling cattle that come from one source and in which the disease incidence will be very low. However, these cattle cost more, and the profit margin is often smaller than that for cattle originating from public auction sales yards. The incidence of disease is much higher in weaned beef calves than in yearling cattle. Steer calves are preferred to heifer calves because of their availability, superior growth rate, higher selling price, and absence of problems associated with estrus and pregnancy in heifers. Lighter-weight calves (less than 500 lb [230 kg]) may be preferred to medium-weight calves (500 to 750 lb [230 to 340 kg]), because they cost less per head and have a greater potential for low-cost gains. Yearlings are preferred in some feedlots, because more groups can be fed per year and the morbidity and mortality from respiratory disease are much lower than in calves. The disadvantages include higher purchase price and higher feed costs per unit of gain. Yearling cattle also may originate from a stocker or backgrounding operation in which calves were placed on pasture or a growing ration for several months. They have adequate body size, gain well in the feedlot, and usually experience minimal health problems.

The principles described in Box 14-5 should be considered when purchasing cattle and introducing them to a highly intensive, heavy feeding environment.

In the simplest system a cow-calf producer weans the calves at 6 to 8 months of age and places them in the home farm feedlot. The calves are gradually brought onto a

Downloaded from Vet-eBooks.com

BOX 14-5

Origin and Purchase of Cattle

Only healthy cattle should be purchased.
Cattle should be obtained directly from the farm of origin if possible.
The disease incidence is lower in yearling cattle than in calves.
Adopt the all-in, all-out principle. The cattle are purchased as a group, fed as a group, and sold as a group. This tends to break the chain of infection from one group to another. A corollary to this principle is to avoid mixing recently arrived cattle with cattle already residing in the feedlot. Because of fluctuations in the supply of cattle, feedlots often continue to assemble and make up groups of cattle over a period of several days or a few weeks. When recently arrived cattle are added to existing groups ("add-ons"), new outbreaks of disease occur, which may be perpetuated for several weeks.
Preconditioned cattle should be purchased if economical.
Cattle should be transported to the feedlot in the shortest time feasible.
A reporting system should be developed to regularly inform the cattle buyer of the condition of the cattle received and their subsequent performance. This will assist the buyer in the purchase of healthy cattle, avoiding unhealthy cattle and ensuring that cattle are transported by the most economical and least stressful method of transportation.

growing diet and then a finishing diet and marketed at 14 to 16 months of age. Alternatively, the calves may be kept on a maintenance and growth diet, such as silage or pasture, until they become yearlings, at which time they are placed in the farm feedlot or sold to a commercial feedlot. These calves are usually vaccinated for clostridial diseases and common infectious agents associated with respiratory disease. If these cattle are kept in their original groups until market, the morbidity and mortality rates may be very low and insignificant. However, unexpected outbreaks of diseases may occur even with the best management.

Preimmunization and Preconditioning

The large economic losses associated with the high morbidity and mortality caused by acute respiratory disease in weaned beef calves that were shipped from the ranch within a few days after weaning to sales yards and then to feedlots led to the development of preconditioning. Preconditioning is defined as the preparation of feeder calves for marketing and shipment and may include vaccinations, castration, and training calves to eat and drink in pens (Taylor and Field, 1998). The concept of preconditioning is based in part on immunological and nutritional principles. First, effective immunity against infectious diseases of the respiratory tract can be achieved only if animals are vaccinated in sufficient time before natural exposure occurs after arrival in the feedlot. Preimmunization, or vaccination of calves 2 to 3 weeks before shipment from the ranch to the feedlot, was the beginning of the practice of preconditioning (Hoerlein, 1973). Initially, vaccination before shipment did not appear to provide sufficient protection against disease in calves after arrival in the feedlot. However, calves were still being subjected to stress during transportation and by sales yard procedures. This led to a broader concept of preconditioning. In addition to vaccination, more recent efforts have been directed toward increasing the number of days weaned before movement and improving management procedures on the ranch, such as genetic selection and nutrition, that will assist calves in making an easier transition to the feedlot.

Preconditioning of beef calves means different things in different areas. In the United States preconditioning has been defined by the following elements (American Association of Bovine Practitioners, 1968):

- Weaned at least 3 weeks before sale.
- Trained to eat from a feed bunk and to drink from a trough.
- Treated for parasites.
- Vaccinated for blackleg, malignant edema, PI3, IBR, *Pasteurella*, and sometimes BVD and *Haemophilus*.
- Castrated and dehorned.
- Identified with an ear tag.
- Sold through special auctions.

The following characteristics were used to define preconditioned calves in Alberta (Schipper et al, 1989):

- At least 4 months old before being vaccinated.
- Owned by the operator 45 days before sale or shipment.
- Weaned for a minimum of 45 days.
- Castrated and dehorned at least 3 weeks before sale or shipment.
- Given IBR, PI3, multiclostridial (seven- or eight-way), and *H. somnus* vaccines 3 weeks before sale or shipment.
- Treated for warbles at least 3 weeks before sale or shipment.
- Tagged with an official ear tag applied under the supervision of a licensed veterinarian.
- Accompanied by an official health certificate that has been completed and signed by both the veterinarian and the producer.

A review of preconditioning programs in 12 different states (Miksch, 1985) found good uniformity of management and guidelines based on American Association of Bovine Practitioners (AABP) guidelines. However, controversy continues to surround the issue of preconditioning, the cost, and specific vaccination recommendations. The most important aspects appear to be weaning and familiarity with a prepared ration. Currently, most preconditioning programs have been replaced by individual programs developed at the producer level and by commercial programs, such as Vac 45 (Odde, 1998), promoted by biologics firms.

When preconditioned calves are placed in a feedlot, they usually begin to eat and drink on arrival; if they have not been subjected to unusual stressors, the incidence of disease will be minimal. However, daily surveillance is still necessary to identify cases of illness.

Proper preconditioning of calves involves cost to the primary producer. The rancher must gather and handle the calves early to vaccinate them and, after weaning, must provide an adequate diet until shipment. The loss of weight after weaning must be made up before the sale. If producers are to incur these costs, they must be compensated adequately. Some reports in the literature indicate that preconditioned calves are healthier when they arrive in the feedlot and that the incidence of respiratory disease is lower than in nonpreconditioned calves (Schipper et al, 1989; Karren et al, 1987; Lynch et al, 1997). However, other field studies indicate that the costs of preconditioning do not economically justify paying a premium for preconditioned calves (Peterson et al, 1989a,b).

Cow-calf producers have shown considerable interest in delivering a quality calf to the feedlot but are understandably reluctant to add extra expense unless the returns are greater

Downloaded From Vet-e-Books.com

than the costs. The future of preconditioning will depend in large part on whether the livestock industry becomes convinced of its value. In most situations, a premium price is necessary to compensate the cow-calf producer for the costs of preconditioning (Basarab et al, 1986), whereas most buyers are unwilling to pay the needed premium (Engelken, 1997). The real return to management is realized when cow-calf producers retain ownership through the entire feeding period. The real costs associated with sickness clearly indicate a need for integrated health programs (Texas A&M, 1992-1995). Early weaning of calves has a beneficial effect on cow winter maintenance requirements, which must be incorporated into the calculation of the costs and benefits of preconditioning. This suggests that there is a need to examine the economics of the entire system of producing calves for beef production, from the cow-calf producer to the feedlot operator. Currently, the availability of relatively inexpensive antimicrobials and the development of relatively effective postarrival management protocols continue to encourage the shipment of recently weaned calves to the feedlot.

Cole (1985) has summarized preconditioning of calves as follows:

Preconditioning is a theoretically sound concept; however, it has not gained wide acceptance by cow-calf producers or feeders owing to logistics and expense. Many of the claims of preconditioning are not substantiated by controlled research data. Many of the positive claims made for preconditioning may be a result of the calves moving more rapidly through the marketing channels. Although preconditioning is profitable to some producers, on average, preconditioning is difficult to justify economically. However, with the increased numbers of producers retaining ownership through the feedlot, the benefits of the procedure are readily apparent. Modifications of the preconditioning concept have the potential to make it more feasible to the majority of cow-calf producers. Any producer or feeder considering a preconditioning program or feeding preconditioned calves should first calculate an economic projection.

Backgrounding

Backgrounding is a variation of preconditioning in which recently weaned calves are grown to yearling feeder cattle weight, usually in a smaller feedlot. The principal objective is to prepare yearling cattle to adjust to a high-energy finishing ration in a feedlot with minimal problems. This is achieved by feeding the calves a growing diet that yields rapid, efficient body weight gains without fattening. Maximum use is made of roughage rations. The spectrum of diseases that occur in backgrounding operations during the first 45 days after arrival of the calves depends on whether the calves were preimmunized, preconditioned, or obtained from several different sources with no preconditioning. Infectious diseases of the respiratory tract (pneumonic pasteurellosis) and of the digestive tract (coccidiosis) account for most of the losses. Cattle that have been through a backgrounding program usually go onto a high-energy finishing diet in a different feedlot with a minimum of problems. Ideally, groups should be maintained as they were formed in the backgrounding feedlot.

Processing of Nonpreconditioned Cattle on Arrival

The preconditioning concept is a valid one, but it deals with only one segment of feedlot replacements. Ranch calves moving directly to the feedlot are only one source of replacements available to large feedlots. Large commercial feedlots must also rely on public sales yards, where cattle are offered for sale by public auction, and on backgrounding feedlots. Cattle marketed through sales yards may or may not receive the benefit of good animal husbandry practices. These cattle usually originate from a variety of areas. After arrival at the sales yard, commingling of the animals is common, and they are subjected to unfamiliar environments, different feed and watering systems, possibly long periods without feed and water, excessive handling, weighing, and mixed into uniform groups to meet the requirements of commissioned buyers who have specific orders from feedlots. In addition, some cattle may be moved to an order buyer facility, spend several days while other cattle are purchased and resorted for final delivery. As well, calves moving through the sales yards may be subjected to stressors such as castration, dehorning, vaccination, and other processing procedures. All these factors, coupled with exposure to multiple infectious agents, provide ideal conditions for the development of respiratory disease (Rogers, 1997).

From the situation just described, cattle are transported to the feedlot. The trip may require only a few hours or up to 48 hours or more. During this time, the cattle may be deprived of palatable feed and water, and inclement weather may occur. Thus, on arrival at the feedlot, the animals are highly susceptible to acute respiratory disease. The mortality rate in sales yard cattle is approximately 75% greater than that in cattle originating directly from ranches or from backgrounding feedlots. In a vaccine study, auction-market derived cattle were 19.5 times more likely to be treated for respiratory disease than preconditioned cattle, and ranch-fresh calves were 5.7 times more likely to be treated than preconditioned cattle (Hansen et al, 1992).

The processing of cattle of unknown background that have been subjected to the stresses of sales yards and transportation and that arrive at the feedlot at unexpected times of the day and in large numbers (often on a daily basis during the peak buying periods) is a challenge for the veterinarian and veterinary assistants. Cattle may arrive during off-hours because of long travel periods. During peak periods it may not be possible to process all cattle for several days, during which time an outbreak of acute respiratory disease may occur in the animals waiting to be processed. Unexpected shortages in personnel, snowstorms, rainstorms, and unforeseen problems elsewhere in the feedlot all contribute to the vulnerability of recently arrived cattle. There will be wide variations in nutritional status, genetic potential, vaccination history, and colostral immunity. Some cattle will have been castrated and dehorned, and the age at which they were castrated and the completeness of the castration will vary considerably. Some will have come from backgrounding yards, order buying facilities, and range; others will have come from geographical areas in which the incidence of siliceous urinary calculi is high; and some will have been implanted with anabolic steroids. Feedlot heifers may have been fed melengestrol acetate (MGA) to suppress estrus, whereas other heifers may be pregnant. These cattle must be conditioned during the first 2 to 3 weeks in the feedlot.

It is generally agreed in the feedlot industry that recently arrived cattle of unknown backgrounds require extra surveillance and care during the first 2 to 3 weeks after arrival. Most of these cattle must be vaccinated as necessary, and some need to be castrated, perhaps dehorned, and given growth promotant implants. Veterinarians have traditionally adopted the approach that nonpreconditioned stressed cattle of unknown backgrounds should be allowed to adjust to their new surroundings for up to 3 weeks after arrival. During this adjustment period the cattle are fed good-quality roughage along with a quantity of a highly palatable, nutrient dense, ration. The calves must be ensured an adequate water supply and provided with adequate bedding,

Downloaded from Vet-eBooks.com

especially during the first few days, so that they can rest. The cattle are checked carefully at least twice daily for evidence of illness, and sick cattle are identified and treated. The provision of only good-quality roughage for the first 2 or 3 weeks has been considered a logical practice. However, controlled field trials in feeder calves subjected to marketing and shipping stresses indicate that increasing the concentrate or energy level in the starting diet to up to about 72% improves performance when compared with lower-energy diets (Lofgreen, 1988).

Large commercial feedlots with experienced personnel may challenge recently arrived cattle with high-energy diets within 2 weeks after arrival. This is done in an attempt to get them on full feed as soon as possible, and economics is the motivating force. However, this system is something like walking a tightrope: most of the time it is successful, but occasionally it is catastrophic. Over the long term, in large feedlots with a large turnover, it may be economical. In small farm feedlots with less experienced personnel, a more conservative approach is recommended.

The major objectives of the feeding program during the introductory period are to get the animals eating, to avoid outbreaks of carbohydrate engorgement, and to avoid outbreaks of indigestion during the period when the cattle are most susceptible to acute respiratory disease. The conservative approach is to provide a highly palatable roughage or silage diet for the adjustment period. After this starter diet, and when the animals are healthy and the common infectious diseases are not a problem, the animals can then be fed the growing and finishing diets.

In the Bruce County Project in Canada, feeder calves were shipped from western Canada to Bruce County in Ontario and placed in small farm feedlots, usually on a one-time basis for the year. Results indicated that the highest mortality rates were associated with the feeding of corn silage rather than hay and with the processing of cattle on arrival (Martin et al, 1980, 1981, 1982). Vaccination against respiratory disease on arrival also appeared to increase the risk of mortality.

Currently, vaccination against certain respiratory diseases within 24 hours of arrival is standard practice for the majority of feedlot and backgrounding operations. The recommendations in Box 14-6 for handling high-risk nonpreconditioned calves are based on experience, efficacy trials, and limited field studies.

Studies by Lofgreen (1988) of the energy level of the diets offered to stressed feeder calves after arrival in the feedlot indicate that diets containing 50% to 75% concentrate promote more rapid recovery of purchase weight than diets containing 25% concentrate. However, diets containing levels higher than 75% appear to increase morbidity and mortality rates from respiratory disease.

In summary, there is a lack of good scientific information to conclude whether nonpreconditioned cattle will benefit from vaccination procedures given within 24 hours of arrival. However, even in the absence of good information, most veterinarians will conclude that the prevention of at least the viral diseases through vaccination is worth the perceived risk of the added stress (Johnson, 1985). In addition, with the use of injectable antibiotics in metaphylaxis programs, processing on arrival can be highly beneficial (Vogel et al, 1998; McClary and Vogel, 1999).

Regardless of the system used, immediately on arrival the cattle should be weighed as a group, examined for evidence of illness, and treated if necessary. Some feedlots administer antimicrobials to all calves considered to be a high risk for acute respiratory disease (Albak et al, 1986). If the illness appears different from the usual case of respiratory disease, a veterinary diagnosis should be sought at the earliest possible time. Close examination and surveillance are desirable for groups of cattle with a history of unusual stress. The youngest and smallest cattle often need special attention, and it may be necessary to separate them from older cattle. All of the available history on each group of cattle should be obtained if possible. A reliable history of vaccination, vitamin injections, implants, and anthelmintic administration would be useful but is usually not available. The major objective during the first few days should be to avoid unnecessary deaths from diseases that normally respond well to treatment. Depending on the condition of the cattle, it may be difficult during the first few days after arrival to easily distinguish sick cattle from healthy cattle, and careful clinical surveillance every few hours may be necessary. Observations at the time of feeding often reveal anorexic animals that should be pulled from the pen and examined.

BOX 14-6

Recommendations for Handling High-Risk Nonpreconditioned Calves

- Feeder calves from different sources or arriving at the feedlot over a period exceeding 7 days are expected to be at high risk of developing respiratory disease and require extra manpower and attention. One person/500 head during this early arrival period is approximately the right ratio.
- High-risk feeder calves should be kept in groups of less than 100. This facilitates early identification of sick calves and minimizes the possible spread of infectious agents.
- Feeder calves should be fed dry, good-quality hay for at least 2 to 3 days. Hay should form the major component of the roughage during the first week.
- Silage should be introduced very gradually and should not become the major roughage during the first 2 weeks after arrival. Preferably it should be limited until the initial upsurge of treatments for illness is over.
- The use of metaphylactic antimicrobials against respiratory disease may be necessary, since it is associated with decreased morbidity and mortality.
- Feeder calves should be processed on arrival if possible; processing should be limited to procedures that are the least stressful to the animal.
- Vaccination with viral vaccines on or shortly after arrival is likely necessary and beneficial. Vaccination should be limited to those products that actually reduce the losses resulting from respiratory disease. Other procedures and products should be delayed for at least 2 to 3 weeks.
- Regular surveillance is necessary to detect and treat sick calves in the earliest stage of disease.
- Handling facilities should be designed to minimize the stress associated with all of the processing procedures to which feeder calves are subjected.

Specific Processing Procedures

Identification. Each animal must be identified immediately, preferably with a color-coded and numbered plastic ear tag that is easily visible from a distance. This is recorded in the record system and, when available, directly into the computer. The color coding allows the attendants to sort and return cattle to their pens, which are indicated by the color code. In many feedlots each animal may not be identified individually but instead receives a tag with a lot number

Downloaded from Vet-eBooks.com

(group) or pen number. This identifies individual animals as belonging to a group or pen but not as individuals. Some commercial feedlots also brand their animals to identify ownership, but hot branding should be discouraged. Systems are now in place that individually identify animals with electronic identification tags. Tag readers are available that can read tags from a distance of 8 to 10 inches. Information can be maintained on individual animals through this technology, including performance, vaccine, and treatment history. These tags remain on the animal until slaughter, at which time a transfer of the identification from the ear tag to the overhead trolley system can be made. Individual identification of each animal, when removed from the pen, allows the practitioner to monitor every animal selected for clinical examination (e.g., whether it had a fever and whether it was treated, including the dates of occurrence). The data can be used to monitor the daily incidence of disease for each pen and for the number of days in the feedlot. These epidemic curves provide useful epidemiological information on how soon after arrival animals become ill. From this information, strategies for the treatment and control of acute undifferentiated respiratory disease can be formulated.

Measurement of Body Temperature. On arrival, some animals may be affected with acute disease, but clinical signs will not be obvious. Many animals will appear fatigued and gaunt but are not affected with clinical disease. It is difficult to distinguish these animals from those with acute infectious disease that should be treated and identified early to minimize mortality. The body temperature of high-risk cattle (e.g., auction mart calves or calves that have been transported long distances over several days) is often measured shortly after arrival, usually at processing. Currently available digital thermometers can register the rectal body temperature of an animal in a few seconds. Animals with a temperature greater than 40° C (104° F) are treated with an antimicrobial. Treated animals may be tagged and noted in the individual animal database or alternatively the total number of animals treated (total amount of drug administered) in a group or pen. Even with treatment of febrile animals on arrival, the case fatality rate may approach 10%, which suggests that animals that are sick on arrival have probably been ill for a few days.

Vaccination. The value of vaccination of feedlot cattle for common infectious diseases, particularly those of the respiratory tract, has been controversial since the introduction of the vaccines. A review of the literature by Martin (1983) examined the published evidence for the claims that vaccination with respiratory disease vaccines actually prevents respiratory disease or influences weight gains in feedlot calves. He concluded that little published data support the use of vaccines against respiratory disease under feedlot conditions. Treatment rates and weight gains usually did not differ among vaccinated and nonvaccinated groups. In fact, the use of live BVD vaccines was associated with a significant subsequent increase in treatment rates. In a review of respiratory vaccine literature (Perino and Hunsaker, 1997), the authors reviewed BRSV, IBR, BVD, and *Pasteurella* studies. Field studies demonstrating effectiveness of vaccines in reducing clinical outcomes of respiratory disease are rare, and yet they are a major focus of veterinary health programs.

Questions exist about the necessity of BRSV vaccines. However, vaccine efficacy appears adequate when modified live vaccines are used. Vaccines against the IBR virus have been used for over 30 years. Some earlier studies indicate a reduction in clinical disease with the use of vaccines. Most practitioners would agree that IBR vaccines must be a part of respiratory disease protection (Perino, 1998). The most controversial virus fraction attributable to respiratory disease is BVD. BVD is a disease of cattle that is still not completely understood. Two options exist to treat BVD: eradicate it or vaccinate against it. In the United States, eradication is a long way off and vaccination is a necessity. The choice of vaccines to the veterinarian and producer are modified live or nonreplicating vaccines. It is becoming clear that modified live vaccines provide the best protection against BVD infection and disease (Ellis, 1998b). The use of *Pasteurella* vaccines in the feedlot continues to be a source of debate. Improved vaccine technology has led to vaccines that now contain antigenic components and protect lung tissue from the effects of *Pasteurella* infection. The basic issue to decide is whether the vaccine will provide protective immunity before the time of greatest *Pasteurella* challenge in the feedlot. Efficacious data on *Haemophilus* immunization strategies are limited, but vaccines may provide some protective effect (Van Donkersgoed et al, 1993).

Nevertheless, a wide variety of vaccines are used in feedlot health programs. Veterinarians have decided, based on their clinical experience, that certain vaccines appear to be efficacious, and they recommend their use. In some cases the feedlot operator is convinced, based on experience, that certain vaccines are efficacious, and thus they are used routinely.

Vaccines are available for the following diseases or infections of feedlot cattle:

- IBR
- Pneumonic pasteurellosis
- PI3 virus infection
- BRSV
- Disease complex caused by *H. somnus*
- BVD

The vaccines available for clostridial diseases are highly efficacious. The number of antigens to be used (two- or eight-way) depends on local prevalence of clostridial diseases. These diseases include the following:

- Blackleg *(Clostridium chauvoei)*
- Malignant edema *(Clostridium septicum)*
- Bacillary hemoglobinuria *(Clostridium novyi,* type D *[haemolyticum])*
- Infectious hepatitis (*C. novyi,* type B)
- Tetanus *(Clostridium tetani)*
- Enterotoxemia (*Clostridium perfringens,* types B, C, and D)
- Leptospirosis (*Leptospira serovars hardjo, pomona, grippotyphosa, canicola, icterohaemorrhagiae)*

Vaccines for leptospirosis in receiving calves are usually not necessary; however, in some areas leptospirosis is endemic and vaccination may be necessary. Vaccines reduce clinical cases of leptospirosis but do not prevent all infections.

A basic vaccination schedule for receiving calves should include a four-way respiratory viral vaccine plus a clostridial vaccine. Additional vaccines should only be included if two criteria can be met: The disease is enough of a risk that prevention is necessary, and efficacious data can be found to support the use of vaccines to prevent disease.

Castration and Dehorning. These surgical procedures are frequently performed at processing but are very stressful to cattle and may reduce performance for up to 90 days and increase the mortality rate (Cole, 1985). It is generally recommended that these procedures be delayed until the animals are adjusted to the feedlot.

Management of Pregnancy in Heifers. Pregnant heifers entering the feedlot are recognized as an economic liability. Economic losses occur from death at calving or from infection, increased treatment costs, additional labor (e.g., to check and calve-out pregnant heifers), and reduced value when sold. The dressing percentage of pregnant heifers and heiferettes at slaughter is reduced from 4.0% to 6.1% (Bennett, 1984; Edwards and Laudert, 1984; Stanton et al, 1988). Dressing percentage has a significant impact on the value of cattle sold on a carcass basis.

Downloaded from Vet-eBooks.com

There are four options for risk management of pregnancy in feeder heifers (Bennett, 1984; Edwards and Laudert, 1984):

1. Buy only heifers that are confirmed open or spayed.
2. Pregnancy-check at point of purchase and sell-back of pregnant heifers.
3. Purchase heifers that are not pregnancy checked at point of purchase (no pregnancy check or abortion at the feedlot).
4. Pregnancy-check heifers at the feedlot and attempt to abort the pregnant ones.

Spayed or confirmed nonpregnant heifers pose the least pregnancy liability risk. Nonpregnant heifers also gain better than those pregnant and aborted or those pregnant and not aborted. Heifers purchased as nonpregnant, or open, should have been examined by a veterinarian, and documents verifying the pregnancy status of the heifers should accompany the shipment.

Losses incurred with either the sell-back or pregnancy-check/abortion option are similar: $8.29 and $8.71 (U.S. dollars), respectively (Table 14-3). The economic risk is greater when using the sell-back option, where those found pregnant are sold and not fed, as compared with the pregnancy check/abortion program. When heifers are palpated and aborted in the feedlot, death losses can be both unpredictable and excessive, especially when groups of heifers experiencing high BRD morbidity rates are aborted, when weather is severe, or both. Economic losses are greatest when no pregnancy management program is in place. Assuming a 16.5% pregnancy rate, the total loss averaged across all heifers in the group is estimated to be $19.04 (U.S. dollars)/head.

When choosing the pregnancy check/abortion management option, heifers pregnant 120 days or less can be aborted successfully using prostaglandins at label dosage. The abortion rate in heifers pregnant over 120 days and treated with prostaglandins alone can be quite low. Those pregnant over 120 days treated with a combination of prostaglandin and 20 mg of dexamethasone will have an abortion rate of about 95 percent (Edwards and Laudert, 1984; Mapletoft and Barth, 1983). Heifers at high risk of BRD should not be injected with abortifacients for at least 21 days after arrival, since heifers that have been aborted recently and suffer BRD are at greater risk of dying (Edwards and Laudert, 1984; Mapletoft and Barth, 1983). MGA should be withheld from the ration for at least 7 days before and after injection (Clay, 1996).

At times feeding heifers can be more profitable than feeding steers. Pregnant heifers are a liability, and if a pregnancy management program is not in place or is not properly executed, losses resulting from calving, abortions, and associated losses can be economically devastating. The economic returns from a pregnancy management program are greatest when heifers are sold on a carcass basis, since dressing percentages and carcass weights strongly influence sale value.

Spayed Heifers. Spaying (ovariectomizing) heifers is a commonly used method to prevent pregnancy in heifers under range conditions. During the period when brucellosis in cattle was endemic, spayed heifers from infected herds could be marketed for grazing or feeding whereas intact heifers could not. Under current regulations, spayed heifers from Mexico can cross into the United States for feeding purposes whereas intact heifers cannot.

The comparative performance of spayed and intact heifers has been reviewed (Rupp and Hamilton, 1995). When a growth promoting implant is not used, intact heifers on finishing rations gain 6.05% more than spayed heifers. The use of a growth promoting implant can overcome this effect and allow the spayed heifer to gain comparably to the implanted intact heifer. Spayed heifers implanted with estradiol benzoate (EB) or a combination of EB and trenbolone acetate (TBA) gain the same as intact heifers implanted with EB and TBA combination (Perino et al, 1995). More attention should be given to reimplanting schedules for spayed heifers, since their performance drops markedly when no active implant is present.

When spaying is performed by an experienced practitioner, complications are usually minimal. Occasionally

TABLE 14-3

*Economic Comparison of Pregnancy Management Options for Feedlot Heifers**

	Sell Back	No Treatment	Pregnancy Check/Abortion
FEEDING PHASE			
Loss/head: all cattle	$8.29	$15.32	$8.02
Loss/head:pregnant (at purchase)	$50.24	$92.87	$45.58
SLAUGHTER			
Loss/head: all cattle	—	$3.72	$0.69
Loss/head: pregnant (at slaughter)	—	$30.00	$30.00
COMBINED LOSS			
Loss/head: all cattle	$8.29	$19.04	$8.71
Loss/head: pregnant (at purchase)	$50.24	$115.42	$52.76

Adapted from Bennett B: *Proc Acad Vet Consult* 12(1):14-27, 1984.
*Losses are calculated in relation to open heifers. Each calculation assumes a 16.5% pregnancy rate.

Downloaded from Vet-eBooks.com

problems resulting from spaying are seen in the packing house. Peritonitis, adhesions of the skin to the body wall when flank spayed, and body wall abscesses are occasionally found. Pregnancy is rare in spayed heifers. If the surgeon left one ovary or a piece of an ovary, the heifer could become pregnant. If the heifer is in late gestation when spayed, she could carry the fetus to term. Either of these problems is minimized when spaying is performed by a competent, experienced surgeon.

There is no need to feed MGA to spayed heifers. This offers another small economic advantage to the spayed heifer.

Anthelmintics and Insecticides. Anthelmintics and insecticides are administered according to local conditions. The feedlot operator and veterinarian should be informed about feeder calves or yearling cattle that have originated from farm situations or areas in which intestinal parasitism is likely. When compared with treatment with a topical organophosphate, treatment with ivermectin can cause improved average daily weight gain and feed conversion in feedlot calves under commercial conditions (Bauck et al, 1989). Young cattle raised on small farms in which the stocking rate on pasture is high may harbor helminths (Armour, 1980). Young cattle may also be affected by chronic verminous pneumonia caused by *Dictyocaulus viviparus*.

Growth-Promoting Agents. Growth-promoting agents are substances that promote increased growth rate of animals without being used themselves to provide nutrients for growth (McCutcheon, 1989). They are generally administered in small amounts with a view toward altering metabolism so that the animal increases body tissues and grows more rapidly. They are anabolic, nonnutritional substances that cause a beneficial change in growth-related phenomena. They promote changes in composition, conformation, mature weight, or efficiency of growth, although these effects are frequently accompanied by changes in the rate of live weight gain. Despite their varied origin and chemical nature, these agents influence the growth process in three general ways:

1. By stimulating feed intake, thereby increasing the supply of nutrients available for growth. Antibacterial agents, estrogens, androgens, and possibly somatotropin increase voluntary intake of feed.
2. By altering the efficiency of the digestive process, thereby improving the supply or balance of nutrients derived per unit of feed consumed. These agents include the antimicrobials (e.g., the tetracyclines, which are fed at subtherapeutic levels, and the ionophores, such as monensin, lasalocid, and laidlomycin, which cause a major shift in the ratio of volatile fatty acids produced in the rumen).
3. By altering the manner in which the animal uses or partitions absorbed nutrients for specific growth processes. These agents include steroids such as estrogens and androgens that promote growth in animals and the β-adrenergic agonists, a class of compounds similar to adrenalin; the best examples are ractopamine, zilpaterol and cimaterol. They improve live weight gain and feed conversion efficiency, increase carcass protein content, reduce carcass fat, and increase carcass yield.

Implants. The efficacy of estrogens and androgens as anabolic agents in increasing live weight gain has been shown in many different growth trials under different husbandry and feeding systems. The best performance results in the feedlot are obtained in steers and heifers treated with preparations combining an androgen with an estrogen. It has become a common practice to implant steroids more than once during the finishing period of beef cattle. The steroids are effective in calves as well as yearlings, and reimplantation extends the period of their effect on growth (Reynolds, 1980).

Long-acting anabolic steroids should not be implanted into animals intended as breeding stock. Changes in behavior after implanting can also be a problem. The incidence of mounting and riding in steers implanted in feedlots has increased with the increased use of anabolic agents. Regulations governing the use of implants are set by the U.S. Food and Drug Administration (FDA). Practitioners must always read and follow the manufacturer's directions before implanting any cattle. The growth promotant implants approved for use in the United States are extremely safe for both producers and consumers of beef. There is no required withdrawal time for slaughter for FDA-approved implants. Therefore it is most important that all implants be placed at the middle of the ear, beneath the loose skin overlying the conchal cartilage. This area is traditionally discarded at slaughter.

Pasture-Stocker Calves. Scientific studies indicate that growth promotant implants usually increase weight gain significantly over nonimplanted animals, in some cases up to 30 lb (14 kg) or more/implant. Genetics, nutrition, and implant program planning are key factors. If the animals are not consuming adequate nutrients above maintenance requirements, the response to implanting will be negligible. The producer should match nutrition and the selection of the appropriate implant to the length of the grazing period in order to achieve maximum growth promotion. The use of implants on pasture-stocker calves may affect (reduce) response to subsequent implants, as well as marbling at slaughter, if the nutrition and implant program are not planned correctly.

Feedlot Steers and Heifers. The proper use of growth promotant implants in feedlot steers has led to improvements in rates of gain up to 30% and feed conversion up to 17% compared with nonimplanted controls, thereby consistently returning $7 to $10/dollar spent/implant period. An understanding of the implant's ingredients, levels, payout period, and impact on performance must be attained, and strategies for appropriate use developed. The first objective is to determine days on feed (DOF). Including projections of DOF in implant considerations requires a paradigm shift or change in rational thinking. Historically, producers have administered estrogen implants at 70- to 100-day intervals after arrival, disregarding the relationship to slaughter date. By projecting DOF initially, the finished animal is the end product and thus becomes the focus of the program. The implants and implant strategy become a tool to influence performance and carcass quality.

Implants influence rate of gain and feed conversion by increasing protein accretion (muscle). They may delay, interrupt, or not affect the actual amount of marbling (fat) deposited. Therefore the producer must set goals for performance, quality grade, or a combination of the performance and quality grade achievable when planning the implant program. The current USDA grading system is a "visual" system, in which the grader is comparing the ratio of muscle to fat. Increases in muscle tissue deposition may change the ratio enough to drop the quality grade. Recent research indicates that possible negative effects on marbling may be minimized if a step-up program in implant dose-effect is used: (1) low dose to higher dose (suckling calf to slaughter), (2) not overlapping one implant effective period on the next, at least not within the first half of the previous implant's estimated effective period, and (3) not exceeding the level of hormone to which the animal can respond in any given growth phase.

The producer should match nutrition and the selection of the appropriate implant(s) to the length of the feeding period, performance goals, and desired carcass parameters.

Descriptions of implants and their use can be found elsewhere (Botts et al, 1997). Box 14-7 shows a list of current approved growth implants.

Downloaded From Vet-e-Books.com

BOX 14-7

Currently Approved Growth Implants

SYNOVEX C, IMPLUS C, COMPONENT E-C
These implants contain 10 mg estradiol benzoate (72% estradiol) and 100 mg of progesterone. They are recommended for use in suckling beef calves weighing up to approximately 400 lb (182 kg). Synovex C may be used in both steer and heifer calves, including one-time use in beef heifers intended for later breeding.*

REVALOR-G
Revalor-G contains 40 mg trenbolone acetate (synthetic androgen) and 8 mg of estradiol in a slow-release delivery system that increases rate of weight gain in pasture cattle (slaughter, stocker, and feeder steers and heifers).

RALGRO
Zeranol, the active drug in Ralgro, is a chemical derivative of resorcylic acid lactone fermentation product, with estrogenic properties. Ralgro contains 36 mg of zeranol and is used to increase the rate of weight gain and improve feed conservation in growing cattle, feedlot heifers and steers, and weaned and suckling calves. Ralgro has been approved for one-time use in beef heifers intended for later breeding.

RALGRO MAGNUM
Ralgro Magnum contains twice the active compound, zeranol (72 mg), as Ralgro. Magnum is used to increase rate of weight gain in steers fed in confinement for slaughter. Because of the increase in zeranol level, Magnum is reported to have a longer growth-promoting effect than Ralgro.

SYNOVEX S, IMPLUS S, COMPONENT E-S
These implants contain 20 mg estradiol benzoate (72% estradiol) and 200 mg of progesterone. They are recommended for use in steers weighing 400 lb (182 kg) or more. When the implants are properly administered, they can help increase rate of weight gain and improve feed efficiency.

SYNOVEX H, IMPLUS H, COMPONENT E-H
These implants contain 20 mg estradiol benzoate (72% estradiol) and 200 mg of testosterone propionate. Synovex H is recommended for use in heifers weighing 400 lb or more. When the implants are properly administered, they can help increase rate of weight gain and improve feed efficiency.

COMPUDOSE 200
Compudose 200 is a silicone rubber implant containing 25.7 mg of estradiol and coated with not less than 0.5 mg of oxytetracycline powder as a local antibacterial. Compudose 200 is intended for increased rate of weight gain in suckling and pastured growing steers, and improved feed efficiency and increased rate of weight gain in confined steers and heifers.

ENCORE
Encore is a silicone rubber implant containing 43.9 mg of estradiol, with a similar coating and animal approval to Compudose 200. It is reported to have a longer growth-promoting effect than Compudose 200.

FINAPLIX-H
Finaplix-H contains 200 mg of a synthetic androgen, trenbolone acetate. Trenbolone acetate has been shown to have 8-10 times the growth promoting ability of an equal amount of testosterone. Finaplix-H increases the rate of weight gain and improves feed efficiency in growing finishing heifers.

REVALOR-H
Revalor-H contains both estradiol (14 mg) and trenbolone acetate (140 mg) for increased rate of weight gain and improved feed efficiency in a slow-release delivery system in heifers.

SYNOVEX PLUS
Synovex Plus contains 28 mg of estradiol benzoate (72% estradiol) and 200 mg of trenbolone acetate. Synovex Plus is recommended for improved feed efficiency in steers and heifers fed in confinement for slaughter.

REVALOR-S
Revalor-S contains both estradiol (24 mg) and trenbolone acetate (120 mg), which increases rate of weight gain and improves feed efficiency in a slow-release delivery system in steers.*

*Generic equivalents, approved by the Food and Drug Administration, are available from Ivy Labs/Vet Life (Component) and the Upjohn Company (Implus).

Growth-Promoting Feed Additives. Several growth-promoting feed additives are available for incorporation into feedlot rations. The economic advantages include improved average live weight gains, improved feed efficiency, and, in some cases, control of certain diseases.

Ionophores. Carboxylic polyether ionophore antibiotics, also known as ionophores, cause an increase in the molar proportion of propionic acid and a concomitant decline in the molar proportion of acetate and butyrate in the volatile fatty acids produced in the rumen (Bergen and Bates, 1984). Monensin has been used most extensively, but other agents, including lasalocid and laidlomycin, have been investigated or are used commercially (Russell and Strobel, 1989). Monensin's mode of action and influence on the performance of cattle have been reviewed by Schelling (1984) and Goodrich et al (1984). Monensin sodium may be used from the beginning of the feeding period until slaughter (Burrin et al, 1988). It improves feed efficiency by about 10% and, when used during the first 28 days of the feeding period, assists in the control of coccidiosis. Lasalocid is also widely used as an ionophore (McCutcheon, 1989).

Tylosin at levels of 60 to 90 mg/head/day is used in the feedlot for the prevention of liver abscesses and can be used along with monensin. Chlortetracycline and oxytetracycline

Downloaded From Vet-eBooks.com

at levels of 10 g/ton of feed may be given to feedlot cattle as growth promotants in some countries. Feeding of chlortetracycline at a subtherapeutic level can benefit nonstressed cattle in a feedlot situation, and responses can be equal to or greater than those observed with monensin or lasalocid (Beacom et al, 1988). The body tissues (muscle, liver, kidney) of animals fed chlortetracycline contained no repeatable detectable residues of the antibiotic. Thus if antibiotics are properly fed and the proper withdrawal period is used, there should not be a residue problem. The development of drug-resistant strains of bacteria in cattle fed the drug for long periods is of concern and must be monitored. The effects of monensin and chlortetracycline in high-concentrate and high-forage diets for implanted and nonimplanted finishing steers and heifers have been compared by Beacom and Mir (1985).

Vitamin Injections. Vitamin injections are used in some processing schedules as a mixture of vitamins A, D, and E. This procedure prevents any possible occurrence of hypovitaminosis A, which may be present in cattle that have originated from a dry carotene-deficient pasture or diet. However, the vitamins may also be supplied in the feed at high concentrations during the conditioning period to increase levels in the liver.

BEEF QUALITY ASSURANCE AND BEEF SAFETY PROGRAMS

The purpose of the beef quality assurance (BQA) program is to identify and avoid areas in the feedlot where quality or safety defects can occur. Feedlots seek all sources of information needed to accomplish BQA goals and objectives. The BQA program is a cooperative effort between beef producers, veterinarians, nutritionists, extension staff, and other professionals. The program encourages everyone involved with beef production to follow the government guidelines for product use and to use common sense, reasonable management skills, and accepted scientific knowledge to avoid product defects at the consumer level. The goal of the BQA program is to assure the consumer that all cattle shipped from a feedlot are healthy, wholesome, and safe and that their management has met all government and industry standards.

The BQA objectives for the feedlot should be as follows:

1. Set production standards for the feedlot that can be met or exceeded.
2. Establish systems for data retention and record keeping. Record-keeping systems that meet government and industry guidelines allow validation of management activities and fulfill the program goal.
3. Provide hands-on training and education for all personnel to meet or exceed the guidelines of the BQA program and to realize the benefits of such program.
4. Use technical assistance available through cattlemen associations, the veterinarian, the nutritionist, and university staff. The feedlot veterinarian should serve as the facilitator of the BQA program for the feedlot.

Quality Challenges

The importance of BQA is obvious when the top eight quality challenges within the beef industry are analyzed. These quality challenges include injection site blemishes, rib brands, excessive external fat, excessive seam fat, dark cutters, inconsistent size of meat cuts, inconsistent cuts, and nonuniform cattle. The primary beef safety concerns are antimicrobial resistance and violative chemical residues.

According to the 1995 National Beef Quality Audit (NBQA), injection site blemishes cost the beef industry $188 million annually, or an average of $7.05/animal. Brands and other hide defects, such as parasite damage, cost the beef industry more than $648 million annually. Typically, these losses are passed to cattle producers by a reduction in live cattle price, or "built-in discounts." This is equivalent to $24.30/head.

The BQA challenge to improve beef quality includes the following: eliminate side and multiple brands, remove horns, improve parasite control, improve red meat yield, improve handling-transport techniques, eliminate IM injections, measure traits that impact value, and eliminate genetic and management systems that negatively affect tenderness, juiciness, and flavor.

History of Beef Quality Assurance in the United States

Consumers demand safe food. Because of concerns with additional government regulation and potential loss of modern production tools, in 1980 cattlemen began investigating ways to ensure that their production practices were safe and would satisfy the concerns of the consumer.

In 1982 the USDA-Food Safety Inspection Service (USDA-FSIS) began working with the beef industry in the United States to develop the Pre-Harvest Beef Safety Production Program. To side-step additional governmental regulatory programs, the beef industry developed the BQA program, a self-regulating program that became an important key for avoiding additional government regulation. Currently 47 states and more than 90 percent of the United States beef production are involved with the voluntary program. Industry self-regulation has proven very successful and will continue to allow industry the flexibility needed to produce safe and wholesome food in an economical manner. Success of the effort is clear; violative chemical residues have nearly disappeared in fed beef cattle, and injection site lesions have been reduced by over 67 percent.

While the BQA program was developing, the Pillsbury Company was implementing a quality control program for the space industry that used many of the same principles. Their program, hazard analysis of critical control points (HACCP), gained universal acceptance and is presently the dominant outline for quality assurance programs in processed foods. Because of USDA regulation, all U.S. packing plants have developed, or will be developing in the near future, HACCP programs.

The HACCP concepts are the same as those of BQA. It is a process of determining what could go wrong, planning to avoid it, and documenting what was done, with the additional step of validation. USDA's HACCP program for the packing industry includes foodborne bacterial pathogen control, a problem that currently is not controllable at the farm, ranch, or feedlot level. When preharvest bacterial pathogen control measures become available or government regulations mandate control measures, the valuable experience working with the present BQA programs will help producers adapt to any new requirements.

Important Points for Beef Quality Assurance to be Successful (Box 14-8)

The feedlot veterinarian, feedlot management, and staff cannot foresee all potential problems. They must identify one area at a time, then develop and implement a plan for ensuring quality in that area of production. The experience gained will make it easier to develop quality assurance in other areas of the operation.

Violative residues and product-related defects can be avoided if animal health products are administered according to government and industry standards and if BQA

BOX 14-8

Beef Quality Assurance Guidelines and Agreements

FEEDSTUFFS AND SOURCES

- The feedlot must maintain a record of pesticide (herbicides, insecticides, etc.) use that could cause a violative residue in feedlot cattle. Governmental regulations describe what records must be kept.
- The feedlot must maintain a quality control program for incoming feed ingredients. Every effort must be made to eliminate contamination resulting from molds, mycotoxins, and chemical contamination, such as pesticides.
- Submit any feed ingredient suspected of contamination for analysis by a qualified laboratory before use.
- Certain ruminant-derived protein sources, such as meat and bone meal, cannot be fed. Other ruminant-derived products, such as blood by-products and tallow, can be used in feedlot diets.

FEED ADDITIVES AND MEDICATIONS

- Only government-approved medicated feed additives can be used in rations.
- All medicated feed additives should be used in accordance with the approved label. Extra-label use of feed additives is strictly prohibited in the United States; however, Canadian law allows for extra-label usage of feed additives when prescribed by a veterinarian.
- The feedlot should ensure that all additives are withdrawn at the proper time to avoid violative residues.
- Medicated feed additives should be used in accordance with good manufacturing practices (GMPs). These include a formula record of all medicated feed rations produced and production records of all batches of feed produced that contain medicated feed additives. Production records must include additive used, date run, ration name or number, and amount produced.
- The feedlot should keep all records for at least 2 years from the date of transfer or sale of the cattle and have the capability of trace-back.

ANIMAL HEALTH PRODUCTS AND INJECTIONS

- Follow all governmental guidelines for product usage.
- All products labeled for subcutaneous (SQ) use must be administered as such in front of the shoulders.
- All products labeled for IM (intramuscular) use must be administered only in the neck region. No injections should be given in locations other than the neck, regardless of calf age.
- Products that cause excessive tissue damage should be avoided whenever possible.
- Products approved for SQ, IV, and oral administration are preferred over those labeled for IM usage.
- Products with low-dose volume are preferred, and proper spacing of injections should be practiced.
- Products should not be administered at more than 10 ml/site unless otherwise stated on the label.
- Aminoglycosides should not be used extra-label because of unknown or unpredictable preslaughter withdrawal time.

ANIMAL HEALTH TREATMENT AND PRODUCT USE RECORDS

- Treatment regimens should follow label directions unless the feedlot veterinarian has determined the need to use a product extra-label.
- Extra-label drug use shall be used only when prescribed by the feedlot veterinarian.
- All cattle treated with medications administered extra-label must comply with prescribed, extended withdrawal times that have been set by the feedlot veterinarian under the guidelines of a valid veterinarian-client-patient relationship (VCPR). The Food Animal Residue Avoidance Databank (FARAD) is the primary resource for determining the preslaughter withdrawal time when an animal has been treated extra-label.

Individual Treatments

- Treatment records should be maintained for all cattle treated individually. This can be done using hand generated records or using a computerized record system. Essential information includes the individual animal identification, treatment date(s), diagnosis, drug administered, serial-lot number, dosage used, approximate weight of animal, route and location of administration, and earliest date the animal could clear the preslaughter withdrawal period.

record-keeping standards are maintained. A number of safeguards built into the beef-feeding system help avoid quality defects. These include handling of animals on an individual basis, length of time required to produce a finished product, and quality and safety built into modern health related technologies of beef production. Every employee must be trained to know, understand, and identify areas where possible quality defects or contamination with violative residues can occur. Suppliers of services, commodities, or products must understand the feedlot's quality assurance objectives.

The feedlot must be able to document all the steps of production. Good production records also allow for documentation, analysis, and improved financial decisions. There are points in production that must be monitored to ensure no residue violations or carcass defects occur. The critical points include, but are not limited to, incoming cattle, products and commodities, cattle handling, and evaluation of outgoing cattle. Some production areas that have higher residue and carcass defect risks than others. High-risk production areas include nonperforming cattle, unusual single source feed ingredients, and suppliers of nonstandard supplies (Smith et al, 1997).

Beef Quality Assurance Good Management Practices

Feedstuffs and Commodity Sources

Monitoring Feedstuffs. It is essential to monitor feed sources. Feedlots purchasing outside feeds should maintain a sampling program to test for quality specifications of feed-

Downloaded from Vet-eBooks.com

BOX 14-8 —cont'd

Group Processing or Mass Treatments

- All animals treated as part of a group (processing or mass medication) should be group or lot identified, and the treatment information should be recorded. Records should include the animal lot or group identification, product used, serial-lot number of the product, date treated, dosage used, route and location of administration, and withdrawal information. A preslaughter withdrawal time is assigned to the entire pen. Recording treatments under this system assumes that every animal in the lot or group received the treatment.
- The health records of cattle shipped to slaughter should be checked by feedlot personnel to ensure that treated animals have cleared the appropriate withdrawal times.
- A release slip should be signed and dated by the person who checks the records before the animals are released from the feedlot.
- The treatment history of cattle with chronic medical problems or those that have a poor, unexplained growth rate, should be scrutinized carefully. In many cases residue screening, such as the live animal swab test (LAST), is advisable. Residue screening should be performed under the supervision of the feedlot veterinarian. The results of such testing determine whether an animal can be released for shipment but cannot be used to shorten the labeled withdrawal time.
- All pesticides should be used in accordance with label directions. Record all pesticide use such as pour-ons or injectables, including product identification, lot-serial number, date used, amount used, and withdrawal time.

RECORD KEEPING

- All records should be kept for at least 2 years after cattle have been shipped from the feedlot.
- All BQA-related records should be inspected periodically by the veterinarian providing consultation service to the feedlot.
- If a violative residue is found in any cattle shipped for slaughter, the feedlot must make applicable records available to the appropriate government agencies. The source and cause of the violative residue should be determined and corrective action taken to prevent reoccurrence.
- Records can be kept on a computer or in written form, as long as they meet the aforementioned specifications and allow for verification of actions taken.

CARCASS QUALITY

- The feedlot should strive to prevent bruising during animal handling. When possible, bruising rates should be monitored at the packing plant.

stuffs, such as moisture, protein, and foreign material. Suppliers should be informed that sampling of delivered products will occur. A good business practice is to require all products to be accompanied by an invoice, which includes the date, amount, and signatures of both the person who delivered the product and the person who received the product. Grain suppliers should understand that protectants can have withdrawal times. Most bonded, reputable suppliers have a quality control testing program of their own, including polychlorinated biphenyls, chlorinated hydrocarbons, organophosphates, pesticides and herbicides, heavy metals, and microbes (*Salmonella*). As part of the BQA program, the feedlot should ask for the test results.

A quality control program for feedstuffs helps prevent chemical residues and ensures high-quality feeds. Visual inspection of feeds can avoid some problems. A checklist—including such items as color (typical, bright, and uniform), odor (clean and characteristic), moisture (free flowing, no wet spots, and moisture testing), temperature (no evidence of heating), no evidence of foreign material, and evidence of bird, rodent, or insect contamination—can serve as a tool to accept or reject a load of commodities or feed.

It is neither efficient nor economically feasible to test every load of grain or forage for contaminants. A logical alternative is to take a representative sample of each batch of newly purchased feed and store it in case a feed-related problem occurs in the future. Commonly, a thorough investigation of suspected feed-related problems is not possible because no representative sample is available for testing. If feed sampling and storage is done on a routine basis and a suspected feed-related problem occurs, samples for appropriate laboratory testing will be available. A recommended sampling method for purchased grains, supplements, or complete feeds is to randomly sample each batch of feed in five to ten locations and pool the individual samples into a larger sample of 2 to 5 lb (0.9 to 2.3 kg). The pooled sample should be placed in a paper bag or small cardboard box, labeled and frozen. Dry samples can be labeled and kept in a dry area. Higher moisture samples should be frozen. A feed tag should be attached to the sample if needed for future reference.

Forage samples should also be collected and stored. If multiple bales of hay are purchased, representative samples should be obtained from several bales and mixed together before storage. Core samples are preferred over "grab" samples, particularly from large bales of hay. Most hay samples can be stored in a labeled paper bag and kept in a clean, dry area.

High-Risk Feeds. High-risk feeds are single loads or batches fed to cattle over a prolonged period, thereby exposing large numbers of cattle. Examples include fats, rendered by-products, plant by-products, supplements, and additives. Typically, these feedstuffs are only a small percent of the total diet and are very expensive to test. Suppliers should understand the feedlot BQA concerns and should provide quality specifications with the product. It is best to do business with a bonded supplier.

Ruminant By-Products. Because of bovine spongiform encephalopathy concerns, certain ruminant-derived protein sources, such as meat and bone meal, cannot be fed. Ruminant-derived products such as tallow and blood by-products are acceptable under the BQA program. Pure porcine

Downloaded from Vet-eBooks.com

and equine meat and bone meals can also be fed to feedlot cattle.

Potential Feed Toxins. It is important that feedlot managers and staff have some knowledge about the relative toxicities of chemicals to livestock so that highly toxic chemicals, such as soil insecticides, will be handled and stored properly. All chemicals should be treated as potential hazards and should be stored away from feed storage and mixing areas. If a feed-related poisoning is suspected, it is critical for the feedlot veterinarian to contact a diagnostic laboratory for assistance in confirming the suspicion. Some poisoning incidents may be reportable to the appropriate federal or state-provincial government agencies.

Naturally occurring mycotoxins also pose a threat to quality beef production in the feedlot. Mycotoxins can be found in grains and forages and, if present in sufficient concentrations, can cause reduced feed consumption, poor production, and adverse health effects. Mycotoxins can be produced in feedstuffs before harvesting or during storage. More commonly found mycotoxins include aflatoxin, vomitoxin, zearalenone and fumonisins in grain, primarily corn, and slaframine in red clover. Ergot alkaloids can be found in either grain or grass hays.

Fats. Steps should be taken to ensure that purchased fats and oils do not contain a residue. Discuss the quality of product with suppliers and request information about the sources, quality, stability, and consistency of the product. Feedlots may be approached by brokers who offer a cheaper source of feed grade fats; however, the potential for contamination increases with cheaper sources of fats.

Reputable dealers should be testing fats for such contaminants as polychlorinated biphenyls, chlorinated hydrocarbons, pesticides, heavy metals, *Salmonella*, and tall oil (hydrocarbon). Verification of testing should accompany the product.

Good Management Practices

Good management practices (GMPs) include feed handling facilities designed to reduce the risk of feed contamination with chemicals, foreign materials and disease-causing infectious agents. All chemicals (pesticides, lubricants, solvents, medications, etc.) should be stored away from feed supplies. Feed-handling equipment should be checked routinely for fluid leaks. Feedstuffs should not be stored around electrical transformers. Dual-purpose equipment, such as loaders (including shovels) that may handle feed and other materials (such as manure or dead animal removal), should be cleaned thoroughly before feed is handled. No vehicles other than feed-handling equipment should be allowed into feed storage areas, such as silage pits. The most common source of infectious agent contamination comes from animal or human feces. Feedstuffs, feed troughs, and water supplies should be protected from contamination with chemicals, foreign material, and feces. Control of rodents, birds, and other wildlife is important to avoid fecal contamination with many common infectious agents.

Animal Treatments and Health Maintenance

Management

Feedlots have done an excellent job of minimizing violative drug residues. This has been accomplished by placing emphasis on the identification of treated cattle and good record keeping. This includes identifying each animal treated; accurately recording the product(s) used, treatment date, and treatment dosage; and following prescribed withdrawal times.

Treatment Protocol Book

The feedlot veterinarian should provide a Treatment Protocol Book specific to the feedlot operation. The Treatment Protocol Book should be reviewed regularly and updated at least every 90 days. One copy of the Treatment Protocol Book should be kept at the treatment facility and another copy should be maintained in the feedlot office. A written treatment protocol, along with current prescriptions (purchase orders), are important documents that the feedlot must have if there is a government inspection of the feedlot facilities, drug usage procedures, and residue avoidance plans. Of greater significance, the treatment book provides written guidelines for animal health programs, thus minimizing chances of mistakes or misunderstandings.

Injections

A critical part of a feedlot BQA program is the proper administration of animal health products. All injections should be given in front of the shoulders—never in the rump or back leg. When possible, IM injections should be

TABLE 14-4

Guidelines for Needle Selection for Feedlot Cattle

	Route of Administration								
	Subcutaneous injection ($\frac{1}{2}$- to $\frac{3}{4}$-in needle) (cattle weight, lb)			Intravenous injection ($1\frac{1}{2}$-in needle) (cattle weight, lb)			Intramuscular injection (1 to $1\frac{1}{2}$-in needle) (cattle weight, lb)		
INJECTABLE VISCOSITY	<300	300-700	>700	<300	300-700	>700	<300	300-700	>700
Thin (e.g., virus vaccine)	18 gauge	18-16 gauge	16 gauge	18-16 gauge	16 gauge	16-14 gauge	20-18 gauge	18-16 gauge	18-16 gauge
Thick (e.g., oxytetracycline)	18-16 gauge	18-16 gauge	16 gauge	16 gauge	16-14 gauge	16-14 gauge	18 gauge	16 gauge	16 gauge

Downloaded from Vet-eBooks.com

avoided. However, some animal health products are labeled for IM use only. If IM medications must be used, they should be administered in the neck at a maximum of 10 ml/injection site. As a general rule, feedlot personnel should not inject more than 10 ml subcutaneously in each injection site; however, some products are labeled for use up to 20 ml/injection site.

Bent and Broken Needles

The veterinarian should educate all feedlot personnel on proper cattle handling, cattle restraint, and proper injection technique. Improper animal restraint is the cause of most bent needle problems. If a needle bends, it should never be straightened and reused. Although rare, a needle can break off in the muscle. A broken needle is an emergency, and time will be of the essence. Broken needles migrate in tissue and if not handled immediately will be impossible to find, requiring the animal to be destroyed. Under no circumstances should animals with broken needles in them be sent to market. The veterinarian should outline procedures for handling such cases in the Treatment Protocol Book. Purchase of high quality needles, changing and discarding of damaged needles, and proper restraint are all preventative measures. Guidelines for needle selection are found in Table 14-4.

PUTTING BEEF QUALITY ASSURANCE TO WORK THROUGH THE HAZARD ANALYSIS CRITICAL CONTROL POINT SYSTEM

"Build on what you know" is the operative phrase in any BQA program. The BQA program road map is the HACCP system. The veterinarian, nutritionist, feedlot management and staff, and other specialists must look for what could go wrong, then determine ways to avoid the problem. A system must be developed to check, verify, and document what has been accomplished. Everyday working techniques must be designed to avoid problems, especially those problems that can cause a safety or quality defect. This includes evaluation of safety hazards that can affect employees (Boxes 14-9 and 14-10 and Figs. 14-10 and 14-11).

Examples of HACCP outlines for feed and product use are shown in Figs. 14-12 and 14-13. The concept of BQA is as simple as considering what can go wrong in production that could cause a quality defect and figuring out how to prevent it from going wrong. The veterinarian cannot monitor what he or she does not measure, so it is important to document and verify the steps taken to avoid having problems occur.

DEVELOPMENT OF ANTIMICROBIAL-RESISTANT BACTERIA

A comprehensive review of the use of antimicrobials in beef cattle health management and the relationship to antimicrobial resistance was published recently (Radostits, 1999). The use of antimicrobials, particularly the subtherapeutic use of antimicrobials, in the feed of feedlot cattle is controversial because it may promote the development of antimicrobial-resistant strains of bacteria. The major concern is that these strains can then be transferred in the meat to humans, causing disease that may be difficult to treat because of drug resistance. It is also possible that resistance plasmids from animal enteropathogens can be transferred by the process of conjugation to human enteropathogens.

The bacteria of major concern in this context are *Campylobacter* and the *Salmonella* spp., which occur commonly in the intestinal tract of animals and are known as enteric bacteria. The use of subtherapeutic levels of antimicrobials in the feed of cattle can result in the emergence of drug-resistant strains of bacteria in the intestinal flora of the animals. The resistance may be to several antibiotics, a phenomenon known as multiple-drug resistance. If these bacteria contaminate beef carcasses, they can become a foodborne pathogen for humans who handle the meat or eat meat that is not cooked adequately.

In the mid-1960s in England, a single antibiotic strain of *Salmonella typhimurium*, phage type 29, caused an extensive outbreak of disease in cattle. Salmonellosis also occurred in some farm personnel. Antimicrobials had been used prophylactically and therapeutically to treat sick cattle, and it

BOX 14-9

Hazard Analysis Critical Control Points (HACCP): Five Preliminary Steps

ASSEMBLE THE FEEDLOT HACCP TEAM: BRING TOGETHER THE HACCP RESOURCES

Everyone involved, including the veterinarian, the nutritionist, extension and university specialists, suppliers, and employees, should help identify production areas where quality problems and defects could occur. The team should review the final HACCP plan to ensure that it is comprehensive and workable.

DESCRIBE THE PRODUCTION SYSTEM AND HOW THE CATTLE ARE MANAGED

Each feedlot will have some differences in its HACCP system. There is a built-in margin of safety for withdrawal times in the feedlot industry, since most withdrawal times for animal health products are shorter than the feeding periods. Feedlot personnel must be aware of high residue-risk situations. Nonperforming cattle (e.g., chronics) could have organ damage, which could prevent normal clearance of a product, causing violative drug residues even after the preslaughter withdrawal time has elapsed.

IDENTIFY WHO BUYS THE CATTLE AND COMMUNICATE WITH THEM

Most feedlots sell cattle directly to packers. There is no room for error in preslaughter withdrawal times or physical injury that causes bruising. The packer should immediately notify the feedlot of any quality or safety defects so that they can be corrected quickly.

DEVELOP AND VERIFY A PROCESS FLOW DIAGRAM

Outline all of the steps of production. The members of the HACCP team should evaluate each step for the potential causes of quality or safety defects. The defects include (1) bacterial contamination, which can cause infectious disease in cattle or employees, (2) chemical usage-contamination, which can lead to violative residues, and (3) physical damage such as injection site damage, bruising, or broken needles in animal tissue.

MEET THE REQUIREMENTS FOR THE BEEF QUALITY ASSURANCE GOOD MANAGEMENT PRACTICES AND STANDARD OPERATING PROCEDURES (SOPs)

Include sanitation SOP (finding ways to prevent or minimize fecal-oral contamination).

BOX 14-10

Seven Specific Hazard Analysis Critical Control Points (HACCP) Steps

IDENTIFY POTENTIAL PROBLEMS OR HAZARDS: BACTERIAL, CHEMICAL, AND PHYSICAL (B-C-P)

Conduct a production analysis to identify potential problems that could occur in the production process. The use of a production flow diagram provides the best guide to ensure no area has been overlooked.

IDENTIFY CRITICAL MANAGEMENT POINTS OR CRITICAL CONTROL POINTS (CCPs)

CCP must be identified in the production process at which potential problems could occur and be prevented or controlled. The use of the production flow diagram-outline-list provides the best guide for identifying where potential problems might occur and points at which training-management activities may reduce or eliminate the hazard.

ESTABLISH CRITICAL LIMITS (CLs) FOR CCPs

Limits must be established for preventive measures associated with each critical management point. Determine how to identify when a production activity is not being conducted properly. Some limits are easy to establish and some are not. For example, giving all injections in the neck is a CCP. Any injection not given in the neck is outside the CL. Providing clean water for cattle to drink might be a CCP, but within minutes of cleaning a water trough, recontamination of the water (outside CL) can occur. The best possible method is to follow a reasonable cleaning schedule. Proper handling of cattle (another CCP) is important, but establishing a well-defined CL is difficult.

ESTABLISH CCP MONITORING PROCEDURES

Each CCP must be monitored to ensure it stays within the established limits set by management. Supervision on a timely basis is the key. This step outlines a person(s) in the feedlot who is designated to regularly check to ensure the activity is being carried out in a manner that meets the feedlot's (management's) objective (the CCP). Simply stated, is anyone checking to make sure that activities are being done like they were intended, or as best as possible under the circumstances? A scheduled checklist is useful. The CCP monitoring list will help employees to keep from overlooking important items. A feedlot's CCP monitoring list may have items scheduled for checks on a daily, weekly, monthly, or yearly basis. Examples of beef quality assurance checklists are shown in Figs. 14-10 and 14-11.

ESTABLISH CORRECTIVE ACTIONS (CAs)

CA must be taken when monitoring determines a critical management point is not within established critical limits. CA should include what will be done in the future to prevent the problem from happening again. "What do you do if ..." needs to be discussed and decided before something goes wrong. There are two reasons it is important to establish CA before a problem occurrs: The problem will be corrected faster, and the CA needed may change the seriousness of the problem. Understanding the seriousness of potential problems may change how prevention of the problem is viewed by employees. The HACCP team should help develop possible and appropriate CAs.

ESTABLISH VERIFICATION PROCEDURES

Testing and other measurements must be used to verify the program is working properly. For example, liver abscess reports from a packer are appropriate for verifying that a feedlot's liver abscess control program is working.

ESTABLISH RECORD-KEEPING PROCEDURES

Keep records that document the management system is being monitored and is working correctly. Any records system will work as long as it is appropriate to meet the needs of the HACCP system developed for the feedlot.

was thought that this use may have been responsible for the proliferation and dissemination of the strain. Subtherapeutic levels of drugs had not been used.

After this outbreak, the British Minister of Agriculture, Fisheries and Food and the Minister of Health appointed a Joint Committee on the Use of Antibiotics in Animal Husbandry and Veterinary Medicine. The committee, chaired by Dr. M. Swann, was asked to collate the available information on the use of antimicrobials in animal husbandry and to determine its impact on animal and human health.

In 1969 the Swann Report concluded that the administration of antimicrobials to farm livestock, particularly at subtherapeutic levels, posed certain hazards to animal and human health. These hazards included an increase in the resistance of enteric bacteria of animal origin to one or more antibiotics; the ingestion by humans of antibiotic-resistant salmonellae, possibly endangering life; the presence of antibiotic residues in animal products, which could induce harmful effects such as allergic reactions or toxicities; and the fact that certain bacteria such as *Salmonella typhi* might acquire resistance to chloramphenicol, which at that time was considered to be the most effective antibiotic for the treatment of typhoid fever.

After the release of the report, antibiotics were officially classified into two categories in England. The first consisted of agents approved for use in animal feeds as growth promotants; these included bacitracin, virginiamycin, and bambermycins. The second consisted of antimicrobials that were used as therapeutic agents in human or animal medicine such as penicillin and the tetracyclines. These were banned for use in the feeds of animals unless prescribed by a veterinarian. Later, unrestricted sale of the macrolide antibiotic tylosin for growth-promoting purposes was allowed, and this agent was retained as a prescription antibiotic for therapeutic purposes in animals. The results of large-scale surveys have indicated that, in general, antibiotic resistance in bacteria has not increased, especially in Europe and North America (Walton, 1988).

In summary, the United Kingdom's experience in restricting the use of antibiotics in feeds has shown that resistance in bacteria probably develops in spite of the controls on subtherapeutic concentrations of "feed" antibiotics not used

Beef Operation _____ Date _____ Evaluator _____

Feeding Facilities
Feed storage inspected for contamination before receiving new loads of ingredients.
Feed storage area only used to store feed ingredients (no pesticides, solvents, etc.).
Water source protected and checked yearly for contamination.
Procedures in place to protect feed-handling equipment contamination.
All feed-handling equipment checked for contamination before each use.

Receiving Feedstuffs
Receiving Log Record: source (verified), date, description.
Training.
Basic Quality Control:
1. As needed for economic evaluation of feedstuff (e.g., moisture, protein).
2. Visual inspection for contaminants (e.g., pink seed corn).
3. Source-verify high oil feeds (e.g., fat from packing plants versus blended fats).
4. Inspect trucks for contaminants (e.g., any signs of hauling dangerous materials before feed).
5. Samples of "high-risk" feeds stored as per nutritionist recommendations.

Feed Additives
Receiving Log Record: source (verified), date, description (including serial-lot no.).
Stored separate from other feedstuffs.
Use Log Record: date, dose per ton, ID of animals.
Physical Inventory Log (can be column in use log).
Training for using feed additives.

Feed Formulas
Record of all feed formulas.
Medicated feed formulas checked by nutritionist or veterinarian for accurate dosing.
Directions for use, including withdrawal.
Training.

Batch/Load
Batch Log.
Minimum/maximum and exception table or chart for ingredients and mixing.
Training.

Feed Delivery
Delivery Log/Load Tickets.
Delivery matches call.
Training.

Cattle Release
Withdrawal checked on all feed records.

in humans. Thus prohibition of subtherapeutic doses of antibiotics in animals has not prevented or even affected the prevalence of resistant bacteria in the United Kingdom. It is also difficult to ascertain the effectiveness of the Swann Committee recommendations, because animal health and production practices have improved substantially and the therapeutic use of antibiotics may be a more important factor in the selection of resistant organisms than subtherapeutic use. Resistant strains of salmonellae and other bacteria have persisted; some have increased in incidence, and others have decreased. The reasons for the changes are unknown but do not appear to be related solely to the presence of antibiotics in the gastrointestinal tract.

One important factor confounds the study of the effects of subtherapeutic use of antimicrobials in animal feeds: a significant proportion of antimicrobial resistance in humans may be a direct result of the therapeutic use of antimicrobials in humans, not of antimicrobial use in agriculture. The use of effective antibiotics simply eliminates a large proportion of the sensitive organisms and allows resistant bacterial species to emerge. Similarly, antimicrobial resistance in veterinary medicine is usually the result of the therapeutic use of antimicrobials in animals. When the prevalence of resistance to any species of bacteria increases, it is usually associated with the introduction of a new antimicrobial, whether in human or veterinary clinical practice.

In 1980 the National Academy of Sciences commissioned the Committee to Study the Human Health Effects of Subtherapeutic Antibiotic Use in Animal Feeds (National

Research Council, 1980). After reviewing the evidence, the committee concluded that "the postulated hazards to human health from the subtherapeutic use of antimicrobials in animal feeds were neither proven nor disproven." The report went on to say that "the lack of data linking human illness with this subtherapeutic use must not be equated with proof that the proposed hazards do not exist." The research necessary to establish and measure a definite risk has not been conducted. The committee also concluded that it is not possible to conduct a feasible, comprehensive epidemiologic study of the effects on human health arising from the subtherapeutic use of antimicrobials in animal feeds, partly because it is impossible to determine the antimicrobial history of the animal from which a particular piece of meat came.

Some published reports in the medical literature claim that feeding of subtherapeutic levels of antibiotics to animals or therapeutically treating animals with various antibiotics results in an increase in the frequency of isolation of *Salmonella* spp. and E. *coli* organisms that are resistant to those antibiotics and that these bacteria can be transferred to humans and cause illness.

Holmberg et al (1984) reported on a human outbreak of infection with *Salmonella newport* resistant to ampicillin, carbenicillin, and tetracycline in several Midwestern states. Food histories and plasmid profiles of the organisms isolated from both affected humans and isolates from livestock in six states led the authors to conclude that the resistant organisms infecting the patients were of animal origin and that the probable source was contaminated

hamburger, the meat of which was derived from a single herd. The editorial that accompanied the report suggested that the study provided "the important missing link" between human disease and bacterial resistance resulting from the feeding of subtherapeutic levels of antibiotics to animals. However, the evidence is incomplete. First, the pathogenic bacterial strain was not recovered from the slaughterhouse or from the hamburger, all of which had already been consumed, and no cases of *S. newport* disease occurred in the cattle or in the people associated with the farm. Second, another processing plant in another state received half the carcasses from this herd and had no apparent problem. Third, the only *S. newport* organisms isolated from an animal that were of a strain identical with the outbreak strain came from a calf that died in an adjacent dairy herd. With regard to the use of antimicrobials in the feed of the feedlot animals, the report stated, "The beef cattle had been fed subtherapeutic amounts of chlortetracycline throughout 1982 for growth promotion and disease prevention, but no therapeutic concentrations of antimicrobials. The farmer added chlortetracycline to the feed by hand, approximately 100 g per ton of feed." However, this was not analyzed or proved, and there is no indication of how long the drug was used. Furthermore, the addition of

an antimicrobial to the feed by hand at a rate of 100 g/ton would be imprecise at best.

According to Spika et al (1987), a 1985 outbreak of multiple-resistant *S. newport* in California "convincingly" demonstrated the entire chain of transmission. The outbreak strain was resistant to chloramphenicol, tetracycline, kanamycin, ampicillin, and sulfisoxazole and was characterized by a single large plasmid. Epidemiological studies identified ground beef as the suspect food vehicle, and many of the patients had consumed ground beef at fast-food restaurants. Microbiological and epidemiological studies traced the epidemic strain through the hamburger, back to meat-processing plants, and ultimately back to the farms from which the animals had been sent for slaughter. The isolates were from ill calves and cows from a number of dairy herds. Isolation of chloramphenicol-resistant salmonellae was associated with chloramphenicol use at those dairies. However, there is no information on how the drug was used, when it was used, how long it was used, and even whether it was used at all. Thus use was not proved. In the two outbreaks just cited, the human patients were receiving physician-prescribed oral antimicrobials for previously diagnosed illnesses. Oral antimicrobials can interfere with competitive bacterial antagonism, a natural defense mechanism for the control of bacteria.

An in-depth study conducted in 1989 by the Institute of Medicine of the National Academy of Sciences concluded that it was not possible to find a substantial body of direct evidence that conclusively established a human health hazard resulting from the use of subtherapeutic concentrations of penicillin and tetracyclines in animal feeds (Institute of Medicine, 1989).

More recently, the USDA and the Center for Veterinary Medicine of the Food and Drug Administration asked the National Research Council (NRC) to form a committee to examine and review the benefits and risks associated with drug use in the food-animal industry (National Research Council, 1999). The NRC assigned the task to the Board on Agriculture, and the Committee on Drug Use in Food Animals was convened. The committee was charged with reviewing, evaluating, and making recommendations related to the need for drugs and their availability and accountability in agriculture, the benefits and risks to human health and food safety associated with food-animal drugs, the development of food-animal drugs and the process of approval of their use, and the emerging trends in animal health care and the availability of alternative management practices for raising food animals. In particular, the sponsors stressed the importance of evaluating the class of drugs known as antimicrobials.

The committee concluded that the use of drugs in the food-animal production industry is not without some problems and concerns, but it did not appear to constitute an immediate public health concern; additional data might alter this conclusion. The greatest concern is associated with the use of antimicrobials in food animals in such a way that there is a potential for antibiotic resistance to develop in or be transferred to pathogens that can cause disease in humans. This report acknowledged that there is a link between the use of antimicrobials in food animals, the development of bacterial resistance to these drugs, and human disease—although the incidence of such disease is very low. The link between the animals fed antimicrobials and transfer of antibiotic resistant enteric pathogens to humans has not yet been demonstrated.

A substantial change in the human health risk posed by antibiotic use would affect not only how animal drugs are reviewed, approved, and used, but also how food animals are produced. It should be noted that antimicrobials are still effective for their intended purposes at the recommended dosages.

Bacterial resistance to antimicrobials is the most important motivating factor in the development of new drugs to fight infections and in the modification of processes by which drugs are approved. Regulatory agency approval practices have improved in recent years and continue to do so. Reasonable balance in accountability, oversight, and veterinarians' access to alternative drugs has increased with the passage of Animal Drug Availability Act (ADAA) and Animal Medicinal Drug Use Clarification Act (AMDUCA). However, those are only temporary solutions to a continuing problem.

Unless new antimicrobials become available, even the extra-label use of antimicrobials is expected to become ineffective. There is a great need to understand better both the magnitude of the risk and the options available to minimize the risk while maintaining the benefits these drugs confer on agriculture. Constant vigilance in monitoring trends in antibiotic resistance in farm animals and humans is strongly encouraged.

New antibiotic drugs are needed to combat emerging animal diseases that do not respond to traditional drugs and so threaten public confidence in animal agriculture and human medicine. Professionals in human health care should be concerned that they do not have enough specialty antimicrobials to treat resistant and emerging infections in humans, as should veterinarians.

In the midst of the debate on the use of antimicrobials in beef cattle, it is obvious that feedlot consultants must emphasize prudent use of antimicrobials. This illustrates to those concerned about antimicrobial use in cattle that beef safety is an important consideration in modern feedlot medicine. Judicious use of antimicrobials will lessen the chances of bacteria becoming resistant, thereby prolonging their usefulness. In 1999 the AABP Board of Directors approved the AABP Prudent Drug Usage Guidelines (Box 14-11), which can serve as a framework for antimicrobial usage by feedlot consultants.

CULLING OF FEEDLOT CATTLE

Culling may be done at any point between examination of the cattle on arrival and a few weeks later, before they are placed on a high-energy diet. Diseases that justify culling include chronic unthriftiness and inappetence of undetermined etiology, chronic laminitis, chronic lameness caused by footrot, chronic bloat, chronic pneumonia, acute and chronic pulmonary abscess, and BVD. Each of these diseases leads to unthriftiness, and a clinical examination is necessary for diagnosis.

FEEDING PROCEDURES

In general, there are three phases in feeding feedlot cattle: starting, growing, and finishing. During the first few days after arrival and until the cattle are introduced to full feed, the traditional general recommendation has been to provide a good-quality roughage. The critical factor is to get the new animals to eat so that ruminal flora and function are restored. Nutritional management of newly arrived cattle focuses on getting them "on feed" as soon as possible. Receiving diets and feeding programs differ depending on the type of cattle, the available feeds, and the owner's objectives. Regardless of the program, however, there are some general principles that apply to the nutrition of newly arrived stressed cattle (Lofgreen, 1988). The intake of stressed cattle is low in the first several days after arrival, and it is necessary to feed them a nutrient-dense diet. A ration containing 50% to 75% concentrate along with grass hay for the first week has provided a good rate of gain. Preconditioned feeder calves and backgrounded cattle will usually start eating and drinking with a minimum of difficulty. Cattle should be fed twice daily or even more often during the adjustment period, so that those that do not eat can be identified and examined more closely. The use of self-feeders during the adjustment period makes it difficult to detect anorexic animals, because animals may eat at any time.

BOX 14-11

American Association of Bovine Practitioner (AABP): Prudent Drug Usage Guidelines

The production of safe and wholesome animal products for human consumption is a primary goal of members of the AABP. In reaching that goal, the AABP is committed to the practice of preventive immune system management through the use of vaccines, parasiticides, stress reduction, and proper nutritional management. The AABP recognizes that proper and timely management practices can reduce the incidence of disease and therefore reduce the need for antimicrobials; however, antimicrobials remain a necessary tool to manage infectious disease in beef and dairy herds. In order to reduce animal pain and suffering, to protect the economic livelihood of beef and dairy producers, to ensure the continued production of foods of animal origin, and to minimize the shedding of zoonotic bacteria into the environment and potentially the food chain, prudent use of antimicrobials is encouraged. Following are general guidelines for the prudent therapeutic use of antimicrobials in beef and dairy cattle.

1. The veterinarian's primary responsibility to the client is to help design management, immunization, housing, and nutritional programs that will reduce the incidence of disease and the need for antimicrobials.
2. Antimicrobials should be used only within the confines of a valid veterinarian-client-patient relationship; this includes both dispensing and issuance of prescriptions.
3. Veterinarians should properly select and use antimicrobial drugs.
   a. Veterinarians should participate in continuing education programs that include therapeutics and emerging and/or development of antimicrobial resistance.
   b. The veterinarian should have strong clinical evidence of the identity of the pathogen causing the disease, based on clinical signs, history, necropsy examination, laboratory data, and past experience.
   c. The antimicrobial selected should be appropriate for the target organism and should be administered at a dosage and route that are likely to achieve effective levels in the target organ.
   d. Product choices and regimens should be based on available laboratory and package insert information, additional data in the literature, and consideration of the pharmacokinetics and pharmacodynamics of the drug.
   e. Antimicrobials should be used with specific clinical outcome(s) in mind, such as fever reduction, return of mastitic milk to normal, or to reduce shedding, contagion, and recurrence of disease.
   f. Herd pathogen susceptibility and therapeutic response should be monitored periodically, especially for routine therapy such as dry cow intramammary antibiotics, to detect changes in microbial susceptibility and to evaluate antimicrobial selections.
   g. Products should be used that have the narrowest spectrum of activity and known efficacy *in vivo* against the pathogen causing the disease problem.
   h. Antimicrobials should be used at a dosage appropriate for the condition treated and for as short a period of time as reasonable (i.e., therapy should be discontinued when it is apparent that the immune system can manage the disease, reduce pathogen shedding, and minimize recurrence of clinical disease or development of the carrier state).
   i. Antimicrobials of lesser importance in human medicine should be used in preference to newer generation drugs that may be in the same class as drugs currently used in humans, if this can be achieved while protecting the health and safety of the animals.
   j. Antimicrobials labeled for use for treating the condition diagnosed should be used whenever possible. The label, dose, route, frequency, and duration should be followed whenever possible.
   k. Antimicrobials should be used extra-label only within the provisions contained within Animal Medicinal Drug Use Clarification Act (AMDUCA) regulations.
   l. Compounding of antimicrobial formulations should be avoided.
   m. When appropriate, local therapy is preferred over systemic therapy.
   n. Treatment of chronic cases or those with a poor chance of recovery should be avoided. Chronic cases should be removed or isolated from the remainder of the herd.
   o. Combination antimicrobial therapy should be discouraged unless there is information to show an increase in efficacy or suppression of resistance development for the target organism.
   p. Prophylactic or metaphylactic use of antimicrobials should be based on a group, source, or production unit evaluation rather than considered standard practice.
   q. Drug integrity should be protected through proper handling, storage, and observation of the expiration date.
4. Veterinarians should endeavor to ensure proper on-farm drug use.
   a. Prescription or dispensed drug quantities should be appropriate to the production-unit size and expected need so that stockpiling of antimicrobials on the farm is avoided.
   b. The veterinarian should train farm personnel who use antimicrobials on indications, dosages, withdrawal times, route of administration, injection site precautions, storage, handling, record keeping, and accurate diagnosis of common diseases. The veterinarians should ensure that labels are accurate to instruct farm personnel on the correct use of antimicrobials.
   c. Veterinarians are encouraged to provide written guidelines to clients whenever possible to describe conditions and instructions for antimicrobial use on the farm or unit.

From American Association of Bovine Practitioners Prudent Drug Use Guidelines, *Bov Pract* 34(1):73, 2000.

Downloaded From Vet-eBooks.com

When cattle have become adjusted to the starting ration and there is no evidence of acute respiratory disease or major infections, the animals may be started on the high-energy growing and finishing rations. A widely accepted and successful practice is to use a complex mixed ration consisting of grain, chopped roughage, protein supplement (if necessary), and the necessary vitamins and minerals. The level of grain is increased and the level of roughage decreased every few days until the predetermined levels are reached for the growing or finishing rations. With this method, feeder calves can be adjusted to a growing ration and yearlings to a finishing ration in 15 to 20 days, usually without carbohydrate engorgement or bloat. In large feedlots with many pens of cattle at different phases of the feeding program, outbreaks of carbohydrate engorgement occur when cattle are accidentally fed a finishing ration when they have only become adjusted to lower-energy rations. A high level of accuracy is necessary in the feed mill and by the personnel delivering the feed to the respective pens. Complete and thorough mixing of the feed must be ensured at all times.

ANIMAL WELFARE IN THE FEEDLOT

Since the 1980s a significant percentage of society has expressed concern about the morality of raising farm animals under intensive conditions (Janzen, 1990h). They believe that livestock production is contrary to the best use of the world's resources for humans' well-being. It is believed that the grains fed to feedlot cattle could be better used to feed humans in developing countries. Feeding animals in confinement in what is perceived to be overcrowded conditions is considered inhumane. The transportation of beef calves to an auction mart where they are sorted, mixed into saleable groups, sold by public auction, perhaps deprived of feed and water for 24 to 36 hours, and then transported to a feedlot and mixed with other cattle, where they ultimately become ill with acute respiratory disease, is considered by some animal welfare and animal rights activists to be unnecessary and cruel.

The feedlot production practices that produce this concern include marketing, stressors, mortality rate, branding, dehorning and castration performed without local anesthesia, delays in treatment of sick animals, inadequate handling facilities, cruel handling of animals, inadequate ground surface conditions that make the feedlot uncomfortable for the animals, and failure to cull and destroy animals affected with incurable illnesses.

The feedlot industry must pay attention to the concerns of organized animal welfare groups. Good feedlot design is important to ensure animal comfort. Handling facilities must be modern and efficient and must not induce animal attendants to be cruel to animals when they are being moved from one location to another; excessive force should not be used to get the animals to move. The pen checkers and treatment crew must be educated about the signs of pain and discomfort associated with certain illnesses and how cattle can be handled humanely.

The veterinarian should emphasize good feedlot design and equipment that will ensure comfort for the animals and minimize pain and stress associated with handling procedures. The veterinarian must also be a vigilant guardian, denouncing inhumane practices and encouraging sound animal welfare management.

BENEFITS OF A HEALTH MANAGEMENT PROGRAM FOR THE FEEDLOT

Feedlot operators who engage veterinarians for programmed preventive medicine invest money for this service because the veterinarian saves them money in the process. In Texas studies the economic losses caused by respiratory diseases alone in feedlot cattle have been estimated at $80/treated animal. This includes loss from shrink, poor feed use, inefficiency of gain, death, lowered carcass quality, and treatment of sick animals. In a study of disease in 407,000 yearling feedlot cattle in Colorado, the morbidity rate was 5.1%, the case fatality rate was 18.9%, and the population mortality rate was 1%. Respiratory tract diseases were the most common and accounted for 75% of illnesses and 64% of the deaths. From these limited data, it would appear that herd health programs can provide significant economic benefits to feedlot cattle operations.

CHAPTER 15

Health and Production Management in Swine Herds

JOHN DEEN, SCOTT DEE, ROBERT B. MORRISON, and OTTO M. RADOSTITS

What does the pig farmer require from the veterinarian? . . . . The fundamental needs of the modern day unit are to maximize production and efficiency, analyze the results and hence the return on investment. . . . The achievement of maximum profitability, however, must be carried out within the economic constraints and accepted practices of animal welfare.

Muirhead MR: *Pig J* 36:101-113, 1996.

The primary reason for domestication of swine was to provide a source of animal protein as food for humans. The unique flavor of pork as human food also contributed to the domestication of swine. During the first half of the twentieth century, pork was the primary meat source in many parts of the world because of its high fat content. In human populations that have high energy requirements, pork fat is an excellent source of highly palatable energy. If the unique culinary qualities of pork were a major reason for domestication, selection programs emphasizing pork quality that lead to improved palatability may have a major impact on consumer demand for pork.

The body of knowledge and the clinical skills of veterinary medicine devoted to the health management and production of swine have expanded tremendously in the last two decades. The swine industry has maintained the consumer demand for pork in comparison with beef and has consistently reduced its cost of production. Much of the success in pig production has been in concert with effective disease control and improvement in productivity. Leadership by the veterinary profession in record keeping and analysis of health and production data and providing of consultation advice on facilities and operational design have helped control diseases and improve productivity. This chapter outlines and describes the methods available to the veterinarian to continue leadership in this consistently changing industry.

The swine industry can be considered an intermediate between the beef and poultry industries. The industry is currently going through a level of consolidation and vertical integration, which occurred in the poultry industry, particularly in the production of broilers many years ago. Historically, the swine industry was similar to the beef industry, with small holdings and an extensive method of rearing, particularly for sows. Recently there has been the development of large centralized facilities for the growing and finishing of pigs, often from many small extensive swine herds. Historically, pigs were fed a variety of diets consisting of grains and by-products from other agricultural enterprises such as skim milk and garden wastes. Pork and pork by-products such as lard were highly regarded within communities as being easily processed for storage.

The swine industry has undergone an extensive transformation since World War II. Consolidation, specialization, intensification, and mechanization have been the central features in the evolution of agriculture. The predominant theme has been improved labor efficiency, and the means to this end involved the substitution of machines for horses and manual labor. Agriculture evolved swiftly from a way of life to a business, and, as competition for the labor force intensified, producers moved to increasingly larger equipment to replace the traditional sources of farm help. Only increasing the scale and intensity of individual operations could offset the resulting escalation of the capital investment required. Increasing farm size was accompanied by consolidation of the hog industry—*a marked decline in the number of production units and an increase in the number of pigs marketed per producer and in total annual marketing*. Specialization in the swine industry in North America began in about 1950, continued into the 1990s, and is still occurring at the beginning of the new millenium. The changes are aptly described in "Positioning Your Pork Operation for the 21st Century" (Boehlje, 1995). Small farms have left the American industry, so that where there were 670,000 farms in 1980, there were only 183,000 in 1996.

The changes in the swine industry are similar to other industrial evolutions. After the decentralized mixed enterprises, farms that specialized in pork production emerged. They still tended to involve extensive operations but tended to use products that were grown on farm, primarily corn and soybeans within the Midwestern United States. If there were modifications into more intensive pig production, they usually involved providing intensive farrowing facilities that allowed greater control of the environments for newly born piglets. In many cases there was still delineation between weaned pig production and growing and finishing units. Many farms considered pig production as an ancillary enterprise to the primary goal of corn production. Sow management was often considered labor-intensive and thus many corn farmers chose to buy pigs at approximately 20 kg and rear them for market at approximately 110-kg live weight.

Changes in methods of a production were relatively few until late in the twentieth century. In many cases pig production was not the primary source of income, and entry into and exit out of pig farming were common. This going "in" and "out" of the industry was invariably in response to market pork prices, and, in turn, price was in response to the supply of pigs. This response to price created the "hog price cycle," which occurred every 4 to 5 years when the supply of pigs would rise and then fall.

However, productivity was relatively poor in these enterprises when compared with current levels. Efficiency in feed

Downloaded from Vet-e-Books.com

conversion and reproductive performance were low, and there were relatively few alternatives for improvement within the structure of production in place. The alternative was to create a more intensive method of production that allowed improvements in productivity measures and thus profitability. Intensification of swine production involved much risky experimentation by swine producers. Penning, flooring, ventilation systems, nutrition schemes, and scale were the subject of many experiments and much improvement, especially during the '60s and '70s. Concurrent with this changing technology came a renewed emphasis on lean pigs. This experimentation resulted in both increased productivity and new challenges, both in understanding the mechanisms of these levels of productivity but especially in disease control (Herrick, 1997).

Historically, veterinarians providing service to swine herds concentrated on the control of infectious diseases and reproductive performance. Although it was called *herd health,* much of the effort went into identification of pathogens and the development of control strategies that reduced the effect of these diseases on production. Intensification of pig production created many new expressions of old diseases and the appearance of some new ones. Pathogens such as *Actinobacillus pleuropneumoniae* devastated many initial attempts at high-density, large-scale pig production. Initial attempts at its control were unsuccessful, since much of the reliance was based on interventions using vaccines and therapeutic antibiotics. Alternative strategies such as elimination of the pathogen from the herd, *"all-in, all-out"* (AIAO) production, and alternative ventilation systems were subsequently and more successfully used. Similar experiences with the porcine reproductive and respiratory syndrome have reinforced the need for veterinary medicine to shift the emphasis from curative medicine of individual animals to health and production of the herd.

Practitioners of veterinary medicine soon realized that the control of pathogens was not an end to itself (Kavanagh, 1998). Pig production led the way in developing record-keeping systems that reflected the objectives of the farm and induced a producer to analyze and improve productivity on the farm. Veterinarians historically assumed that minimization of pathogens would maximize productivity. In many cases, this was not true and therefore veterinarians began to emphasize productivity, with disease control being a secondary concern. The aims of maximizing pigs per sow per year and feed conversion became common goals on these farms.

With this emphasis, remarkable improvements were seen in maximizing reproductive performance of the herd. Record-keeping systems illustrated large herd differences in indexes such as farrowing rates, preweaning mortality rates, and litter size. Changes were made in genotypes to achieve increased reproductive output, and other changes such as diet and lactation lengths were examined. To achieve these improvements in productivity the veterinarian began to take much more of a *whole-farm* approach and became knowledgeable about not only production indexes but also genetics, housing, reproduction, nutrition, and personnel management.

The emphasis on productivity, however, did not adequately consider the need for control of the costs of inputs. It became evident, especially with improvements in grower and finishing pig productivity, that there was a need for greater emphasis on cost control. The whole-farm approach was expanded to include knowledge of the factors involved in minimizing the cost per pound of gain, often guided by partial budgeting. This led to advances in nutrition and feeding in which alternative diets were fed in the nursery, and the nutrients were more closely aligned with the requirements of the pig. Moreover, feed delivery and feeder management was refined to minimize feed wastage.

The industry continues to develop from cost minimization to profit maximization. Recently, much more emphasis has been placed on increasing the value of the output, namely market hogs, to improve profitability. Factors such as weight, leanness, and carcass yield have gained greater emphasis. In addition, there has been a greater sensitivity to the requirements of the consumer and the packer and the demands on pig production have been expanded to include the control of antibiotics residues; pale, soft, and exudative pork; and other contaminants such as *Salmonella typhimurium.*

There has been considerable change in the past, and the future holds more of the same. The imbalance between supply and demand has led to considerable financial hardship for independent pork producers during the late 1990s. Furthermore, there is an increased amount of integration or cooperation between packers and pork producers so that price discovery is becoming difficult. In addition, there is considerable benefit in coordinating pig production and the meat processing industry so that there is an increased amount of common ownership of both pork production and meat processing. This in turn has induced even more change in swine production and has allowed for considerable increases in the scale of units. Currently, reproductive units as large as 25,000 sows are being established in the American Midwest. Discomfort with these changes in pig production along with an increased public sensitivity over production methods and the resultant level of odor, manure and changes in purchasing practice in the community has led to regulatory constraints on further expansion (Penny, 1998).

Future economic survival in the swine industry will depend on some essential factors: (1) keeping useful records for the monitoring and evaluation of performance so that improvements in every aspect of production can be made quickly and efficiently, (2) developing an understanding of the cost-price equation, which means that producers who want to make a profit have to be better than the average, as defined through bench-marking, (3) using strategic contracts with buyers and suppliers to manage risk, and (4) evaluating capital management and economic feasibility to maintain support through price fluctuations.

The skills and abilities of the industry to consider many challenges and constraints are a probable long-range major constraint to pork production. Effective analysis and consistent implementation of solutions to challenges are crucial. Cost minimization and maximization of productivity are often been presented as methods of partially meeting a goal of profit maximization. However, decisions now must also include consideration of ensuring a place in the market. Productivity improvements must be seen as inevitable and as part of the goal of swine production.

It must be recognized that stability of the process has been underemphasized. Increasingly, there is emphasis on robust technology instead of simply productive technology. Methods are being examined and tested, which are predictably producing pigs that are sometimes not to their maximum potential, but to the potential at which it can be done on a regular basis. There is emphasis on reducing the variability of the growth rates within a herd and reducing the variability of output of the sow herd on a weekly basis, all in an effort to make the overall enterprise operate more smoothly. To meet these demands in the swine industry, some objectives in pig production can be considered.

Downloaded from Vet-eBooks.com

OBJECTIVES IN PIG PRODUCTION

Efficient Use of Variable Cost Inputs

In most cases, the major variable input is feed. Fig. 15-1 illustrates an example of the component costs of a hog production system. Feed efficiency and feed costs are major concerns that must be monitored. The minimization of costs has been a historic emphasis in successful swine production. An economic analysis of swine operations in Hawaii showed that the efficient use of inputs such as feed, most of which is imported and therefore has high costs, is more important to profitability than is maximizing pigs weaned per sow per year (Sharma et al, 1997).

Efficient Use of Fixed Costs (Capacity Utilization)

In most cases the fixed inputs are labor and facilities, and thus it is important to ensure that capacity is used efficiently. Thus the planning of introducing pigs and looking closely at optimum turnovers is an important part of growing pig management. Nonetheless, it cannot be the primary purpose, because it must be done within the realm of the other constraints of the barn. In many cases, maximization of output, especially pounds per square foot, is an ineffective measure because it does not maximize profits.

Improve the Quality and Value of the Pigs

Improvement of the quality and value of the pigs may appear intuitive but historically has been examined rarely within pig record-keeping systems. Too much time can be spent in cost minimization when, in fact, other areas that can improve profitability should be examined. This is an area that examines opportunity to improve profits instead of real costs and thus is often not as intuitive as cost minimization.

Create, and Improve on, a Robust System to Achieve the Above Goals

Not only must the system for achieving the aforementioned goals be efficient, it must not "crash and burn" but improve. Pig production and marketing is relatively complex, unstable, and influenced by current economic constraints. Therefore production and marketing plans change and will continue to change depending on the performance of the pigs among other factors. Thus any record-keeping system must be current and is a "backbone" of swine health management.

Staying Ahead of the Competition

To begin an analysis of health and production in a swine enterprise, some level of comparison is needed. Benchmarking is a process that has been called inherently useful and useless. Many have argued that the best measure of success in pig production is the historic productivity of the particular farm compared with other farms. However, productivity itself may not be a fair measure. There has been much frustration with benchmarks, since they have often been used by outside agencies such as banks to measure the success of farms. These benchmarks have been used with little regard for their accuracy, comparability, and utility.

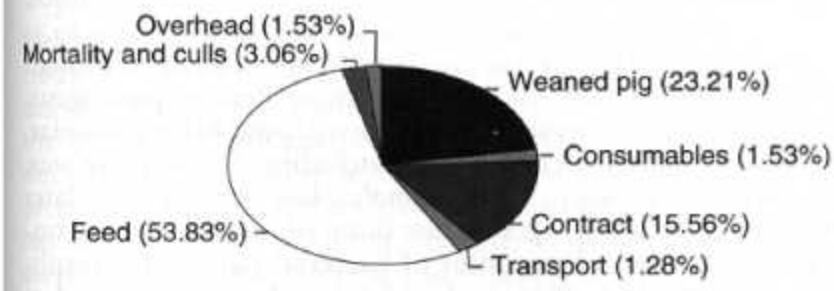

FIG. 15-1 Breakdown of costs of production.

CHANGES AND TRENDS IN SWINE INDUSTRY AND HEALTH MANAGEMENT

The U.S. National Animal Health Monitoring System (NAHMS) 1995 National Swine Study provides statistically valid national estimates of parameters related to swine management on operations throughout the major pork-producing regions of the United States, and it examines changes and trends in the swine industry from previous national swine surveys (Losinger et al, 1998a,b; USDA: APHIS:VS, 1995). Phase I collected information about management and production in swine operations. Phase II focused on the phase of the pork industry by collecting information from operations with more than 300 finishing pigs.

Data on changes in the U.S. Pork Industry from 1990 to 1995 are available in a publication of October 1997 from http://www.aphis.usda.gov/vs/ceah/cahm/Swine/sw95trnd.htm. Some of the main findings follow:

Demographic Changes in the U.S. Pork Industry

- The swine population continues to increase.
- The number of U.S. swine operations decreased more than 30% from 1990 to 1995.
- The proportion of herds with an inventory of 1000 or more head continued to increase.
- A larger proportion of the U.S. pig inventory is shifting to herds consisting of 2000 or more head.

Health and Productivity

- A steady increase in the number of pigs saved per litter has occurred each year since 1990.
- From 1990 to 1995, reported stillbirths and mummified fetuses per litter decreased nearly 25% (from 0.87 to 0.65), whereas born alive per litter decreased 1%.
- The total number of pigs born per litter decreased (10.34 to 10.02), but the percent born alive per litter increased from 91.59 to 93.51.
- Preweaning deaths per litter decreased 20% (from 1.10 to 0.88). Preweaning deaths per litter were 11.62 were in 1990 and 9.39 in 1995.
- Number of pigs weaned per litter was 8.37 in 1990 and 8.49 in 1995.
- The causes of preweaning deaths reported in the two surveys were as follows:

	1990 (%)	1995 (%)
Diarrhea	23.9	15.1
Laid on	40.4	48.7
Starvation	20.4	20.5
Other problems	9.0	6.6
Unknown problems	6.3	9.1

  Piglets being laid on is the leading cause of preweaning deaths. A significant decrease in diarrhea-related deaths was reported.
- The culling rate of breeding-age females culled over a 12-month period as a percent of sow and gilt inventory for 1990 and 1995 was 43.5% and 41.2%, respectively.

Downloaded from Vet-eBooks.com

- The percent of pig deaths in the nursery ranged from 2.4 to 2.3 from 1990 to 1995, respectively.
- The major causes of death in the nursery are diarrhea and respiratory disease, which account for about 50% of deaths. Other known and unknown problems account for about 41%.
- Deaths in the growing and finishing phases of production ranged from 1.8% to 2.1%.
- The major cause of death in the growing-finishing pigs was respiratory disease.

Management Changes in the U.S. Pork Industry

- Pen-mating using multiple females and one or more boars continued to be the most frequent breeding technique.
- The percentage of operations using artificial insemination (AI) doubled from 1990 to 1995 (from 3.8% to 7.8%, respectively). The percentage of sows and gilts bred by AI increased from 1.1% to 11.1%.
- The use of antibiotics in sows, gilts, and boars increased significantly.
- Approximately half of operations practiced AIAO management in the farrowing phase. The overall inventory of females managed as AIAO increased from 55% to 65%. Larger operations are using AIAO management in the farrowing phase.
- In 1990 the most frequent waste management system used was hand cleaning (41% of operations), which declined to 28% in 1995. In 1995 pit holding was used most frequently (41%).
- The percentage of operations using dewormers, injectable antibiotics, and mange-lice treatment as preventive practices for piglets increased over the 5 years; use of injectable or oral iron decreased.
- The average weaning age of piglets decreased approximately 3 days (from 28.5 to 25.7 days) on an individual pig basis but remained unchanged for the average operation.
- The proportion of nursery pigs managed as AIAO increased 16% during the 5-year period (from 53.5% to 69.8%), but the percentage of operations practicing AIAO management remained unchanged at about 47%.
- Pigs left the nursery at an average age of 60 days.
- The percentage of growing-finishing pigs managed as AIAO increased from 24% to 51%, and larger operations adopted AIAO management in the growing-finishing phase more frequently than smaller operations.
- The average market age on growing-finishing operations decreased from 183.2 days to 176.8 days.
- Overall, in 1995 (compared with 1990), the average pig was weaned 3 days younger, stayed in the nursery 1.7 days longer, and had about the same length of stay in the growing-finishing phase (118 days).
- The majority of swine operations continued to be independent producers who marketed their own animals. Total inventory marketed through contract producers increased over the 5-year period but still accounted for less than 10% of pig inventory.
- A pocket diary or calendar was the most widely used record-keeping system, and use increased from 64% to 72% over the 5-year period. Record card and service bureau-based systems were used less frequently, while computer-based systems gained popularity (increasing from 8% to 13.5% over the 5-year period).
- The percentage of operations using vaccines regularly for the following diseases were erysipelas (49%), *E. coli* (38%), parvovirus (44%), leptospirosis (47%), and porcine reproductive and respiratory syndrome (22%).
- Separation-quarantine and health testing of new arrivals decreased for breeding animals (33.6% to 19.5% for females; 61% to 33% for males) and increased for feeder pigs (2% to 10%). Of those producers who separated-quarantined new breeding stock, approximately two thirds also health tested them.
- Less than one half of all operations (49%) used veterinarians for any purpose in 1995. Large declines in the use of veterinarians occurred for vaccination consultation, individual pig treatments, and provision of drugs.
- Most carcasses (pigs that died) were disposed of by burial on the farm (59%). Burning and renderers decreased significantly; 10% of operations used on-site composting of carcasses.
- Use of cats as the primary means of rodent control decreased from 88% to 71% in all operations over the 5-year period. Other methods included traps (13%) and bait or poison (74%).
- For biosecurity, 40% of operations allowed only employees to enter the premises. Showers or footbaths were rarely required on those operations that allowed others on the premises (feed-delivery personnel and livestock handlers).
- The distances to nearest swine operation remained relatively stable in distribution, with over 70% being within 3 miles apart. Most operations were 5 or more miles away from a swine market.
- Rates for condemnations for deads increased from 1990 to 1995 (from 0.782 to 1.467/1000 pigs slaughtered, respectively) and remained the largest single reason for condemnation. Condemnation rates for abscess, pyemia, and arthritis declined. The number of carcasses condemned for residues decreased.
- The most frequently isolated *Salmonella* serotypes isolated from swine are *Salmonella choleraesuis, derby,* and *typhimurium*.
- The number of outbreaks of foodborne illness associated with pork or ham has declined over the last 20 years.

Advances in Health Control

No one single factor has the ability to influence performance, health, and well-being of pigs as severely as exposure to infectious diseases. Exposure to bacterial and viral pathogens occurs frequently in the life of an individual animal and can spread throughout large populations at a rapid rate. Depending on the level of immunity within the population and the degree of management under which they are raised, the clinical effect can be severe, particularly if concurrent infection of multiple pathogens occurs. Therefore the need to mitigate the effect of disease factors to improve animal health and productivity has led to the evolution of disease-control strategies for pig production systems.

A major breakthrough in understanding the relationship of disease control and pig production occurred in the early 1980s with the adaptation of segregated production based on the principles of medicated early weaning (Alexander et al, 1980). Further work in this area emphasized the advantage of age-segregated rearing of weaned pigs (Connor, 1990). As this work progressed, weaning age decreased to as low as 7 to 10 days throughout the global industry. Although this practice caused the elimination of certain pathogens, such as *A. pleuropneumoniae* and *Mycoplasma hyopneumoniae*, it enhanced the effect of others, including *Streptococcus suis, Haemophilus parasuis,* and *Actinobacillus suis*. It was later found that weaning ages of less than 14 days caused inconsistent mucosal colonization of bacterial pathogens, resulting in the mixing of infected and non-infected naive piglets at weaning (Pijoan, 1997) As maternal antibodies declined, these pathogens were shed from colonized to noncolonized

Downloaded From Vet-e-Books.com

pigs, leading to elevated postweaning mortality rates (4% to 12%). This work, in combination with a reduction in breeding herd prolificacy and longevity associated with early weaning, resulted in the global industry selecting longer lengths of lactation. Whereas the length of lactation may have been fixed by welfare laws (≥21 days in Europe), other countries have chosen to select intermediate lactation lengths (e.g., 16 to 18 days) in order to maximize health status and to minimize the negative impact on breeding herd productivity.

In the late 1980s, reports of a devastating epidemic of reproductive failure, in conjunction with a high level of respiratory disease, were relayed throughout the pig-producing areas of the world. The problem continued for 3 years, until Wensvoort and colleagues (1991) isolated a viral agent, fulfilled Koch's Postulates, and defined the disease of porcine reproductive and respiratory syndrome (PRRS). Called the "disease of the decade," no other health problem has caused such extensive losses and frustration to so many producers around the world. A brief review of this infectious disease is presented in the section on reproductive failure of swine.

Efforts to control PRRS initially focused on the postweaning period through the adaptation of nursery depopulation (ND), a protocol to prevent the horizontal transmission of the virus through the removal of the entire nursery pig population on a given day (Dee and Joo, 1994a,b; Dee et al, 1997a,b). Yet, as breeding herd inventories increased (≥1000 sows), so did the inability of ND to control the disease long term because of recurrent transmission of the virus within the breeding herd and the generation of infected piglets before weaning. The concept of breeding herd subpopulations demonstrated that infected and noninfected adult animals could coexist within the same population (Dee et al, 1995b). Through the use of a battery of serological tests, virus shedding was demonstrated from chronically infected sows to naive animals, indicating that varying levels of exposure to the virus within populations did indeed exist.

A prominent risk factor that contributed to the development of subpopulations was the replacement gilt. Recurrent episodes of PRRS induced reproductive failure after direct introduction of seronegative or actively infected gilts into the breeding herd (Dee and Joo, 1994a,b; Dee et al, 1995a). This led to the development of several strategies for the introduction of gilts into commercial farms. The primary emphasis of these strategies consisted of the introduction of younger animals, in larger groups, more frequently throughout the year. Today, it is not uncommon for gilts to enter a designated development facility at weaning or at 25-kg body weight. Furthermore, the concept of establishing farms where the sole purpose is to raise, breed, gestate, and farrow gilts has been proposed as a management strategy to emphasize gilt performance and health status. These types of operations, called "parity 1 (P1) production farms," would provide P1 females for commercial farms, thereby eliminating the need for a gilt pool in these operations.

During the early 1990s the concept of commingling weaned pigs from a number of sow sources evolved. Initially, it seemed to be an excellent strategy to maximize production and health status. However, the inability to control the spread of PRRS virus (PRRSV) through early weaning reduced its effectiveness in commercial pig production. The problem arises from the inability to equalize the health status of infected sow herds, leading to subpopulations of weaned pigs, some infected and others noninfected.

In order to counteract this variability in health status, the ability to completely fill and empty a facility on a given day with a single source of pigs AIAO by airspace") led to improved postweaning performance, in contrast with animals housed under an AIAO by-room (continuous-airspace) basis (McManus, 1991). This concept was further expanded, with the end result being the development of the weaning-to-finishing building (Connor, 1990). This facility houses pigs from the time of weaning until they are marketed, eliminating the stress of mixing at 25 kg and reducing labor cost while taking advantage of the benefit of stage depopulation. Data from wean-to-finish facilities collected from over 28,000 pigs indicate mortality rates of 3.1%, feed conversion ratios of 2.54, and daily growth rates of 0.69 kg from entry (4.2 kg) to market weights of 115 kg.

Molecular Diagnostics

The recent advances in molecular diagnostics, such as polymerase chain reaction (PCR) and its application to the swine industry, has led to an improved level of accuracy in determining the presence of certain pathogens within pig populations (Braun et al, 1999). PCR has the potential to improve speed, sensitivity, and specificity of diagnostic testing. PCR assay is not recommended as a herd screening diagnostic test because of its expense. Its use should be reserved for situations in which it is essential to know whether a specific pathogen is present in tissues or body fluids.

PCR assays are available for both porcine viral and bacterial agents. Viruses that cause the following infections can be detected: PRRSV, transmissible gastroenteritis (TGE), porcine respiratory coronavirus (PRCV), and pseudorabies (PR).

Bacteria that can be detected are: *Lawsonia intracellularis, Brachyspira* (formerly *Serpulina) hyodysenteriae, Salmonella* spp., and *Mycoplasma* spp. PCR is a sensitive diagnostic tool for confirmation of the presence of *L. intracellularis* from mucosal samples (Jordan et al, 1999).

A reverse transcriptase PCR for amplification of the open reading frame 6 region of the PRRS viral genome has enhanced the level of "quality health assurance" in breeding swine. This test, in conjunction with serologic assays (ELISA), are effective means to accurately profile the pattern and chronology of viral infection within pig populations. Furthermore, PCR assists in detecting peracute infection before generation of antibodies. Possessing a high level of sensitivity and specificity, PCR has enhanced detection of persistently infected animals within breeding herds.

Biosecurity in Swine Production

Biosecurity is any practice or system that prevents the spread of infectious agents from infected animals to susceptible animals or that prevents the introduction of infected animals into a herd, region, or country in which the infection has not yet occurred. Biosecurity, an integral part of any successful livestock enterprise, reduces the risks and consequences of introducing an infectious disease. The components of biosecurity, which include management and placement programs, farm layout, decontamination, pest control, and immunization, directly affect productivity and profitability. Biosecurity for the swine herd is defined as the protection of a swine herd from the introduction of infectious agents (Amass and Clark, 1999).

The information required to consider biosecurity protocols for the swine herd includes the origin and method of transmission of pathogens and the survival characteristics of the pathogens (in dust and uncleaned rooms, flooring, soil, manure, water supplies, and composted carcasses). Cleaning and disinfection of housing facilities and equipment are of paramount importance in infectious disease control.

Downloaded from Vet-e-Books.com

Infectious diseases in the swine herd can be spread among pigs within the herd or introduced into the herd by infected pigs; contaminated semen; aerosol transmission; rodents, flies, mosquitoes, and ticks; birds; domestic and nonporcine feral animals; feed, including the feeding of garbage; vehicles; personnel; and visitors (Amass and Clark, 1999). Foot-and-mouth disease (FMD) virus and swine influenza virus are the only swine pathogens that have been shown to be transmissible from infected pigs to humans. Whether or not people (workers, veterinarians, and others) should shower before entry into a production unit is controversial. There are no reports of the effect of showering on the carriage of bacteria and viruses.

For some diseases it is desirable to prevent the spread of infectious agents from a certain age group of animals to younger age groups. One example is the attempt to control the spread of the virus causing porcine reproductive and respiratory syndrome in pigs by depopulation of the nursery pens.

The introduction of new infections into herds can be prevented or minimized by purchasing animals directly from herds that are known to be free of a particular disease. The adoption of this principle requires awareness of the possibility of purchasing unknown infected animals and testing animals for the infection before entry into the herd. It may also require keeping the introduced animal in quarantine for several weeks after arrival before it is mixed with the other animals. Producers can evaluate the effectiveness of biosecurity protocols by recording information about the movement of people, animals, feed, and equipment to, from, and within their production facilities. Records can also help identify the likely source of disease introduction should an outbreak of disease occur.

Biosecurity practices for the prevention of infectious disease introduction are critical in today's global industry. A comprehensive review of the biosecurity principles for swine units is available (Moore, 1992). A summary of the peer-reviewed literature on biosecurity in the swine industry is also available (Amass and Clark, 1999). Many decisions concerning biosecurity protocols in swine herds are currently based on empirical experience of producers and veterinarians, and not on scientific research. Consequently, research is needed in many areas to validate current protocols or to develop new scientifically based biosecurity protocols for the pork industry.

As an example, in 1985, the transmission of *M. hyopneumoniae* through aerosols and its survivability outside the pig was researched. This helped establish minimum distances for the placement of units (3.2 km apart) and the recommended period of downtime for personnel before entering swine operations (48 hours). Biosecurity can be further enhanced through the use of AI. However, studies have demonstrated the capability of transmitting PRRSV by raw and extended semen (Yaeger et al, 1993; Swenson et al, 1995).

Advances in Nutrition and Feeding

The steady advances in the science of animal nutrition that occurred during the first half of the twentieth century were quickly adopted by the swine industry. Although the period before the 1960s was highlighted by identification and establishment of most of the nutrients required by pigs, in the past 40 years only one item—selenium—has been added to the list of required nutrients commonly added to swine diets. Much progress has been made in refining the requirements of nutrients that were already considered essential. The prediction of nutrient requirements based on growth requirements has been refined, and a number of computer models have been developed.

The feeding and nutrition of young pigs has changed markedly. When begun, the practice of weaning pigs at 3 weeks of age was invariably associated with problems such as postweaning diarrhea. Today, pigs averaging about 5.5 kg are housed in modern nursery facilities, where they attain a weight of 22 kg by 9 weeks of age with a mortality of no more than 3%. Weaned pigs are now raised in nurseries with carefully controlled environments and specialized diets.

Many aspects of feeding technology received considerable research attention, such as the design of equipment for automatic feed delivery, the consequences of diet dilution or other methods of controlling feed intake, and processing techniques to enhance nutrient digestibility and nutrient density. Linear programming for formulating least-cost diets led to the development of modern computer programs that can formulate diets according to the cost and nutrient composition of available dietary ingredients.

Performance Trends

In the same period under consideration, dressing yield increased from 69.5% to 71%, and percentage yield of backfat decreased from 14.6% to 5.3%. In Canada, there has been a steady increase in the proportion of carcasses that index above average (index of 100) in a measure of the anticipated yield of trimmed retail product. The reduction of backfat also has continued at an undiminished rate. Although there is no evidence in either the United States or Canada to indicate the relative contributions of genetics, nutrition, and management to these changes in carcass merit, the steady rate of change is highly suggestive of a substantial and continuous genetic component. The development of larger herds as well as a greater economic incentive to succeed may also have contributed to a gradual improvement in the average levels of most production components, including carcass merit.

There has been considerable improvement in sow productivity in the last 20 years. The average number of pigs marketed per litter in the United States has increased from eight to almost nine in just the last 7 years (Fig. 15-2).

It is necessary for veterinarians, hog producers, and others associated with the swine industry to use the same terms when considering pig production. Stage One (breeding production stage) is where the breeding females and boars are kept and managed for the purpose of reproduction. Stage Two (nursery production stage) is the stage associated with nursery pigs, and Stage Three (finishing production stage) deals with finishing pigs. The term *Isowean* includes segregated weaning, early weaning and age-segregated rearing. The different types of production systems are also described (one-site, traditional two-site, two-site Isowean, and three-site).

INDUSTRIALIZATION OF SWINE INDUSTRY

Food-producing animal production is moving toward an industry structure of fewer, larger production units that feature centralized control of technology and production processes. This is known as the intensification or industrialization of food-producing animal agriculture. Over the last few decades, companies involved in the production of meat and poultry have vertically integrated their operations through contracts with producers who grow the animals. These agricultural organizations own feed mills to produce feed, produce their own pigs on farrow-to-finish and finishing farms, and raise their own replacement stock by multiplying high-genetic purchased reproductive animals. They may own an abattoir and even a meat-processing plant. Owner-operated farms are often referred to as independent farms, in comparison with those belonging to integrated organizations, referred to as integrated farms. Integration is a way for a company to ensure a reliable supply of animals for processing into consumer-ready products.

A survey in Quebec, Canada, of owner-operated, swine-breeding farms and integrated organizations found that production tended to be more specialized and concentrated in integrated operations (Ravel et al, 1996). More new practices have been adopted on integrated farms, and their stockpersons have a more proactive style of management in farrowing quarters. Swine production methods, especially piglet rearing, are different between independent farms and integrated organizations specializing in swine production. These differences are related to organization size. The specialization, concentration, and intensification of production, as well as the pursuit of higher performance through the adoption of new practices, are considered essential by integrated organizations, given the importance of their investment.

The industrialization of U.S. animal production is taking place in nearly every state. Typically, animals are grown within 50 miles of a processing facility because of the expense of shipping live animals. Proximity to feed mills is also desirable because of the costs of shipping the large quantities of feed required to grow pigs to slaughter weights.

A major consideration in locating production facilities is the disposal of animal wastes: land must be available relatively near the growing facilities for that purpose. The producer is responsible for removal and disposal of dead animals, as well as recycling the animal wastes that accumulate during the growing process. Also important is an adequate supply of workers for production and processing.

Vertical integration of animal production is designed to increase efficiency, lower expenses, and produce additional value. In vertical integration, one firm owns and controls the raw material, the means of production, and the final product. Producers enter into contracts with integrators to provide housing for the animals, feed them, ensure their health, and provide for waste disposal. The producer typically owns the housing and the feed storage facilities that are used in the production of the animals. The integrators own the animals. Contracts stipulate what feeds and animal health products farmers use, as well as the prices paid for their products.

The industrialization of agriculture has a number of positive and negative aspects. It is important to understand the real and perceived effects of integrated production systems. These include a variety of both positive and negative influences on social and economic conditions and on the environment. Most producers and governmental agencies believe the swine industry has had major benefits for the rural economy. Industry leaders or government officials may not recognize the negative impacts associated with industrialization.

Industrialized, corporate farming fosters the rapid adoption of technology. Some changes in technology can also negatively influence small-scale producers. The diffusion of agricultural technology can widen the gap between large and small farmers. One consequence for the early adopter of certain technologies is either windfall profit or loss. Once the use of the technology is widespread, the total productivity of an industry increases, which leads to oversupply and a reduction in the price of the product. Technology can widen the inequality gap, since early innovators are the ones who can afford to adopt and profit from new technology.

The effects of large-scale swine operations on rural health have been examined (Thu and Durrenberger, 1998). Rural health is the physical, social, economic, environmental, and political well-being of people living in rural areas. Considerable research is being devoted to understanding various pieces of the complex puzzle (e.g., odor, manure application, ground and surface water protection), whereas less time and energy are spent articulating the range of issues involved and their interrelationship.

The swine industry has undergone a dramatic shift in the past decade, characterized by increased concentration of production, loss of independent swine producers, geographical shift of production within and outside the United States, and the growth of large-scale swine operations. The number of U.S. swine producers has declined precipitously from 750,000 in 1974 to 157,000 by the end of 1996. Between 1994 and 1996 one out of every four producers left the business. By the end of 1996, 3% of producers, representing the largest corporate operations in the United States, produced 51% of all the pigs, while 21% of all pigs were grown under contract. In Iowa, 55% of all new swine facilities permitted by the Iowa Department of Natural Resources from 1987 through 1995 were owned by or under the effective control of large-scale corporate swine producers.

Large-scale operations are defined as firms that possess the following combination of features: (1) management, labor, and ownership are separate, (2) family labor plays a limited role in the operation, (3) owners, management, and labor do not live on or near the operation, and (4) a non-family corporate or company organizational structure.

The characteristic features just described of emerging large-scale swine operations reflect the continuing industrialization of agriculture. It is a food production system heavily dependent on fossil fuel–based energy inputs such as fertilizers, machinery, pesticides, and gasoline. Anthropologists claim that, based on measures of energy expended per calorie of food produced, industrial agriculture is the most inefficient form of food production in the history and prehistory of humankind. Large-scale operations characteristically substitute capital-intensive, fossil fuel-based technology for people. Concentration of production and distribution into relatively few firms, which integrate highly specialized operations such as food processing and marketing, is common. Also, a highly specialized political apparatus extending into national, regional, and local governing bodies, as well as state-supported institutions to support and replicate the system, is typical of human organizations associated with industrial agriculture (Thu and Durrenberger, 1998).

Proponents and opponents of industrial agriculture have respectable support in academia. Frequently invoked evidence for the economic advantages of industrial agriculture are the wide availability of abundant food at extremely low cost to consumers and the record productivity and efficiency of modern farmers. In contrast, critics of industrial forms of agriculture point to the narrow focus of economic measures of development and efficiency that typically exclude assessments of the social, environmental, physical, psychological, political, and rural economic health of people. Most

Downloaded From Vet-eBooks.com

of these issues are not incorporated into economic analyses of food production (treated as externalities), but each has a distinct, often measurable, and human cost, as summarized briefly here.

The range of rural consequences of large-scale swine production to be assessed fall into six categories: (1) air quality, (2) water quality, (3) human health, (4) community social health, (5) rural economic health, and (6) political health.

Air Quality

Air quality issues can be divided into two general areas: odor and public health. Most of the attention to air quality issues has concentrated on odor, such as identifying sources of odor, measuring it, and developing control techniques. Less attention has been paid to the potential consequences of odor on the health of neighbors, even though some studies indicate deleterious human health consequences are present.

The evidence collected thus far indicates efforts to control odors are not synonymous with addressing the potential public health problem. Moreover, no systematic data are being collected to determine which forms of production, particularly which kinds of producers, are more likely to be responsible to their neighbors in controlling air quality.

Water Quality

In 1996 an EPA Comparative Environmental Risk Assessment was completed for Iowa that demonstrated water quality related to the changing swine sector was a primary environmental and social concern statewide (Thu and Durrenberger, 1998).

The evidence justifies rural resident concerns. The Iowa Statewide Rural Well Water Survey shows that in north-central Iowa, 10% to 15% of all wells (all depths) exceed the recommended drinking water limit for nitrate-nitrogen and over 30% of all water supplies are positive for total coliform bacteria. Runoff related to livestock manure is the number one source of fish kills in Iowa streams (Thu and Durrenberger, 1998). Despite the concerns and evidence, little systematic data exist to assess the actual performance of large-scale swine operations relative to contamination to surface water, groundwater, and precipitation. No systematic data are being collected to determine which forms of production, particularly which kinds of producers, are more likely to be responsible for good water quality. In the National Swine Study between 1989 and 1991, the nitrates in drinking water, at the concentrations found, were not associated with farrowing swine health or productivity parameters examined (Thu and Durrenberger, 1998).

Human Health

One of the most well researched areas related to swine production is the relationship between exposure to the interior environment of swine confinement production and worker health. Twenty-five studies from the United States, Canada, Sweden, Denmark, the Netherlands, Germany, and England have consistently found a number of work-related health problems among swine confinement workers. Approximately 25 percent of all swine confinement workers have one or more respiratory conditions. However, there remains the unanswered long-term health question concerning the health risks for workers spending 40 or more hours/week, which is typical of large-scale operations.

People working inside confined swine production environments are exposed to certain health hazards associated with organic dusts, gases, and odors (Donham, 1998). People working in these confinement operations include owner-operators, employees, children, veterinarians, and other service workers. Workers may spend several hours per day in these facilities preparing feed, feeding animals, cleaning buildings, sorting and moving animals, giving vaccines and other treatments, and working at various other management and maintenance procedures.

Bioaerosols, fine airborne dust containing bacteria and bacterial products, are a major problem. These complex mixtures originate primarily from the animals and dried feces and feed. Bioaerosol particles contain approximately 25% protein. One third of breathed particles are so small that they are not filtered out in the nose and throat and thus enter the airways; the smallest particles may reach the lungs. Bioaerosol and gas concentrations increase during the winter months when facilities are tightly closed and ventilation rates are reduced to conserve heat. Typical ventilation systems in swine buildings are designed to control heat and humidity but do not necessarily reduce bioaerosol or gas levels adequately to ensure a healthy environment for humans or animals.

Workers may develop flu-like symptoms with coughing and sneezing, wheezing, chest tightness and phlegm, and sometimes a fever with muscle aches. Swine confinement workers in the United States, Sweden, and Canada have similar rates of acute bronchitis—approximately 55%, or about twice the rate of chronic bronchitis (Donham, 1998). Veterinary students visiting swine confinement units experienced eye irritation, headache, and tiredness (Jolie et al, 1998). Cough, nasal and throat irritation, and sinus inflammation were the most prevalent respiratory tract symptoms that usually developed the day of the visit and disappeared within 3 days after exposure. The presence of clinical signs was not significantly different between students who wore a mask during the farm visit or those who did not. Students with preexisting allergies were more likely to develop respiratory symptoms than students who did not have allergies (Jolie et al, 1998). Two-strap respiratory protective face masks reduce the total and respirable dust concentrations more so than the one-strap face masks, but they are still not highly effective. Surveys of swine producers regarding employee health and safety have found a need for training materials on first aid, animal handling and care techniques, air-quality monitoring, and lung function testing for employees (Tripp et al, 1998). Employee health and safety protection is part of doing business, and there is a need for educational and research programs to address the issues.

Hydrogen sulfide gas is most hazardous when the manure pits are located directly beneath the production buildings. The gas poses a potentially lethal hazard when the liquid manure is agitated, which operators commonly do to suspend the solids so the pits can be pumped out. During agitation, the gas can be released rapidly, increasing from levels of less than 5 ppm to lethal levels of over 500 ppm within seconds. Numerous cases have been reported of workers and animals dying or becoming seriously ill when hydrogen sulfide levels increases from agitated pits.

The decomposition of animal urine and feces produces gases, most notably ammonia and hydrogen sulfide, which affects the health of workers.

Community Social Health

Social issues refer to personal, family, neighborhood, and community relationships and quality of life. Measurable social problems result from absentee-owned large-scale agriculture. Community divisions are created and frequently become acutely disruptive as the result of large-scale swine operations. More fundamental than any single issue is the

Downloaded from Vet-eBooks.com

deep-seated frustration that people feel from the lack of adequate local means of problem resolution. The lack of local control causes an escalating social pathology in many rural areas. A continual recurrence of discords and attempts to find an outlet has led to a pattern of community distrust that is at odds with core values of rural Iowans. This intense conflict acts as a pressure cooker, and with no outlet attitudes and behaviors that resonate with extremism can and will develop.

Rural Economic Health

The rural economic impact from smaller and more diversified farms is better than from large-scale swine facilities, because they add greater value to the community economy (Thu and Durrenberger, 1998). Considerable research indicates that a better measure of industry health for rural areas is not the total volume of hogs produced, but the number of farmers producing those hogs.

Hogs are not as important as people. Traditional economic assessments of large-scale swine facilities have been overly narrow in scope in dealing with job creation and tax bases, and generally ignore environmental, social, and human health costs. Large-scale swine facilities are by their very nature intended to displace people with capital intensive technology, and it is therefore erroneous to project job creation gains because the displacement of independent swine producers will result in a net job loss.

Political Health

Perhaps the most disturbing aspect of swine industry change is its consequences for the democratic health of the country. Anthropological cross-cultural research clearly demonstrates that concentration of power over the production and distribution of a precious research is antithetical to democratic process. This is illustrated quite clearly in the following quote from former U.S. Senator Robert Morgan's experience from North Carolina (Thu and Durrenberger, 1998):

Before I became State Attorney General of North Carolina, I spent some years as a country lawyer. We lawyers all knew each other and we took our cases down to the courthouse where we went up against each other but all played by the same rules. When big business steps in it is no longer that way. This situation was brought to my attention in early 1992 when a group of homeowners and small farmers asked me to represent them in their efforts to protect themselves against damage done by a large-scale hog operation. The defendants brought in a law firm with more than fifty lawyers and assigned several to our case. These lawyers had virtually unlimited time and money. The industry's resources helped the defendants in more subtle ways. When attorneys for the plaintiff, armed with a court order, inspected the facilities, they found that the owners were accompanied by several professors from North Carolina State University, a land grant college with responsibilities for agricultural research.

Framing the Priorities and Envisioning the Future

The relative importance of the six issue areas just outlined can be gauged by asking a simple question: "If it's broken, why can't I get it fixed?" If we accept the evidence that there are in fact significant water quality, air quality, economic, social, and worker health problems associated with large-scale swine operations, we are then faced with the question of why we have failed in our efforts thus far to fix them. The answer is that the political system, the system that should respond to these problems, has also been broken along the way. This is the fundamental problem. By unjustly and incorrectly dismissing the voices of rural Iowans and rural Americans as overly emotional, unscientific, antigrowth, or anti-agriculture, our political leaders have violated a fundamental democratic tenet of trust and faith in due process by exchanging human dignity for the hollow rhetoric of economic development. More fundamentally, trust lost is not easily regained. Loss of faith in our leaders, in our political system, in our academic institutions, and in our country is a heavy price to pay.

The future holds hope and promise. In our vision for the future we must remember that people are always more important than commodities; the best measure of industry health is the number of people producing hogs, not the number of hogs produced. Assumptions that define and promote ideas of productivity and efficiency as inevitable and of industrialized swine production as natural convince those who suffer the costs that there is nothing they can do about it. Something *can* be done about it. Recent strides in sustainable agriculture have succeeded in establishing a foothold relative to the dominant industrial agricultural paradigm. Sustainable agriculture is often perceived to be associated with specific farm practices to deal with such issues as soil erosion or decreasing fertilizer use. Criticism is often leveled at sustainable agriculture that it is nebulous and ill defined, and that it has no pragmatic program or mechanism for ensuring profitability among farmers who make the transition. However, we must remember that any newly emerging system of adaptation requires a range of variation to increase its likelihood of success. Sustainable agriculture would be doomed to failure if its tenets were clearly defined and rigidly practiced at the outset. The underlying point of sustainable agriculture is not precisely what it is, but what it means and why it is emerging.

Agricultural industrialization can have adverse effects on rural communities. There may be loss of political power because of small farmers' not being as organized as specialized commodity groups, outmigration of rural populations, and displacement of farm workers because of mechanization. Furthermore, the simultaneous demise of small farms and the rise of large-scale agribusiness in a community often brings rising unemployment and declining economic well-being for the community. For example, industrialized operations tend to contract with national suppliers and distributors rather than local suppliers.

Large livestock farms clearly benefit the farm economy. The industry is economically viable and probably will remain so because the worldwide demand for products is expected to continue to grow in the future. However, there are winners and losers as a result of industrialized agriculture. Because of the demise of the independent producers, service jobs have been lost. Many small feed mills and other farm service firms are no longer in business. These and other impacts need to be balanced against the economic effects.

SUSTAINABILITY OF THE SWINE INDUSTRY

Sustainable swine production systems are defined as those that combine production and management techniques to enhance profit and improve the ecological and socioeconomical surroundings. Over the long term, the systems should maintain or enhance the environment and resource base, the quality of life for the producers and society as a whole, the profit level of producers, and the quality of pork produced. Swine production is rapidly changing to fewer and larger production units. At the interface of sustainable

Downloaded From Vet-eBooks.com

agriculture and swine production are several levels of issues: the farm, the rural community, the society or consuming public, and the ecosystem or environment. The challenge beyond identifying issues is to incorporate sustainable concepts into profitable, ecologically based swine production systems.

For long-term success the social, economic, and environmental dimensions of industrialized swine production need to be carefully considered at the farm, rural community, consumer, and ecosystem levels (Honeyman, 1996). Rapid changes in the swine industry structure influence all of these levels in fundamental ways. Young, beginning producers are vital to the future of swine production and must have access to technology, genetics, markets, and information. Manure nutrient management is the key linkage between swine and crop production. Quality pork to meet the consumer's needs helps ensure a vibrant industry. New sustainable alternatives are needed that select the appropriate technologies and combine them into management-intensive systems coupled with crop production. Virtually every issue involving sustainable swine production provides opportunities for research, education, dialogue, and change. The implications of sustainable swine production are a wholesome balanced environment; healthy rural families and communities; many profitable, modest-sized, family-based swine-crop farms; and quality pork.

Pork Quality

Pork quality is a significant problem for the U.S. swine industry. The U.S. pork supply has about 16% pale, soft, and exudative (PSE) pork, and 10% is dark, firm, and dry (DFD). Increasingly, hogs are being purchased on a carcass merit basis. Therefore leanness and muscling are becoming more important to producers. The porcine stress syndrome (PSS) gene is related to both leanness and PSE-DFD pork. The selection of pigs for fast deposition of lean may lead to lower levels of intramuscular fat or marbling, which may produce drier or less tasteful pork. Consumers are also concerned about the use of antibiotics in swine production and the potential for violative levels of drug residues in pork. Pork Quality Assurance (PQA) programs and producer education activities have been successful in reducing drug residues.

Swine Manure Management

Waste management has become a hotly contested topic with the expansion of intensive livestock operations, especially large-scale swine operations. The large number of animals confined on these operations results in large amounts of animal waste with a relatively high potential for pollution. As controversy has arisen over livestock waste, local and national governments have responded with stricter environmental regulations. Other consequences of industrialization of agriculture are the effects on the environment adjacent to human populations. Two frequent concerns expressed whenever large-scale swine enterprises are discussed are water pollution and odors. Odor is often the most immediate impact, but citizens are also concerned about water quality and other issues (Miner, 1999).

Pig manure is primarily a mixture of urine and feces, and it contains undigested dietary components, endogenous end products, and indigenous bacteria from the lower gastrointestinal tract. Manure contains a variety of organic compounds (complex to simple in nature), inorganic compounds, and, potentially, feed additives, depending on the makeup of the diet. Odoriferous volatile organic compounds, short-chain volatile fatty acids, and other volatile carbon-, nitrogen-, and sulfur-containing compounds from microbial fermentation in the gut of pigs can be emitted immediately after feces are excreted. Furthermore, the release of urinary ammonia from the enzymatic conversion of urea can occur within a short time after excretion. Depending on the type of manure-handling system used and duration of storage, odors can be emitted during organic matter decomposition of manure. Methods used to control odor emissions from manure have included dilution with water; low temperatures; solid-liquid separation; aeration; anaerobic digestion; application of enzymes, chemicals, bacterial cultures, and masking agents; filtration of ventilation air; and diet manipulation. Control of on-farm odors with feed or manure additives is often cited as an odor control option for producers. The manipulation of diets to reduce odors is feasible and practical (Sutton et al, 1999).

Swine producers are under increasing pressure from regulators, legislators, neighbors, and environmental groups about manure management. Manure has been cited as a contributor to the increasing nitrate levels of groundwater. Improper manure management is a contributor to the increased phosphorus, nitrate, and fecal coliform bacteria in some rivers. To maintain a viable swine industry, manure management issues must be addressed and action taken in a proactive manner.

Manure handling systems vary among producers. Systems include manure collection, storage, and use (Schmitt et al, 1996; Schmidt et al, 1996). One major difference in manure handling is the use of solid or liquid systems. Collection systems are used to collect and remove manure from a confinement facility. Manure storage structures include deep pits, earthen structures, and above- and below-ground concrete tanks. Manure application to cropland is the traditional method of manure use. Cropland application methods affect odor and gas emissions, water quality, and nutrient availability to crops. Solid manure can be broadcasted on the soil surface, whereas liquid manure can be either broadcasted on the soil surface or injected under the soil surface. Surface-applied manure, either liquid or solid, can be incorporated into the soil through several tillage methods. The location of manure application in relationship to surface water is a critical issue in preventing contamination of surface and ground waters.

Most large-scale swine operations constructed to date have incorporated anaerobic lagoons into overall manure treatment and storage strategies. Well-designed lagoons provide three specific functions:

1. They provide a location for anaerobic bacteria to decompose the residual organic compounds into more easily handled end products. This means a conversion of the solid material into liquids, which is similar to the process that occurs in a household septic tank system.
2. They provide a storage volume to accumulate treated and partially treated manure until the time for convenient or economically productive application of the material to cropland.
3. They provide a facility to capture and store any contaminated runoff that might be generated by rainfall on manure-contaminated surfaces that may be outside the roofed areas.

Two major concerns are water pollution and odor. Water pollution can occur whenever large quantities of organic waste materials are concentrated in one area. A lagoon may overflow, or, if lagoon contents are purposefully drained into a surface waterway, the material may contaminate the receiving water. Groundwater pollution may occur from leakage from the lagoon or manure storage reservoir moving down-

Downloaded From Vet-e-Books.com

ward into groundwater. Also, the application of excessive effluent to cropland may cause more nitrogen being applied than is used by the crop. The nitrogen may be transported beyond the root zone and may eventually appear in groundwater as an increased nitrate concentration. Odors are primarily the products of anaerobic decomposition of manure. Heavily loaded lagoons are a notorious source of odor.

There are alternatives to minimize the environmental impact of large swine production units (Miner, 1999). Technology and management techniques exist to achieve higher levels of environmental acceptability. Engineers and construction professionals have the ability to construct basins that do not leak or that have dikes that will not erode and dump large quantities of manure into receiving streams. Groundwater sampling and monitoring techniques are available to identify when lagoons are leaking. Manure management options to reduce odor are available. Enclosed anaerobic digesters can reduce organic content by 90% while producing a biogas that can be converted to electricity. Lagoons can be covered and the collected gas diverted to a soil absorption system. Permeable covers for lagoons are also available that greatly decrease odors.

Composting Dead Animals

Improper disposal of dead pigs can lead to odor problems, transmission of pathogens, and water contamination. Three typical methods of dead pig disposal are rendering, incineration, and burial. Composting is now being practiced on several thousand farms in the United States, primarily on poultry farms for the handling of mortalities (Kashmanian and Rynk, 1995). Composting is an alternative method for the disposal of fetal placenta and dead pigs (Morrow et al, 1995). A compost pile requires nutrients, water, and oxygen. The process disintegrates most of the carcasses, including most of the bones, and reaches temperatures sufficient to kill all of the *Erysipelothrix rhusiopathiae*, pseudorabies virus, and most of the *Salmonella*. There is little odor associated with the pile and few flies. Veterinarians have the opportunity to include the management of dead pig disposal in the consulting services they offer.

Pork Quality Assurance Program

The National Pork Producers Council (NPPC) in the United States introduced the PQA program in 1989 as a three-level management education program. The PQA program emphasizes good management practices in the handling and use of animal health products and encourages producers to review their approach to health management of their herds. It is a multi-level producer education program to enhance the quality of pork sold to the world's consumers.

The PQA program is for all pork producers, regardless of the size of their operation. The benefits of participation for the individual producer are to the following:

- To improve management practices
- To avoid violative drug residues
- To decrease production costs
- To increase awareness of food safety concerns

Pork Quality Assurance: the Veterinarian's Role

The PQA program consists of three levels. Level I is a self-study program for producers that covers the importance of food safety to the pork industry, producer attitudes and responsibilities, use of animal health products, the current regulatory system, and on-farm testing. Level II is a producer self-review of the information provided in Level I. Levels I and II are contained in the same booklet as Level III. The booklet is available from NPPC. Levels I and II are also available at NPPC's website at http://www.nppc.org.

The producer completes the Level III program in association with a verifier. Verifiers can be veterinarians, university agriculture extension personnel, and agricultural educators. The Level III program contains ten good production practices (GPP). The GPPs ensure compliance with the Food and Drug Administration (FDA) compliance policy guide "Proper Drug Use and Residue Avoidance by Non-Veterinarians (CPG 7125.37)" and meet the minimum expectations of the government and packers. The first six GPPs address food safety; the other four focus on the efficient production of a quality product. After completion of the educational and evaluation program, both producer and verifier sign the verification form. The signed form is then sent to NPPC. A certificate of program completion is then sent to the producer. The producers then review their herd health program with their verifiers annually and recertify every 2 years.

Benefits of participating as a verifier for veterinarians include the following:

- Shows producers that veterinarians are current with the industry.
- Strengthens the image of the veterinarian's practice as a source of educational materials.
- Reinforces the importance of the veterinarian-client-patient relationship (VCPR) in responsible use of animal health products.
- Expands client base through increased interactions with current clients and the addition of new clients through referrals.
- Provides a basis for discussing the role of veterinarians in herd management practices.
- Contributes to the pork industry's long-term goal of making pork "the meat of choice" in the twenty-first century.

A set of slides with a script is available from the NPPC that can be used by veterinarians or others to efficiently present the PQA program to groups of producers.

Food Safety in the Pork Industry

The issue of food safety has been influenced and maintained by highly publicized outbreaks of foodborne disease in humans. These outbreaks have stimulated consideration and revision of regulations for food inspection in packing plants and have produced consumer groups' advocation of the control of foodborne pathogens in animal production systems. The United States has recently become a net exporter of pork, and quality assurance of product is becoming a focus of competition in export markets (Davies, 1997). Perceptions of food safety can have profound effects on consumer attitudes, government regulations, and market access. Quality assurance standards can have a profound effect on domestic and international markets for pork-producing countries.

The major foodborne pathogens in the United States and relative importance of pork as a source are as follows (Davies, 1997):

Pathogen	U.S. Department of Agriculture Ranking	Relative Importance of Pork
Salmonella	1	++
Campylobacter	2	+
Toxoplasma gondii	3	+++
E. coli 0157:H7	4	—
Listeria monocytogenes	5	+
Trichinella spiralis	6	++++
Yersinia enterocolitica	6	++++

Downloaded from Vet-eBooks.com

Human trichinellosis, a parasitic nematode infection with worldwide distribution, is caused by tissue-dwelling roundworms of the species *Trichinella spiralis*. The parasite is acquired by eating raw or inadequately cooked meat products containing encysted larvae. Historically, pork products from domestic swine have been the principal sources of infection in the United States; however, meat from a variety of game animals has also been responsible for infections in humans. The incidence of human trichinellosis continues to decrease since national reporting was initiated in 1947. However, the continued identification of cases related to commercial pork consumption and the histories of consumption of uncooked meat indicate the continuing need for public education about trichinellosis and the dangers of consuming inadequately cooked meat (Moorhead et al, 1999).

A trichinella herd certification pilot project was successfully completed in northeast Iowa, and an eradication program may be in the near future. Control steps include the following:

1. Eliminate exposure to domestic and wild animals including domestic and feral cats
2. Implement and maintain an effective rodent control program
3. Eliminate sources of infection from feed
4. Avoid environmental exposure to toxoplasma oocysts
5. Prevent or control cannibalism among pigs

Out of a total of 80 million swine slaughtered annually in the United States, the number of carcasses identified with cysticercus lesions *(Cysticercus cellulosae)* is extremely low, ranging from 1 through 44 during each of the 10 years (Saini et al, 1997). Swine cysticercosis (unlike cattle cysticercosis), with man being an alternative intermediate host, poses serious public health concerns with sometimes fatal consequences manifested through neurocysticercosis *(Cysticercus cellulosae)* (Saini et al, 1997). Although human cysticercosis is still rare in the United States, recent reports have indicated an increase in diagnosed cases. These are primarily the result of an increasing number of immigrants and international travel to and from endemic areas.

Hazard Analysis of Critical Control Points

The U.S. Department of Agriculture (USDA) Food Safety and Inspection Service has required hazard analysis of critical control points (HACCP) principles be put in place in meatpacking plants. The HACCP system is designed to prevent food safety problems instead of relying on finding them after they happen. The pork producer's responsibility under the packer's HACCP plans is to supply the packer with animals that are free from violative tissue levels of antimicrobials and chemicals and free from physical hazards such as broken needles and other metals in the meat.

The seven basic principles of the HACCP system include the following:

1. Identify hazards.
2. Find critical control points in the process.
3. Establish critical limits for each critical control point.
4. Monitor critical points.
5. Take corrective action if monitoring shows there are deviations outside the limits of a critical control point.
6. Keep records on each critical control point.
7. Verify that the HACCP plan is working correctly.

Application of the HACCP system in packing plants is done by identifying groups of hazards that can affect the safety of the meat, such as the following:

- Microbial contamination
- Chemical hazards such as antimicrobial and chemical tissue residues
- Physical hazards, such as the accidental presence of broken needles or other metals

The slaughter of swine is an open process with many opportunities for the contamination of the pork carcass with potentially pathogenic bacteria (Borch et al, 1996). The major contamination points during slaughter are pig-related, such as fecal and pharyngeal, and environmental. HACCP and good manufacturing practice (GMP) in swine slaughter must be focused on limiting this spread. The pathogens that may contaminate pork include *Campylobacter* spp., *Salmonella* spp., and *Yersinia enterocolitica*, all of which originate from the pig. Contamination of the carcasses with these pathogens may be limited, provided that only strict slaughtering procedures are used. Other organisms such as *Aeromonas* spp., *Listeria monocytogenes/Listeria* spp., and *Staphylococcus aureus* may be endemic in the processing environment, and since they can be controlled by proper cleaning and disinfection, they are useful as indicators for the success of GMP.

The packers address microbial contamination through an in-plant HACCP process. Producers must, however, help control antimicrobial and chemical residues and physical hazards. The producer is responsible for properly observing withdrawal times to ensure there are no violative antimicrobial tissue residues.

The Food and Drug Administration (FDA) has published a compliance policy guide, "Proper drug use and residue avoidance by non-veterinarians," that outlines the producer's responsibilities when using animal health products. Following these guidelines ensures the products continue to be available for use when necessary. They should be observed whether the product is administered as an injection, spray, or through the feed and water.

For responsible use of animal health products the producer must do the following:

1. Identify and track animals to which drugs were administered. They can be identified by the following:
   - Individual
   - Pen
   - Lot
2. Maintain medication and treatment records that identifies the following:
   - Animals treated
   - Date(s) of treatment
   - Drug(s) administered
   - Who administered the drug(s)
   - Amount administered
   - Withdrawal time before slaughter
3. Properly store, label, and account for all drug products and medicated feeds.
4. Obtain and use only veterinary prescription drugs through a licensed veterinarian based on a valid VCPR.
5. Educate all employees and family members involved in treating, hauling, and selling the animals on the following:
   - Proper administration techniques
   - Observance of withdrawal times
   - Methods to avoid marketing adulterated products for human food

Several bacterial species pose a food safety hazard, with salmonella being the most prevalent. One of the challenges regarding on-farm control of salmonella is potential high prevalence of infection but only mild or even no clinical signs in the pigs. In fact, many serovars that cause illness in humans are not pathogenic in swine. The following control methods are recommended to decrease salmonella on the farm and in so doing, decrease salmonella prevalence in pigs delivered to the slaughterhouse:

1. Periodic thorough pressure washing and disinfection of facilities

2. AIAO pig flow
3. People movement within and between farms; all accompanying potential fomites should be managed to reduce carrying salmonella
4. Control of the rodent population
5. Prevention of birds entering the facilities
6. Clean-up of feed spills outside the facility to discourage birds, rodents, and other wildlife from accumulating at the site
7. Vaccination with *S. choleraesuis* has been reported to reduce shedding of *S. typhimurium* (Gibson et al, 1999) and *S. derby* (Groninga et al, 2000)
8. Feed ingredients are free from salmonella contamination
9. Proper ventilation of facilities to decrease survival of the bacteria in the environment

Veterinarians are a critical component of the food safety control program. They have a unique understanding of the production conditions that exist on the farm and how these might be managed to decrease exposure to important zoonotic pathogens.

WELFARE OF SWINE

A concern of society is the welfare of pigs raised under intensive conditions. When pigs were kept extensively in an outdoor system with a large living space, their welfare was normally considered to be adequate. However, current husbandry methods usually lead to pigs remaining indoors during their entire life, and the numbers kept per unit is steadily increasing. Ruth Harrison's book, Animal Machines (1964), subsequently led to the Brambell Report (Brambell, 1965), which recognized the possible detrimental effect of limited space, diet, ventilation, bedding, and companionship on animals' well-being. The report observed, "It is because of these various restraints imposed on animals by the artificial environment of intensive husbandry that the role of welfare has become so crucial today. Welfare is a wide term that embraces both the physical and mental well being of the animal. Any attempts to evaluate welfare, therefore, must take into account the scientific evidence available concerning the feelings of animals, that can be derived from their structure and function, and also from their behavior." The establishment of the Farm Animal Welfare Council in 1979 in Great Britain followed this report. The Council has been given the responsibility of reviewing the welfare of farm animals on agricultural land, at markets, in transit, and at the place of slaughter. It advises agriculture ministers of any legislative or other changes that may be necessary. In 1988 the Farm Animal Welfare Council made an assessment of pig production systems and recommended the banning of high temperature-high humidity (e.g., sweat box) system for finishing pigs, the phasing out of multi-tier weaner pig pens, and that the dry sow should not be housed with stalls and tether systems (both girth and neck types) and that, as a matter of urgency, the government should introduce legislation to prevent all further installation of units of these designs (Farm Animal Welfare Council, 1988).

Various types of stressors occur mainly as a result of intensification of production processes at many points in the life of a pig (Ayo et al, 1998). Common stressors in modern pig production include high ambient temperature or heat stress, effects of road transportation, changes at weaning, overcrowding, aggressiveness and cannibalism, nutritional inadequacies, and veterinary procedures (e.g., vaccination, castration, tail amputation, collection of blood samples). As a result of stress, pigs may lose weight or gain very slowly, convert feed to meat less efficiently, sustain physical injury, become more susceptible to diseases, or have reduced meat quality.

The behavior of the animal attendants in swine herds affects the behavior of pigs; the behavior of the pigs, in turn, is an important factor in the effectiveness of managing modern systems (Seabrook, 1988). The attendant can have a profound positive or negative effect on productivity of the animals. The role of the pig stockperson is not just important from an economic viewpoint; it is vital for animal welfare too. In the United Kingdom, the *Code of Recommendations for the Welfare of Livestock-Pigs* states: "Stockmanship is a key factor because, no matter how otherwise acceptable a system may be in principle, without competent, diligent stockmanship, the welfare of animals cannot be adequately catered for" (Seabrook, 1988).

Agriculture Canada (1993), in coordination with the Canadian Federation of Humane Societies, has published "Recommended code of practice for care and handling of farm animals: pigs." The voluntary code is intended to be used by the industry, scientists, and animal welfare groups as an educational tool in the promotion of sound husbandry and welfare practices. The recommendations attempt to define high standards of pig production and well-being in commercial, research, educational, and other farm operations. This code of practice is currently being revised and updated and can be viewed at http://carc-crac.ca/english/codes_of_practice/factsheets/PIGS.htm.

There are now major concerns about the continuous close confinement of breeding females in cages or tether stalls. Pigs kept in such systems, alternating with farrowing crates during late gestation and lactation, are unable to exercise regularly for the whole of their reproductive life. Some studies indicate that sows kept in neck-tethers show a chronic physiological stress response, increased aggression between adjacent animals, and some evidence of changes in social behavior compared with group-housed pigs (Barnett et al, 1985). Animal welfare concerns are just beginning to surface, and it behooves animal scientists, veterinarians, and others involved in the swine industry to become involved in the investigations of and solutions to these concerns.

The aims of modern pig rearing are directed toward constant improvement of productivity. The resulting rearing conditions are more and more removed from the original way of life of the wild animal. The fundamental characteristic of wild boar and feral hog populations is their great adaptability to environmental conditions. This characteristic permits the use of a large range of rearing systems, extensive or intensive, to which the species can adapt.

There is growing worldwide concern for the welfare of pigs raised intensively in total confinement. Some countries have enacted legislation that states the minimum housing and management requirements. These minimum requirements include the following:

1. The possibility of being able to stand up or lie down in a manner characteristic of the species and to adopt a relaxed position (e.g., lying on their side with stretched limbs). This necessitates sufficient space.
2. During the rearing period, young animals should be given enough space to satisfy their instinct of play (e.g., running, fighting). This requires a suitable floor.
3. The floors of stalls or pens should allow the animals to tread and stand safely and to lie down without suffering injury. Perforated floors do not always fulfill these demands. Therefore at least the resting area should be bedded with a material like straw. Dry straw is an irresistible attraction to any pig, because it occupies and distracts the animals. Behavioral disturbances such as ear chewing or tail biting may be reduced by the presence of straw. Bedded floors also decrease the need for high ambient temperatures.

4. A restricted feeding system requires sufficient space for each animal at the trough. Care should be taken that the animals disturb each other as little as possible when feeding.
5. To avoid placing individual animals at disadvantage, they should be kept in groups of uniform sizes.
6. The animal's environment (or microclimate) must be appropriate for its particular age group.

The welfare of the intensively reared pig, its environment, and the incidence of disease are interrelated. Sows kept in confinement are exposed to more stress factors than sows kept free in pens. A definite relationship has been shown between herd size and increased frequency of toxemic agalactia, traumatic injuries in sows, piglet morbidity, and mortality. The health of litters in pens with straw as bedding was superior to that of litters in pens with other bedding materials. Litters in pens without bedding showed the poorest results. Herds in houses with liquid-manure handling systems were associated with poorer pig health than those with solid-manure handling systems. Postlactational anestrus was seen more frequently in sows confined in individual stalls compared with those free in pens.

TYPES OF SWINE PRODUCTION UNITS

Swine production units can be characterized as follows:

- *Farrow-to-finish.* Produces pigs through its sow herd and rears the pigs through to market at approximately 100 kg of live weight on the same site. This is a classical method of rearing pigs and is restricted in size and opportunities for disease control.
- *Farrow-to-feeder.* Produces pigs up to approximately 25 kg of body weight, at which time the pigs are sold or removed from the site to a growing-finishing unit.
- *Farrow-to-weaning.* Produces pigs that are sold or removed to the weaning to finishing site at time of weaning. Normally these pigs are weaned before 21 days of age to afford some level of disease control.
- *Growing/finishing.* Receives pigs from a farrow to feeder operation and markets them at a targeted body weight of 100 kg or greater.
- *Wean-to-finish.* Receives pigs from a farrow to wean unit and markets the pigs at a targeted weight of 100 kg or greater.
- *Breeding stock herds.* Specialized swine units that produce breeding stock. Multipliers are those that produce gilts for commercial pig units. Grandparent or great-grandparent herds produce pigs to populate the multiplier herds. Boar studs produce semen to be used for AI within the commercial units.
- *Segregated early weaning units.* There is a need to also differentiate swine herds based on the ability to control disease. A major change in pig production has been to introduce the concept of segregated early weaning (SEW) and AIAO production. SEW means that the progeny of sows are removed from the site to another rearing site—either the nursery or the wean to finish barn. All-out-out production means that before a new group of pigs enters the facility, the facility is cleared of all pigs and is thoroughly cleaned. In most cases the facility is a barn; however, for some diseases, all-in, all-out production is much more effective if the entire site is cleared of pigs. The combination of these two strategies has been called high health production, although it is often a misnomer. It has allowed for increased scale of production and has fit in well with contract production (Amass, 1998). It should also be emphasized that the best method of infectious disease control is the absence of the pathogen. Prevention of entry is through the selection of stock and control of fomites.
- *Contract finishing units.* Contract production is common in poultry production; however, it has only recently become common in swine production. In contract production the contractee normally provides facilities and labor to rear pigs. In many cases the owner of the pigs owns or manages the sow units and then contracts various producers to rear the pigs in nurseries' grow-finish units or wean-to-finish units. Normally these units are operated on an AIAO basis.

TARGETS AND CURRENT LEVELS OF PERFORMANCE

It has been said that "the way you manage and exchange information and the way you learn as a company are your only sustainable advantages" (Friedman, 1999). This is certainly true for today's pork producers. There are four key steps for monitoring performance:

- Rank the parameters being measured to define the key drivers at this farm that need close attention (a driver is a strong motivating force or stimulus)
- Benchmark periodically (e.g., quarterly for reproduction) among other herds within and outside the system (benchmarking is a standard for comparison, usually over a certain period)
- Monitor these drivers on a regular basis to ensure that the business is performing as expected
- Set goals for the key drivers and establish management plans to achieve them

Performance benchmarking is done to understand how a farm is performing relative to other farms. The objective is to understand those practices that will provide a competitive advantage. The process is to analyze the strengths and weaknesses of a farm's work processes, know the competition and industry leaders to determine who is the best, incorporate the best practices, and gain superiority to become the new benchmark.

The PigCHAMP database is commonly used for benchmarking (Table 15-1). Average 1-year values for breeding herd performance from the 1999 PigCHAMP database are listed in Tables 15-2 to 15-4. Table 15-2 is a summary of 1366 herds from seven countries, and Tables 15-3 and 15-4 are for U.S. and Canadian herds, respectively.

TABLE 15-1

PigCHAMP DataSHARE Participating Farms by Country (until November, 1999)

Country	No. of Participating Farms	Frequency (%)
Australia	1	0.1
Brazil	10	0.8
Canada	363	26.5
Japan	93	6.8
Korea	25	1.8
Mexico	19	1.4
United States	855	62.6
Total	**1366**	**100**

TABLE 15-2

PigCHAMP Breeding Herd Crude Summary (1999)

Measurement	Average	Median	Upper 25%	Upper 10%
BREEDING PERFORMANCE				
Repeat services (%)	12.9	12.6	8.7	5.7
Multiple matings (%)	84.5	92.6	97.6	99.4
Entry-to-service interval (days)	41.0	36.7	23.5	15.3
Sows bred by 7 days (%)	84.1	86.1	90.6	94.4
Weaning-to-first-service interval	7.7	7.1	6.2	5.4
Average nonproductive days	80	73	58	47
FARROWING PERFORMANCE				
Average gestation length	115	115	115	114
Average parity of farrowed sows	3.2	3.4	3.9	4.3
Farrowing interval	148	147	143	141
Farrowing rate (%)	77.3	78.5	83.3	86.8
Average total pigs/litter	11.2	11.2	11.6	12.0
Average pigs born alive/litter	10.2	10.2	10.6	10.9
Average stillborn pigs	0.8	0.8	0.6	0.5
Average mummies/litter	0.2	0.2	0.1	0
Percent <7 born alive	11.6	11.3	8.9	7.1
Preweaning mortality for farrowed and weaned	12.3	11.8	10.0	8.0
Litters/female/year	2.10	2.18	2.30	2.38
Litters/mated female/year	2.29	2.33	2.43	2.50
Old litters/mated female/year	2.25	2.33	2.44	2.54
Litters/farrowing crate/year	14.0	13.5	15.7	18.2
WEANING PERFORMANCE				
Pigs weaned/litter weaned	9.0	9.1	9.5	9.9
Average age at weaning	19.2	18.7	16.8	15.3
Adjusted 21-day litter weight (lb/kg)	128/57	128/57	137/62	146/66
Pigs weaned/sow	8.9	8.9	9.3	9.7
Pigs weaned/ mated female/ year	19.8	20.6	22.2	23.6
Old pigs weaned/mated female/year	20.6	21.0	22.9	24.6
Pigs weaned/female/year	18.5	19.3	21.0	22.5
Pigs weaned/lifetime	31.1	32	41	50
Pigs weaned/farrowing crate/year	125	122	140	165
POPULATION				
Average female inventory	662	380	857	1531
AFI/farrowing crate	6.7	6.4	7.3	9.0
Average gilt pool inventory	44	28	62	112
Sow:boar ratio	27	21	37	53
Average parity	2.6	2.6	3.1	3.6
Replacement rate (%)	54	50	39	29
Culling rate (%)	43	41	32	26
Death rate (%)	5.8	5.1	3.4	2.0
Average parity of culled sows	3.5	3.7	4.7	5.6

Farm n = 1366; median is a 50th percentile.

The 1998-1999 PigCHAMP growing-finishing database included 17,912 groups from 268 producers (Tables 15-5 to 15-8). The data were extracted from the PigCHAMP database on a group basis. The producers were located in Canada, Mexico, and the United States. Six conventional measurements for growth performance were calculated as follows:

- Average initial weight (Weight In): average weight when a group is placed in a location
- Average final weight (Weight Out): average weight when a group is moved to market or other location
- Mortality: included dead and destroyed pigs
- Average daily gain (ADG): includes only live pigs

TABLE 15-3

PigCHAMP Breeding Herd Summary in the United States (1999)

Measurement	Average	Median	Upper 25%	Upper 10%

- Average daily feed intake (ADFI): uses only live pigs
- Feed conversion (FC): contains only live pigs (feed conversion is feed:gain ratio).

For presentation, the data were divided into four groups based on closing weights: <66 lb, 66-220 lb, >220 lb, and wean-to-finish. Table 15-5 is the first group (nursery with <66 lb close out); Table 15-6 is growing groups with >66 and <200 lb; Table 15-7 is finishing groups (>220 lb), and; Table 15-8 is wean-to-finish groups.

ECONOMICS OF PIG PRODUCTION AND THE MAJOR CAUSES OF ECONOMIC LOSS

A complete farrow-to-finish enterprise is a major financial consideration. In the year 2000 the cost of establishing a 1000-sow unit ranged from $3000 to $6000 (U.S. dollars)/sow, including the cost of the breeding stock. The producer investing this sum of money is faced with high interest rates, fluctuations in the price of market pigs

Farm n = 292; median is a 50th percentile.

because of the pig cycle, and cash flow requirements to operate the enterprise.

The level of profitability in pig production is largely determined by the relationship of feed and market hog prices. On average, feed forms about 75% of total costs for farrow-finish herds but ranges from 65% for breeding herds selling weaners to 85% for feeding only herds that buy in weaners. Feed prices usually increase at a greater rate per year than pig prices; consequently, gross and net margins have usually been small, and a change in feed prices without a corresponding change in pig prices will affect profit margins. Total feed cost per hundredweight (100 wt) of pork produced is the product of the rate of feed conversion (e.g., 100 wt of feed/100 wt of gain) and the average cost per 100 wt of feed of all the feedstuffs used. There

is as much variation in profit between producers as there is between the peaks and valleys of the hog cycles, which should persuade and convince producers, extension workers, and veterinarians to conclude that improved cost control and marketing practices have more potential for increasing profits than waiting for higher prices. The main factors that explain the variation in profitability among herds are the output (e.g., the number of pigs produced per sow in a herd each year) and feed (e.g., the quantity used and the price per unit).

The efficiency of feed conversion in the swine herd depends on the following:

1. Reproductive efficiency of the sow, whose maintenance represents a substantial portion of the total feed budget
2. Disease control, including clinical and subclinical disease
3. Feed wastage
4. Energy-expensive excessive fat carried by market pigs

Pig producers have increased production steadily by increasing the number of pigs weaned per sow per year and by improving feed conversion. A major contribution to containing production costs, however, has been the forced reduction in labor costs. Economic conditions have forced the pig industry to dispose of any surplus labor, and those that remain employed have increased their productivity.

In order to maintain financial viability, the enterprise must achieve certain production objectives (e.g., targets of performance), such as a minimum number of pigs per sow per year. The points in the production cycle that are most critical and vulnerable and that affect the number of pigs produced per sow per year and in turn can cause major economic losses include the following factors:

*Group n = 389 in 38 herds.

- *Reproductive performance.* A decrease in farrowing rate and a drop in the number of pigs born alive can cause major economic losses because of lost opportunity of profit. Every economic effort must be made to achieve and maintain the birth rate at between 10 and 11 pigs born alive/litter.
- *Neonatal mortality.* The greatest losses in pigs born alive occur during the first 3 days of life. Preweaning mortality may reach 20% to 25% but can be reduced to below 10% with good management and adequate farrowing area management.
- *Number of pigs weaned per litter.* The number of pigs weaned per litter is a function of the number of pigs born alive per litter and the preweaning mortality. An increase in the number of pigs weaned per litter from eight to nine in a 2400-sow unit means over 4800 extra pigs weaned/year.
- *Feed efficiency in pigs from weaning to market.* A major cause of economic loss during the growing and finishing periods is the inadequate level of feed efficiency. The presence of subclinical and clinical diseases affects feed efficiency. Suboptimum performance will occur because of overstocking in feeder pens, inadequate ventilation, and tail-biting.
- *Average daily gain.* As growth rate increases, more kilograms of pork will be produced in the same growth period. Although production costs and market prices will dictate the optimum market weight for a farm, most farms can increase profit by increasing rate of gain. Similarly, if disease is reducing daily gain, average weight at market

will usually be less, again because of the limited capacity for growing pigs at the farm.

- *Specific infectious diseases.* The economic losses resulting from specific infectious diseases are due to mortality, the cost of treatment, and the loss of potential production. The magnitude of the economic losses associated with the common diseases of pigs has been estimated and is described in the following text.

On an industry-wide basis, the economic losses associated with disease in pig production include the cost of veterinary fees, laboratory diagnosis, and medicines; the cost of the resources incorporated in breeding and other pigs, which are not recovered; and the resources used that are not recovered in the course of production. An overall reduction in mortality would enable the present level of output to be achieved with a smaller breeding herd, and there would be substantial savings in feed costs. A simple model for calculating the macroeconomic effect of improving livestock efficiency through better herd health such as reducing preweaning mortality in swine herds indicates how consumers gain from improved animal health (Ott et al, 1995).

The economic losses associated with condemnation of pig carcasses at slaughter because of the presence of disease that renders the meat unfit for human consumption is estimated at about 0.5% of all pig carcasses.

Subclinical Disease and Inadequacies of Management

Although the previous information on the costs of clinical disease is interesting and provides some clues about the nature of the diseases that concern producers, the causes and the magnitude of the economic losses associated with subclinical disease and inadequacies in management in swine herds are not known. It is probable that these losses are greater than those associated with clinical disease. There are a number of health and fertility problems that are generally present in a swine herd but vary greatly in degree, frequency, and severity among farms (Dijkhuizen, 1989). Often the individual farmer can do much to control or manage these problems. Identification of the economic impact of these problems, however, is not simple, because their effects are not always obvious. They are influenced by management factors such as housing and nutrition; they have a temporal dimension that adds to the complexity of evaluating their economic impact at different stages in time; and they commonly manifest in a complex with other diseases. It therefore is easy for producers to underestimate the economic impact of these problems, especially when they become accustomed to the presence of such problems. For example, weaning pigs older than 3 weeks of age, on average, has an adverse affect on sow productivity per year. A survey of productivity and its component interrelationships in Canadian swine herds revealed a wide range among farms in sow productivity, in growing-finishing efficiency, and in the efficiency of resource use (Wilson et al, 1986). Larger herds made better use of available physical resources, as indicated by the greater number of pigs weaned per farrowing crate per year and the greater number of feeder pigs marketed per square meter of feeder pen space per year. They also tended to have greater biological efficiency, as indicated by the greater number of pigs weaned per sow per year. The study suggested that a significant number of swine producers may be underutilizing both their capital and their human resources. By measuring the productivity gap, the study indicated the great potential that exists in the industry for increasing the efficiency of swineherds.

The further extension of swine health and production management techniques that are already in place in efficient herds should cause an increase in efficiency of pig production. The economic impact of these inadequacies in management can be determined using a variety of techniques, and the costs and benefits of control can be determined directly on the farm or by economic modeling (Dijkhuizen, 1989). For example, there is growing evidence that swine producers are losing income by culling sows when they are too young. Calculations for conditions that are typical in the United States indicated an economic optimum of 10 litters in a life span for sows of average productive performance, and young sows with a litter size of even 50% below average should not be culled before their third litter. A microcomputer program called PorkCHOP can predict the benefits of increased life span for sows and can help producers make economically sound decisions about culling sows with poor productive or reproductive performance (Dijkhuizen et al, 1986).

VETERINARIAN IN SWINE HEALTH AND PRODUCTION MANAGEMENT

The veterinarian in the swine industry has three main roles: the diagnosis and treatment of individual animals; the diagnosis and treatment of groups of animals or whole herds; and the provision of advisory services to the farm to improve production, health, and productivity. The first role is diminishing, and the third role is increasing (Muirhead, 1996). The changing roles are a reflection of the ever-changing swine industry. The number of herds is decreasing, and the size of herds is increasing. One view is that the general practitioner can handle most problems in herds with up to 150 sows. In herds larger than this, a specialist's knowledge of the swine industry and herd is necessary. The very large swine producer or farming company with herds of 500 to 1000 sows requires the services of a veterinarian who can deal with the complex interrelationships that exist in such large herds. The characteristics of the large swine producer of the 1990s include the following: they produce over 500 litters/year; it is a family farm; the second-generation members of the family have college degrees; the family is hard working, conservative, quite wealthy, and has several employees; the farm is also involved in the production of crops; and the producer takes risks (Vinson, 1986).

There has been a gradual increase in demand for consultancy veterinary services and a marked decrease in emergency type visits. In the United Kingdom, the veterinarian/sow ratio in 1996 was considered stabilized at 1/15,000 sows (Muirhead, 1996).

Veterinarians can have an economically viable practice from large swine farms through the sale of drugs, vaccines, other animal health supplies, and premixes; veterinary services; and consultation (Vinson, 1986). Because of competition from other sources, the revenue from the sale of drugs and vaccines is limited. Veterinary services include the routine diagnosis of disease, writing of prescriptions, government regulatory work, acute disease drug therapy, and specialized surgery. The consultation services consist of helping producers with intermediate and long-term decisions regarding disease management, cost-benefit nutrition, genetic program evaluation, environmental management, and the logistics of production flow of pigs.

In the study of the U.S. livestock market for veterinary medical services in 1994, swine practitioners generated the highest individual practitioner revenue and the highest percentage revenue from sales of animal health products (Wise, 1995).

Requirements for the Swine Specialist

How does the veterinarian acquire specialist expertise to provide service to these large sophisticated swine enterprises?

The requirements necessary to obtain specialist knowledge in a general farm practice modified according to Muirhead (1996) are listed in Box 15-1.

Education of the Swine Specialist

The education of the swine specialist begins at the undergraduate veterinary student level and continues with postgraduate studies and learned experience in a specialty practice. The undergraduate curriculum should provide the basic sciences, the paraclinical sciences, and the clinical sciences necessary for the student to learn the fundamentals of swine health and production. Species specialization before graduation is not possible and should not be attempted. A critical analysis of the undergraduate teaching of swine medicine in North American veterinary schools found a deficiency in the amount of time allocated to classroom and clinical teaching of swine medicine (Backstrom, 1989). Veterinary colleges should consider how to provide the basic classroom and clinical teaching in swine medicine to those students who are interested in pursuing swine practice. This can be done with quality elective courses and in-depth postgraduate courses. There is a need for a coordinated effort between swine practitioners, university faculty, swine producers, and consumers to consider ways and means of providing the appropriate undergraduate and postgraduate education required to produce swine veterinary specialists.

Postgraduate education and specialization in a species has been considered for many years. Graduate degrees in swine medicine are available from a number of veterinary colleges in the United States, including Iowa State and the University of Minnesota. Specialization in an area such as production-oriented swine medicine requires not only an increased understanding of the knowledge base in swine health and production but also practical experience on different swine farms with a variety of production problems. Veterinary colleges can usually supply the knowledge base but usually do not have sufficient clinical teaching practice. Some postgraduate clinical residency positions are available at veterinary colleges, but these are minimal in number. Self-directed learning in a specialty practice is the alternative option for those wanting to become pig specialists. This can be done on an individual basis, with the addition of several-day short courses and workshops in swine health and production management. This self-directed learning in practice can be followed by certification by examination, which is now possible in the United Kingdom through the Royal College of Veterinary Surgeons. There are currently two levels of examination. The certificate should be attainable by any veterinary graduate who has been working regularly in the treatment and control of pig diseases for at least 2 years beyond graduation. The certification covers the same subjects in more depth and breadth and is for the veterinarian who has worked the equivalent of 5 years in pig practice and who has acted as a consultant in major pig problems (Muirhead, 1996). Studying for the examinations concentrates veterinarians on pig production and medicine, with an emphasis on the interaction between health and production of the herd. It requires considerable self-motivation and self-education to achieve specialty status, and the most important requirement is the development of the correct organizational framework within the practice to satisfy the necessary details listed in Box 15-1. Swine specialization must be learned in practice after graduation.

BOX 15-1

Professional Requirements of Swine Veterinary Specialist

- Practice in a species-specialist veterinary practice
- Access to a veterinary practice library with visual aids
- Access to a veterinary college library when necessary
- Availability of farming publications
- Membership in a swine specialist society
- Participation in a continuing professional development program 14 days annually
- Good foundation in individual animal medicine
- Good laboratory facilities that can provide rapid service
- Practice policy of continuing specialized education
- Ongoing teaching by specialists in the practice
- Regular time periods for case studies
- Computer literate and able to use appropriate software programs for swine production
- Provisions for studying and analyzing farm reports
- Studies to understand farm management in depth
- Organized workload
- Preparation of papers and case reports
- Preparation and delivery of seminars at the farm level
- Good internal practice liaison
- Access to research and knowledge of development and economics of production
- Graduate education, (e.g., MS and/or Ph.D.)
- Board certification (American Board of Veterinary Practitioners or similar certification boards in other countries)
- Fluent understanding of Spanish
- Access to a laptop computer for on-farm use
- Ability to interpret production and financial data

Providing Veterinary Service

The provision of a health and production management veterinary service to swine herds requires commitment from the veterinarian and the veterinary practice to develop the specialty. The veterinarian must be interested in acquiring the knowledge and skills necessary to provide the service, and the practice must allow the veterinarian to schedule blocks of time to visit swine farms, become thoroughly acquainted with all aspects of production, and consider the health and production records in detail (Straw and Friendship, 1986). The veterinary practice must have the technical and secretarial staff necessary to assist the veterinarian in scheduling visits, ordering supplies, entering data into the computer, preparing reports, and other routine activities associated with providing such a service. The scheduling of farm visits must be done well in advance, and every effort must be made to adhere to the schedule; this necessitates excellent communication and the flexibility to meet unforeseen circumstances.

The success of a health and production management veterinary service depends heavily on the compliance of the producer. The producer may not have confidence in the veterinarian as a health management advisor; the veterinarian may overwhelm the producer with too many recommendations at once; the veterinarian may not be aware of the client's expertise or financial constraints; and there may be a failure of communication between the veterinarian and the

producer about the production goals for the herd and how they are to be achieved (Friendship, 1989).

Implementation of the veterinarian's recommendations requires time for the producer to appreciate their value, and the veterinarian must use certain strategies to gain their acceptance and make the recommendations in stages. It may take months for the producer to understand and appreciate new health and production techniques. Initially, the veterinarian should gain the confidence of the producer by attempting to solve an obvious but simple problem, then move to the more complex ones. The veterinarian must be aware of the financial constraints of the producer before making recommendations requiring major capital investments. The level of knowledge and the goals of the producer must be considered before making recommendations. Taking the time necessary to analyze and interpret the health and production records of the herd often motivates producers to take action to improve performance. Making interfarm comparisons of performance often activates the interest of producers on how they are doing relative to other anonymous producers. Consultation with other specialists can be effective in persuading a producer to consider certain recommendations for the solution of a problem. When producers appreciate that the techniques have been successful elsewhere, they will often consider adopting them much more quickly.

As swine production systems and the attitudes of producers towards the veterinarian have evolved, so has the means of charging for professional fees. Early efforts to earn a professional income from swine practice consisted of charging a specified fee for a given service, such as vaccinating or castrating pigs, or farrowing a sow. However, with time, producers learned some of these skills, and many of these services are no longer provided by veterinarians. This led to an emphasis on the sale of animal health products (antibiotics and vaccines), often coupled with free veterinary consulting services, or the development of hourly or daily herd health consulting fees. Ultimately, innovative charging methods developed that linked the practitioner's income with the success or failure of the producer, such as a certain dollar amount per pig weaned, according to the producer's production data. Other methods of income generation include annual fees on a "per head of breeding animal" basis, or an hourly fee for time spent on the farm and in preparation of reports in the veterinarian's office. Some swine specialists do international consulting as well as field trials for pharmaceutical and biological companies. Others are employed as full-time resident veterinarians within integrated firms.

Population-Based Problem Solving in Swine Herds

Swine practitioners providing health and production services must be systematic and comprehensive problem solvers who can understand and operate within the complex biological and economic systems that compose pork production. There is a need to provide proactive advisory services that control disease and manage the effect of disease in the herd. Population-based problem solving is an integral part of effective health management of a livestock operation. The first requirement is reliable information. In a swine herd, information is crucial to being able to diagnose problems in herd productivity. Effective problem solving in a swine herd requires production and financial data, as well as herd and animal specific demographic data, and reliable cost estimates (Polson et al, 1998). The data for a herd are made meaningful by establishing benchmarks for that herd and monitoring performance over a period of time. In this way a "performance-related diagnosis" can be made when "performance indicators" indicate unacceptable productivity. Production benchmarks (e.g., pigs weaned per female per year) quantify what is "normal" for a specific herd. Problems in a herd are indicated by a deviation in performance from what is expected or considered normal. The major challenge in population-based diagnosis is differentiating between the inherent variability normally expected in the herd and deviations from the benchmarks that represent "real "problems with productivity. Knowing the important risk factors that are related to each of the various diagnostic indicators allows the problem solver to set priorities and plan interventions.

Swine Producer and Health and Production Management

Health management of swine herds emphasizes herd-level disease control and production analysis. Individual animal medicine emphasizes clinical examination of the individual animal using all the diagnostic and laboratory tests deemed necessary and economical in order to arrive at a diagnosis so that treatment and control can be provided. Health management of the herd involves examination of the herd using all available techniques, particularly record analysis, to determine the various levels of production, and the reasons for failing to achieve predetermined levels of production, and profit.

Producers who use swine veterinary specialists as regular consultants in a swine health management and production program are knowledgeable about swine production and are financially successful (Deen et al, 1995b). They are also the producers who are willing to take risks and are not financially overextended. Producers who have not adopted health management veterinary services usually do not appreciate the effects of subclinical disease, their primary goals do not include optimizing health and economic performance, and they do not maintain an effective recording system.

A comparison of producers who use regularly scheduled health management veterinary services with those who do not found that the following factors were positively associated (Deen et al, 1995b):

- Farms that were larger, had more leverage financially, and used record-keeping and modern nursery technologies employed veterinarians. Herds with a debt level of more than 50% were 1.87 times more likely to use the service. Herds that kept records were 3.5 times more likely to use the service.
- Number of pigs marketed annually. Herds with annual sales of more than 1000 pigs were 1.58 times more likely to use health management services.
- Use of slatted floors in the nursery.
- Washing of floors in the nursery.
- Farms that primarily finished pigs were less likely to use the service.

In a survey of American swine producers, 49% reported veterinarians to be a very important source of herd health advice, whereas 37% considered veterinarians to be somewhat important (Wise, 1987).

MONITORING PRODUCTION AND DISEASE IN THE SWINE HERD

A successful swine herd health and production program depends heavily on a simple, reliable record-keeping system to monitor performance and incidence of diseases. A regular analysis and interpretation of the records combined with a regular clinical examination of the herd—including necropsy examination of pigs that die naturally or

of selected sick pigs—allows the veterinarian to identify problems that are interfering with production and to institute corrective measures. Records define the levels of achievement in the herd and thereby outline the need for change or improvement. It is essential, however, that the information recorded be consistently meaningful. The information can be used to determine whether productivity is being maintained at a predetermined level or if fluctuations are occurring in any particular parameter over a period of time.

Records alone, however, are not enough to identify the problems, and a clinical examination of the herd is essential. Once established, the recording system and data analysis will indicate the actual performance in that herd, which can be compared with predetermined targets. These levels may be ultimate standards, which will not be improved with existing knowledge, or standards defined at selected points in an improvement program.

Terms and Definitions

Animal production recording systems require precise definition of the various classes of animal identified and the periods of time measured. There is no comprehensive list of the terms and definitions used in pig recording. In the past, production recording systems have relied on undefined terms, and as a result, the same classes of pigs may be described in different ways. The U.S. NPPC (1999) published a "Production Standards Technical Manual" with suggested definitions and equations for all software providers. The intent is to give producers the ability to compare production and financial performance even when they use different software. Their definitions, suggested comparison indexes, and methods of calculation are very similar to traditional methods, but a few marked differences exist. First, the manual suggests that all pork production systems comprise one or more distinct phases or stages, including breeding stage (including gestation and farrowing), nursery production, and finishing production. Second, it is suggested that all female pigs intended for breeding be classified in one of four categories, with the transition between categories being driven by the occurrence of events in the female's life history record:

- *Prospective breeding female:* a female pig kept for the purpose of future entry into the breeding herd.
- *Unmated breeding female:* a female pig entered into the breeding herd but not yet mated.
- *Mated breeding female:* a female pig mated at least once and not yet removed from the breeding herd.
- *Removed breeding female:* a breeding female that is no longer consuming assets or resources of the breeding herd.

Third, growing pigs are classified as preweaned pigs (triggering event being the farrowing), nursery pigs (pigs moved into a nursery facility), or finishing pigs (pigs moved into a finishing facility). Fourth, they recommend that the term litter be classified as birth litter, wean litter, or nurse litter. Fifth, they define and recommend the use of the term *cohort* as a group of animals that share a common event within a defined period. A cohort can be a group of mated breeding females or a group of finishing pigs placed in a finishing facility within a defined time period. And finally, they recommend that all inventory calculations should be on a pig-day basis, in which a pig-day is defined as one live pig for 1 day, counted at the end of the day.

The recommendations just described are being used by some software providers to offer additional reports that will allow their users to compare performance across software products. As data accumulate, practitioners will be able to establish benchmarks with these new definitions. In the interim the traditional and still most widely used terms, as described below, continue to be accepted.

Breeding Herd

- *Sow:* Any breeding female that has been served and is on the farm.
- *Maiden gilt:* A female transferred to the breeding herd but not yet mated.
- *Boar:* A male pig older than 6 months of age and intended for use in the breeding herd.
- *Sow cull:* Any live sow removed from the farm.
- *Boar/sow ratio:* The ratio of boars to sows as defined above. Any definition must take into account the nonworking boar.
- *Herd size:* The average number of sows present in the herd as recorded on 12 or more equally spaced occasions during a year.

Fertility Data

- *Service:* One or more completed and recorded matings within the same estrus period.
- *Date of service:* Date of the first mating during any one estrus period (counted as Day 0).
- *First litter sow:* A female pig between the date of first effective service (i.e., a service that results in pregnancy) and the date of the next effective service after successful completion of pregnancy.
- *Farrowing:* Production of a litter of one or more live or dead pigs on or after Day 110 of pregnancy; day of service is Day 0 (see explanatory note 1 in the following section).
- *Farrowing rate:* The number of sows that farrow to a given number of services expressed as a percentage.
- *Induction:* The use of a drug that is capable of inducing farrowing. Usually used from 1 to 3 days before the expected farrowing date to synchronize the farrowing of a number of sows on the same day.
- *Conception rate:* The number of sows that conceive to service, expressed as a percentage of these services. Conception is assumed by nonreturn to estrus 21 days after service or identified by pregnancy diagnosis. This measure is not precise, and the term is therefore of limited use.
- *Return to service:* A sow re-served after a return to service.
- *Regular return:* A return to service 18 to 24 days after the date of service (see note 2).
- *Irregular return:* A return to service outside the 18- to 24-day period after the date of service (see note 2).
- *Herd farrowing index:* The number of farrowings taking place in 365 days divided by the average number of sows in the herd during that period, as defined in the last section for *herd size*.
- *Weaning date (sow):* The date on which a sow ceases to suckle piglets.
- *Weaning-to-service interval:* The interval between date of weaning and the date of first service (date of weaning is Day 0; see note 3).
- *Nonproductive days:* Nonproductive days are average number of that a sow or gilt is not lactating or gestating (see note 9).
- *Abortion:* The observed production of fetuses between service and up to and including the 109th day of pregnancy, when none of the fetuses survive more than 24 hours (see note 1).
- *Premature farrowing:* The observation of fetuses before the 110th day of pregnancy, when some fetuses survive for more than 24 hours (see note 1).
- *Failure to farrow:* Sow not farrowed by 120 days after a presumed effective service.

Progeny: Preweaning Period

- *Litter:* The production of a farrowing.
- *Number of piglets per litter:* The total number of piglets born per litter, including stillborn and mummified pigs.
- *Live-born piglets:* Piglets that are born alive.
- *Stillborn piglets:* Piglets found dead behind the sow farrowing; if necessary, perform postmortem examination to determine if the piglets have breathed.
- *Mummified piglets:* The number of dead piglets that are born degenerate (e.g., discolored and shriveled), which means they died some time before farrowing.
- *Premature pigs:* Piglets born alive before the 110th day of pregnancy and surviving for more than 24 hours (see note 1).
- *Small litter index* (sometimes referred to as *litter scatter*): The percentage of litters born within any specified period in which the number of piglets in any litter (see *number of piglets per litter*) falls below x, where x is the nearest whole number lower than 1 standard deviation (SD) below the mean number of piglets per litter (see note 4).
- *Live birth weight of litter:* The total weight of piglets alive at birth or who have survived the first 24 hours of life (see note 5).
- *Suckling pig or piglet:* Piglet between birth and weaning.
- *Preweaning mortality:* The percentage of live-born piglets that die before weaning.
- *Fostering:* The transfer of piglets from one litter to another for management purposes. Fostering-on is the introduction of extra piglets, and fostering-off is the removal of pigs from a litter.
- *Weaning (piglets):* The act of permanently removing piglets from the sow.
- *Age at weaning:* The number of days from farrowing to weaning (day of farrowing is Day 0).
- *Herd weaning age:* The average number of days from farrowing to weaning for the herd.

Progeny: Postweaning Period

- *Nursery pig:* A weaned pig is a pig between weaning and either at the end of the stay in the nursery accommodation or 30 kg if it is to remain in the same accommodation until slaughter. Since pigs are weaned at vastly different ages, this definition can cover a wide age range.
- *Nursery mortality:* The number of nursery pigs that die expressed as a percentage of the total number of pigs in that group initially.
- *Feeder-finishing:* Any pig in the stage of life between the end of the nursery period and slaughter weight or the time of transfer to the breeding herd.
- *Pigs marketed:* Pigs marketed alive in any form or transferred to the breeding herd, not including sales from the breeding herd.

Feeder-Finishing Data

These are classes of finishing pigs that are categorized by weight. Different recording schemes and marketing systems use different weights (see note 6).

- *Live weight gain:* The live weight gain of the pig when sold minus its birth weight. If the birth weight is not available, it is counted as 1 kg.
- *Days to slaughter:* The age of a pig at slaughter is the number of days from the date of birth (Day 0) to the date of slaughter of that pig.
- *Daily live weight gain:* The live weight gain of a pig divided by the number of days between two weighings.
- *Feed conversion ratio (FCR):* The total weight of dry food consumed by a pig divided by its live weight gain (see note 8).
- *Feeder-finishing mortality:* The number of feeder-finishing pigs that die in a group expressed as a percentage of the total numbers of feeder-finishing pigs in that group initially.
- *Average days to slaughter:* The average number of days to slaughter for a group of pigs, excluding those that die.
- *Average weight at slaughter:* The average live weight at slaughter (see note 7).
- *Transit death:* A pig that dies in transit on the truck between the end of loading at the farm and the end of unloading at the abattoir or final disembarkation point.
- *Lairage death:* A pig that dies between the end of unloading at the abattoir and the point of slaughter.
- *Condemnation:* A carcass condemned wholly or in part.
- *Casualty-culls:* Any pig for which payment is received that is slaughtered on welfare grounds or for persistent slow growth.

Explanatory Notes on the Terms and the Definitions

1. *Gestation length:* This varies between herds according to breed and other factors, but data held at Weybridge that relate to a large body of accumulated information from British herds give a mean figure 114.5 days ± 1 SD 1.5 days. From this it can be said that the 95% confidence interval is 111.5 to 117.5 days.

2. *Estrous cycle length:* A review of all available information suggests a mean estrous cycle length of 21 days ± 1 SD 1.5 days. These figures give 95% confidence interval of 18 to 24 days, and this is the range that has been used for the calculation of regular and irregular returns.

3. *Weaning-to-service interval:* This depends on many factors, not the least of which is the length of lactation. Analysis of data from a variety of sources suggests that, for all practical purposes, a mean figure of 7.5 ± 1 SD 2.5 days is acceptable. The interval is variable because a wide range of factors (e.g., level of nutrition, disease status, management systems) affects it. But this figure is a satisfactory working guide in relation to weaning-to-service interval.

4. *Total litter size:* It must be clearly recognized that litter size is affected by a great many factors, including maternal age, breed, and disease status, and that it may vary from country to country. For the purpose of this book, some figure that can be regarded as characteristic of the British situation and the variability that occurs between individuals is given. For British herds the mean figure for litter size is 10.75 ± 3 piglets. It is from this figure that the small litter index (see term as defined above) is calculated (i.e., for the above figures, the small litter index is the percentage of litters that contains less than seven pigs).

5. *Piglet birth weight:* Some indication of the mean and variability of normal piglet birth weights may be useful, and data obtained from Weybridge and other sources indicate that the mean is 1250 g ± 1 SD 250 g.

6. *Values for slaughter pigs:* Values for different grades of carcasses.

7. *Herd values for slaughter pigs:* Herds do not operate under a system of production that identifies individual slaughter pigs. There are two methods of calculating growth performance. Smaller herds will often move pigs continuously through finishing facilities, and over time, estimates of performance can be calculated. More commonly, batches or groups of pigs are moved together and group record will be calculated for growth performance. The equations follow in entry no. 9.

8. *Feed conversion ratio:* On the farm, FCR estimates are required either for groups of pigs or for the whole finishing herd. If this is to be done accurately for any given period, it is necessary to record the weight of the feed in inventory at the beginning of the period, the weight of feed entering

inventory during the period, and the weight in inventory at the end of the period.

Similarly, it is necessary to know the weight of pigs in the group at the beginning and end of the period in question as well as the weight of the pigs entering or leaving the group during the period. This means that all pigs entering and leaving the group need to be weighed and that all the pigs in the group are weighed at the beginning and end of the recording period.

In the assessment of pig feed conversion efficiency as indicated by FCR, notes should be made regarding the nutritive density of the diet.

9. *Nonproductive days.* The number of nonproductive days gives an indication of the regularity or rhythm of a herd's breeding performance. The merit of this particular index is that it is easy to collect and gives a continuous indication of the regularity of breeding within the herd.

$$\text{Average weight of pigs sold} = \frac{\text{Total weight of sales} + \text{Total weight of transfers}}{\text{Number of sales} + \text{Number of transfers}} \quad [1]$$

$$\text{Average weight of pigs on entry} = \frac{\text{Total weight of purchases} + \text{Total weight of transfers in}}{\text{Number of purchases} + \text{Number of transfers in}} \quad [2]$$

$$\text{Total weight gain} = \text{Total weight of sales} + \text{Total weight of transfers out} + \text{End of period total weight} - (\text{Total weight of purchases} + \text{Total weight of transfer in} + \text{Start of period total weight}) \quad [3]$$

$$\text{Percent mortality} = \frac{\text{Deaths} \times 100}{\text{Number of sales} + \text{Transfers out} + \text{Deaths}} \quad [4]$$

$$\text{Feed conversion ratio} = \frac{\text{Total weight of feed consumed}}{\text{Total weight gain}} \quad [5]$$

$$\text{Daily live weight gain} = \frac{\text{Average weight gain/pig}}{\text{Average number of days in herd}} \quad [6]$$

$$\text{Average weight gain} = \text{Average weight of pigs sold} - \text{Average weight of pigs entering} \quad [7]$$

$$\text{Average days in herd} = \frac{\text{Average number of pigs in feeding herd} \times 30.4}{\text{Average number of sales and transfers out per month}} \quad [8]$$

Statistical Note

SD is a measure of the scatter of individual readings about the mean (e.g., average). Where values are normally distributed, approximately 66% of values will fall between 1 SD on either side of the mean, 95% within 2 SD, and 99% within 3 SD.

Identification of Pigs

Accurate identification of individual breeding females is essential for any comprehensive production recording system. Some form of permanent marking is required for performance assessment, herd security, disease surveillance, and quality control. Identification marks should be easy and painless to apply, legible at a distance, and tamperproof. At present, there is no single system that has all these attributes, the most common failing being the loss or illegibility of the identification mark well before the end of the animal's life in the herd. The methods commonly used include ear marking by notching, tattooing, or tagging, or body marking (e.g., slap marking). If animals destined for breeding purposes are to be identified correctly, experience suggests that the best system is tattooing supplemented by a large flexible plastic tag inserted in each ear when the pig enters the breeding herd.

Data Recording on the Farm

The following events and animal identities are the basis of a pig recording system. The amount of data will vary from herd to herd and depends in part on the facilities available.

Data Recorded in the Breeding Herd

- Sow identity
- Birth date or date of entry
- Service date and boar used
- Abortion date
- Farrowing date
- Number born alive
- Number born dead
- Number mummified
- Total litter weight at birth
- Piglet deaths (recorded as they occur)
- Weaning date and number weaned
- Weight at weaning (total litter or individual pigs)
- Weaner deaths (recorded as they occur)
- Sow culling date
- Feed consumed by breeding females and by piglets in nursery

Data Recorded in the Feeder-Finishing Barn

- Identity of group
- Date of entering nursery-feeder-finishing unit or date at which 30-kg live weight reached
- Group weight at entry
- Date sold off the farm
- Weight at date of sale
- Total amount of feed consumed to determine feed conversion ratio
- Death losses (recorded as they occur)

Methods of Recording Data

The events and animal identities just mentioned are recorded by the herdsperson. He or she may use a notebook to jot down observations as they are made, but these have to be transferred to some kind of record form. Record forms that are completed and kept in the piggery are called *barn records.* Record forms that are completed from notebook records or barn records but are kept in the farm office are called *office records.* Barn records or office records are used to calculate indexes of performance. The calculations may be carried out manually, in which case it is important that the barn or office records be kept in such a way that calculation of indexes requires the simplest possible manipulation of data. Calculations may also be carried out with the aid of computers. The calculation of indexes is a simple task for the computer and allows for the calculation of far more sophisticated indexes than is practical with a manual system.

Barn Records. Many different styles of barn records have been developed for use in the barn. The essential feature is that they allow the recording of the necessary data, which can then be extracted easily for the calculation of performance indexes. Regardless of the system used, it should be

simple and readily accessible to each herdsperson, the supervisor in the case of large herds, and the veterinarian. The records should be kept in a central location.

The minimum requirements for barn records include the following:

- Sow record card
- Daily diary or handheld data recorder
- Sow service card
- Daily record

Sow Record Card. This is also called the *litter card,* and it is essential that each sow has a record card that is kept with the animal. Normally these cards record events over one parity (e.g., weaning to weaning), although some sow records kept in the piggery contain a listing of events over the sow's adult lifetime. When the single parity record is complete, it can be stored in the office or can be used to complete a lifetime record. Sow cards may be clipped to the sow's stall and moved when the sow is moved from the dry sow area to the farrowing barn and back again to the dry sow barn. Sow cards should be covered with a piece of removable transparent plastic because they can become wet and soiled and difficult to read.

Daily Diary or Handheld Data Recorder. The daily diary is a useful technique for recording events throughout the day while the animal attendant is in the barn. The diary is pocket-sized and self-duplicating so that the duplicate copies may be collected regularly and the data posted directly into a computer bank. Handheld devices have the advantage of avoiding double data entry because they can transfer data directly to the record system at the end of the work day.

Sow Service Card. The service card records all service events, including returns to service. The service card is ideal for bringing into the office for copying onto office records or for the direct calculation of indices.

Daily Record Card. This is a register of events occurring over a 24-hour period. It should be completed at the same time each day and has two purposes: (1) it provides data for analysis by the veterinarian, and (2) it provides the herdsperson with a day-to-day summary of the productivity of the animals in the herd. Each card lasts 1 month and is kept on a clipboard. At the end of the month, the card is passed to the office, where monthly totals are calculated, and passed back to the herdsperson. This toting-up procedure is the simplest possible way of keeping a monthly record of events and is far easier than making calculations from individual sow cards. In the early stages of a recording system, irrespective of the size of the unit, a weekly module rather than a monthly module may be desirable. With experience, this can be expanded to a 28-day system, but a weekly summary will give the manager more information as the system becomes established.

Performance Records. Individual sow lifetime records are an extension of the single-parity record. The monthly herd performance record is an extension of the daily record. The herd performance report can be constructed with a minimum of manual computation from the barn records (e.g., sow card, service card, and daily event record). The herd performance report provides a record of all the main indexes of performance required, and it provides a ready comparison of present performance with the previous 6-month average as well as with a target figure set by the veterinarian. Sow reproductive performance according to parity also can be plotted as the sows farrow and summarized on a periodic basis.

Visual Sow Charts and Wheels. Breeding wheels and wall calendar charts have been in common use on pig farms for many years. They usually take the form of a large disc or fixed board or chart. These visual display systems are a simple but effective method of providing immediate information on the present and future position of sows in the breeding herd. They are not in themselves a data-recording system, since they do not provide a permanent record, and they are no substitute for accurate and complete barn and office records. They are management tools used on a daily basis to indicate to the herdsperson the flow of breeding animals through the herd. The system indicates to the herdsperson when groups of sows are due to be moved from the gestation barn to the farrowing barn in sufficient time for adjustment to occur. This avoids sows farrowing in the gestation barn. It also reminds the herdsperson to prepare for the weaning of a group of sows.

At a glance and on a daily basis, the sow breeding calendar wheel indicates the following information:

1. Expected date of farrowing of each sow, which allows the producer to transfer the sow to the farrowing crate several days before the expected farrowing date
2. Actual date of farrowing of each sow
3. Dates the pigs should be weaned and actual dates of weaning, which allow adequate preparation of nursery pens and weaning of most litters at about the same time
4. Date each sow should come into heat after weaning her pigs
5. Actual dates of heat and breeding
6. Number of times the sow was bred
7. The identity of the sows that have been diagnosed as pregnant

Computer-Based Recording Systems. Some form of manual recording system is adequate for a small herd, but as the size of the herd increases, the limitations of such a system become obvious. A computer system is capable of storing extensive records on large numbers of animals, and it easily manipulates complex sets of data that would be impractical to handle manually.

The need for computerized record systems for swine production data has led to a variety of sources, such as large mail-in service bureaus, on-farm computerized records, and in-practice systems as part of a health management service. The most common program used in the industry is called *PigCHAMP* and was developed at the University of Minnesota in 1985 (Stein et al, 1987; Stein, 1988). A continuous flow of production data is the cornerstone of health management services, and the computer can provide continuous analysis of the data. The computer provides assistance for problem solving at the herd level by determining any deviation between actual herd production (e.g., what is happening) and a target (e.g., what is expected to happen). Problem-oriented population medicine involves (1) production monitoring, (2) production analysis, (3) production reference values, (4) production targets, and (5) action plans. Production monitoring is the process of continually reviewing current production data to determine whether production targets are being achieved and to identify trends that may influence future planning and action (Stein, 1988).

Data Capture Sheets. The first step in recording is similar in both manual and computer-based systems: that is, recording of the initial observations. The initial observations are recorded on data capture sheets, which are used for direct entry into the computer. Examples of capture sheets are as follows (Figs. 15-3 to 15-8).

This step is labor intensive, and each time data are handled or transferred from one sheet to another, the number of errors increases. One way to minimize errors is to record the observations directly into an electronic notepad, which in turn reports directly to the computer.

Many organizations provide whole-herd recording systems, which depend on sending input to and receiving output from a central bureau. The emphasis in each system may be different. Some monitor the performance of the swine

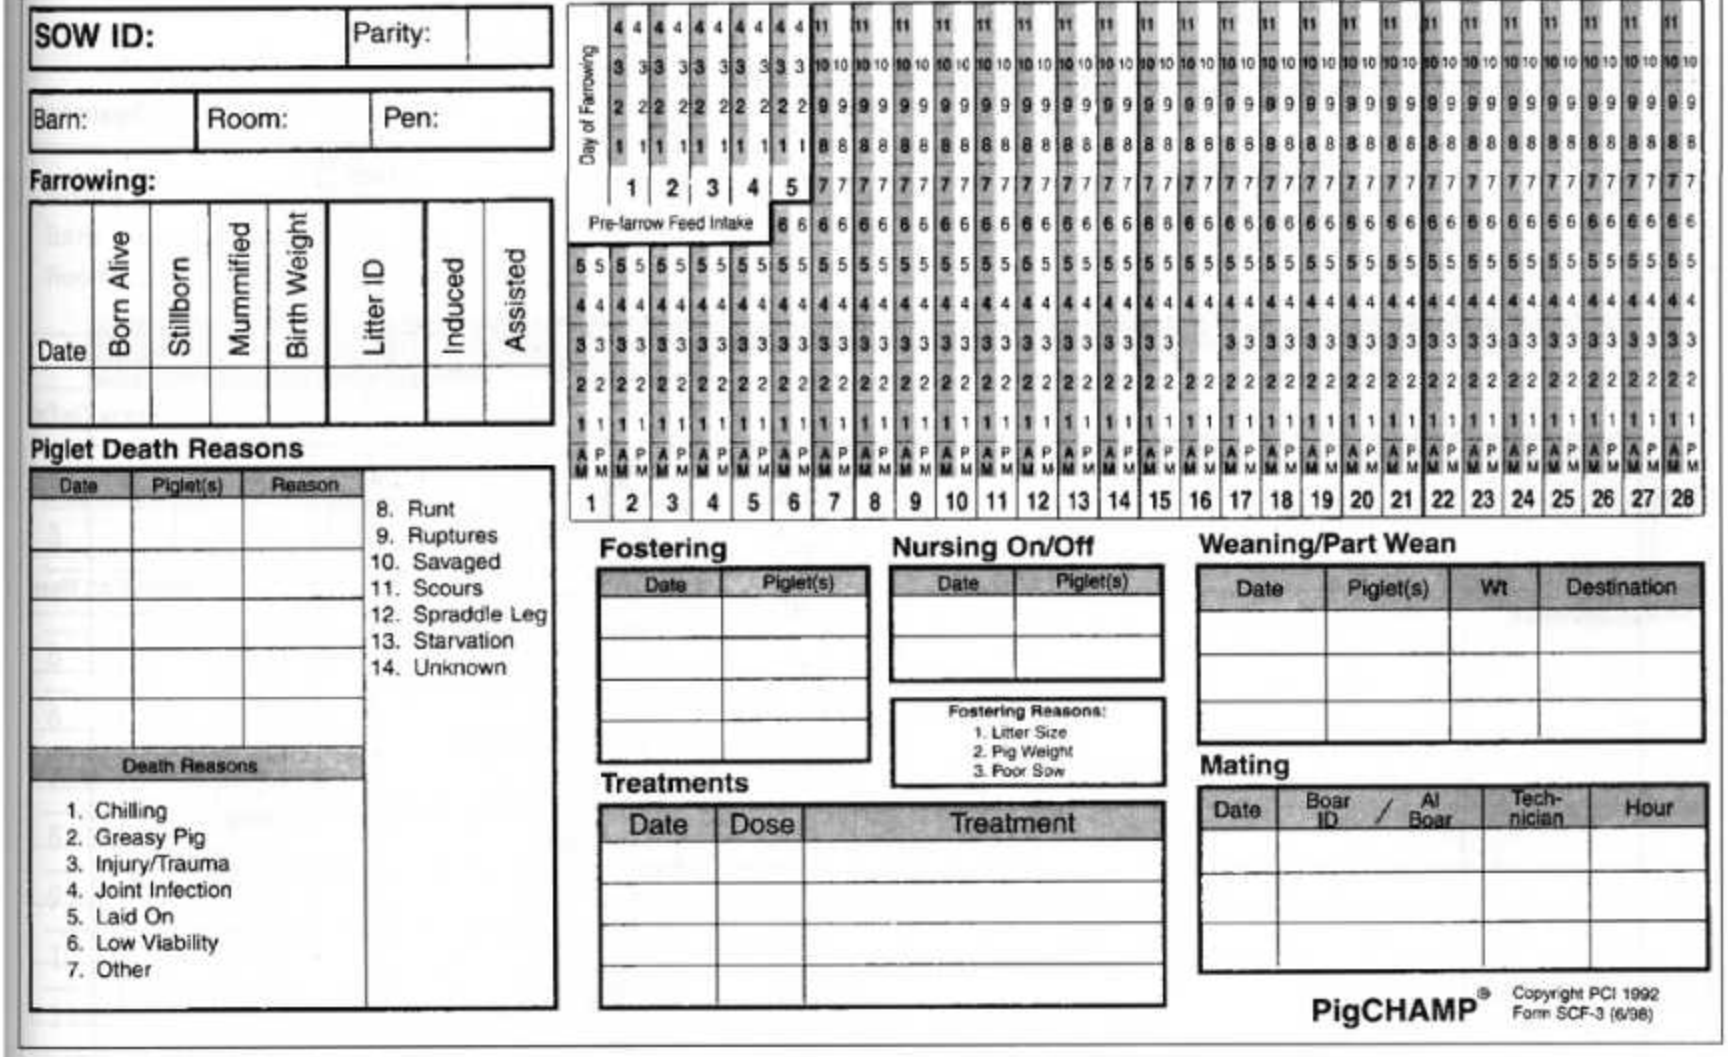

FIG. 15-3 Sow card with data recording area. (Courtesy University of Minnesota PigCHAMP Program, St Paul, Minn.)

herd, and key factors such as farrowing index and feed conversion ratio are calculated on a 6-month rolling average. Individual herd performance may be compared with that of several hundred other participating herds. Record systems that use the Internet are just becoming available.

Output Data. Data are transferred from each site to a central server where reports are run and sent back electronically. Such systems reduce the time lag between data collection and reporting. The possible outputs for a breeding herd are shown in Box 15-2.

Other computer-based systems are available that will monitor the physical and financial performance of the breeding unit, feeding unit, or both. Financial results are reported for each unit and can be given per pig and per sow if requested.

Computer-based recording systems that are oriented toward health and production are available. The computer's store of records consists of a status file and a history file; an archive file is updated each week, and the status file is used for a series of printouts, some of which are produced weekly, whereas others are provided only on demand. These include a weekly inventory of breeding stock; a record of services showing the boar number, sow number, and number of days since weaning; and a list of sows with regular and irregular returns to estrus and sows resulting from farrow.

The history file contains a record of each sow and boar in the herd. The file is used to compute herd productivity data when required. The archive file records sows and boars that have been culled.

A program to monitor reproductive efficiency and weaned pig production using only one data recording sheet is available. Reports will include the following:

- *Production data:* litters produced, numbers born and weaned, mortality rates, and live weight gain of piglets
- *Production efficiency:* pigs weaned per sow in the herd and feed used per weaned pig and per kilogram of weaned pig produced
- *Reproductive efficiency:* analysis of weaning-to-service intervals, farrowing intervals, returns to service, farrowing rates, and boar data comprising numbers born and farrowing rates
- *Records of the lifetime performance of sows and culling rates*
- *Finishing data:* analysis of the live weight gain and grading of bacon pigs

The computer-based program should provide the following:

- *A period report:* this is the most commonly used format and is returned to the producer at the end of each reporting period
- *Performance graph:* simple graphs of several parameters are plotted, using the values for the last six to twelve reporting periods

Computer-based recording systems are an aid to the veterinarian and the swine producer. When each printout is made available, both parties must take the time to analyze and interpret the results of the computer analysis, identify problem areas, investigate those areas clinically, take corrective action, and observe the results.

Event Reference List

The following is an alphabetical list of the events used to record information and individual sow/boar records. The letters capitalized in the event names represent the abbreviations that are required to enter the events in **PigCHAMP**. Following the event names are the data fields for each event. **(R)** denotes a required field, and **(O)** denotes an optional field.

Event	Data Fields
ABortion	
AI	Boar ID (O) • Technician (O) • Hour (O)
Boars In	Boar ID (O) • Technician (O) • Hour (O)

BOX 15-2

Possible Outputs for a Breeding Herd

Average number of sows and gilts in herd
Average number of unserved gilts
Average number of sows and gilts per boar
Average number of litters per sow and gilt
Average number of pigs born per litter
Average number of pigs born alive per litter
Average number of pigs reared per sow and gilt
Average number of pigs reared per litter
Average weight of pigs reared (kg)
Feed per pig reared (kg)
Total feed cost per pigs reared
Total feed consumption per kilogram pig produced
Total feed cost per kilogram pig produced
Quantity of sow feed per sow and gilt
Cost of sow feed per sow and gilt
Quantity of pig feed per pig reared
Cost of pig feed per pig reared
Cost per hundredweight of feed

Problems are identified by comparing actual production with targets and then finding significant deviations. Monitoring answers the questions, "What is happening now, and how does actual production compare with the targets?" Production analysis is the investigative or diagnostic stage of the process of monitoring production. Its purpose is to answer the question, "What are the possible causes of the identified problem?" Production reference values provide the standards of health by which the performance of the breeding herd is assessed. Production reference values are averages and SDs for production values achieved by a large group of similar herds.

Production targets are the short-term future goals for a given production unit. They are typically set annually in a 1-year action plan and ought to be based on long-term trends and the actual performance in the previous year. These targets must be biologically feasible, economically realistic, and possible in that particular herd. Targets answer the question, "What do you want to achieve in the next year?" An action plan is a treatment plan based on the results of the analysis and target setting. An action plan lists a set of specific recommendations that, when implemented, should lead to the herd meeting its 1-year production and productivity targets. Action plans may include the use of vaccines, antimicrobials, or other health products; remodeling buildings or making other changes to an environment; redesigning a job description; making personnel changes; restructuring the organization; introducing new genetic lines; and reformulating diets or making other feeding system changes (Stein, 1988).

One difficulty that veterinarians commonly encounter is knowing when to intervene. That is, as performance continues, there will be random fluctuations from week to week. Two types of errors are well described in statistics. It may have appeared that there was a "real" change when in fact there was not, or it may have been assumed there were no changes when there really were. The dilemma is that one never really knows which of these errors is being committed. But it is certain that they occur daily in herd management.

Statistical Process Control. Statistical process control (SPC) is a technique being implemented on many farms to help determine when to intervene. Different farms focus their attention on different production parameters. The following guidelines have been suggested as parameters to monitor (Montgomery, 1996):

- Start by applying control charts to any part of the product characteristic or production process believed to be important (Fig. 15-9). Over time, remove those charts that are unnecessary and add any considered necessary.
- Apply the charts as early in each stage of the production process as possible.
- Implement and maintain the charts as close to the applicable area as possible so that feedback is rapid. Ultimately the data should be collected and charts maintained and interpreted by the staff in charge of that facet of production.
- Anything monitored over time can be analyzed by SPC to interpret the data. This includes measures of production, health, and financial performance.

Possible health and production measures include the following:

- *Breeding herd*: conception rate, farrowing rate, litter size, preweaning mortality, cull rate, and mortality rate
- *Growing herd*: feed and water use, medication use, mortality, gain, fed efficiency, carcass trim, and condemnations
- *Health*: in addition to morbidity indicators and mortality, the prevalence of specific diseases through serology, slaughter checks, and antibiotic resistance can be monitored

Besides the effort and time required to chart every measure, there is good reason to monitor the optimum, not the maximum, number of parameters. This is because some of the time, unusually high or low values will occur and yet nothing has happened in the herd to cause this value. For example, preweaning mortality may be unusually low one week, which may be attributed to an improvement in management. However, it is possible that a relatively low percentage of weeks may have extraordinarily high or low preweaning mortality by chance alone. Interpreting such a signal as a real change would be an incorrect interpretation. Therefore the more measures that are monitored with SPC, the more signals can be expected to be both real and false. Unfortunately, it is not known which signals correctly indicate a change in the herd and which are false. With standard SPC charting, a false signal may be expected approximately every 370 data points. If 100 measures are being tracked at a farm every week, a false signal may be expected every 3 to 4 weeks. But if service is being provided to 50 herds, approximately 15 false signals may occur per week. Each signal requires investigation because it is difficult to know whether it is an indication of a real problem deserving attention or a false signal. The need to attach a cost to each investigation and the cost of monitoring too many parameters become apparent.

The only management step that can be taken to avoid false signals is to minimize the number of parameters to those that are essential. The measures tracked will vary among herds and systems. As described previously in the charting guidelines, the exact parameters and chart techniques will evolve to identify the best method for that farm. The process is charted so that the veterinarian can help the managers do their job.

Interpretation of Animal Health and Production Data

The collection and analysis of health and production data is of little value unless they are used to improve or maintain the efficiency and profitability of the swine enterprise. Whether the data are analyzed manually or with the use of a computer, the actual performance of the herd must be examined and interpreted.

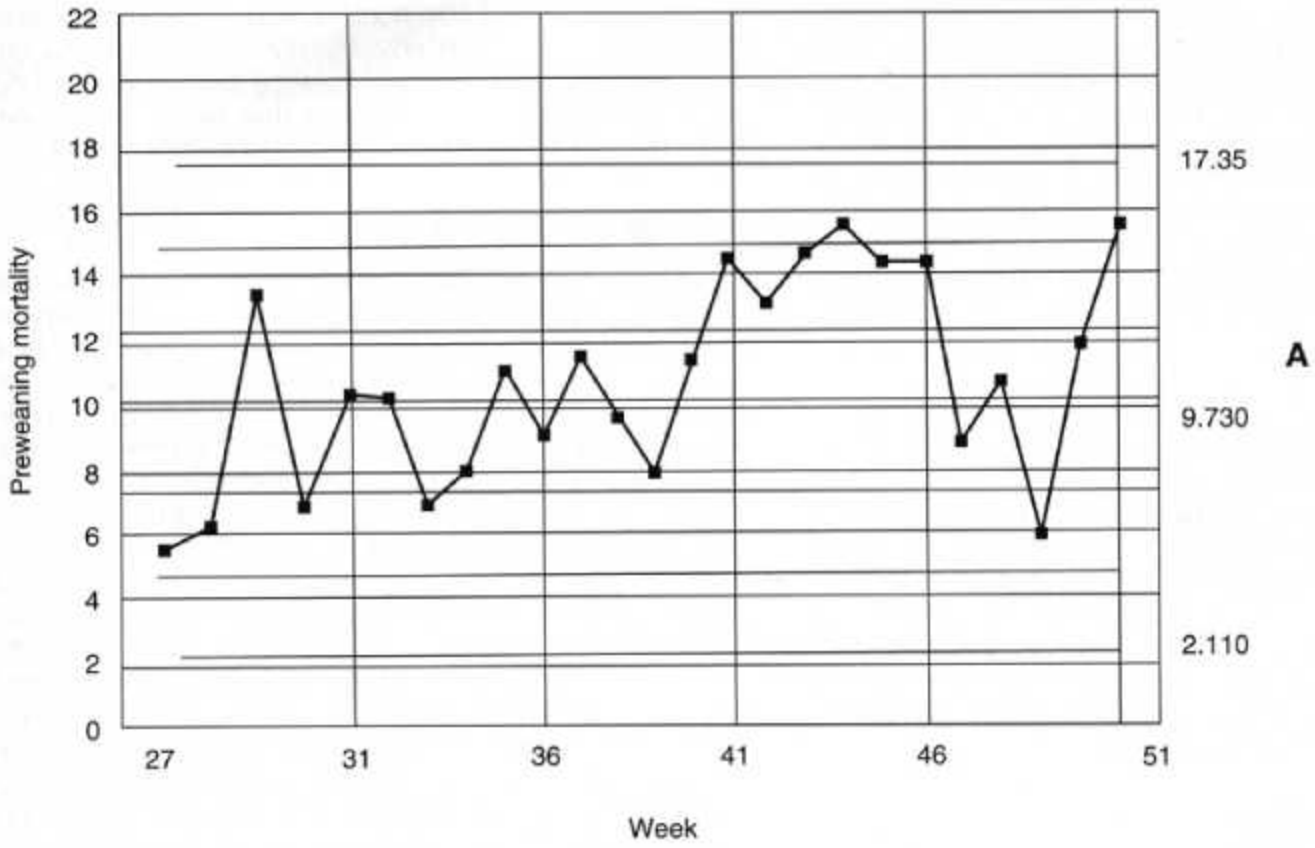

FIG. 15-9 Control chart for preweaning mortality for, **A,** farm 1 and, **B,** farm 2.

The efficiency of the swine unit depends on maintaining a constant flow of pigs through the buildings to make the most effective use of the available labor and facilities, which represents a considerable financial investment. One of the first tasks in planning production that can be achieved with the fixed resources of a swine unit is to set production targets. Subsequently, monitoring of the herd's actual performance reveals whether these initial targets are capable of being achieved. If they are not, they can be adjusted to more realistic levels, but the shortfalls may be due to disease or other problems interfering with the production cycle, and these have to be investigated and corrected. This process of setting targets, monitoring and assessing performance, investigating shortfalls, and revising targets is a continuous one and is dependent on comprehensive and accurate production records.

The best use of resources is achieved by aiming at a level output of pigs throughout the year. This usually means a weekly system of farrowing, with the size of the group being appropriate to the size of the herd that can be sustained. It is important to decide on the size of the herd in the early stages of planning; thus the number of reproductive cycles

can be predicted, and the amount of accommodation for various phases of production can be calculated.

During the first 12 months after the establishment of a swine herd health program, the targets of performance should be assessed at frequent intervals. The critical indexes are the number of services and the number of farrowings per week. These indexes provide a rough analysis of the production process and do not allow an investigation of the cause of shortfalls. A more comprehensive list of indexes must be examined in detail to determine where losses are occurring.

Disease Recording

The records already described are only demographic (e.g., vital statistics). They do not, except by reference, describe clinical disease. The recording of specific disease incidents has not been a major feature of swine herd recording systems. Often, a specific diagnosis of a sick pig is not made by the animal attendant, and the veterinarian is usually not called to examine and treat individual pigs. However, a daily diary should be kept of sick pigs and their location, the treatment given, the number of pigs that died with and without treatment, and the results of necropsies.

Health Status of the Herd

It is often desirable that some overall record of the health status of the herd be available. This can be of value in selling breeding stock and for admission to livestock shows and sales. It is also a guide to whether or not veterinary advisers are succeeding. The report should consist of a list of production indexes for the last 6 to 12 months and the status of the herd with regard to the common infectious diseases, such as atrophic rhinitis (AR), enzootic pneumonia, TGE, swine dysentery, parvovirus infections, sarcoptic mange, and erysipelas. The results of the examination of heads and lungs of pigs sent to slaughter within the last 12 months may also be included. The methods used to determine the disease status of the herd must accompany the report and be certified by the veterinarian. The report should also include a summary of the clinical observations made by the veterinarian over a period of 12 months.

COMPONENTS OF A PLANNED ANIMAL HEALTH AND PRODUCTION PROGRAM

The success of a swine herd health and production program depends on the enthusiasm and competency of the veterinarian and the willingness of the producer to maintain a high level of production through compliance with the consultant's advice as well as good management. This section will describe in general terms some of the methods commonly used to improve and maintain a high level of production and disease control in the swine herd.

Regular Farm Visits

The veterinarian must make regularly scheduled visits to the herd. The frequency of the visits and the length of time actually spent on the farm depend on the size of the herd and the current health and production status of the herd. In the initial stages of a program, the veterinarian may visit the herd once weekly for a few months to gain experience with the herd, to identify obvious problems, and to establish a recording system. Once the program is established, one visit per month to a 100-sow farrow-to-finish operation is often adequate. For larger operations, more frequent visits may be desirable. Telephone consultations, emergency visits, and necropsy services may be provided between the regular farm visits.

The objective of the regular visit is to strive continually for increased productivity by managerial, environmental, and therapeutic control of disease in order to obtain maximum physiological function in that herd. A procedure for routine visits to a swine herd is shown in Box 15-3.

Emergency Farm Visits

Outbreaks of infectious disease that may occur sporadically should be investigated by the veterinarian. Prescriptions for mass medication of the feed or water supplies may be necessary, and it may be legally necessary to examine the pigs. Producers should be encouraged to notify the veterinarian of an unusually high incidence of mortality and of conditions such as dystocia, coughing, and agalactia—all of which should be investigated immediately rather than waiting until the next monthly visit.

A descriptive study of the farm visits made by animal health specialists to growing and finishing pig farms in the Netherlands found that the majority (82%) of visits were made to investigate the cause of health, welfare, and performance problems (problem-solving visits) (Enting et al, 1998). Respiratory diseases were the most common reason for requesting the farm visit. In 18% of the visits the specialists screened for herd-health management factors that did not meet standards for the control of disease. For both types of visits, the common factors detected were abrupt changes in feed composition or feed suppliers, inadequate measures to prevent introduction of pathogens by people or vehicles, and incorrect adjustment of the ventilation system. The diversity of risk factors identified stresses the importance of an overall investigation of farm factors that deviate from the desired standards and the need for an integrated approach.

Nutritional Advice

Veterinarians involved in health management of swine herds must be well informed about the nutrient requirements of the different age groups of pigs. Since feed constitutes 60% to 80% of the cost of producing a market pig, every effort must be made to increase the economic efficiency of feed use. Some surveys of well-managed swine farms in Alberta, Canada, found a 20% difference in feed costs, and it is estimated that in the industry the range in feed costs is likely to be near 50% (Patience and de Lange, 1996). Reduction of the feed cost of the highest costing farm to that of the lowest costing farm would save that farm more than $23,000 annually, which is equivalent to a cost reduction in production of $6.80/pig. The trend is to use complete feeds formulated by feed company nutritionists who are familiar with the nutrient composition of local feedstuffs. With complete diets, specific nutrient deficiencies are uncommon.

The major problem is the efficiency of utilization of the different feeds throughout the life cycle of the pig. The nutrient requirements of the pig at various phases of growth from birth to market weight and of breeding stock are well established. The remaining questions appear to be about the levels of feed that should be provided during the different phases of the growth of the pig in order to achieve optimum production and to yield the best carcass. Proper nutrition can greatly increase the efficiency of swine production, because feed represents such a large percentage of the cost involved. The following are some recommended practices for increasing efficiency of feed utilization with swine:

- Provide well-balanced diets with adequate levels of amino acids, energy, vitamins, and minerals necessary to meet the particular demands of the pig at each stage of its life cycle. The diet depends on the demands, usually characterized as the growth rate or lean deposition. Feed intake

BOX 15-3

Procedure for Routine Visit to Swine Herd

PREVISIT PREPARATION

An appointment is made with the producer at least 1 week in advance; it is important to be punctual at the scheduled time. The following are reviewed and prepared for discussion with the producer:

- Interpretation of previous production reports
- Laboratory results
- Ongoing investigations
- Special topic preparation

CLINICAL AND ENVIRONMENTAL EXAMINATION

Examination of summaries of production indexes and disease incidence since the last visit in order is conducted to identify problem areas:

- Visual examination of each unit of the herd
- Clinical examination of selected sick pigs
- Necropsy examination when appropriate
- Collection of laboratory samples as necessary
- Review of housing, ventilation, sanitation, hygiene, stocking density, and comfort of animals
- Review of feeds and feeding systems

A series of checklists may be used to examine all aspects of each area of the herd. The clinical inspection is made with the herdsperson, and each item in the checklist defines a possible problem and serves as a prompter for the herdsperson to indicate the presence of a problem.

Reproduction and Service Area

Boar/sow ratio
Boar fertility, service problems
Boar usage
Boar condition (e.g., presence of mange, lameness, and other problems)
Weaning-to-service intervals
Return rate and interval of returns to estrus
Farrowing rate
Sow stocking density
Sow body condition (e.g., presence of trauma, stress, lameness, and other problems)
Housing, environment, and temperature
Nutritional levels
Estrus abnormalities
Uterine discharges
Treatments and hormones
Pregnancy diagnosis

Dry Sow Area

Environment and temperature
Stocking densities and stall and tether problems
Feed levels and dung state
Body condition score
Udder line and chronic mastitis
Lameness
Estrus abnormalities
Vulvar discharges
Abortions
Sows not pregnant
Culls and reasons
Sudden death and results of necropsies
Parasite control
Treatments used and reasons

Farrowing and Nursery Area

Sow body condition score
Sows not pregnant
Mastitis, metritis, and agalactia
Farrowing fever
Parturition difficulties
Sudden deaths and results of necropsies
Litter size and scatter
Stillbirths and mummifications
Piglet viability, splay-leg, and congenital defects
Neonatal diarrhea, starvation, and trauma
Mortality levels
Piglet comfort (e.g., use of a heat lamp)
Respiratory disease in nursing piglets (e.g., sneezing, ocular and nasal discharge, nasal deformity, coughing)
Sudden deaths
Diseases of the skin
Parasite control
Treatments used and reasons

Growing and Finishing Area

Age at weaning, body weight, and variability in weight
Nutrition and water availability
Evenness of growth
Postweaning diarrhea
Housing, environment, and stocking densities
Temperature, air quality, and ventilation
Rhinitis and pneumonia
Skin conditions and mange
Vaccination programs
Sudden deaths and results of necropsies
Culls and lameness
Tail biting and ear chewing
Swine dysentery
Days to slaughter
Feed conversion rates
Other diseases
Parasite control
Treatments used and reasons

ANALYSIS AND DISCUSSION OF THE RESULTS OF THE VISIT

Records of performance
Evaluation of diseases encountered
Epidemiological discussions (e.g., what environmental, nutritional, managerial, or other factors are contributing to disease)
Remedial actions and recommendations

Continued

BOX 15-3 —cont'd

Procedure for Routine Visit to Swine Herd—cont'd

SPECIAL TOPICS
Each month a selected special topic may be investigated:
Herd security
Stock introduction, herd replacement policies, and gilt selection
Economic losses in the herd and feed costs and utilization
External and internal parasite control, vermin control, and vaccination program
Fertility and boar management
Herd security check and diseases of the farrowing sow
Piglet problems
Diseases, mortality, and management of the weaned and finishing pigs
Housing use, alterations, and associated diseases
Labor management and productivity
Slaughterhouse monitoring and pathological tests
Twelve-month appraisal and analysis

GENERAL PROBLEMS
Such as flow of pigs through the entire enterprise

PREPARATION FOR NEXT VISIT
Arrange date and special problems to be investigated
Arrange for possible consultation with other specialists (e.g., geneticist, nutritionist, agricultural engineer)

PREPARATION OF THE REPORT
The report is usually prepared in the veterinarian's office and sent to the producer within 2 days after the farm visit

is the supply function. Feed intake is limited by appetite, and thus other nutrients are matched to expected energy intake and subsequent growth.

- Use least-cost formulation to the extent that it is feasible. The least-cost energy source in most of the pig-rearing areas is corn, and the most common protein source is soybean meal.
- Restrict the level of a properly balanced diet for sows during gestation to avoid overfeeding. Sows that have lost excessive body weight in the previous lactation need supplemental feed during the dry period to avoid the thin-sow syndrome.
- Ad-lib feeding for growing pigs is usually optimum unless the genotype deposits excess fat during the latter stages of growth.
- Market pigs as close to optimum slaughter weight as possible to maximize margin over feed costs.
- Avoid feed wastage by using well-designed feeding systems and proper adjustment of those feeders.
- Use pelleting of diets to increase digestibility, especially of small grains, and to decrease feed wastage. However, pelleting also predisposes pigs to gastroesophageal ulcers.

The feed efficiency of the pigs from weaning to market should be monitored regularly. It is often difficult to obtain accurate data on this item for specific groups of pigs, because the amount fed to each group may not be calculable when a common feeding system is in use. However, the total amount of feed used and the total weight of pigs marketed will give an estimate of feed efficiency.

The National Research Council (NRC) in the United States provides an important service in establishing the nutrient requirements of swine and other species. The tenth revised edition of the *Nutrient requirements of swine* was published in 1998 (National Research Council, 1998). The 200-page edition incorporates the wealth of new research information that has emerged over the past 10 years since the eighth edition and addresses new areas such as modelling nutrient requirements and reducing nutrient excretion (Cromwell, 1999).

Even though the nutrient requirements of swine are well known, they do continue to change because of changes in growth and production characteristics of pigs. Pigs with high lean-growth rates require higher levels of amino acids to support their increased rate of body protein deposition. Similarly, high milk-producing sows nursing large litters have increased amino acid requirements.

In the tenth edition, a new approach is used to produce estimates of nutrient requirements that take into consideration not only the pig's body weight, but also its accretion rate of lean (protein) tissue, gender, health status, and various environmental factors. To accurately estimate nutrient needs of gestating and lactating sows, there is a need to account for body weight, weight gain during gestation, weight loss during lactation, number of pigs in the litter, weight gain of the litter (a reflection of milk yield), and certain environmental factors (Cromwell, 1999).

A series of integrated mathematical equations was used to account for the many factors now known to influence nutrient requirements. These equations provide the framework for modelling the biological basis of predicting requirements. The NRC models predict the levels of nutrients (outputs) needed to achieve a certain level of production under a given set of environmental conditions (inputs).

Five principles were used to develop the models. The models: (1) were made for ease of use by people with varying levels of nutritional expertise and with limited information, (2) were developed for continued relevance for several years to come, (3) were intended to be structurally simple, so they could be understood readily by users, (4) were developed to be transparent so that all of the equations could be available to the user, and (5) were firmly anchored to empirical data at the whole-animal level rather than being simply based on theoretical values. Three independent models were developed for growth, gestation, and lactation. The growth model estimates amino acid requirements of pigs from weaning to market weight, and the gestation and lactation models estimate energy and amino acid requirements of gestating and lactating sows.

Few revisions were made in the previously published mineral requirements. Based on recent findings, higher dietary requirements for sodium and chloride in the young pig were established. The manganese requirements were increased from 10 to 20 ppm for gestating and lactating sows.

Udder quality	40-50
Skeletal shape	40-60

Several changes were made in the feed composition tables. Nutrient composition of feeds was obtained from as many data bases as possible, including from the feed industry and from data sets outside the United States and Canada.

The information on water was expanded considerably with more detailed information on the factors that influence water intake. There is additional new information on nonnutritive feed additives, such as antimicrobial agents, anthelmintics, microbial supplements, oligosaccharides, enzymes, acidifiers, flavors, odor control agents, antioxidant pellet binders, flow agents, high-mineral supplements, and carcass modifiers.

A new chapter on minimizing nutrient excretion is included in the tenth edition. It addresses environmental issues and the importance of reducing the excretion of nutrients, particularly nitrogen and phosphorus, which can potentially contribute to environmental pollution.

Pig Genetics and the Selection and Acquisition of Breeding Stock

Veterinarians have traditionally not provided advice on genetics and breeding programs in swine herds. However, veterinarians who become involved in providing a complete swine herd health and production program should be aware of the components of a breeding program: the basic concepts of swine genetics, the heritability estimates of the economically important performance and carcass traits, the importance of records in selection, the performance testing procedures, the value of crossbreeding, and the problems associated with the acquisition of breeding stock that are free of infectious agents.

Basic Concepts of Swine Genetics

Most traits of economic importance in swine may be classified as quantitative traits, that is, traits that exhibit some measurable or observable quantity such as litter weight, growth rate, or backfat thickness. It is true that many qualitative traits such as coat color do exist, but the economic significance of these traits is usually much less than that for the quantitative traits. The exception may be some detrimental recessive traits such as lethal genes or blood disorders that cause either prenatal or postnatal death. These genetic defects should be selected against by choosing breeding stock that are free from defects and whose relatives and ancestors were as free from defects as possible. Basically, qualitative traits are influenced or determined by only one or a very small number of pairs of genes, and the environment plays little or no role in determining phenotype. On the other hand, quantitative traits are influenced by many, perhaps thousands, of pairs of genes, and the environment may play a major role in determining the phenotypic (e.g., performance) value for these traits. The majority of the genes that influence quantitative traits act in an additive manner to influence phenotype. Consequently, selection to improve quantitative traits is aimed at selecting breeding stock with the greatest additive value for a given trait. The fact that the environment also influences phenotype prevents the producer from always being certain that the pig with the highest phenotypic value also has the highest sum of additive genes for the respective trait.

The concept of heritability confronts the problem of separating the influence of genes from the influence of environment upon phenotype. Heritability may be defined as the degree to which relatives are more alike than are nonrelated individuals. Heritability may also be defined as the percent of phenotypic variability among a population of animals that is due to the variability in additive gene action among the members of the population. In simpler terms, heritability refers to the proportion of variability for a trait in a population that is due to additive genes. The remainder of the variability is the result of environmental influences and other types of gene action or interactions. Heritability estimates for several economically important traits in swine are presented in Table 15-9.

It should be clear that, through selection, genetic progress will be more rapid for more highly heritable traits. By simply selecting the boars and gilts with the most desirable phenotypic values, and by using production records and following the practice of mating the best boars to the best sows, the producer should be able to make rather rapid changes for the more highly heritable traits. Both generation interval and intensity of selection play a role in the rate of genetic progress. However, evidence in Canada suggests that selection has been neither intense nor cohesive among breeders, and selection limits are unlikely to be evident for several more decades.

Traits that relate to linear measurements, shape, or composition of pigs are generally high in heritability, and therefore genetic progress can be quite rapid for these traits within purebred swine herds. It is for this reason that breeders have been successful in reducing the fat composition and in increasing the lean or muscle tissue in pork carcasses. Rate and efficiency of gain are also improved through selection, but not as rapidly as traits relating to composition. The best method for improving feed efficiency is to select for increasing the rate of lean growth. This may be accomplished by selecting to increase the rate of growth and decrease backfat thickness.

It is unfortunate that the most important traits from an economic standpoint (e.g., fertility, prolificacy, liveability, libido, and longevity) are quite low in heritability. In fact,

almost all traits that relate to physical fitness or environmental adaptability are low in heritability. This does not mean that purebred breeders should ignore these factors, but rather that genetic progress is generally slow in improving these traits by selective mating.

Genetics of the Pig. An recent book titled *The genetics of the pig* (Rothschild and Ruvinsky, 1998) is excellent. The book provides a complete, comprehensive, and updated description of the modern genetics of the pig. The various chapters by specialists combine the essential knowledge from the various fields of genetics integrated with livestock management in order to provide a useful and informative guide on the genetic improvement of the pig. Recent genetic improvements over the past decade in the pig industry have been dramatic. Tremendous progress has been made in understanding the genetic control of the pig, and considerable success has been made in porcine genome mapping. The book is addressed to a diverse audience including students, researchers, veterinarians, and pig breeders. The initial chapters are devoted to taxonomy and domestication and overview of several pig breeds. There is extensive coverage of the genetics of coat color, morphological characteristics, and inherited disorders. Molecular, biochemical, and immunological genetics are described, and considerable new information is presented. Recent advances in pig gene mapping are included. New areas of developmental and behavioral genetics are explored, as are the genetics of reproduction and new emerging technologies that combine genetics and reproductive biology. The genetics of performance traits and carcass and meat quality traits are included, and there is a section devoted to overall genetic improvement. The major centers of swine breed development were England, China, and the United States (Jones, 1998). The salient features of the common breeds are presented by Porter (1993) and Jones (1998).

Inherited Defects. Inherited disorders of pigs have been of considerable importance, from an agricultural perspective (malignant hyperthermia) and in terms of animal models for inherited human diseases. The literature on inherited disorders has been reviewed (Nicholas, 1998). A total of 161 traits and disorders have been reported in pigs. A complete set of up-to-date references for each entry is available by accessing Online Mendelian Inheritance in Animals (OMIA) on the Internet at http://www.angis.org.au/Databases/BIRX/omia/.

The molecular and gene-mapping revolutions will result in a large amount of information in this area in the years ahead.

Biochemical and Serological Markers. The different porcine biochemical and serological genetic markers and their significance in pig genetics and breeding has been reviewed (Juneja and Vogeli, 1998). One of the main applications of blood markers in pigs has been for parentage testing. Studies of the genetic structure of breeds and populations, estimation of heterozygosity of populations, and estimation of genetic distance between breeds, as well as for linkage studies and gene mapping, have been done. Some studies have led to the detection of the economically important halothane linkage group. The recent finding of linkage between the blood group locus S and the gene determining susceptibility to edema disease may be important in practical pig breeding (Juneja and Vogeli, 1998).
